CLINICAL OBSTETRICS

THE FETUS & MOTHER

EDITORS

E ALBERT REECE & JOHN C HOBBS

Blackwell
Publishing

Clinical Obstetrics

The Fetus & Mother

Dedication

To Sharon, Kelie, Brynne, and Sharon-Andrea with greatest love and gratitude.

~E. Albert Reece MD, PhD, MBA

To the memory of my father, who was the best role model anyone could have had, and my mother, who always gave me love and support (despite her never quite understanding what I did for a living).

~John C. Hobbins MD

Clinical Obstetrics

The Fetus & Mother

E. Albert Reece MD, PhD, MBA

Vice President for Medical Affairs, University of Maryland, and
John Z. & Akiko K. Bowers Distinguished Professor and
Dean, School of Medicine,
Baltimore, Maryland

John C. Hobbins MD

Professor of Obstetrics and Gynecology
University of Colorado School of Medicine
University of Colorado Health Sciences Center
Denver, Colorado

FOREWORD BY

Norman F. Gant Jr. MD

Professor and Chairman Emeritus
University of Texas Southwestern Medical School
Executive Director, The American Board of Obstetrics and Gynecology
Dallas, Texas

Contents

Contributors, viii

Foreword, xiv

Preface, xv

Preface to the first edition, xvi

Acknowledgments, xvii

Abbreviations, xviii

Overview: historical perspectives of fetal medicine, xxv

Part I: Conception and Conceptus Development

- 1 Early conceptus growth and immunobiologic adaptations of pregnancy, 3
Kenneth H.H. Wong and Eli Y. Adashi

- 2 Normal embryonic and fetal development, 19
Trivedi Vidhya N. Persaud and Jean C. Hay

Part II: Pregnancy and the Fetoplacental Unit

- 3 Normal and abnormal placentation, 35
Soheila Korourian and Luis De Las Casas
- 4 Fetoplacental perfusion and transfer of nutrients, 59
Henry L. Galan and Frederick C. Battaglia
- 5 Endocrinology of pregnancy and the placenta, 68
Alan DeCherney, Jessica Spencer, Tim Chard, and Karen A. Hutchinson

Part III: Fetal Developmental Biology

- 6 Fetal lung development and amniotic fluid analysis, 85
Ian Gross and Matthew J. Bizzarro
- 7 Fetal cardiovascular physiology and response to stress conditions, 93
Jean-Claude Fouron and Amanda Skoll
- 8 Immunology of the fetus, 114
Josiah F. Wedgwood and James G. McNamara
- 9 Fetal endocrinology, 124
Charles E. Wood and Maureen Keller-Wood
- 10 Fetal hematology, 132
Véronique Cayol and Fernand Daffos

Part IV: Variations in Embryonal and Fetal Growth and Development

- 11 Sporadic and recurrent pregnancy loss, 143
Robert M. Silver and D. Ware Branch

- 12 Ectopic and heterotopic pregnancies, 161
Arnon Wiznitzer and Eyal Sheiner

- 13 Multifetal pregnancies: epidemiology, clinical characteristics, and management, 177
Michelle Smith-Levitin, Daniel W. Skupski, and Frank A. Chervenak

- 14 Biology of normal and deviant fetal growth, 203
Andrée Gruslin and the late Carl A. Nimrod

Part V: Fetal Infections and Teratogenesis

- 15 Developmental toxicology, drugs, and fetal teratogenesis, 217
Robert L. Brent and Lynda B. Fawcett
- 16 Drugs, alcohol abuse, and effects in pregnancy, 236
Stephen R. Carr and Donald R. Coustan
- 17 Teratogenic viruses, 248
Antonio V. Sison
- 18 Transplacentally acquired microbial infections in the fetus, 262
Santosh Pandipati and Ronald S. Gibbs
- 19 Antibiotics and other antimicrobial agents in pregnancy and during lactation, 284
Janet I. Andrews and Jennifer R. Niebyl

Part VI: Fetal Diseases

- 20 Principles of human genetics: chromosomal and single-gene disorders, 295
Joe Leigh Simpson and Maurice J. Mahoney
- 21 Genetic counseling in prenatal and perinatal medicine, 318
Jeff Milunsky and Aubrey Milunsky
- 22 Basic principles of ultrasound, 336
Mladen Predanic, Frank A. Chervenak, and E. Albert Reece
- 23 Prenatal diagnosis of central nervous system malformations, 347
Gianluigi Pilu and Sandro Gabrielli
- 24 Prenatal diagnosis of thoracic and cardiac abnormalities, 361
Gianluigi Pilu, Philippe Jeanty, and Juliana M.B. Leite

- 25 Gastrointestinal and genitourinary anomalies, 377
Sandro Gabrielli, Nicola Rizzo, and E. Albert Reece
- 26 Fetal skeletal anomalies, 401
Luís F. Gonçalves, Patricia L. Devers, Jimmy Espinoza, and Roberto Romero
- 27 First- and second-trimester prenatal diagnosis, 473
John C. Hobbins
- 28 First- and second-trimester screening for open neural tube defects and Down syndrome, 485
James E. Haddow, Glenn E. Palomaki, and Ronald J. Wapner

Part VII: Methods of Evaluation of Fetal Development and Well-being

- 29 Prenatal diagnosis of deviant fetal growth, 507
E. Albert Reece and Zion J. Hagay
- 30 Three- and four-dimensional ultrasound and magnetic resonance imaging in pregnancy, 526
Teresita L. Angtuaco
- 31 Doppler ultrasonography and fetal well-being, 561
Brian J. Trudinger
- 32 Antepartum and intrapartum surveillance of the fetus and the amniotic fluid, 586
Lami Yeo, Michael G. Ross, and Anthony M. Vintzileos

Part VIII: Fetal Therapy

- 33 The fetus at surgery, 609
Robert H. Ball and Michael R. Harrison
- 34 Fetal medical treatment, 617
Mark I. Evans, Yuval Yaron, Charles S. Kleinman, and Alan W. Flake

Part IX: Maternal Biological Adaptations to Pregnancy

- 35 Maternal biological, biomechanical, and biochemical changes in pregnancy, 633
Edward K.S. Chien and Helen Feltovich
- 36 Maternal nutrition, 645
Barbara Luke

Part X: Maternal Diseases Complicating Pregnancy

- 37 Trauma, shock, and critical care obstetrics, 657
Erin A.S. Clark, Gary A. Dildy, and Steven L. Clark
- 38 Hypertensive diseases in pregnancy, 683
Frederick U. Eruo and Baha M. Sibai
- 39 Cardiac diseases in pregnancy, 700
Kjersti Aagaard-Tillery and Steven L. Clark

- 40 Maternal pulmonary disorders complicating pregnancy, 718
Steven L. Clark and Calla Holmgren
- 41 Diabetes mellitus in pregnancy, 740
Carol J. Homko, Zion J. Hagay, and E. Albert Reece
- 42 Endocrine disorders in pregnancy, 762
Fred H. Faas
- 43 Gastrointestinal diseases complicating pregnancy, 777
Washington Clark Hill and Alfred D. Fleming
- 44 Liver disease in pregnancy, 797
Vivek Raj
- 45 Pregnancy complicated by renal disorders, 811
Michelle W. Krause and Sudhir V. Shah
- 46 Neurological disorders in pregnancy, 818
R. Lee Archer, Stacy A. Rudnicki, and Bashir S. Shihabuddin
- 47 Thromboembolic disorders of pregnancy, 825
Michael J. Paidas, Christian M. Pettker, and Charles J. Lockwood
- 48 Coagulation and hematological disorders of pregnancy, 849
Carl P. Weiner and Chien Oh
- 49 Maternal alloimmunization and fetal hemolytic disease, 867
Anita C. Manogura and Carl P. Weiner
- 50 Maternal infections, human immunodeficiency virus infection, and sexually transmitted diseases in pregnancy, 885
Richard L. Sweet and Howard Minkoff
- 51 Rheumatologic and connective tissue disorders in pregnancy, 931
Gustavo F. Leguizamón and E. Albert Reece
- 52 Dermatologic disorders during pregnancy, 947
Thomas D. Horn and Jerri Hoskyn
- 53 Cancer and other neoplasms in pregnancy, 961
Peter E. Schwartz and Masoud Azodi

Part XI: Medicosocial Considerations in Pregnancy

- 54 Pregnancy before age 20 years and after age 35 years, 987
Helen H. Kay
- 55 Essentials in biostatistics and perinatal epidemiology, 1007
Paula K. Roberson and Benjamin P. Sachs
- 56 Sexuality in pregnancy and the postpartum period, 1016
Kirsten von Sydow

- 57 Psychiatric problems during pregnancy and the puerperium, 1022
Linda L.M. Worley and Jennifer L. Melville
- 58 Ethical and legal dimensions of medicine of the pregnant woman and fetus, 1039
Judith L. Chervenak, Frank A. Chervenak, and Laurence B. McCullough

Part XII: Obstetric and Periparturient Events

- 59 Bleeding in the third trimester, 1049
Lawrence W. Oppenheimer and the late Carl A. Nimrod
- 60 Normal and abnormal labor, 1065
Wayne R. Cohen
- 61 Operative vaginal delivery, 1077
Edward R. Yeomans
- 62 Preterm labor, 1085
Erol Amon and Thomas D. Myles
- 63 Prelabor rupture of the membranes, 1130
Joaquin Santolaya-Forgas, Roberto Romero, Jimmy Espinoza, Offer Erez, Lara A. Friel, Juan Pedro Kusanovic, Ray Bahado-Singh, and Jyh Kae Nien

- 64 Prolonged pregnancy, 1189
Curtis L. Lowery and Paul Wendel
- 65 Anesthesia in the high-risk patient, 1198
Danny Wilkerson and Richard B. Clark
- 66 Puerperium and lactation: physiology of the reproductive system, 1206
Judy M. Hopkinson, Pamela D. Berens, and E. Albert Reece

Part XIII: The Newborn Infant

- 67 Premature birth and neurological complications, 1221
Alan Hill
- 68 Common problems of the newborn, 1232
Fernando R. Moya and Matthew Laughon
- Index, 1261

Companion CD-ROM with searchable text (inside back cover)

Clinical Obstetrics: The Fetus & Mother—Companion CD-ROM

Contents

- The complete text
- Color versions of over a hundred illustrations from the book
- Full text search

The CD should load automatically on insertion. Alternatively, or to restart after quitting, browse the CD and double-click the file **BMJ_Books_PC** (if using Windows 98 or higher) or **BMJ_Books_MAC** (if using Mac OS 10.2.2 or higher).

Contributors

Kjersti Aagaard-Tillery MD, PhD

MFM Fellow, Division of Maternal-Fetal Medicine, University of Utah, Salt Lake City, UT, USA

Eli Y. Adashi MD

Dean of Medicine and Biological Sciences, Brown Medical School, Providence, RI, USA

Erol Amon

Professor and Director, Department of Obstetrics, Gynecology, and Women's Health, Division of Maternal-Fetal Medicine, St Louis University, St Louis, MI, USA

Janet I. Andrews MD

Associate Maternal-Fetal Medicine, Department of Obstetrics and Gynecology, University of Iowa, Iowa City, IA, USA

Teresita L. Angtuaco MD, FACR, FAIUM, FSRU

Professor of Radiology, Obstetrics, and Gynecology, Director, Division of Imaging and Chief of Ultrasound, Department of Radiology, University of Arkansas for Medical Sciences College of Medicine, Little Rock, AR, USA

R. Lee Archer MD, FAAN

Associate Professor, Department of Neurology, University of Arkansas for Medical Sciences College of Medicine, Little Rock, AR, USA

Masoud Azodi MD

Assistant Professor, Department of Obstetrics and Gynecology, Yale University School of Medicine, New Haven, CT, USA

Ray Bahado-Singh MD

Professor, Department of Obstetrics and Gynecology, Division of Maternal-Fetal Medicine, Wayne State University/Hutzel Women's Hospital, Detroit, MI, USA

Robert H. Ball MD

Associate Professor, Department of Obstetrics, Gynecology, and Reproductive Sciences and Radiology, UCSF Fetal Treatment Center, San Francisco, CA, USA

Frederick C. Battaglia MD

Professor Emeritus, Departments of Pediatrics and Obstetrics-Gynecology, University of Colorado School of Medicine, University of Colorado at Denver and Health Sciences Center, Perinatal Research Center, Aurora, CO, USA

Pamela D. Berens MD

Associate Professor, Department of Obstetrics, Gynecology, and Reproductive Sciences, University of Texas Medical School – Houston, Houston, TX, USA

Matthew J. Bizzarro MD

Assistant Professor, Department of Pediatrics, Yale University School of Medicine, New Haven, CT, USA

D. Ware Branch MD

Professor and H.A. & Edna Benning Presidential Endowed Chair, Department of Obstetrics and Gynecology, University of Utah Health Sciences Center, Salt Lake City, UT, USA

Robert L. Brent MD, PhD, DSc

Distinguished Professor, Departments of Pediatrics, Radiology, and Pathology, Thomas Jefferson University and Alfred I. duPont Hospital for Children, Wilmington, DE, USA

Stephen R. Carr MD

Associate Professor, Department of Obstetrics-Gynecology, Division of Maternal-Fetal Medicine, Brown University, Women and Infants' Hospital, Providence, RI, USA

Véronique Cayol MD

Assistante, Institut de Puériculture et de Périnatalogie, Paris, France

Tim Chard MD, FRCOG

Professor of Obstetrics and Gynaecology, St Bartholomew's Hospital and the Royal London School of Medicine and Dentistry, West Smithfield, London, UK

Frank A. Chervenak MD

Professor and Chairman, Department of Obstetrics and Gynecology, Weill Medical College of Cornell University, New York, NY, USA

Judith L. Chervenak MD, JD

Of Counsel, Heidell, Pittoni, Murphy & Bach, LLP, New York, NY, USA

Edward K.S. Chien MD, FACOG

Assistant Professor, Department of Obstetrics and Gynecology, Women and Infants' Hospital of Rhode Island, Brown University, Providence, RI, USA

Erin A.S. Clark MD

Chief Resident, Department of Obstetrics and Gynecology, University of Utah Hospital, Salt Lake City, UT, USA

Steven L. Clark MD

*Director of Perinatal Medicine, Hospital Corporation of America,
St. Marks Hospital, Salt Lake City, UT, USA*

Richard B. Clark BSM, MD

*Professor Emeritus, Departments of Anesthesiology and Obstetrics
and Gynecology, University of Arkansas for Medical Sciences
College of Medicine, Little Rock, AR, USA*

Wayne R. Cohen MD

*Chairman, Department of Obstetrics and Gynecology,
Jamaica Hospital Medical Center, Professor of Clinical
Obstetrics and Gynecology, Weill–Cornell Medical College,
Jamaica, NY, USA*

Donald R. Coustan MD

*Chace/Joukowsky Professor and Chair, Department of Obstetrics
and Gynecology, Brown Medical School, Chief Obstetrician and
Gynecologist, Women and Infants' Hospital of Rhode Island,
Providence, RI, USA*

Fernand Daffos MD

*Head of the Fetal Medicine Department, Institut de Puériculture de
Paris, CDPME, Paris, France*

Alan H. DeCherney MD

*Chief, Reproductive Biology and Medicine Branch, National
Institute of Child Health and Human Development, National
Institutes of Health, Bethesda, MD, USA*

Luis E. De Las Casas MD

*Staff Pathologist, Pathology Professional Services, El Paso, TX,
USA*

Patricia L. Devers MS, CGC

*Perinatology Research Branch, National Institute of Child Health
and Human Development, National Institutes of Health,
Department of Health and Human Services, Wayne State University
School of Medicine, Detroit, MI, USA*

Gary A. Dildy MD

*Associate Professor, Division of Maternal–Fetal Medicine,
Department of Obstetrics and Gynecology, University of Utah
School of Medicine, UT, USA*

Offer Erez MD

*Research Associate, Perinatology Research Branch, National
Institute of Child Health and Human Development, National
Institutes of Health, Department of Health and Human Services,
Wayne State University School of Medicine, Detroit, MI, USA*

Frederick U. Eruo MD, MPH

*Instructor, Department of Obstetrics and Gynecology, University of
Cincinnati, Cincinnati, OH, USA*

Jimmy Espinoza MSc MD

*Assistant Professor, Department of Obstetrics and Gynecology,
Wayne State University/Hutzel Women's Hospital, and Perinatology
Research Branch, National Institute of Child Health and Human
Development, National Institutes of Health, Department of Health
and Human Services, Detroit, MI, USA*

Mark I. Evans MD

*President, Fetal Medicine Foundation of America, Director,
Comprehensive Genetics, Professor of Obstetrics and Gynecology,
Mt. Sinai School of Medicine, New York, NY, USA*

Fred H. Faas MD

*Staff Physician, VA Hospital, Professor of Medicine, University of
Arkansas for Medical Sciences College of Medicine, Little Rock,
AR, USA*

Lynda B. Fawcett PhD

*Assistant Professor, Department of Pediatrics, Alfred I. duPont
Hospital for Children, Wilmington, DE, USA*

Helen Feltovich MD, MS

*Minnesota Perinatal Physicians, Abbott Northwestern Hospital,
Minneapolis, MN, USA*

Alan W. Flake MD

*Professor, Departments of Surgery and Obstetrics and Gynecology,
University of Pennsylvania School of Medicine, Ruth and Tristram
C. Colket Jr. Chair of Pediatric Surgery and Director, Children's
Institute of Surgical Science, Children's Hospital of Philadelphia,
Philadelphia, PA, USA*

Alfred D. Fleming MD, FACOG

*Professor and Chairman, Department of Obstetrics and
Gynecology, Creighton University School of Medicine, Omaha, NE,
USA*

Jean-Claude Fouron MD, FRCP

*Professor, Department of Pediatrics, Université de Montréal,
Director of the Fetal Cardiology Unit, Division of Pediatric
Cardiology, Hôpital Sainte-Justine, Montréal, QC, Canada*

Lara A. Friel MD, PhD

*Fellow, Division of Maternal–Fetal Medicine, Department of
Obstetrics and Gynecology, Wayne State University/Hutzel Women's
Hospital, Detroit, MI, USA*

Sandro Gabrielli MD

*Attending Physician, Prenatal Medicine, S. Orsola-Malpighi
University Hospital, Bologna, Italy*

Henry L. Galan MD

*Associate Professor, Department of Obstetrics–Gynecology,
Division of Maternal–Fetal Medicine, University of Colorado
Health Sciences Center, Denver, CO, USA*

Norman F. Gant Jr. MD

*Professor and Chairman Emeritus, University of Texas
Southwestern Medical School, Executive Director, American Board
of Obstetrics and Gynecology, Dallas, TX, USA*

Ronald S. Gibbs MD

*Professor and Chairman, E. Stewart Taylor Chair in Obstetrics and
Gynecology, Department of Obstetrics–Gynecology, University of
Colorado School of Medicine, Denver, CO, USA*

CONTRIBUTORS

Luís F. Gonçalves MD

Director of Prenatal Diagnosis, Perinatology Research Branch, National Institute of Child Health and Human Development, National Institutes of Health, Department of Health and Human Services, Bethesda, MD, and Detroit, MI, Assistant Professor, Department of Obstetrics and Gynecology, Wayne State University/Hutzel Women's Hospital, Detroit, MI, USA

Ian Gross MD

Professor of Pediatrics, Department of Pediatrics, Yale University School of Medicine, New Haven, CT, USA

Andrée Gruslin MD, FRCS

Associate Professor, Division of Maternal–Fetal Medicine, Department of Obstetrics and Gynecology, University of Ottawa, Ottawa, ON, Canada

James E. Haddow MD

Vice President and Medical Director, Foundation for Blood Research, Scarborough, ME, USA

Zion J. Hagay MD

Professor and Chairman, Department of Obstetrics and Gynecology, Kaplan Medical Center, Rehovot, Israel

Michael R. Harrison MD

Professor of Surgery and Pediatrics, Director, Fetal Treatment Center, Department of Surgery, University of California, San Francisco School of Medicine, San Francisco, CA, USA

Jean C. Hay BSc(Hons), MSc

Associate Professor of Anatomy (retired), Department of Human Anatomy and Cell Science, University of Manitoba, Winnipeg, MB, Canada

Alan Hill MD, PhD

Professor, Department of Pediatrics, University of British Columbia, Consultant Pediatric Neurologist, British Columbia's Children's Hospital, Vancouver, BC, Canada

Washington Clark Hill MD, FACOG

Chairman, Department of Obstetrics and Gynecology, Director, Maternal–Fetal Medicine, Sarasota Memorial Hospital, Sarasota, Clinical Professor, Department of Obstetrics and Gynecology, University of South Florida, College of Medicine, Tampa, Clinical Professor, Department of Clinical Sciences, OB-GYN Clerkship Director–Sarasota, Florida State University College of Medicine, Tallahassee, FL, USA

John C. Hobbins MD

Professor, Department of Obstetrics and Gynecology, University of Colorado School of Medicine, Health Sciences Center, Denver, CO, USA

Calla Holmgren MD

Fellow, Maternal–Fetal Medicine, Department of Obstetrics and Gynecology, University of Utah, Salt Lake City, UT, USA

Carol J. Homko PhD, RN

Assistant Professor, Department of Obstetrics, Gynecology, and Reproductive Sciences, Temple University Hospital, Philadelphia, PA, USA

Judy M. Hopkinson PhD, IBCLC

Associate Professor, Department of Pediatrics, Baylor College of Medicine, Houston, TX, USA

Thomas D. Horn MD, MBA

Chairman, Department of Dermatology, Professor, Departments of Dermatology and Pathology, University of Arkansas for Medical Sciences College of Medicine, Little Rock, AR, USA

Jerri L. Hoskyn MD

Assistant Professor, Department of Dermatology, University of Arkansas for Medical Sciences College of Medicine, Staff Physician, Central Arkansas Veterans' Hospital Administration, Little Rock, AR, USA

Karen A. Hutchinson MD

Director of Medical Education, Bridgeport Hospital, Bridgeport, CT, USA

Philippe Jeanty MD, PhD

Tennessee Women's Care, PC, Nashville, TN, USA

Helen H. Kay MD

Professor and Chair, Department of Obstetrics and Gynecology, University of Arkansas for Medical Sciences College of Medicine, Little Rock, AR, USA

Maureen Keller-Wood PhD

Professor and Chair, Department of Pharmacodynamics, College of Pharmacy, University of Florida, Gainesville, FL, USA

Charles S. Kleinman MD

Professor of Clinical Pediatrics in Obstetrics and Gynecology, Columbia University College of Physicians and Surgeons/Weill Medical College of Cornell University, Chief, Pediatric Cardiac Imaging, New York – Presbyterian Hospital, Division of Pediatric Cardiology, Babies Hospital, New York, NY, USA

Soheila Korourian MD

Associate Professor, Department of Pathology, University of Arkansas for Medical Sciences College of Medicine, Little Rock, AR, USA

Michelle W. Krause MD, MPH

Assistant Professor of Medicine, Division of Nephrology, Department of Internal Medicine, University of Arkansas for Medical Sciences College of Medicine, Little Rock, AR, USA

Juan Pedro Kusanovic MD

Research Associate, Perinatology Research Branch, National Institute of Child Health and Human Development, National Institutes of Health, Department of Health and Human Services, Wayne State University School of Medicine, Detroit, MI, USA

Matthew Laughon MD, MPH

Assistant Professor, Department of Pediatrics, Division of Neonatal/Perinatal Medicine, The University of North Carolina at Chapel Hill, Chapel Hill, NC, USA

Gustavo F. Leguizamón MD

Assistant Professor, Chief, High Risk Pregnancy Unit, Department of Obstetrics and Gynecology, CEMIC University, Buenos Aires, Argentina

Juliana M.B. Leite MD

Nashville, TN, USA

Charles J. Lockwood MD

The Anita O'Keefe Young Professor and Chair, Department of Obstetrics, Gynecology, and Reproductive Sciences, Yale University School of Medicine, New Haven, CT, USA

Curtis L. Lowery MD

Professor and Director, Maternal–Fetal Medicine, Department of Obstetrics and Gynecology, University of Arkansas for Medical Sciences College of Medicine, Little Rock, AR, USA

Barbara Luke ScD, MPH, RN, RD

Professor of Nursing, Obstetrics, and Pediatrics, School of Nursing and Health Studies, University of Miami, Coral Gables, FL, USA

Laurence B. McCullough PhD

Professor of Medicine and Medical Ethics, Center for Medical Ethics and Health Policy, Baylor College of Medicine, Houston, TX, USA

James G. McNamara MD

Chief, Clinical Immunology Branch, Division of Allergy, Immunology, and Transplantation, National Institute of Allergy and Infectious Diseases, National Institutes of Health, Bethesda, MD, USA

Maurice J. Mahoney MD, JD

Professor, Departments of Genetics, Pediatrics, and Obstetrics, Gynecology and Reproductive Sciences, Department of Genetics, Yale University School of Medicine, New Haven, CT, USA

Anita C. Manogura MD

Fellow, Maternal–Fetal Medicine, Department of Obstetrics and Gynecology, University of Maryland, Baltimore, MD, USA

Jennifer L. Melville MD, MPH

Assistant Professor, Department of Obstetrics and Gynecology, University of Washington School of Medicine, Seattle, WA, USA

Aubrey Milunsky MB, BCh, DSc, FRCP, FACMG, DCH

Professor, Departments of Human Genetics, Pediatrics, Pathology, and Obstetrics and Gynecology, Center for Human Genetics, Boston University School of Medicine, Boston, MA, USA

Jeff Milunsky MD, FACMG

Associate Professor, Departments of Pediatrics, Genetics, and Genomics, Boston University School of Medicine, Boston, MA, USA

Howard Minkoff MD

Chairman, Obstetrics and Gynecology, Maimonides Medical Center, Distinguished Professor, Obstetrics and Gynecology, SUNY Downstate, Brooklyn, NY, USA

Fernando R. Moya MD

Director of Neonatology, Coastal AHEC, Wilmington, Professor, Department of Pediatrics, University of North Carolina, Chapel Hill, NC, USA

Thomas D. Myles MD

St. Louis University, Richmond Heights, MO, USA

Jennifer R. Niebyl MD

Professor and Head, Department of Obstetrics and Gynecology, University of Iowa Roy J. and Lucille A. Carver College of Medicine, Iowa City, IA, USA

Jyh Kae Nien MD

Fellow, Perinatology Research Branch, National Institute of Child Health and Human Development, National Institutes of Health, Department of Health and Human Services, Bethesda, MD, and Detroit, MI, USA

The late Carl A. Nimrod MB, BS, FRCS(C)

Formerly Professor and Chair, Department of Obstetrics and Gynecology, University of Ottawa, Ottawa, ON, Canada

Chien Oh MD

Fellow of Maternal–Fetal Medicine, Department of Obstetrics, Gynecology, and Reproductive Sciences, University of Maryland, Baltimore, MD, USA

Lawrence W. Oppenheimer MB, FRCOG, FRCS(UK), FRCS(C)

Associate Professor, Division of Maternal–Fetal Medicine, Department of Obstetrics and Gynecology, University of Ottawa, Ottawa, ON, Canada

Michael J. Paidas MD

Associate Professor, Department of Obstetrics, Gynecology, and Reproductive Sciences, Co-Director, Yale Blood Center for Women and Children, Yale University School of Medicine, New Haven, CT, USA

Glenn E. Palomaki

Director of Biometry, Foundation for Blood Research, Scarborough, MA, USA

Santosh Pandipati MD

Instructor-Fellow, Maternal–Fetal Medicine, University of Colorado Health Sciences Center, Denver, CO, USA

Trivedi Vidhya N. Persaud MD, PhD, DSc,
FRCPath(Lond)
*Professor Emeritus, Department of Human Anatomy and Cell
Science, University of Manitoba, Winnipeg, MB, Canada*

Christian M. Pettker MD
*Instructor and Clinical Fellow, Division of Maternal–Fetal
Medicine, Department of Obstetrics, Gynecology, and
Reproductive Sciences, Yale University School of Medicine,
New Haven, CT, USA*

Gianluigi Pilu MD
*Associate Professor, Department of Obstetrics and Gynecology,
Prenatal Medicine, S. Orsola-Malpighi University Hospital,
Bologna, Italy*

Mladen Predanic MSc, MD
*Fellow, Division of Maternal–Fetal Medicine, Department of
Obstetrics and Gynecology, Weill Medical College of Cornell
University, New York, NY, USA*

Vivek Raj MB, BS, MD, MRCP(UK)
*Associate Professor, Interim Director, Division of Gastroenterology,
University of Arkansas for Medical Sciences College of Medicine,
Little Rock, AR, USA*

E. Albert Reece MD, PhD, MBA
*Vice President for Medical Affairs, University of Maryland, and
John Z. & Akiko K. Bowers Distinguished Professor and Dean,
School of Medicine, and
Professor, Departments of OB/GYN and Reproductive Sciences;
Medicine; and Biochemistry and Molecular Biology; Baltimore,
MD, USA*

Nicola Rizzo MD
*Professor of Obstetrics and Gynecology, Prenatal Medicine,
S. Orsola-Malpighi University Hospital, Bologna, Italy*

Paula K. Roberson PhD
*Professor and Chair, Biostatistics, Colleges of Medicine and Public
Health, University of Arkansas for Medical Sciences College of
Medicine, Little Rock, AR, USA*

Roberto Romero MD
*Chief, Perinatology Research Branch, Intramural Division, National
Institute of Child Health and Human Development, National
Institutes of Health, Department of Health and Human Services,
Bethesda, MD, and Detroit, MI, USA*

Michael G. Ross MD, MPH
*Professor and Chairman, Department of Obstetrics and
Gynecology, Harbor–UCLA Medical Center, Torrance,
CA, USA*

Stacy A. Rudnicki MD
*Associate Professor of Neurology, University of Arkansas for
Medical Sciences College of Medicine, Little Rock, AR, USA*

Benjamin P. Sachs MB, BS, DPH, FACOG
*Obstetrician–Gynecologist-in-Chief,
Harold H. Rosenfield Professor of Obstetrics, Gynecology, and
Reproductive Biology, Harvard Medical School, Department of
Obstetrics/Gynecology, Beth Israel Deaconess Medical Center,
Boston, MA, USA*

Joaquin Santolaya-Forgas MD, PhD

Foreword

When asked to write the foreword to the third edition of *Clinical Obstetrics—The Fetus & Mother*, I had two immediate thoughts, the first being that I liked the new title better than the former title, *Medicine of the Fetus & Mother*. The second was that those already acquainted with the former title might not recognize the new one. As I had no control over either, I was pleased that I at least could remind readers of the importance of this current work.

When considering a new or forward-thinking idea, concept, or treatise, it is often a good idea to consider where we have been and where we are going. This is especially true when considering clinical obstetrics, which today means both fetus and mother.

Although the fetus could be evaluated prior to the early 1960s, the methods were crude when considered retrospectively. Auscultation and radiography were the primary tools and little could be accomplished to alter fetal outcome other than by delivery. This changed in 1961 with Lily's pioneering work with the use of amniocentesis to manage Rh-isoinmunization.

In less than one professional lifetime, the fetus has become our patient, not just the mother. This rapid evolution has been helped by pioneers in electronic fetal heart rate monitoring, such as Edward Hon, and of course by the use of ultrasound and Doppler evaluations of the fetus. In this last field it is important to acknowledge individuals such as Ian Donald in

the United Kingdom. He struggled in the 1960s to develop ultrasound as a useful clinical tool when many of our colleagues in radiology considered such machines to be toys. Certainly, as is obvious in the current textbook, the authors' efforts over the past two decades have proven Dr. Donald right. Many of their own studies have formed the basis for maternal and actual fetal therapy.

It is critically important to recognize in the current textbook that maternal–fetal medicine now encompasses the areas of conception and fetal growth, extending into the neonatal time period. It is now apparent that the basic fundamental biology of conception likely will lead to a better understanding of stem cell biology and basic immunology. Finally, an entire new field of study is developing in understanding how fetal/neonatal illness may result in adult disease(s) many years after birth.

Both the student of obstetrics and the practitioner should read this third edition of what is becoming an essential update of maternal–fetal knowledge. Today's practice is founded upon the principles and practices so clearly presented in this book. This third edition provides the proof that learning can be fun!

Norman F. Gant Jr. MD
2006

Preface

The field of clinical obstetrics and maternal–fetal medicine is undergoing major advances, with rapid strides being made.

The first edition was introduced as the fulfillment of a concept: to combine into one source maternal medicine—an established field focusing primarily on medical complications of pregnancy—and the rapidly evolving field of fetal medicine. The acceptance of this single source book has been overwhelming. The text has been embraced not only by clinical obstetricians but also by maternal–fetal medicine specialists, resident physicians in training, medical students, and others who use the book primarily for its comprehensive obstetrical coverage. The second edition was an updated version of the first edition.

However, this third edition is not only entirely revised, but now has a strong clinical emphasis, while maintaining a scholarly orientation that is expected to be appealing to both clinicians and academicians. The new book title, *Clinical Obstetrics—The Fetus & Mother*, reflects the new orientation of this third edition.

This text is a comprehensive treatise in obstetrics and maternal–fetal medicine. It discusses subjects from the time of conception to delivery, including the normal processes and disease states of the fetus, as well as diagnostic and therapeutic measures that can be used to effect fetal well-being. The fetal

medicine section includes prenatal diagnosis and places a strong emphasis on the biology of early pregnancy and the fetal–placental unit, fetal development, and variations in normal embryonic and fetal growth. The influence of teratogens, infections, and fetal diseases on outcome is also discussed. Extensive coverage is given to the prenatal diagnosis of congenital malformations using a variety of modalities, both noninvasive and invasive. The various biophysical and biochemical means of evaluation of fetal well-being are also discussed in great detail. The application of fetal therapy, both surgical and medical, is presented, with limited coverage on the evolving field of gene and cell therapy. In addition, maternal medical complications of pregnancy are thoroughly covered.

Although comprehensive, this book is designed to provide readily accessible information. The overall balance, scope, content, and design fully serve the needs of academic subspecialists, obstetricians, and house staff physicians, as well as other keen students of medicine.

E. Albert Reece MD, PhD, MBA
John C. Hobbins MD
2006

Preface to the first edition

The field of maternal–fetal medicine developed into a recognized subspecialty from the 1950s through the 1970s and subsequently has become the academic arm of obstetrics. With greater sophistication, the field has widened to encompass many other allied areas, including genetics, teratology, diagnostic imaging, fetal and maternal physiology, and endocrinology. In spite of these advances the fetus remained, until recently, inaccessible to the obstetrician/perinatologist. Specialized medical care was provided primarily to the mother with the hope that improving the maternal condition would benefit the fetus. In recent years, the fetus has become accessible through various technologic advances, permitting fetal disease to be diagnosed by various methods including genetics, sonographic or direct *in utero* testing, and treatment administered either medically or surgically.

With the fetus having emerged as a bona fide patient, the field of maternal–fetal medicine has entered a new era. It may no longer be regarded as dealing with medical complications of the mother during pregnancy, but, rather, is to be seen as embodying both normal and diseased processes of both the fetus and the mother. The editors of this textbook believe that physicians in the practice of maternal–fetal medicine need, therefore, to become familiar with the complications of preg-

nancy that affect the fetus and/or the mother as well as the variety of modalities that are available for diagnosis, evaluation, and treatment.

This textbook is a comprehensive treatise on maternal–fetal medicine. It discusses subjects from the time of conception to delivery, including normal processes and disease states of the fetus, as well as diagnostic and therapeutic measures that can be used. In addition, all maternal medical complications of pregnancy are discussed in detail. A separate volume consisting of a compilation of questions and answers corresponding to each chapter is available for the student of medicine who wishes to test his or her knowledge of the subject.

Although this textbook is comprehensive, it is designed in such a manner that information relating to either the fetus or the mother is readily accessible. The overall balance in scope, content, and design will serve the needs of academic subspecialists, obstetricians, and house staff physicians, as well as other keen students of medicine, very well.

Acknowledgments

The editors are deeply indebted to all of the contributors, who have invested an enormous amount of time and energy in this project. We count ourselves extremely fortunate to have colleagues and friends who are willing to make this type of investment. The collective efforts have resulted in an entirely revised and most up-to-date book series.

We truly appreciate the invaluable efforts of Ms. Veronika Guttenberger, project specialist in the College of Medicine at the University of Arkansas for Medical Sciences, who assisted in coordinating this entire project. We remain grateful and indebted to her. Carol Homko, PhD, from Temple University School of Medicine made invaluable editorial contributions to this project and we are most appreciative of her assistance.

Finally, we are greatly appreciative of the editors at Blackwell Publishing Ltd., especially Ms. Rebecca Huxley and Dr. Stuart Taylor, for their wise counsel and enduring patience.

The collective efforts of all who contributed to this project are a true testimony of scholarship, commitment, and selflessness. Our lives have been touched by the willingness of everyone to be so generous in sharing their time and talents. Thank you very kindly.

We want to especially acknowledge and thank our good friend and colleague the late Dr. Carl Nimrod, MB, BS, FRCS(C), who contributed so generously to this book series and prior editions. His untimely death saddens us all, but his life and scholarly contributions will brighten our memories.

Overview: historical perspectives of fetal medicine

Edward J. Quilligan and Fredrick P. Zuspan

The fetus has never been considered a separate patient but rather an integral part of the pregnancy. It was thoroughly protected from any diagnosis or manipulation; nothing could be done to alter the course or condition of the fetus. It was a passenger, not a patient.

If we can define a patient as someone about whom we can make a diagnosis and treat so as to alter that individual's course, then the fetus became a patient in the period between 1500 and 1600. In 1500, Jacob Nufer, a swine gelder, performed the first recorded successful Cesarean section on his wife. Rousset published a book on Cesarean section in 1588, and in the first Italian book on obstetrics, Mercurio advocated Cesarean section for patients with contracted pelvises.¹ Peter the Elder of the Chamberlen family invented the obstetric forceps.² Both of these methods of delivering the fetus, although developed primarily to assist the mother during a difficult delivery, had the potential to alter the fetal environment and thus could be said to treat the fetus, albeit indirectly. The first attempts at fetal diagnosis can be attributed to Marsac, who, in the seventeenth century, first heard the fetal heart beat. In 1818, Mayor, a Swiss surgeon, reported the presence of fetal heart tones; 3 years later, Kergaradec suggested auscultation would be helpful in the diagnosis of twins and the fetal lie and its position.³ In 1833, Kennedy⁴ suggested that the fetal heart rate was indicative of fetal distress. Such distress, if diagnosed late in pregnancy, could be treated using forceps for delivery; however, it was not until relatively recent times that Cesarean section was used to treat fetal distress during the first stage of labor. Douglas and Stromme,¹ in their 1957 text *Operative Obstetrics*, state that "fetal distress was virtually nonexistent as a cause for Cesarean section on our service [New York Hospital] until 10 years ago."

Rh disease

The next major diagnostic step was made by Bevis⁵ in 1952. He found a good correlation between amniotic fluid nonheme iron (obtained by amniocentesis) and the severity of fetal anemia. This pioneering work was amplified by Liley,⁶ who in 1961 demonstrated that the spectral peak at 450 mU reflected the severity of hemolysis. This gave the obstetrician a method

with which to follow the patient with Rh sensitization and, in some cases, deliver the fetus prematurely for fetal salvage. The next major step in the treatment of these Rh-sensitized fetuses was also made by Liley,⁷ who in 1964 demonstrated that one could successfully treat these anemic fetuses *in utero* by transfusing blood into the fetal abdomen.

Fetal heart rate monitoring

During this same period, Hon⁸ was developing methods for continuous recording of the fetal heart rate and, more important, the factors acting in the fetus that altered the fetal heart rate in response to uterine contractions. He identified three basic patterns: early, late, and variable decelerations, which were due to head compression, uteroplacental insufficiency, and umbilical cord compression, respectively. This permitted the attending obstetrician to assign a cause for the fetal heart rate decelerations that had been described in the 1800s. It also permitted a more individualized therapy for the deceleration: change of position for the variable deceleration and maternal oxygen for the late decelerations. Baseline heart rate change and heart rate variability were also related to specific fetal or maternal conditions.

The association of late decelerations and fetal oxygen deficiency was carried into the antepartum period by Hammacher⁹ in 1966. He observed that those infants who had late decelerations of their fetal heart rate in association with spontaneous uterine contractions had lower Apgar scores at birth and a higher stillbirth rate. Pose and Escarcena¹⁰ induced the contractions with oxytocin and found a similar correlation. Ray et al.¹¹ conducted the first prospective blind trial in the USA and confirmed the results of Hammacher and Pose and Escarcena.

Biochemical monitoring

The fetal heart rate changes are best characterized as biophysical changes. During this same period, fetal biochemical changes related to fetal well-being were being observed. The initial biochemical change associated with fetal health was its ability to make estriol.

Although Spielman et al.¹² and Smith and Smith¹³ demonstrated the association between maternal urinary estriol excretion and fetal health in 1933, the test was not used extensively until the 1950s owing to the lack of a reliable and easily performed chemical assay. Brown developed such an assay, and the test was used for many years, finally succumbing to less expensive, more accurate biophysical tests.¹⁴ Another biochemical marker of fetal distress was the acid–base balance of the fetal scalp blood introduced by Saling and Schneider¹⁵ in 1963. This is still a reasonable test to use in selected situations.

Genetic testing

The foregoing discussion of fetal monitoring deals primarily with the oxygenation of the fetus. The development of a method of culturing and examining the chromosomes of the fetal cells residing in the amniotic fluid of the first- and early second-trimester fetus permitted the diagnosis of chromosomal abnormalities when pregnancy could be safely interrupted. In 1949, Barr and Bertram¹⁶ identified the sex chromatin that allowed several investigators^{17–20} to use amniotic fluid to determine whether a sex-linked genetic aberration was a possibility in a given pregnancy. Culture of amniotic fluid cells was reported by Jacobson and Barter²¹ in 1967. They used available techniques to search for chromosomal abnormalities in 56 pregnancies before 20 weeks of gestation, with a greater than 90% success rate in obtaining adequate chromosomal patterns. Knowledge of chromosomal abnormalities has increased as new techniques such as banding allowed the geneticist a more detailed look at the chromosomal structure; more recently, the development of genetic probes has significantly widened the field of genetic diagnosis. Chromosomal abnormalities were not the only fetal problems that could be determined using amniotic fluid; biochemical determinations allowed the diagnosis of such inheritable diseases as Tay–Sachs disease and many others. Although amniotic sac puncture to obtain fluid had relatively few risks, there were some. This, coupled with the significant work and cost associated with analyzing amniotic fluid for chromosomal abnormalities, has led to restricting the test to those most at risk: older pregnant patients and patients who have a genetic problem in the family or had an abnormal prior pregnancy. The development of maternal blood markers for fetal abnormalities was extremely important because, using the criteria described above, one would miss a significant proportion of fetal problems. For example, although the risk of trisomy 21 is much greater in infants of patients older than age 35 years, screening only these patients failed to detect 75% of the trisomy 21 patients, because these patients were younger than 35 years of age. In 1944, Pederson²² described a protein found only in the fetus, fetuin. This was the first specific fetal protein. Bergstrand and Czar²³ found another fetal-specific protein, which migrated between the albumen and α globulin fraction. This was named *α -fetoprotein* by Gitlin and Boesman²⁴ in

1966. In 1972, Brock and Sutcliffe²⁵ reported elevated levels of α -fetoprotein in the amniotic fluid surrounding fetuses with neural tube defects, and, in 1984, Merkatz and his colleagues²⁶ noted that pregnant patients with a trisomy 21 fetus had lower than expected maternal levels of α -fetoprotein. This marker allows all pregnant patients to be offered screening for neural tube defects and some trisomies. Placental and fetal cells enter the maternal circulation, albeit in small numbers. Investigators are currently working on methods of harvesting and culturing these cells, which would obviate the need for amniocentesis.

Sonography

In 1955, Ian Donald^{27,28} introduced a technical innovation to obstetrics and gynecology that brought the fetus to the obstetrician's fingertips. Ultrasound changed the way obstetrics was practiced because, for the first time, the fetus, placenta, and umbilical cord were visualized with increasing clarity. One could assess fetal position, fetal growth, fetal weight, and fetal structure for anomalies, as well as placental and umbilical cord location and vessel number. As ultrasound improved technically, it became possible to perform fetal echocardiograms and evaluate fetal blood flow through umbilical, uterine, and numerous fetal vessels. This clarity of observation allowed the obstetrician fetal access in terms of placing needles in the umbilical vessels to perform fetal diagnostic studies or therapy such as transfusion.

Although the fetus could be very accurately visualized, and sometimes treated, using ultrasound, there were some conditions, such as diaphragmatic hernia, that required a surgical approach during the second trimester if pulmonary hypoplasia was to be avoided. Although removal of the fetus from the uterus had been tried since 1980, it was not successful owing to premature labor or fetal death *in utero*. In 1990, Harrison and his colleagues²⁹ reported the successful repair of a diaphragmatic hernia on a midtrimester fetus that was placed back into the uterus. The pregnancy continued into the third trimester, with delivery of a live fetus.

Development of maternal–fetal medicine

The fetus has become a patient the obstetrician can diagnose and treat. This is recognized in a variety of ways. The American Board of Obstetrics and Gynecology developed certification for the specialist in maternal–fetal medicine in 1974. Centers of excellence in care of the fetus have developed throughout the country, receiving referrals for difficult maternal and fetal management problems from the generalist obstetrician–gynecologist. Texts such as this stress fetal diagnostic and therapeutic approaches.

The saying “you’ve come a long way, baby” has never been

so true from the standpoint of both the fetus and the newborn. This is reflected in the continuing decline in perinatal mortality; however, the statement “you still have a long way to go” is also very true. We still do not know for certain precisely what triggers the onset of premature labor, which is responsible for the greatest number of perinatal deaths. Research needs to continue at an accelerated pace, taking diagnosis and treatment to the molecular level. In addition to providing the known material in this field at a very high level, this text asks the questions that need to be asked.

Conception and Conceptus Development

Early conceptus growth and immunobiologic adaptations of pregnancy

Kenneth H.H. Wong and Eli Y. Adashi

Reproduction will only be successful if a multitude of intricate sequences and interactions occur. This reproductive process begins with the formation of individual male and female gametes. Following gamete formation, a mechanism must be provided to ensure that these gametes attain close proximity to each other so fertilization may take place. After successful fertilization, the newly formed embryo must develop correctly and finally implant in a nourishing environment. Recently, there have been many advances in the understanding of these reproductive processes; however, it is beyond the scope of this chapter to provide detailed information on gamete formation, fertilization, and implantation. The interested reader is referred to several excellent texts for more specific information.^{1,2} Rather, this chapter summarizes key normal developmental and physiologic events in early conceptus growth and immunobiologic adaptation of a pregnancy.

Gametogenesis

Gametogenesis is the maturational process that produces specialized gametes: the spermatozoon in the male and the oocyte in the female. Both cytorreduction and division prepare gametes for fertilization, which involves the union of male and female gametes. In order to maintain a constant chromosome number, the gametes undergo meiosis, a specialized form of cell division responsible for reducing the diploid number (46) of chromosomes to the haploid number (23).

At approximately 5 weeks of gestation, primitive germ cells migrate, presumably by way of amoeboid movement from the yolk sac to the gonadal ridges. Following their migration, the germ cells are surrounded by somatic cells derived from the mesonephros forming the primary sex cords.³

In the first meiotic division, homologous chromosomes pair during prophase. In the pachytene stage of prophase, independent assortment and recombination of genetic material occurs among the gametes. Separation of the paired chromosomes occurs in anaphase, whereupon each new daughter cell

contains the haploid chromosome number or 23 double-structured chromosomes.

Shortly after the first division, the cell enters the second meiotic division. Each double-structured chromosome divides to form two separate chromosomes containing one chromatid. The resultant products include four daughter cells each containing the haploid number of chromosomes. Thus, one primary oocyte gives rise to four daughter cells, each receiving 22 autosomes and an X chromosome, and the primary spermatocyte gives rise to four daughter cells, each receiving 22 autosomes and either an X or a Y chromosome.

Fertilization

Embryonic development begins with the process of fertilization, the union of individual male and female gametes (Fig. 1.1). The fusion of two haploid cells, each bearing 22 autosomes and one sex chromosome, creates an offspring whose genetic makeup is different from that of both parents. Fertilization consists of a regulated sequence of interactions that will ultimately result in embryo development (Fig. 1.2).

Prior to any sperm-egg interaction, a requisite maturation of spermatozoa, termed capacitation, must occur.^{4,5} The spermatozoa gain this ability during the transit through the female reproductive tract. Triggered exocytosis is the final consequence of capacitation.⁶ The importance of capacitation has long been recognized, with the initial observation that capacitated sperm can readily penetrate the cumulus.⁷ Capacitation is characterized by the acrosome reaction (AR), the ability to bind to the zona pellucida (ZP), and the acquisition of hypermobility.

Spermatozoa must pass through an investment of cells and matrices, the cumulus, before any sperm-egg interaction may take place. The cumulus is composed of granulosa cells and a matrix consisting primarily of hyaluronic acid and proteins. Sperm capacitation and the hyperactivated motility seem to be important in the sperm's ability to penetrate the cumulus. Investigations have revealed that the sperm protein PH-20 is

Figure 1.1 Fertilization. A sperm is shown penetrating an oocyte. The spermatozoon must first undergo capacitation. Next, the sperm must penetrate the cumulus (the investment of cells and matrix surrounding the oocyte). After cumulus penetration, the sperm binds to the zona pellucida via specific receptors. The plasma membranes of the sperm and oocyte fuse. The sperm and tail of the sperm enter the oocyte, leaving the sperm's plasma membrane.

also involved with cumulus matrix penetration.⁸ Although PH-20 degrades hyaluronic acid and possesses similar protein properties to hyaluronidase, the exact role of this enzyme still remains uncertain.

The ZP is an acellular glycoprotein coat that covers and protects the ovum. The ZP is the last physical barrier that spermatozoa must pass before fertilization with the ovum. The initial interaction between the sperm and the oocyte ZP appears to be a receptor-mediated process. The ZP consists principally of three heavily glycosylated proteins: ZP1, ZP2, and ZP3.^{9,10} Extensive studies, especially in the mouse, have revealed ZP2 and ZP3 function in sperm binding, whereas ZP1 serves a structural role.^{5,11} Moreover, ZP3 has been demonstrated to be responsible for primary sperm binding (binding prior to the acrosome reaction) and triggers the acrosome reaction, while ZP2 is involved with secondary binding (binding with sperm following the acrosome reaction).^{12,13}

The AR involves fusion between the sperm's plasma and acrosomal membrane with exocytosis of the enzyme contents of the acrosome. These enzymes, including hyaluronidase and acrosin, appear to play a role in ZP penetration. Furthermore, the AR changes the sperm head membranes in preparation for the eventual fusion of the inner acrosomal membrane with the

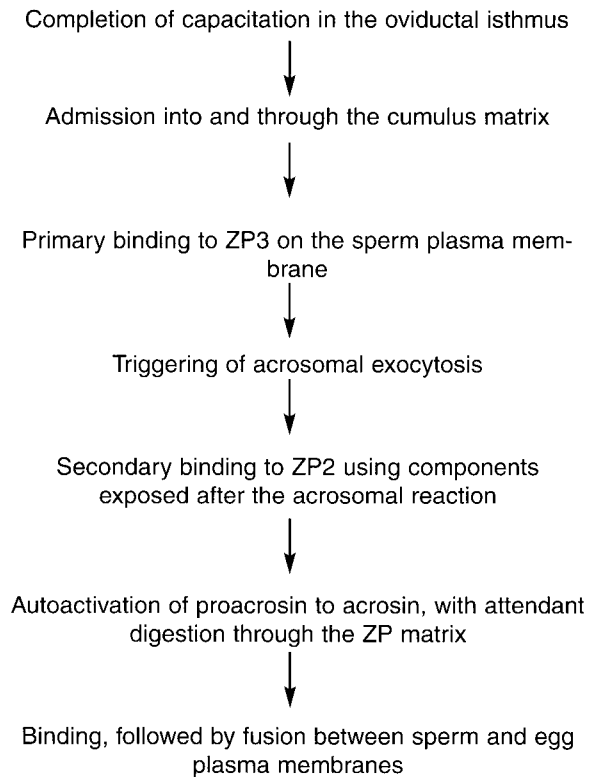

Figure 1.2 Proposed sequence for mammalian gamete interaction. ZP, zona pellucida. (Adapted from ref. 35, with permission.)

oocyte's plasma membrane. Acrosome-intact sperm are unable to fuse with oocytes.¹⁴ Thus, the AR is an absolute prerequisite for sperm fusion with the oocyte membrane.

Once the ZP has been penetrated, the spermatozoon enters the perivitelline space at an angle and crosses quickly. The sperm then binds to the oocyte plasma membrane (oolemma) and soon the entire head enters the cytoplasm of the oocyte (ooplasm). Subsequently, there is fusion of the sperm and egg membranes with specific proteins mediating this process. One such fusion protein is fertilin (formerly called PH-30).^{8,15} This sperm membrane protein appears to bind to the oolemma via an integrin receptor-mediated mechanism.⁸ Following fusion, several morphologic and biochemical events are initiated in the fertilized ovum.

Upon fusion of the egg and sperm membranes, there is a triggering of the cortical and zona reactions. As a result of the release of cortical granules in the oocyte, the oolemma becomes impenetrable to spermatozoa. Furthermore, the ZP alters its structure, possibly due to ZP2 and ZP3 protein rearrangement, to prevent further sperm binding.⁵ These are the primary blocking mechanisms to polyspermy.

Besides the cortical and zona reactions, a number of biochemical and molecular events are activated in the oocyte after sperm-egg fusion. Initially, there is a transient release of

intracellular calcium in a repeated oscillatory fashion.^{16,17} These calcium pulses may be initiated by membrane depolarization and propagated through inositol triphosphate production. Consequently, the release of calcium induces exocytosis of the cortical granules. Eventually, these events will lead to initiation of the cell cycle and DNA synthesis.

Upon initiation, the oocyte will resume the second meiotic division that had been arrested at metaphase 2. One of the daughter cells will be extruded as the second polar body, while the other daughter cell, containing a haploid number of chromosomes, becomes the definitive oocyte. Restoration of the diploid number of chromosomes results from the addition of chromosomes from the sperm upon fertilization.

The female pronucleus is formed from the maternal chromosomes remaining in the oocyte. Meanwhile, the sperm head's chromatin decondenses, while enlarging the head in the ooplasm, forming the male pronucleus. The two pronuclei enlarge and migrate toward each other in the center of the fertilized egg. As the pronuclei move into close proximity, the nuclear membranes break down. Syngamy then begins as the chromosomes condense during the first cell division.

Preimplantation embryo

The initial phases of embryonic growth following fertilization are concerned with rapid cell division (Fig. 1.3). This initial increase in cell numbers is critical in establishing a sufficient number of cells in the embryo, which can then initiate differentiation. These cells are known as blastomeres. Beginning

with the first division, approximately 24–30 hours after fertilization, the blastomeres become smaller with successive divisions. Until the eight-cell stage, the cells are in a loosely arranged clump; however, following this cleavage stage, blastomeres begin merging into a coherent mass of cells marked by the formation of gap and tight junctions.^{18,19} This process of compaction segregates inner cells from outer cells and represents the onset of embryonic differentiation. Approximately 3 days after fertilization, the berry-like mass of cells, termed the morula, enters the uterus.

The next event in embryo development is the formation of a fluid-filled cavity, the blastocoele. With blastocyst formation, there is a partitioning of cells between an inner cell mass, the embryoblast, and an outer mass of cells, the trophoblast. E-cadherin, a molecule involved with cell–cell binding, seems to be important for trophoblast and blastocyst formation.²⁰ This polarization of blastomeres permits differentiation to proceed. Differentiation allows for the development of the three primitive tissue layers: the endoderm, mesoderm, and ectoderm. The primitive endoderm arises from a flattened layer of cells, the hypoblast, which lies on the surface of the inner cell mass and faces the blastocoele. Meanwhile, both the mesoderm and the ectoderm develop from the epiblast, the high columnar cell of the inner cell mass.

Until this stage in its growth, the blastocyst is still entirely surrounded by the ZP. The primary function of the ZP appears to be prevention of polyspermy. However, the ZP must be shed prior to embryo implantation to allow for the increasing cell mass and to enable contact between the embryo and the endometrium. This is achieved by hatching, where the embryo wiggles and squeezes out of this investment through a hole. In

Figure 1.3 Cleavage and blastogenesis. Cleavage occurs in stages and results in the formation of blastomeres. The morula is composed of 12–16 blastomeres. The blastocyst forms when approximately 60 blastomeres are present. Note that the zona pellucida has disappeared by the late blastocyst stage. Until the zona pellucida is shed, the developing embryo essentially does not increase in size.

mice, the initial hole in the ZP is created by the enzyme trypsin.²¹ In contrast, the exact mechanism in the human is still unknown, and human hatching has only been seen *in vitro*.²²

After entering the uterus, the developing blastocyst floats inside the endometrial cavity for about 2–3 days. The embryo begins implantation approximately 6 days after fertilization, while the primitive germ layers develop between days 6 and 8. Following initial implantation, the embryo is completely imbedded within the endometrium by approximately 8–9 days after ovulation.

Intermediary metabolism in the developing embryo

Like all other cells, the developing embryo has nutritional requirements and possesses few nutrient stores, so it must depend on external sources. The metabolic requirements may vary depending on the particular embryonic stage of development. One requirement of particular interest is that pyruvate appears to be the major energy source for early embryo development, while glucose metabolism becomes activated in later cleavage stages. Besides pyruvate and glucose, there are many embryo nutrients and stimulants, including amino acids, intermediaries regulating calcium, and free radical scavengers, to name a few (see Fig. 1.4).

Molecular synthesis in the developing conceptus

The early conceptus exhibits a high level of metabolic activity and is capable of the synthesis and secretion of a number of macromolecules that have diverse effects on the success of implantation, placentation, and maintenance of pregnancy.

Among the earliest substances secreted by the preimplantation embryo is a soluble ether phospholipid, platelet activating factor (PAF). Correlation between the production of embryo-derived (ED)PAF and the pregnancy potential of embryos suggests that it may serve a fundamental role in the establishment of pregnancy.²³ Apparently, human embryos release variable amounts of PAF within 48 hours after fertilization.²⁴ Conclusive evidence for the essential role of PAF in the establishment of pregnancy was provided by Spinks and O'Neill, who used inhibitors of PAF activity *in vivo* to induce implantation failure in animals.²⁵

Human chorionic gonadotropin (hCG) is a glycoprotein composed of one α and one β subunit with amino acid sequences similar to luteinizing hormone. It is produced by the early human trophoblast beginning about the eight-cell stage and is essential for the survival of the conceptus by stimulating progesterone production from the corpus luteum and thus preventing luteolysis and menstruation. In the human, implantation occurs on day 6 after ovulation, and hCG is first measurable on day 9 following ovulation.²⁶ The hCG production

of human blastocysts *in vitro* has been correlated with their morphology and maturity, with the best embryos producing more hCG.²⁷

Early pregnancy factor (EPF) has been described based on an alteration in lymphocytic reactivity in the lymphocyte rosette test, which was devised to assess the immunosuppressive characteristics of antilymphocyte serum *in vitro*.²⁸ Isolation of EPF in embryo growth media has been reported in several species. An immunosuppressive role has been implicated, possibly by modulating the maternal immune system.²⁹ Recently identified as part of a highly conserved heat shock family of molecules, EPF consists of an amino acid sequence with approximately 70% homology to chaperonin 10 and may be involved in protein binding.³⁰ EPF becomes positive in maternal serum as early as 24–48 hours after conception and therefore may be useful in the evaluation of early pregnancy failure.³¹ Consequently, disorders of menstruation may be distinguished from early spontaneous abortion.

The human zygote produces a factor *in vitro* that is directly immunosuppressive.³² Unlike the immunosuppressive actions of EPF or EDPAF, the actions of immunosuppressive factor (IF) are direct. The factor obtained from culture media of human embryos after *in vitro* fertilization suppresses mitogen-induced proliferation of peripheral lymphocytes, and those embryos producing the factor alone result in pregnancy. The presence of embryo-associated IFs at various stages of gestation may play a role in suppressing maternal cellular immune responses and prevent maternal rejection of the fetal allograft. Although IF was thought initially to derive from the developing embryo, recent evidence has localized IF to decidual cells.³³

Although the mechanism has not been elucidated, histamine is thought to play a role in implantation of the blastocyst. Embryo-derived histamine releasing factor (EHRF) has been identified in culture medium used to grow developing embryos.³⁴ Both calcium and temperature dependent, EHRF induces histamine release from sensitized basal cells. Although the role of this factor remains to be clarified, EHRF could represent a message sent by the embryo to the mother to induce histamine release at the time of implantation.

Cytokines and growth factors regulating implantation

A critical stage in development involves embryonic implantation, a continual synchrony between the embryo itself and a complex series of molecular and cellular events induced in the uterus by estrogen and progesterone. Much of this maternal environment/embryonic “talk” is mediated in an autocrine/paracrine manner by cytokines and growth factors produced by both the embryo and the uterus. Although there exists a myriad of information concerning cytokine and growth factor involvement with implantation, the complete details of this mechanism are still incomplete. For a more comprehensive

Figure 1.4 Embryonic nutrients and secreted products. review, the interested reader is referred to several reviews.^{35,36} At least three cytokines, colony-stimulating factor 1 (CSF-1), leukemia inhibitory factor (LIF) and interleukin 1 (IL-1) appear to be involved in implantation.³⁷

Apposition and adhesion of the embryo to the endometrium

The blastocyst lies unattached in the uterine endometrial cavity for approximately 2 days before implantation. Implan-

tation begins as the embryo becomes closely apposed to the endometrial epithelium (Fig. 1.5). The initial contact is made via the polar trophoblast. Apposition seems to allow the complementary binding proteins of the embryo and endometrial epithelium to function effectively during implantation by the interdigitating of epithelial cells and trophoblast with microvilli.

The adherence of the blastocyst to the endometrial epithelium appears to be mediated through ligand-receptor complexes. The expression of specific adhesion molecules, such as integrins, in the embryo and specific substrates and receptors,

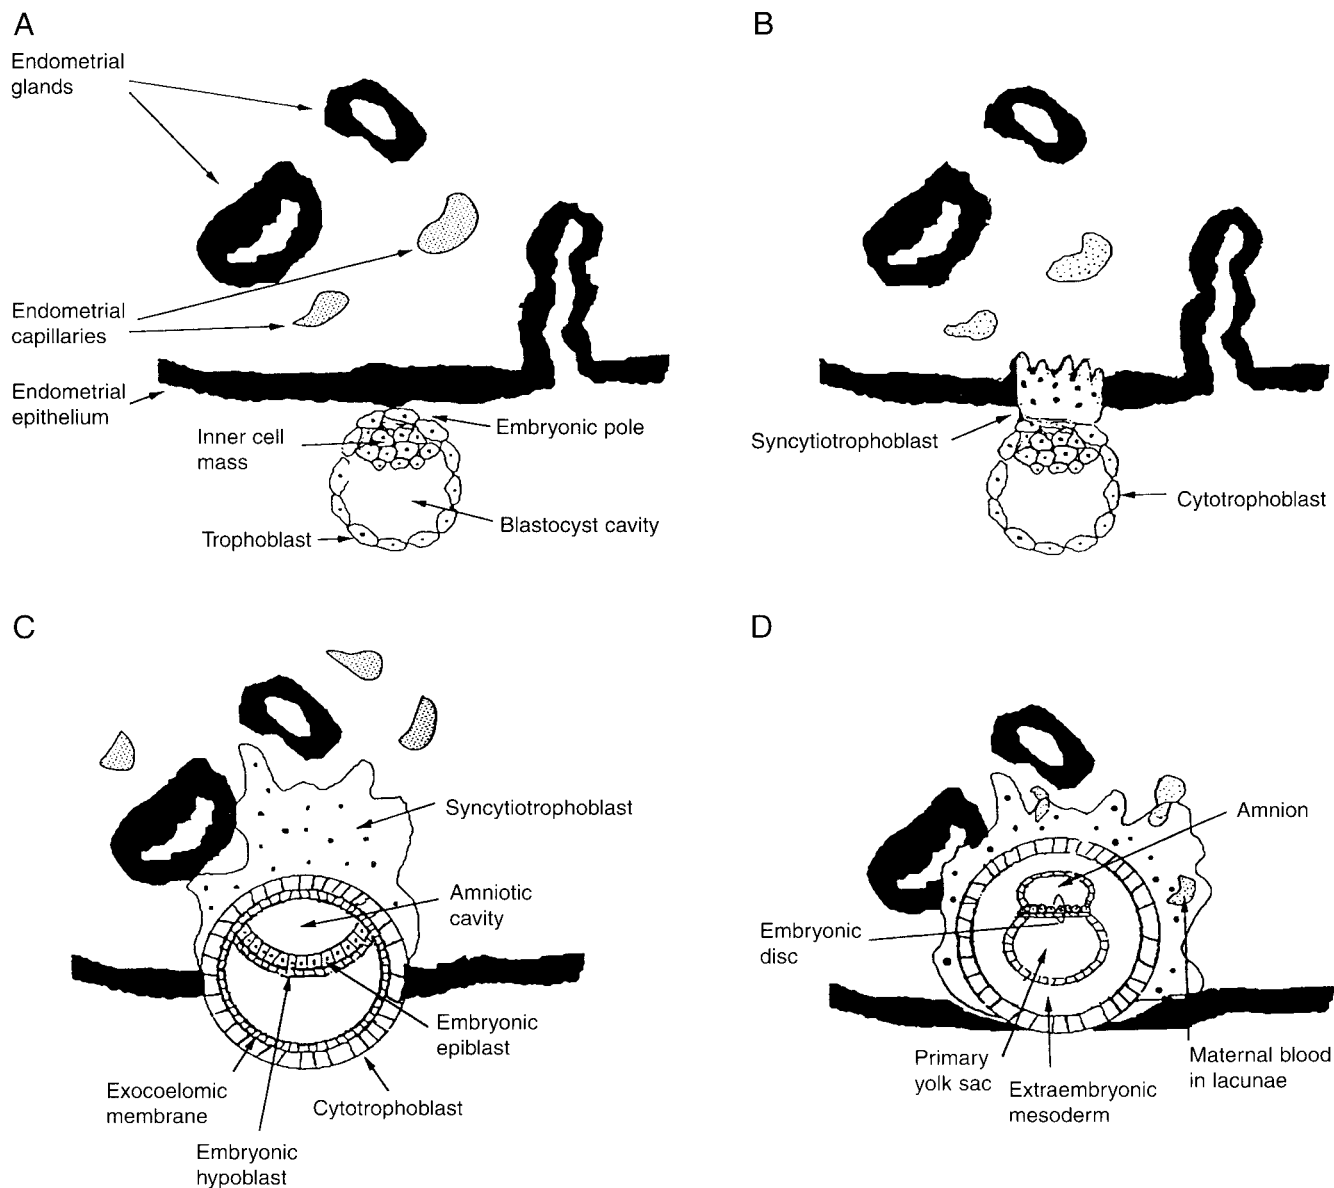

Figure 1.5 Implantation. (A) After floating free for 2 days, the polar trophoblast of the embryo apposes the endometrial epithelium. (B) Penetration begins with rapid proliferation and differentiation into two cell types, the cytotrophoblast and the syncytiotrophoblast. The syncytiotrophoblast, a multinucleated mass of cells with no cell

boundaries, extends through the endometrial epithelium to penetrate the stroma. (C) The inner cell mass differentiates into the epiblast, which gives rise to the mesoderm and ectoderm, and the hypoblast, which gives rise to the endoderm. (D) The embryo becomes completely embedded 7–13 days after ovulation.

such as laminin, fibronectins, and collagen IV, in the uterine epithelium and decidua appears to be involved with these ligand–receptor complexes. After adhering to the uterine epithelium, the blastocyst will begin penetrating through the basement membrane and into the uterine stroma.

Penetration of the epithelium

Immediately following adhesion, the blastocyst begins penetration into the endometrial epithelium and stroma (Fig. 1.5). For trophoblast cells to invade, they have to degrade and remodel the epithelium and stroma. Thus, embryos must produce specific molecules and other enzymes to assist in their penetration. A delicate coordination must exist, however, between the invading embryo and the underlying endometrium to prevent excessive penetration and yet provide adequate invasiveness.

The enzymes and molecules implicated in implantation include the proteases, proteinases, and their inhibitors, which are all involved with degradation of the extracellular matrix. There is a high degree of tissue reorganization that occurs during implantation. At present, the significance of these substances is not fully understood, although their importance in implantation is paramount. Clearly, further studies are needed to elucidate whether one or more of these systems are involved in embryo penetration or if they are redundant systems for “back up” in case one of the systems should become ineffective.

The early human trophoblast

The blastocyst attaches to the endometrial epithelium at the embryonic pole 6 days after fertilization (Fig. 1.5). After the trophoblast has attached to the endometrial epithelium, rapid cellular proliferation occurs, and the trophoblast differentiates into two layers consisting of the inner cytotrophoblast and an outer syncytiotrophoblast, a multinucleated mass without cellular boundaries. Syncytial trophoblast processes extend through the endometrial epithelium to invade the endometrial stroma. Stromal cells surrounding the implantation site become laden with lipids and glycogen, become polyhedral in shape, and are referred to as decidual cells. These decidual cells degenerate in the region of the invading syncytiotrophoblast and provide nutrition to the developing embryo. The blastocyst superficially implants in the stratum compactum of the endometrium by the end of the first week. The trophoblast then invades the surrounding myometrium as the blastocyst becomes completely imbedded in the decidua. Capillary connections are formed as the trophoblast invades, and the blood supply to the developing fetus is established through which it will obtain its support until delivery occurs.

Immunobiologic adaptations of pregnancy

The primary role of the immune system is to protect the body from invasion by foreign organisms and their toxic products. This requires an ability to discriminate between self and nonself antigens, so that immune destruction can be targeted against the invading organism and not against the animal's own tissues. In pregnancy, the antigenically foreign fetus grows in its mother for 9 months, unharmed by her immune system. Clearly, immune adaptations must occur in pregnancy that are central to the survival of the fetus while maintaining the mother's ability to fight infection.

The maternal–fetal interface

Trophoblast

The fetus itself does not come into direct contact with maternal tissue. The trophoblast of the placenta and fetal membranes forms the interface between mother and fetus. Two areas of contact between mother and fetus are established: (1) a large surface area formed by the syncytiotrophoblast of the chorionic villi that is bathed by maternal blood; and (2), within the deciduas, extravillous trophoblast (mostly cytotrophoblast but with some syncytial elements) that mingles directly with maternal tissues.

Fetal–maternal cell traffic

The villous syncytiotrophoblast, adjacent to blood, and the nonvillous cytotrophoblast, in contact with maternal deciduas, are the main areas where maternal lymphocytes might be sensitized to trophoblasts. However, the interface between mother and fetus is extended by the traffic of fetal cells into the maternal circulation, carrying fetal antigens to other parts of the maternal immune system, where priming responses could also occur (Table 1.1).

Trophoblast deportation

It has been known for many years that trophoblast cells enter the maternal circulation.³⁸ There are two ways in which this might happen. First, trophoblast “buds” (called syncytial sprouts) often form on the syncytiotrophoblast surface and

Table 1.1 Contact between maternal and fetal tissues.

Local	Syncytiotrophoblast lining intervillous space Cytotrophoblast in decidua
Systemic	Fetal red and white cells entering maternal blood Trophoblast deportation

may break free and enter the maternal blood. This disruption of the syncytiotrophoblast could also lead to the underlying villous cytotrophoblast entering the mother's blood. Alternatively, the endovascular cytotrophoblast that lines the spiral arteries may be carried away into the bloodstream. There is evidence for both multinucleate (syncytiotrophoblast) and mononuclear (cytotrophoblast) cells entering the maternal uterine vein,³⁹ but it is not yet established whether the mononuclear cells are villous or extravillous cytotrophoblasts in origin. It is also a matter of great controversy whether trophoblasts enter the peripheral circulation to a major extent in pregnancy,⁴⁰ or whether they become trapped in the lungs.⁴¹

Traffic of fetal blood cells

Direct contact of fetal (as opposed to placental) cells with maternal cells can come about only by the passage of fetal blood into the maternal circulation. There is now good evidence that fetal nucleated erythrocytes can enter the maternal blood in early pregnancy,⁴² and it must be assumed that fetal leukocytes will enter at the same time.⁴³ Therefore, it appears that more cells traverse the placental barrier as the fetus and the placenta grow.⁴⁴ Their presence is presumed to result from fetal-maternal hemorrhage, although the mechanism by which this occurs has yet to be defined.

Maternal immune cells in decidua

The decidua is the tissue in which immune recognition of trophoblasts is most likely to occur. Immunohistologic and flow cytometric studies of the first-trimester pregnancy decidua into which trophoblast invades have shown that it is composed predominantly of immune cells.⁴⁵ Approximately 10% of the stromal cells are T lymphocytes (although there are virtually no B cells) and 20% are macrophages;⁴⁶ these two cell types are essential for cell-mediated graft rejection responses. However, the main immune cell population is large granular lymphocytes or natural killer (NK) cells, comprising 45% of the decidual cells.⁴⁷ Immunohistologic studies show that the extravillous cytotrophoblast is in close contact with these immune cells, which raises the question as to how the trophoblast avoids recognition and rejection.

Maternal immune responses to trophoblast

Expression of major histocompatibility complex (MHC) antigens by trophoblast

The way in which the mother's immune system responds to trophoblast cells will depend on which, if any, MHC antigens they express; therefore, this has been an area of intense study. Studies using monoclonal antibodies that recognized all forms of class I antigens [human leukocyte antigen (HLA)-A, -B, and

Table 1.2 MHC expression in human development.

-C] revealed that, although the syncytiotrophoblast and underlying villous cytotrophoblast were negative for class I, the invasive extravillous cytotrophoblast in the placental bed and the amniochorion strongly expressed this antigen.⁴⁸ Subsequent biochemical^{49,50} and molecular analyses⁵¹ have shown that the trophoblast class I antigen is in fact HLA-G. HLA-G differs from HLA-A, -B, and -C in that it is nonpolymorphic and has a lower molecular weight. The latter characteristic arises from a termination codon in exon 6, resulting in the transcription of a protein with a truncated cytoplasmic tail.⁵²

Polyclonal antibody studies have confirmed that HLA-G protein is expressed only by extravillous cytotrophoblast⁵³ (Table 1.2). Neither oocytes⁵⁴ nor sperm express surface class I or class II antigens, although sperm are reported to express mRNA for both HLA-B and -G.⁵⁵ Similarly, oocytes appear to be negative for both class I and class II antigens. Cleavage-stage embryos and blastocysts were also thought to be negative for class I,⁵⁶ but there is no evidence that a proportion of blastocysts express both HLA-G mRNA and protein, which may be associated with more rapid cleavage rates.⁵⁷ Thus, expression of HLA-G at this stage could be vital to protect the embryo as it implants into the decidua.

Immunoregulatory role of HLA-G

Soluble class I HLA molecules are known to be shed into the serum of patients with HLA-mismatched organ grafts.⁵⁸ These donor-derived, soluble, class I antigens are believed to prolong graft survival by inhibiting the activity of alloreactive cytotoxic lymphocytes.⁵⁹ This may occur through their binding to the T-cell receptor or its coreceptor, CD8, which induces apoptosis of the cytotoxic T cell.⁶⁰ It has been proposed that soluble HLA-G may likewise be shed from the surface of the trophoblast and may eliminate maternal cytotoxic T cells by a similar mechanism.⁶¹ In support of the hypothesis, evidence for a soluble HLA-G molecule has been obtained at both the

Table 1.3 Properties and functions of HLA-G.

Protein expression restricted to extravillous cytotrophoblast
Exists in both membrane-bound and soluble forms
Heavy chain (40-kDa) has truncated cytoplasmic tail
May have limited polymorphism or is nonpolymorphic
Forms class I complexes with β_2 -microglobulin and antigenic peptides
Expression is associated with TAP1
Appears not to stimulate maternal T-cell responses
Downregulates NK cell-mediated cytotoxicity

NK cell, natural killer cell; TAP1, transporter associated with peptide presentation.

molecular⁶² and the protein level,⁵⁰ and other studies have shown that HLA-G binds to CD8.⁶³

HLA-G expression may also serve a protective role for trophoblasts. HLA-G inhibits the proliferation of CD4+ T lymphocytes⁶⁴ and decreases decidual cell production of interferon (IFN)- γ and tumor necrosis factor (TNF)- α .⁶⁵ Addition of HLA-G to mixed lymphocyte cultures increases the production of IL-10 and decreases IFN- γ and TNF- α production causing a shift from a Th1 to a Th2 phenotype.⁶⁶

Protection against NK cell attack

It might seem that, in evolutionary terms, it would be simpler for the trophoblast not to express class I MHC and thereby avoid immune recognition. However, a major threat to trophoblast invading the decidua is presented by the large granular lymphocytes (NK cells). NK cells preferentially kill target cells that lack class I MHC. The presence of class I antigens on the cell surface is thought to be essential for protection from NK cell-mediated attack. Experiments using cell lines have shown that variants with low levels of class I expression are highly susceptible to NK lysis,⁶⁷ but that transfection with both classical class I and HLA-G genes can confer protection.^{61,68} The expression of HLA-G may therefore be essential to protect extravillous cytotrophoblast from decidual NK cells.^{69,70} Thus, HLA-G may serve a dual role in protecting trophoblast from both cytotoxic T cells and NK cells.

The properties and possible functions of HLA-G are summarized in Table 1.3.

Maternal immune responses to trafficking cells

Fetal leukocytes

In the placenta, class I antigen expression occurs in the mesenchyme of the chorionic villi as early as 2.5 weeks, although it is sporadic and weak. Class II-positive cells are found in the placenta by 14 weeks' gestation.⁷¹ In the fetus itself, class

I- and class II-positive cells have been found in the thymic epithelium at 7 weeks' gestation.⁷² Thus, if fetal leukocytes enter the maternal circulation, they could potentially stimulate maternal immune responses.

Antibody responses

Antifetal (paternal) HLA alloantibodies can develop during a first pregnancy,⁷³ and may occur after an abortion,⁷⁴ which indicates that immunization is not necessarily the result of events at delivery, but usually develops after 28 weeks, with the incidence increasing with parity.⁷⁵ These antibodies do not develop in all pregnancies. The rate is approximately 15% of women in their first pregnancies and never more than approximately 60% among multiparous women.⁷⁶ Antibodies may develop against both class I and class II antigens.⁷⁷

None of these antifetal antibodies appears to cause harm to the fetus, probably because they cannot bind to the syncytiotrophoblast, given that it does not express MHC antigens. This would be sufficient protection were it not for the placenta's role in the transfer of immunoglobulins from the maternal to the fetal circulation – a process by which the fetus acquires immunity from infection in the perinatal period. Fc receptors on the surface of the syncytiotrophoblast bind free immunoglobulin G (IgG) molecules and transport them to the villous stroma, where they enter the fetal circulation. Only IgG is transported; antibodies of other classes remain in the maternal blood. However, antibodies to fetal (paternal) HLA appear to be effectively filtered out by binding HLA antigens on cells in the villous stroma. IgG that is aggregated or complexed with antigen is removed by Fc receptor-bearing macrophages.⁷⁸ This illustrates the concept of the placental “sponge.” Thus, only maternal IgG antibodies to antigens not represented in placental tissues escape the “sponge” and reach the fetal circulation.⁷⁹

Cell-mediated responses

If the mother can develop antibodies to fetal HLA antigens, it would be expected that she can also develop cell-mediated immunity because T- and B-cell sensitization to fetal HLA should occur together. It is therefore surprising that there is only sporadic evidence for T-cell sensitization, as judged by the detection of a secondary maternal–paternal (fetal) mixed lymphocyte reaction or paternal (fetal)-specific cytotoxic T cells.⁸⁰

A search for maternal cytotoxic T cells against paternal and unrelated control target cells at term found clear evidence for their presence in only 2 of 20 pregnant women.⁸¹ In a further series of experiments, no sensitization to paternal HLA was seen in 25 normal first-trimester pregnancies.⁸² Even when cytotoxic T cells were found, they did not appear to harm the fetus because these women had normal pregnancies. This implies that cytotoxic T cells cannot cross the placental barrier to gain access to the fetus.

Table 1.4 Maternal immune responses to fetal cells.

	Antibody response	Cell-mediated response

Trophoblast	+/- (?)	-

+, response; -, no response; (?), conflicting evidence.

Immunoregulation

From the discussion above, it is clear that there is a paradox in pregnancy in that, although the mother's ability to produce antibodies is apparently normal, her ability to mount cell-mediated immune responses is weakened (Table 1.4). This concept is supported by clinical observations that pregnant women, although not grossly immunocompromised, are more susceptible to diseases that are normally dealt with by cell-mediated immune responses. Certain viral infections, such as hepatitis, herpes simplex, and Epstein-Barr virus, are more common in pregnancy.⁸³ Diseases caused by intracellular pathogens (e.g., leprosy, tuberculosis, malaria, toxoplasmosis, and coccidioidomycosis) appear to be exacerbated by pregnancy. Furthermore, approximately 70% of women with rheumatoid arthritis (caused by cytotoxic T cells in the joints) experience a temporary remission of their symptoms during gestation, whereas systemic lupus erythematosus (caused by autoantibodies) tends to get worse during pregnancy.⁸⁴

Many investigators have attempted to characterize the maternal immune response by determining immune cell subsets and immune cell function during pregnancy. In general, immune function is similar in pregnant and nonpregnant women (Table 1.5). Taken together, there is no clear trend toward either the enhancement or the suppression of immune function during pregnancy.

Immunoregulatory factors

Placental suppressor factors

The placenta itself can release factors that suppress T-cell and NK-cell activity.⁸⁵ Microvillous preparations of syncytiotrophoblast and culture supernatants from placental cells and choriocarcinoma cell lines^{86,87} nonspecifically suppress mitogen responsiveness and allogeneically stimulated lymphocytes in the mixed lymphocyte reaction along with the cytolytic activity of cytotoxic T cells and NK-cell activity.⁸⁸ Suppressive activity may appear very early in gestation, given that animal⁸⁹ and human preimplantation embryos have been reported to produce inhibitory factors within 24 hours of fertilization.⁹⁰

Table 1.5 Alterations in maternal cellular immunity during pregnancy.

Component	Alteration in pregnancy	Reference
B-cell numbers	No change	102, 103
T-cell numbers	No change	104, 105, 106
T-cell function	No change	107
	Decreased	108, 109
NK-cell function	Decreased	110, 111

Decidual suppressor factors

Suppressive factors released by the placenta into the blood may inhibit lymphocyte responses systematically, but other mechanisms may be involved locally to prevent alloimmune recognition of extravillous cytotrophoblast that invades the decidua. Suppression of cell-mediated responsiveness *in vitro* by cell populations⁹¹ from first-trimester human decidua has also been demonstrated. Decidual cells secrete various proteins that might mediate these suppressive activities. Transforming growth factor β , a cytokine that strongly inhibits proliferation of B cells and T cells and the cytolytic activity of NK cells, has been localized to the large granular lymphocytes in the human decidua.⁹²

Cytokines and pregnancy

The strongest candidates for the suppressor factors derived from the placenta and decidua are cytokines. It has been proposed that the maternal immune changes in pregnancy are brought about by a shift in the balance of cytokines that favors antibody production and depresses the potentially harmful cell-mediated immune responses.

Type 1 and type 2 cytokines and the immune response

It has become apparent that antibody production and cell-mediated responses are controlled through two distinct populations of CD4+ Th cells.⁹³ Type 1 CD4+ Th cells (Th1) control cell-mediated responses by secreting cytokines such as IL-2, TFN- β , and IFN- γ , which stimulate cytotoxic T cells and NK cells (Th1 response). Type 2 CD4+ Th cells (Th2) produce IL-4, which stimulates IgE and IgG antibody production by B cells (Th2 response) (Fig. 1.6A). These two systems are also interactive in that IFN- γ produced by T1 cells inhibits B-cell development induced by Th2 cells, and Th2 cells in turn produce IL-10, which inhibits cytokine synthesis by Th1 cells (Fig. 1.6B). Thus, Th1 and Th2 cytokines are mutually inhibitory but, in the normal state, they are in balance, allowing both forms of immune response to coexist. However, a deviation in the pattern of cytokine production could lead to one type of response being favored over the other.

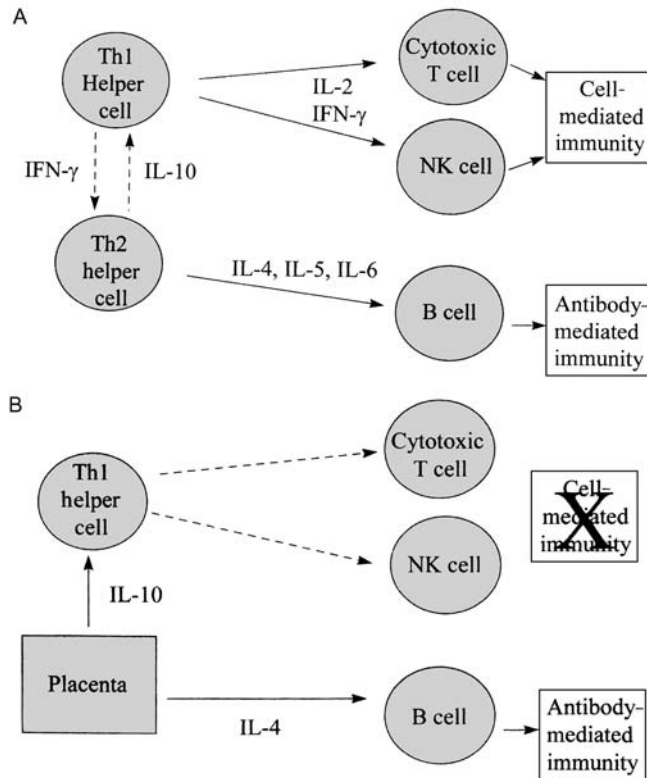

Figure 1.6 (A) Th1 and Th2 cytokines in immune responses. (B) Th1 and Th2 cytokines in pregnancy. IFN, interferon; IL, interleukin; NK, natural killer; Th1, type 1 T helper cells; Th2, type 2 T helper cells.

Type 1 and type 2 cytokines in pregnancy

In pregnancy, it is proposed that there is a shift away from Th1 responses and toward Th2 responses.⁹⁴ The cause of this shift is thought to be the production of Th2 cytokines by the placenta (Fig. 1.6B). Thus, excess IL-4 released from the placenta would stimulate maternal antibody responses. At the same time, excess IL-10 production would inhibit Th1 cells,

leading to the suppression of cytotoxic T cells and NK-cell activity, which has been observed.

Experimental evidence for this hypothesis is largely confined to the mouse. Several groups have demonstrated that production of Th2 cytokines by tissues at the maternal-fetal interface^{95,96} and injection of Th1 cytokines TNF- α , IFN- γ , and IL-2 into pregnant mice can increase fetal resorption rates and inhibit mouse embryo development and implantation *in vitro*.⁹⁷ So far, evidence in the human is restricted to localization studies showing that IL-4 is present in the syncytiotrophoblast, the cytotrophoblast of the fetal membranes, and decidual macrophages,⁹⁸ and that IL-10 is secreted by HLA-G-positive cytotrophoblast.⁹⁹ In contrast, IL-10 knockout mice¹⁰⁰ and IL-10, IL-4 double knockouts¹⁰¹ have normal pregnancies. Thus, the immunologic relationship between mother and fetus may be more complex than originally thought.

Immune circuit

It is clear from the foregoing discussion that, in normal pregnancy, fetal growth progresses side by side with the development of a number of immune mechanisms that function at several levels. These can be summarized by constructing an immune circuit (Fig. 1.7A). The first stage in this circuit is the exposure of the maternal immune system to both fetal trophoblast and leukocytes. This could potentially lead to immune recognition and the development of cell-mediated and antibody responses to fetal antigens, which in turn would lead to rejection of the fetus (placenta). However, this circuit is broken at several stages (Fig. 1.7B). First, on the basis of current evidence, the maternal immune system does not recognize the trophoblast because it either fails to express HLA or expresses HLA-G. Second, although fetal leukocytes can be recognized by maternal immune cells, only antibody responses occur because the placenta's production of Th2 cytokines downregulates cell-mediated immunity. Finally, the production of antipaternal antibodies is not harmful because the placenta filters out these antibodies before they reach the fetal circulation. Thus, it is the combination of these many immune adaptations of pregnancy that ensure the success of the fetus.

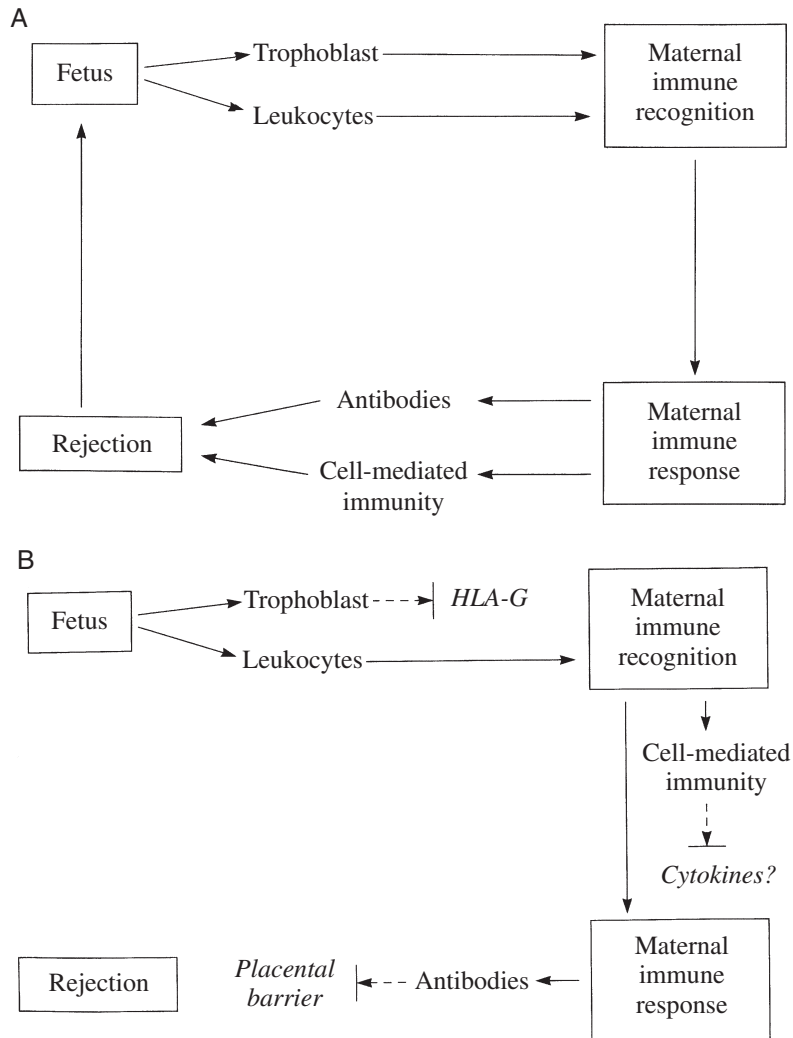

Figure 1.7 (A) Immune responses in pregnancy that could lead to rejection of the fetus. (B) Immuno-regulatory mechanisms in pregnancy that prevent the rejection of the fetus.

Key points

- 1 During meiosis, the primary oocyte gives rise to four daughter cells, each receiving 22 autosomes and an X chromosome. The primary spermatocyte also gives rise to four daughter cells, each receiving 22 autosomes and either an X or a Y chromosome.
- 2 Prior to sperm–egg interaction, capacitation of the spermatozoa must occur.
- 3 Capacitation is characterized by the acrosome reaction, fusion between the sperm's plasma and acrosomal membrane with exocytosis of the enzyme contents.
- 4 The zona pellucida is an acellular glycoprotein coat covering the ovum and consists of three principal proteins: ZP1, ZP2, and ZP3.
- 5 Upon fusion of the egg and sperm membranes, the cortical and zona reactions are triggered.
- 6 After egg–sperm fusion, the oocyte will resume the second meiotic division and extrude the second polar body.
- 7 The morula enters the uterus 3 days after fertilization and floats inside the endometrial cavity for 2–3 days. The embryo begins implantation approximately 6 days after fertilization.
- 8 Human chorionic gonadotrophin is a glycoprotein produced by the early conceptus and is essential in stimulating the corpus luteum to produce progesterone.
- 9 Three cytokines appear to be involved in implantation, colony-stimulating factor 1, leukemia inhibitory factor, and interleukin 1.
- 10 The adherence of the blastocyst to the endometrial epithelium is mediated through ligand–receptor complexes.

- 11 HLA-G protein is expressed only by extravillous cytotrophoblast.
- 12 Fetal nucleated erythrocytes and leukocytes can enter the maternal blood in early pregnancy.
- 13 First-trimester pregnancy decidua is composed predominantly of immune cells. Approximately 10% of the stromal cells are T lymphocytes, 20% are macrophages, and the main immune cell population is large granular lymphocytes or NK cells, comprising 45% of the decidual cells.
- 14 HLA-G inhibits the proliferation of CD4+ T lymphocytes and decreases decidual cell production of IFN- γ and TNF- α .
- 15 HLA-G may serve a dual role in protecting trophoblast from both cytotoxic T cells and NK cells.
- 16 In the placenta, class I antigen expression occurs in the mesenchyme of the chorionic villi as early as 2.5 weeks; class II-positive cells are found in the placenta by 14 weeks' gestation.
- 17 There is no clear trend toward either the enhancement or the suppression of immune function during pregnancy.
- 18 The placenta can release factors that suppress T-cell and NK-cell activity.
- 19 Type 1 CD4+ Th cells (Th1) control cell-mediated responses by secreting cytokines such as IL-2, TNF- β , and IFN- γ , which stimulate cytotoxic T cells and NK cells (Th1 response).
- 20 Type 2 CD4+ Th cells (Th2) produce IL-4, which stimulates IgE and IgG antibody production by B cells (Th2 response).

Normal embryonic and fetal development

Trivedi Vidhya N. Persaud and Jean C. Hay

This chapter is a synopsis of the main events in normal human development. The reader should consult the references¹⁻⁹ for a more detailed discussion of individual topics.

Fertilization normally occurs in the ampulla of the uterine tube and results in the formation of a zygote (Fig. 2.1). The zygote undergoes cleavage to form blastomeres. Contraction of smooth muscle in the wall of the uterine tube propels the dividing zygote toward the uterine cavity. About day 3, the morula, composed of approximately 16 blastomeres, enters the uterine cavity and forms a blastocyst consisting of the outer cell mass or trophoblast, the inner cell mass or embryoblast, and the blastocyst cavity. At about day 6, the blastocyst begins to implant in the endometrium. As the trophoblast penetrates the endometrium, it differentiates into the syncytiotrophoblast and cytotrophoblast. By the end of this week, a layer of cells, the hypoblast, appears on the side of the inner cell mass facing the blastocyst cavity.

The second week is marked by the completion of implantation and the formation of the bilaminar embryonic disk (Fig. 2.2). The amniotic cavity develops between the inner cell mass and the cytotrophoblast. The epithelial roof of this cavity is the amnion. The layer of inner cell mass cells forming the floor of the cavity constitutes the epiblast. The epiblast and hypoblast form the bilaminar embryonic disk. The extraembryonic membrane, continuous with the hypoblast, surrounds a cavity called the primary yolk sac. Cells from the trophoblast form the extraembryonic mesoderm, which surrounds the amnion and primary yolk sac. Fluid-filled spaces in the extraembryonic mesoderm coalesce to form the extraembryonic coelom or chorionic cavity. As the extraembryonic coelom develops, the primary yolk sac is reduced and, as hypoblast cells grow out and line it, the secondary or definitive yolk sac forms. Except for the connecting or body stalk, the extraembryonic coelom splits the extraembryonic mesoderm into two layers: the extraembryonic splanchnic mesoderm covering the yolk sac; and the extraembryonic somatic mesoderm that covers the amnion and lines the trophoblast. The trophoblast and the extraembryonic mesoderm lining it form the chorion. The prechordal plate, a midline circular

thickening of the hypoblast, marks the future mouth region and the cranial end of the embryonic disk.

During the third week, the trilaminar embryonic disk is formed, differentiation of the germ layers begins, and a primitive circulatory system is established (Fig. 2.3). A midline thickening of epiblast, the primitive streak, appears in the caudal region of the embryonic disk. Epiblast cells move to the primitive streak and pass laterally and cranially between the epiblast and the hypoblast to form the intraembryonic mesoderm. The epiblast is now called the embryonic ectoderm. Epiblast cells are thought to displace much of the hypoblast to form the embryonic endoderm. Cells from the primitive node pass between the endoderm and the ectoderm in the midline and extend cranially to the prechordal plate, which will give rise to the notochord. At the cranial and caudal ends of the embryonic disk, the endoderm and the overlying ectoderm fuse to form the oropharyngeal membrane and the cloacal membrane respectively. Embryonic mesoderm passes between the ectoderm and the endoderm except at the oropharyngeal and cloacal membranes, and where the notochord extends in the midline. Mesoderm cranial to the oropharyngeal membrane forms the cardiogenic area. Normally, the primitive streak will regress and disappear.

The notochord and adjacent mesoderm induce the overlying ectoderm to form the neural plate. Differential growth gives rise to a neural groove flanked by neural folds. The neural folds fuse to form the neural tube with a central neural canal. Fusion of the neural folds commences in the future cervical region and extends cranially and caudally (the anterior neuropore closes between days 25 and 26 of gestation, followed by the posterior neuropore 2 days later). It has been suggested that there are multiple closure sites involved in the formation of the neural tube. Some neuroectodermal cells are not incorporated into the neural tube and form the neural crests. The neural tube detaches from the ectoderm, and the surface ectoderm mainly forms the epidermis and the structures derived from it.

Differentiation of the mesoderm on each side of the notochord forms the paraxial mesoderm, which becomes

Figure 2.1 Diagram illustrating the first week of development.

(A₂ and B₂) Transverse sections of the embryonic disk at the levels indicated in (A₁) and (B₁). (C and D) Dorsal views of the embryonic disk showing differentiation of the mesoderm and formation of the

organized into 42–44 pairs of somites. Each somite is composed of a dermatome, which contributes to the dermis; a myotome, which gives rise to skeletal muscle; and a sclerotome, the cells of which migrate around the neural tube and notochord to form the precursors of the vertebrae and the ribs. It also forms the intermediate mesoderm, a small area of mesoderm lateral to the paraxial mesoderm. This is associated with the development of the urogenital system. Finally, it forms the lateral mesoderm at the margins of the disk. Spaces in this mesoderm coalesce to form the horseshoe-shaped intraembryonic coelom, which will form the pericardial, pleural, and peritoneal cavities. This coelom splits the lateral mesoderm into somatic and splanchnic layers. The somatopleure, the embryonic somatic mesoderm and ectoderm, will form the body walls. The splanchnopleure, the embryonic splanchnic mesoderm and endoderm, will form the primitive gut and the structures derived from it. In the cardiogenic area, mesoderm cranial to the embryonic coelom forms the septum transversum, which will form part of the diaphragm.

intraembryonic coelom (the developing neural tube has been omitted). (E₁ to E₄) Development of the neural tube and neural crests. (F) Transverse section of the embryonic disk at the level indicated in (D).

Concurrently, chorionic villi, consisting of a core of extraembryonic mesoderm covered with cytotrophoblast and syncytiotrophoblast, develop around the chorionic sac. The allantois, a finger-like extension of endoderm from the caudal wall of the yolk sac, extends into the mesoderm of the connecting stalk.

Blood vessels first appear in the extraembryonic mesoderm (except that covering the amnion) and shortly thereafter in the embryo. Clusters of cells, the blood islands, acquire lumina. The surrounding cells form the endothelium and other layers of the vessel wall. As the vessels develop and sprout, the intra- and extraembryonic vessels are linked. Blood cells develop in association with the vessels of the yolk sac and allantois. Blood cells may arise from cells trapped within the lumen as the vessel forms, or from cells shed into the lumen. Paired endothelial heart tubes develop in the cardiogenic area. These fuse to form a single contractile heart tube and, by the end of the third week, a primitive circulation is established between the embryo and the chorion.

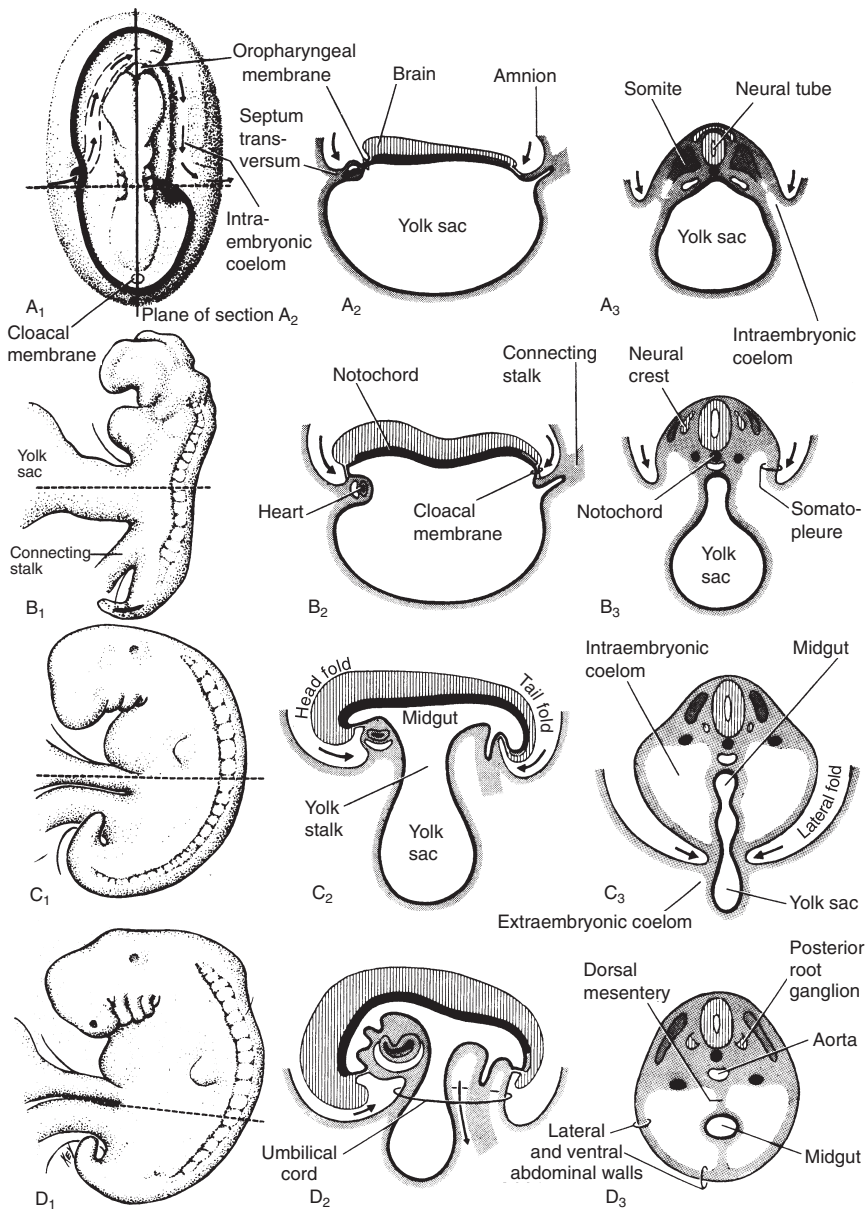

Figure 2.4 Diagrams illustrating folding of the embryonic disk during the fourth week. (A₁) Dorsal view. (B₁ to D₁) Lateral views of the embryo. (A₂ to D₂) Longitudinal sections at the levels shown in (A₃ to D₃). (From Moore KL. *The developing human*, 4th edn. Philadelphia, PA: W.B. Saunders, 1988 with permission.)

The embryonic period

The embryonic period extends from the beginning of the fourth week to the end of the eighth week. During this period, all the major internal and external structures begin their development. By the end of this period, the embryo has acquired characteristic human features. In the fourth week, the embryonic disk undergoes folding (Fig. 2.4). Folding converts the flat embryonic disk into a cylindrical embryo. Folding in the longitudinal axis results in the formation of the head and tail folds. With the head fold, the developing heart and pericardial cavity are swung onto the ventral surface, and the septum transversum then lies caudal to the developing heart. The dorsal part of the yolk sac is incorporated into the embryo to

form the foregut. This is separated by the oropharyngeal membrane from the stomodeum or primitive oral cavity. With the tail fold, the body or connecting stalk, the future umbilical cord, is swung onto the ventral surface, and part of the allantois is incorporated into the embryo. The dorsal part of the yolk sac is incorporated into the embryo to form the hindgut. The terminal portion of the hindgut dilates to form the cloaca, which is separated from the amniotic cavity by the cloacal membrane. Folding in the transverse axis results in the somatopleure forming the lateral and ventral body walls. As the dorsal part of the yolk sac is incorporated into the embryo, the splanchnopleure forms the primitive gut. The midgut is connected to the yolk sac by the narrow vitelline duct. The remnant of the yolk sac ultimately degenerates. As the caudal limbs of the intraembryonic coelom are moved ventrally,

Figure 2.5 Diagrams illustrating the pharyngeal apparatus. Inset indicates the level of the horizontal sections shown in (A) and (B).

they are initially separated by a ventral mesentery. This mesentery disappears, except in the region of the foregut, and a single peritoneal cavity is formed. From the pericardial cavity, the pericardioperitoneal canals or future pleural cavities pass dorsally and caudally to communicate with the peritoneal cavity.

The fetal period

The fetal period extends from the beginning of the ninth week until birth. The main features of this period are the growth and differentiation of those tissues and organs that began their development in the embryonic period. Few new structures (hairs, nails) appear. During this period, fetal movement begins, and the life-sustaining reflexes (sucking, swallowing, etc.) are established.

Pharyngeal apparatus

In the fourth week, ridges and grooves appear in the future neck region (Fig. 2.5). These form part of the pharyngeal apparatus, which consists of the following: six pairs of pharyngeal arches numbered in a craniocaudal sequence (in humans, the fifth pharyngeal arch is absent); the pharyngeal grooves or clefts between the arches; the pharyngeal pouches (lined by endoderm and occurring internally between the arches); and the pharyngeal membranes, formed by the ectoderm and endoderm between the arches. The first or mandibular arch gives rise to the maxillary and mandibular prominences. The second or hyoid arch enlarges and grows caudally, concealing the posterior arches and creating an ectodermal depression, the cervical sinus; this arch ultimately fuses with the upper thoracic wall, giving the neck a smooth

Table 2.1 Major derivatives of the pharyngeal arch components.

Arch	Nerve	Muscles	Cartilages	Arteries
I	Trigeminal (V)	Muscles of mastication	Malleus, incus	Part of maxillary
II	Facial (VII)	Muscles of facial expression	Stapes, styloid process, part of hyoid bone	None
III	Glossopharyngeal (IX)	Stylopharyngeus	Remainder of hyoid bone	Common carotids, part of internal carotids
IV	Vagus (X) superior laryngeal branch			Part of arch of aorta and right subclavian
V		Muscles of palate, pharynx and larynx	Laryngeal cartilages (except epiglottis)	None
VI	Vagus (X) recurrent laryngeal branch			Pulmonary arteries and ductus arteriosus

contour. The first branchial groove, between the first and second arches, persists as the primordium of the external auditory meatus. In the mesodermal core of each arch are a cranial nerve, a skeletal muscle element, an artery, and a rod or bar of hyaline cartilage that is derived from neural crest cells. The ventral portions of the first arch or Meckel's cartilage disappear, and the mandible is derived from intramembranous ossification. The second arch cartilage is also called Reichert's cartilage. The derivatives of the branchial arch components are summarized in Table 2.1.

The first pair of pouches (between the first and second arches) forms the tympanic cavity and pharyngotympanic tube. The first branchial or closing membrane forms the tympanic membrane. The second pair of pouches persists in part to form the tonsillar fossa. This pair is associated with development of the palatine tonsils. The third pair of pouches develops dorsal and ventral portions. The dorsal portions separate, attach to the posterior aspect of the thyroid gland, and form the inferior parathyroid glands. The ventral portions fuse to form the thymus, which descends into the thorax. The fourth pair of pouches also develops dorsal and ventral portions and loses the connection with the pharynx. The dorsal portions separate, attach to the posterior aspect of the thyroid gland, and form the superior parathyroid glands. The small ventral portions of the fourth pouches and the rudimentary fifth pouches form the ultimobranchial bodies, which are incorporated into the thyroid gland to form the parafollicular cells.

In the fourth week, a thickening of endoderm appears in the floor of the pharynx; this grows downward to form the thyroid diverticulum. It grows caudally, becomes bilobed and is connected by the isthmus. The gland reaches its definitive position in the seventh week and is attached to its site of origin by the thyroglossal duct. This duct normally degenerates except for a small pit, the foramen cecum, in the tongue (see Fig. 2.5). In about 50% of individuals, the caudal portion of the duct persists to form a pyramidal lobe that extends upward from the isthmus. The endoderm becomes organized into fol-

licles, and the parafollicular cells are derived from the ultimobranchial bodies. The thyroid gland is functional by the 12th week of gestation.

The primordia of the tongue appear in the floor of the pharynx in the fourth week.

The body or oral part consists of the anterior two-thirds. Proliferation of mesoderm at the ventromedial ends of the first branchial arches forms the median tongue bud (tuberculum impar) just anterior to the foramen cecum. This bud is flanked by the two distal tongue buds (lateral lingual swellings). The median tongue bud is overgrown as the distal tongue buds enlarge and fuse, and the median sulcus indicates the plane of fusion. The root or pharyngeal part consists of the posterior one-third. The copula, just posterior to the foramen cecum, is formed by proliferation of mesoderm at the ventromedial ends of the second branchial arches. Posterior to the copula, the hypobranchial eminence is derived from proliferation of mesoderm at the ventromedial ends of the third and fourth branchial arches. The cranial part of this eminence overgrows the copula; the caudal portion will form the epiglottis. The sulcus terminalis roughly demarcates the junction of the root and the body. The intrinsic muscles of the tongue are derived from myoblasts that migrate from the occipital somites, and this explains why they are innervated by the hypoglossal nerve rather than by the branchial arch nerves.

The face

The primordia of the face appear at the end of the fourth week and are related to the stomodeum or primitive oral cavity as follows: the frontonasal prominence forms the cranial boundary, the maxillary prominences form the lateral boundaries, and the mandibular prominences form the caudal boundary. These prominences, formed by accumulations of mesenchyme, are separated by grooves and furrows. During development, the prominences merge with one another as the grooves are

smoothed out by proliferation of the underlying mesenchyme. Much of the mesenchyme in the facial region is considered to be of neural crest origin. Merging occurs mainly during the fifth to eighth weeks. Ectodermal thickenings on the inferolateral aspects of the frontonasal prominence form the nasal placodes. Mesenchyme around the placodes proliferates to form the medial and lateral nasal prominences, and the placodes then lie in depressions, the nasal pits or future nostrils. Expansion of the back of the head moves the eyes forward and contributes to the growth of the facial components toward the midline. The maxillary prominences merge with the medial nasal prominences, and the medial nasal prominences merge with each other to form the intermaxillary segment. The mandibular prominences merge with each other in the midline. The adult derivatives are the frontonasal prominence – the forehead, dorsum, and apex of the nose; the lateral nasal prominences – the alae of the nose; the merged medial nasal prominences (intermaxillary segment) – the columella, philtrum of the upper lip, the maxilla that bears the incisors (the premaxilla), and the primary palate; the maxillary prominences – the lateral portions of the upper lip, the upper cheeks and face, the rest of the maxilla, and the secondary palate; and the mandibular prominences – the lower lip, lower cheeks and face, and the mandible. Myoblasts from the second branchial arch migrate into the facial region to form the muscles of facial expression. Along the nasolacrimal groove between the lateral nasal and maxillary prominences, a cord of cells sinks into the underlying mesenchyme; this canalizes to form the nasolacrimal duct.

The palate

The palate develops from two primordia: the primary palate, a wedge-shaped mass of mesoderm from the innermost aspect of the intermaxillary segment that appears in the fifth week, and the secondary palate, which develops from the lateral palatine processes, shelf-like projections of mesoderm from the medial aspects of the maxillary prominences. These processes appear in the sixth week. As the developing tongue occupies most of the oral cavity, the lateral palatine processes assume a vertical position. As the stomodeum enlarges, the tongue drops down to the floor of the stomodeum, and the lateral palatine processes elevate to a horizontal position; this elevation occurs slightly later in females. Beginning anteriorly and proceeding posteriorly, the lateral palatine processes fuse with the posterior margin of the median palatine process, the inferior border of the nasal septum, and each other. Fusion involves epithelial contact, adhesion, and the replacement of the epithelial seam by mesoderm. Fusion begins in the ninth week and is completed by the 11th week in males and the 12th week in females. Intramembranous ossification spreads into the palate from the maxillary and palatine bones and extends to the posterior border of the nasal septum. Posterior to this, the unossified

portion forms the soft palate and uvula. The palatal muscles are derived from the branchial arches.

The respiratory system

The nasal pits deepen to form the nasal sacs. The oronasal membrane separating the oral and nasal cavities ruptures, and the cavities communicate just posteriorly to the primary palate. The nasal septum, a midline downgrowth from the frontonasal prominence, separates the nasal cavities. In the late fetal period, the paranasal sinuses develop as bone is resorbed, and most of their expansion occurs postnatally. The epithelium of the nasal placodes, located in the roof of the nasal cavities, forms the olfactory epithelium. In the fourth week, the laryngotracheal groove appears in the floor of the pharynx; it deepens to form the laryngotracheal diverticulum. As it grows caudally, longitudinal folds of mesenchyme fuse to form the tracheoesophageal septum, which separates the laryngotracheal tube (ventrally) from the esophagus (dorsally). The laryngotracheal tube gives rise to the larynx and trachea. A lung bud develops at the caudal end of the tube, and this soon bifurcates to give two bronchopulmonary or lung buds. The right lung bud develops two secondary buds, and the left lung bud gives rise to one secondary lung bud; these buds demarcate the future lobes of the lung. Dichotomous branching forms the air-conducting passages, the bronchi and bronchioles. Respiratory tissue – the respiratory bronchioles, alveolar ducts and sacs, and the alveoli – develops at the terminal ends of the bronchioles and continues to develop postnatally. As the lungs grow into the medial aspects of the pericardioperitoneal or pleural canals, they acquire a layer of visceral pleura.

The digestive system

The primitive gut forms during the fourth week as the head, tail, and lateral folds incorporate the dorsal part of the yolk sac into the embryo (see Fig. 2.4). The endoderm of the primitive gut gives rise to the epithelium and glands of most of the digestive tract; the epithelium at the cranial and caudal ends of the tract is derived from the ectoderm of the primitive oral cavity (stomodeum) and the anal pit (proctodeum) respectively. The muscular and fibrous elements of the digestive tract and the visceral peritoneum are derived from splanchnic mesenchyme. The primitive gut is divided into three parts: the foregut, midgut, and hindgut. The derivatives of the foregut are the pharynx and its derivatives, the lower respiratory tract, the esophagus, the stomach, the duodenum, proximal to the common bile duct, and the liver, biliary tract, gallbladder, and pancreas. The esophagus develops from the cranial part of the foregut. The striated muscle of the esophagus is derived from the caudal branchial arches, and the smooth muscle of the lower esophagus develops locally from the surrounding

splanchnic mesenchyme. The lumen of the esophagus becomes occluded by proliferation of the endodermal cells, but these cells degenerate and the lumen is recanalized. The stomach appears during week 4 as a fusiform dilation of the caudal part of the foregut; this primordium soon expands and broadens dorsoventrally. The dorsal border grows more rapidly than the ventral border and forms the greater curvature. As the stomach enlarges and acquires its adult shape, it rotates 90° in a clockwise direction about its longitudinal axis. Thus, the ventral border (lesser curvature) moves to the right, and the dorsal border (greater curvature) moves to the left. The original left side becomes the ventral surface, and the right side becomes the dorsal surface. The stomach is suspended from the dorsal wall of the abdominal cavity by the dorsal mesentery (dorsal mesogastrium). As the dorsal mesogastrium is carried to the left during rotation of the stomach, the lesser sac forms. Isolated clefts develop in the dorsal mesogastrium and coalesce to form the lesser peritoneal sac, which communicates with the greater peritoneal cavity through the epiploic foramen. The dorsal mesogastrium, the greater omentum, hangs from the greater curvature anterior to the developing intestines. As the embryo lengthens, the caudal part of the septum transversum thins and becomes the ventral mesentery, which attaches the stomach and the duodenum to the ventral wall of the abdominal cavity. The ventral mesentery persists only where it is attached to the caudal part of the foregut. The final shape and position of the stomach are influenced by the development of the liver and the omental bursa. The duodenum develops from the most caudal part of the foregut and the most cranial part of the midgut. These parts grow rapidly and form a C-shaped loop that projects ventrally. The junction of the foregut and the midgut is at the apex of this duodenal loop, and is demarcated by the duodenal papilla.

The liver arises as an endodermal bud from the most caudal part of the foregut; this hepatic diverticulum extends into the septum transversum, enlarges rapidly, and divides into a larger cranial part, the primordium of the liver, and a smaller caudal part, which will form the gallbladder and cystic duct. The stalk connecting the hepatic and cystic ducts to the duodenum becomes the common bile duct. The proliferating endodermal cells give rise to interlacing cords of liver cells and the epithelial lining of the intrahepatic portion of the biliary apparatus. As the liver cords invade the septum transversum, they break up the umbilical and vitelline veins to form the hepatic sinusoids. Hemopoiesis begins in the liver during the sixth week. The lobes of the liver grow extensively and soon fill most of the abdominal cavity. Initially, the lobes are about the same size, but the right lobe becomes much larger; the caudate and quadrate lobes develop as subdivisions of the left lobe. The ventral mesentery gives rise to the lesser omentum (gastrohepatic ligament and duodenohepatic ligament), the falciform ligament (liver to the anterior abdominal wall), and the visceral peritoneum of the liver.

The pancreas develops from dorsal and ventral pancreatic buds. The ventral pancreatic bud forms as an evagination of

the hepatic diverticulum, and the dorsal pancreatic bud is derived from the proximal part of the duodenum, opposite the hepatic diverticulum. As the duodenum grows and rotates to the right, the two buds come together and fuse. The ventral pancreatic bud gives rise to the main pancreatic duct, the uncinate process, and the lower part of the head of the pancreas. The rest of the pancreas and the accessory pancreatic duct are formed from the dorsal pancreatic bud. The two pancreatic ducts usually anastomose to form a single pancreatic duct. The spleen is derived from the fusion of mesenchymal nodules located in the dorsal mesogastrium.

The derivatives of the midgut are the small intestines (except for the duodenum from the stomach to the entry of the common bile duct), the cecum and appendix, the ascending colon, and the proximal one-half to two-thirds of the transverse colon.

The dorsal mesentery, which suspends the midgut from the dorsal abdominal wall, elongates rapidly. The midgut elongates during the sixth week, forming a ventral, U-shaped intestinal loop.

The midgut loop has a proximal or cranial limb, and a distal or caudal limb. The communication of the midgut with the yolk sac is reduced to the narrow yolk stalk or vitelline duct, which is attached to the apex of the loop and marks the junction between the two limbs. The midgut loop migrates into the umbilical cord. This “herniation” of the intestines occurs because there is not enough room in the abdomen, mainly because of the relatively large size of the liver and kidneys. The proximal limb grows rapidly and forms intestinal loops, but the caudal limb undergoes very little change except for development of the cecal diverticulum. The midgut loop then rotates within the umbilical cord. During the 10th week, as the intestines return rapidly to the abdomen, they undergo further rotation. The midgut segment undergoes a total counterclockwise rotation of 270°. This “reduction of the midgut hernia” is usually attributed to an increase in the size of the abdominal cavity and a decrease in the relative size of the liver and kidneys. The primordium of the cecum and appendix appears during the sixth week as the cecal bud, a conical pouch of the caudal limb of the midgut loop. The apex of this blind pouch does not grow as rapidly as the rest of the cecum and forms the vermiform appendix. Elongation of the proximal part of the colon results in the cecum and appendix “descending” from the upper to the lower right quadrant of the abdomen. As the intestines assume their final positions, in some places the mesentery fuses with the parietal peritoneum and disappears; those parts of the midgut become retroperitoneal. The proximal part of the duodenum and the ascending colon become retroperitoneal. Other derivatives of the midgut loop retain their mesenteries. The transverse colon is attached to the greater omentum.

The derivatives of the hindgut are the distal one-third to one-half of the transverse colon, the descending colon, the sigmoid colon, the rectum and the upper portion of the anal canal, and part of the urogenital system. The expanded ter-

minal part of the hindgut, the cloaca, is separated from the amniotic cavity by the cloacal membrane. The cloaca receives the allantois ventrally. A mesodermal partition, the urorectal septum, which develops between the allantois and the hindgut, divides the cloaca into the rectum and upper anal canal dorsally and the urogenital sinus ventrally. By the end of the seventh week, the urorectal septum fuses with the cloacal membrane, dividing it into a dorsal anal membrane and a ventral urogenital membrane. Proliferation of mesenchymal tissue around the anal membrane elevates the surface ectoderm and forms the shallow anal pit or proctodeum. The anal membrane at the floor of this pit ruptures by the end of the seventh week, forming the anal canal. The caudal part of the digestive tract is now in communication with the amniotic cavity. The proximal (upper) two-thirds of this canal is derived from the hindgut; the distal (lower) one-third develops from the proctodeum. The pectinate line indicates the approximate former site of the anal membrane and the junction of endoderm and ectoderm. The other layers are mesenchymal in origin.

The urinary system

At the beginning of the fourth week, the intermediate mesoderm on each side detaches from the somites and forms the nephrogenic cords. From the nephrogenic cords, three successive sets of excretory organs develop: the pronephros, the mesonephros, and the metanephros. The pronephros is formed in the cervical region and is a transitory nonfunctional structure. It regresses soon after its formation, leaving the pronephric ducts, which run caudally to enter the cloaca. These ducts will become the mesonephric ducts. The mesonephros also appears during the fourth week, caudal to the degenerating pronephros. Cell clusters in the nephrogenic cords give rise to mesonephric tubules, which drain into the mesonephric duct. The mesonephros serves as a temporary excretory organ and probably functions in urine production, but it degenerates during the latter part of the embryonic period. In the male, the mesonephric ducts form some components of the reproductive system. In the female, the mesonephric ducts degenerate, except for vestigial remnants. The permanent adult kidney, the metanephros, begins to develop early in the fifth week and is functional 2–3 weeks later. The ureteric bud develops as an outgrowth from the mesonephric duct, close to its entry into the cloaca. The ureteric bud grows dorsally and cranially to meet the metanephrogenic blastema (intermediate mesoderm). The ureteric bud forms the ureter, renal pelvis, calyces, and collecting tubules. The nephrons are derived from the metanephric blastema. At birth, the nephrons, approximately one million in each kidney, are formed, but are still short. No new nephrons are formed after birth. During infancy, the nephrons complete their differentiation and increase in size until adulthood. Initially, the metanephros is located in the

sacral region of the embryo and receives its blood supply from the dorsal aorta at that level. The metanephros gradually ascends, probably as a result of caudal growth of the embryo. This results in a relative change in the position of these organs, and they receive their blood supply from progressively higher levels. As the kidney ascends, it rotates, and the position of the hilum changes from ventral to medial.

The urinary bladder is derived from the cranial part of the urogenital sinus. It is lined by endoderm; the other layers are derived from the adjacent splanchnic mesenchyme. The mucosa and musculature of the trigone area are mesodermal in origin; possibly this mucosa is later overgrown by endodermal epithelium. The allantois, continuous with the bladder, constricts to form the urachus. The adult derivative of the urachus is the median umbilical ligament, which passes from the apex of the bladder to the umbilicus. In both sexes, the urethra is derived from the caudal part of the urogenital sinus. The epithelium of the entire female urethra is derived from the endoderm of the urogenital sinus. In the male, except for its most distal part, which is derived from ectoderm, the urethral epithelium has a similar origin. In both sexes, the other layers of the urethra are derived from adjacent splanchnic mesenchyme. Rupture of the urogenital membrane brings the urinary system into communication with the amniotic cavity. The suprarenal (adrenal) glands: aggregates of mesenchymal cells, derived from the mesothelium lining the posterior body wall, form the cortex. The medulla is derived from cells of neural crest origin.

The genital system

The genetic sex of the embryo is determined at fertilization by the type of spermatozoon that fertilizes the oocyte. There is no morphological indication of sexual differences until the eighth week, when the gonads begin to acquire sexual characteristics. Initially, all normal human embryos are potentially bisexual; male and female embryos have identical gonads, genital ducts, and external genitalia. This period of early genital development is referred to as the indifferent stage of the reproductive organs. The gonads appear during the fifth week of development, as the intermediate mesoderm on the dorsal body wall forms the gonadal ridges. The coelomic epithelium grows into the underlying mesenchyme and forms the primary sex cords. A week later, the cords become populated by primordial germ cells, precursors of the spermatogonia or oogonia. The Y chromosome has a strong testis-determining effect on the indifferent gonad. Under its influence, the primary sex cords differentiate into seminiferous tubules. Absence of a Y chromosome results in the formation of an ovary. Thus, the type of sex chromosome complex established at fertilization determines the type of gonad that develops from the indifferent gonad. The type of gonad then determines the sexual differentiation of the genital ducts and external genitalia.

Two pairs of genital ducts develop in both sexes: mesonephric (wolffian) ducts and paramesonephric (müllerian) ducts. In the male, the fetal testes produce at least two hormones: one stimulates development of the mesonephric ducts into the male genital tract, and the other suppresses development of the paramesonephric ducts. Some mesonephric tubules near the testis persist and are transformed into efferent ductules or ductuli efferentes, which connect the rete testis to the epididymis. The mesonephric duct becomes the ductus epididymis and the vas deferens. The seminal vesicles develop from paired lateral diverticula from the caudal ends of the mesonephric ducts. The part of the mesonephric duct between the duct of this gland and the urethra becomes the ejaculatory duct. The appendix of the epididymis and the paradidymis are nonfunctional rudiments of the mesonephric duct and mesonephric tubules respectively. In the male, the paramesonephric ducts largely degenerate, except for two vestigial remnants: the appendix of the testis and the prostatic utricle.

In female embryos, the mesonephric ducts regress and the paramesonephric ducts give rise to the female genital tract. The cranial unfused ends of the paramesonephric ducts form the uterine tubes. The caudal portions of the ducts converge and fuse in the midline to form the uterovaginal primordium, which gives rise to the uterus, cervix, and possibly part of the vagina. The development of the vagina is not entirely settled. One theory is that the uterovaginal primordium induces the formation of paired, endodermally derived outgrowths from the urogenital sinus. These fuse to form a solid vaginal plate, which eventually canalizes to become the vagina. Thus, the vaginal epithelium is derived from the endoderm of the urogenital sinus, and the fibromuscular wall of the vagina develops from the mesenchymal cells of the uterovaginal primordium. Another view is that the uterus and upper third of the vagina are formed from the uterovaginal primordium and surrounding mesenchyme, while the lower two-thirds of the vagina is presumed to be derived from the vaginal plate and the surrounding mesenchyme. A few blind mesonephric tubules, the epoophoron, may persist in the mesovarium. Parts of the mesonephric duct may persist as Gartner's duct in the broad ligament along the lateral wall of the uterus, or as a Gartner's cyst in the wall of the vagina.

The external genitalia also pass through an indifferent stage that is not distinguishable as male or female. Early in the fourth week, a genital tubercle develops ventrally to the cloacal membrane; this elongates to form the phallus. By the sixth week, labioscrotal swellings and urogenital folds develop on each side of the future urogenital membrane. In the male, masculinization of the indifferent external genitalia is caused by androgens produced by the testes. The phallus will form the penis. The urogenital folds fuse with each other along the ventral (under) surface of the penis and form the penile urethra. The paired labioscrotal swellings grow toward each other and fuse to form the scrotum. In the female, because of the absence of androgens, feminization of the indifferent

external genitalia occurs. The phallus elongates rapidly at first but, as its growth gradually slows, it becomes the relatively small clitoris. The unfused urogenital folds form the paired labia minora, whereas the labioscrotal swellings give rise to the labia majora. The caudal portion of the urogenital sinus gives rise to the vestibule of the vagina.

The cardiovascular system

The development of the heart begins in the third week in the cardiogenic area (see Fig. 2.3). Splanchnic mesoderm ventral to the pericardial cavity aggregates to form a pair of elongated heart cords. By day 17 of gestation, these cords are canalized to form endothelial tubes, called endocardial heart tubes. As the lateral folds develop, the heart tubes fuse to form a single median endocardial heart tube; fusion begins cranially and rapidly extends caudally. A single endocardial tube is formed by day 22. It is surrounded by a myoepicardial mantle and separated from the endothelial lining by cardiac jelly. With the development of the head fold, the cardiac tube comes to lie dorsal to the pericardial cavity and ventral to the foregut (see Fig. 2.4). As the tubular heart elongates, it differentiates into four main regions. From cranial to caudal, these are the bulbus cordis, ventricle, atrium, and the sinus venosus. The bulbus cordis represents the arterial end of the heart and consists of a proximal part, the conus, and a distal part, the truncus arteriosus. The sinus venosus represents the venous end of the heart. It receives the umbilical veins from the placenta, the vitelline veins from the yolk sac, and the common cardinal veins from the embryo. The arterial and venous ends of the heart tube are fixed by the pharyngeal arches and the septum transversum respectively. Because the bulbus cordis and the ventricle grow faster than the other regions, the heart tube bends upon itself, forming a U-shaped bulboventricular loop. It later becomes S-shaped. As the heart tube bends, the atrium and the sinus venosus come to lie dorsal to the bulbus cordis, truncus arteriosus, and ventricle. By this stage, the sinus venosus has developed lateral expansions, called right and left horns. The right horn of the sinus venosus subsequently becomes larger than the left. The developing heart tube now gradually invaginates into the dorsal aspect of the pericardial cavity.

Partitioning of the atrioventricular canal, the atrium, and the ventricle begins about the middle of the fourth week and is essentially complete by the end of the seventh week. At first, the atrioventricular opening is round. In the region of the atrioventricular canal, two thickenings of subendocardial tissue, the endocardial cushions, appear in the dorsal and ventral walls of the heart. During the fifth week, these cushions grow toward each other and fuse, dividing the atrioventricular canal into right and left atrioventricular canals. The primitive atrial chamber communicates posteriorly with the sinus venosus, and inferiorly with the ventricle through the atrioventricular canal. A crescent-shaped membrane, the septum primum,

grows down toward the endocardial cushions. A large gap, the foramen primum, exists between its lower free edge and the endocardial cushions. As the septum primum grows toward the endocardial cushions, the foramen primum becomes progressively smaller. Before the foramen primum is obliterated, an opening, the foramen secundum, appears in the upper part of septum primum. Concurrently, the free edge of the septum primum fuses with the left side of the fused endocardial cushions and obliterates the foramen primum. At this stage, the left atrium receives most of its blood from the right atrium via the foramen secundum. Toward the end of the fifth week, a second membrane, the septum secundum, arises from the roof of the atrium on the right side of the septum primum. As this septum grows downward toward the endocardial cushions, it gradually overlaps the foramen secundum. The septum secundum forms an incomplete partition with an oblique opening, the foramen ovale, through which the two atria communicate. The upper part of the septum primum gradually degenerates, while the remaining part of the septum primum persists as the valve of the foramen ovale. Whereas the lower border of the septum secundum (crista dividens) is thick and firm, the edge of the septum primum is thin and mobile, and offers no obstruction to blood flow from the right to the left atrium. The foramen ovale persists throughout fetal life. Initially, the sinus venosus is a separate chamber, opening into the part of the primitive atrium that will become the right atrium. The left horn of the sinus venosus and its tributaries regress, leaving the coronary sinus. After the formation of the interatrial septum, the right horn of the sinus venosus becomes incorporated into the wall of the right atrium, forming the smooth part of its wall. Most of the wall of the left atrium is smooth and is derived from the primitive pulmonary vein. Initially, a single pulmonary vein opens into the primitive left atrium. As the atrium expands, this vein is gradually incorporated into the wall of the left atrium, and the proximal portions of its branches are progressively absorbed. This results in four pulmonary veins, which open separately into the atrium.

The ventricles are derived from the primitive ventricular chamber and the proximal part of the bulbus cordis, the conus. The infundibulum of the right ventricle and the aortic vestibule of the left ventricle arise from the conus. Partitioning of the primitive ventricle into right and left ventricles is first indicated by a muscular ridge, the interventricular septum, which grows upward from the floor of the bulboventricular cavity, and divides it into right and left halves. Initially, most of the growth of the interventricular septum results from dilation of the ventricles on each side of it. Later, there is active growth of septal tissue as the muscular portion of the interventricular septum forms. The gap between the upper free edge of the interventricular septum and the endocardial cushions permits communication between the right and left ventricles until about the end of the seventh week. Proliferation of tissue from several sources forms the membranous portion of the interventricular septum, and it completes the partitioning of the ventricles. During the fifth week, opposing ridges of

subendocardial tissue, the bulbar ridges, arise in the wall of the bulbus cordis. Similar ridges also form in the truncus arteriosus and are continuous with those in the bulbus cordis. The spiral orientation of the ridges is possibly caused by the streaming of blood from the ventricles. Fusion of these ridges results in a spiral aorticopulmonary septum. The septum subdivides the bulbus cordis and the truncus arteriosus into two channels, the ascending aorta and the pulmonary trunk. Blood from the aorta now passes into the third and fourth pairs of aortic arch arteries, and blood from the pulmonary trunk flows into the sixth pair of aortic arch arteries. Because of the spiral orientation of the septum, the pulmonary trunk twists around the ascending aorta. Proximally, the pulmonary trunk lies ventral to the aorta but, distally, it lies to the left of the aorta. The bulbus cordis is gradually incorporated into the walls of the ventricles. Closure of the interventricular foramen, at about the end of the seventh week, results from the fusion of subendocardial tissue from the right bulbar ridge, the left bulbar ridge, and the fused endocardial cushions. The membranous part of the interventricular septum is derived from proliferation of tissue from the right side of the fused endocardial cushions. This tissue fuses with the aorticopulmonary septum and the muscular part of the interventricular septum. Following closure of the interventricular foramen, the pulmonary trunk is in communication with the right ventricle and the aorta with the left ventricle. Cardiac valves develop as swellings or ridges of subendocardial tissue that become hollowed out and reshaped.

Six pairs of aortic or branchial arch arteries arise from the aortic sac, a dilated region of the truncus arteriosus, and terminate in the dorsal aorta of the corresponding side. Their derivatives are: first pair, parts of the maxillary arteries; second pair, no adult derivatives; third pair, common carotid arteries and part of internal carotid arteries; fourth pair, left – part of arch of aorta; and right – part of right subclavian artery; fifth pair, no adult derivatives; sixth pair, left – proximal: proximal part of left pulmonary artery; distal: ductus arteriosus (acts as a shunt in prenatal life); and right – proximal: proximal part of right pulmonary artery; distal: degenerates.

Fetal circulation

Well-oxygenated blood returns from the placenta in the umbilical vein. About half the blood passes through the hepatic sinusoids; the remainder bypasses the sinusoids by going through the ductus venosus into the inferior vena cava. This blood flow is regulated by a muscular sphincter in the ductus venosus near the umbilical vein. After a short course in the inferior vena cava, the blood enters the right atrium. Because the inferior vena cava also receives deoxygenated blood from the lower limbs and viscera, the blood entering the right atrium is less oxygenated than that in the umbilical vein. The blood from the inferior vena cava is largely directed by the lower border of the septum secundum (the crista dividens) through the

Table 2.2 Major derivatives of the three primary brain vesicles.

Primary vesicles	Secondary vesicles	Derivatives	Lumen
Prosencephalon	Telencephalon	Cerebral hemispheres consisting of the olfactory system, corpus striatum, cortex, and medullary center	Lateral ventricles and part of the third ventricle
	Diencephalon	Thalamus, epithalamus, hypothalamus, and subthalamus	Major part of the third ventricle
Mesencephalon	Mesencephalon	Midbrain: colliculi and cerebral peduncles	Cerebral aqueduct
Rhombencephalon	Metencephalon	Pons and cerebellum	Fourth ventricle
	Myelencephalon	Medulla oblongata	Fourth ventricle and part of the central canal

foramen ovale into the left atrium. In the left atrium, it mixes with a relatively small amount of deoxygenated blood returning from the lungs via the pulmonary veins. From the left atrium, the blood passes into the left ventricle and leaves via the ascending aorta. Consequently, the vessels to the heart, head and neck, and upper limbs receive rather well-oxygenated blood. A small stream of oxygenated blood from the inferior vena cava is diverted by the crista dividens and remains in the right atrium. This blood mixes with deoxygenated blood from the superior vena cava and coronary sinus and passes into the right ventricle. From the right ventricle, the blood enters the pulmonary trunk. Only a small amount of this blood reaches the lungs. The greater part of the blood is diverted through the ductus arteriosus into the aorta. Some of this blood circulates to the abdominal and pelvic viscera and the lower limbs and is returned to the fetal heart, but much of the blood in the aorta is transported by the umbilical arteries to the placenta.

Changes occur in several fetal blood vessels. Muscle in the walls of the umbilical arteries contracts, occludes the lumen, and thus prevents the loss of fetal blood. When the umbilical vein is occluded and blood flow from the placenta ceases, the pressure in the right atrium is lowered. The ductus venosus also becomes occluded. Occlusion of the ductus arteriosus results in all the blood from the right ventricle going to the lungs for oxygenation. Because this increases the volume of blood returning to the left atrium from the lungs, the pressure in the left atrium is raised. As a result of the difference in pressure between the right and left atria, the valve of the foramen ovale closes. Anatomical closure of the fetal blood vessels by fibrous tissue forms various ligamentous remnants: umbilical arteries, medial umbilical ligaments; left umbilical vein, ligamentum teres of the liver; ductus venosus, ligamentum venosum; ductus arteriosus, ligamentum arteriosum.

The nervous system

The neural tube (see Fig. 2.3) gives rise to the entire central

nervous system, with the exception of its blood vessels and certain neuroglial cells. At first, the neural tube consists of a layer of pseudostratified columnar neuroepithelial cells. As a result of continuous cell proliferation, the walls of the neural tube become thickened and develop an inner ventricular (ependymal) layer, an intermediate (mantle) layer, and an outer marginal layer. All nerve and macroglial cells (astrocytes and oligodendrocytes) are derived from the neuroepithelial cells; the microglial cells differentiate from mesenchymal cells that have entered the central nervous system with developing blood vessels. The sulcus limitans separates the dorsal alar plate (sensory) from the ventral basal plate (motor). The cranial part of the neural tube grows rapidly to form the three primary brain vesicles: the forebrain vesicle (prosencephalon), the midbrain vesicle (mesencephalon), and the hindbrain vesicle (rhombencephalon). The lumen of the neural tube mainly forms the ventricles of the brain. The derivatives of the primary brain vesicles are summarized in Table 2.2. The rapid growth of the brain results in the formation of two flexures, the cranial (midbrain) and caudal (cervical) flexures. Later, a third flexure, the pontine flexure, appears between the metencephalon and myelencephalon.

The spinal cord develops from the caudal part of the neural tube. From the alar and basal plates, the posterior and anterior horns are derived respectively. These plates contribute to the formation of the lateral horn. The neural canal becomes the central canal of the spinal cord. From the neural crest cells, the following structures differentiate: sensory ganglia of the cranial and spinal nerves, autonomic ganglia, neurilemmal (Schwann) cells, cells of the suprarenal medulla, and melanocytes. Neural crest cells contribute to the development of the connective tissues of the head, the meninges, and the pharyngeal arches.

The pituitary gland (hypophysis) develops from two sources: the neurohypophysis develops as a downgrowth from the floor of the diencephalon, and the adenohypophysis develops from an ectodermal outgrowth (Rathke's pouch) from the roof of the stomodeum.

The musculoskeletal system

By the end of the fourth week, the limb buds appear as paddle-shaped thickenings of the somatic mesoderm at the level of the lower cervical and lumbosacral somites. At the apex of each limb bud, the overlying ectoderm thickens to form the apical ectodermal ridge. The apical ectodermal ridge induces proliferation of the underlying mesenchyme, some of which differentiates into cartilage. The cartilaginous segments of the limbs are sequentially established in a proximodistal order. The flattened hand and foot plates develop five mesenchymal condensations (digital rays), which will give rise to the metacarpals, metatarsals, and phalanges. Programmed cell death or apoptosis is responsible for the degeneration of the loose mesenchyme between the digital rays which separates

the fingers and toes (interdigital clefts). By the seventh week, endochondral ossification begins. The limb muscles develop from myogenic precursor cells in the limb buds, which probably originate from the somites. Immediately following their formation, the muscles are penetrated by nerves. The muscle masses separate into extensor (dorsal) and flexor (ventral) compartments. Between the seventh and ninth weeks, the developing limbs rotate longitudinally in opposite directions at the elbow and knee regions. Whereas the arm buds rotate laterally, the limb buds rotate medially. Thus, the anterior (flexor) compartments of the arm and forearm are homologous to the posterior compartments of the thigh and leg.

The skull consists of the neurocranium, which surrounds the brain, and the viscerocranium or facial skeleton. The flat bones surrounding the brain form the membranous part of the

Key points

- 1 The fertilized oocyte (zygote) undergoes cleavage, forming a morula and, by day 6, it differentiates into a blastocyst, which then implants in the endometrium.
- 2 Implantation is completed by the end of the second week as a bilaminar embryonic disk of epiblast and hypoblast is formed.
- 3 Intraembryonic mesoderm forms the somites, which give rise to the dermis and skeletal muscle, and precursors of the vertebrae and the ribs.
- 4 The intraembryonic coelom, which is formed in the lateral mesoderm, gives rise to the pericardial, pleural, and peritoneal cavities.
- 5 Blood vessels first appear as clusters of differentiated mesenchymal cells (blood islands) that acquire lumina.
- 6 The embryonic period extends from the beginning of the fourth week to the end of the eighth week; the fetal period is from the beginning of the ninth week until birth.
- 7 Folding converts the flat embryonic disk into a cylindrical embryo.
- 8 The thyroid diverticulum forms in the floor of the pharynx, grows caudally, and becomes functional by the 12th week of gestation.
- 9 The primordia of the face (the frontonasal prominence, the maxillary prominences, and the mandibular prominences) merge during the fifth to eighth weeks to form the facial structures.
- 10 The palate develops from two primordia: the primary palate, a wedge-shaped mesodermal mass from the innermost aspect of the intermaxillary segment (fifth week); and the secondary palate from the medial aspects of the maxillary prominences (sixth week).
- 11 Fusion of the primordia of the palate begins in the ninth week and is completed by the 11th week in males and the 12th week in females.
- 12 The larynx, trachea, and lung buds develop from the laryngotracheal tube.
- 13 The foregut derivatives are the pharynx and its derivatives, the lower respiratory tract, the esophagus, the stomach, the duodenum, proximal to the common bile duct, and the liver, biliary tract, gallbladder, and pancreas.
- 14 Three successive sets of excretory organs develop: transitory, the pronephros; a temporary mesonephros; and the definitive metanephros that will give rise to the kidneys.
- 15 Two pairs of genital ducts develop in both sexes: mesonephric (wolffian) ducts and paramesonephric (müllerian) ducts, which contribute to the male and female urogenital systems.
- 16 In female embryos, the mesonephric ducts regress, the paramesonephric ducts give rise to the female genital tract, and the cranial unfused ends of the paramesonephric ducts form the uterine tubes.
- 17 The caudal portions of the ducts fuse in the midline to form the uterovaginal primordium, which gives rise to the uterus, cervix, and possibly part of the vagina.
- 18 The development of the heart begins as a single endocardial heart tube, which forms the heart by the end of the embryonic period.
- 19 The notochord induces the overlying ectoderm to form the neural plate, which gives rise to the neural tube, the primordium of the central nervous system: the forebrain vesicle (prosencephalon), the midbrain vesicle (mesencephalon), and the hindbrain vesicle (rhombencephalon).

neurocranium, and the cartilaginous part gives rise to the bones of the base of the skull. The skull develops from the mesenchyme surrounding the developing brain, with contributions from the first four occipital somites and the first pharyngeal arch. The frontal, parietal, zygomatic, palatine, nasal, and lacrimal bones, the maxilla, and the vomer are formed by intramembranous ossification. Only the ethmoid bone and the inferior nasal conchae are completely formed in cartilage. Bones formed by intramembranous and endochondral ossifications include the occipital, sphenoid, and temporal bones, and the mandible.

Pregnancy and the Fetoplacental Unit

Normal and abnormal placentation

Soheila Korourian and Luis De Las Casas

Anatomy, structure, and function

Proper function and development of the placenta is critical to the survival of the embryo. The placenta is not only responsible for implantation but it is also necessary for the transport of nutrients and redirection of the maternal endocrine, immune, and metabolic functions to support the embryo.

The ovum is fertilized in the fallopian tube and develops rapidly, reaching the endometrial cavity as a blastocyst. A surge of estrogens, secreted by ovarian follicles, triggers and induces implantation. In the absence of this surge, implantation cannot occur.^{1–5}

The trophoblasts grow rapidly and circumferentially, invading the endometrium and the wall of the spiral arteries of the endometrium. Table 3.1 shows some of the crucial developmental stages of the conceptus during the first postcoital (p.c.) month. Allantoic vessels establish connectivity with the vessels developing in the villi, resulting in fetoplacental circulation by the fifth week of gestation (Fig. 3.1). Initially, villi surround the entire chorionic cavity, but as the chorion grows into the endometrial cavity, the villi on the implantation aspect continue to proliferate, forming the definitive chorionic plate, while the villi oriented toward the uterine cavity undergo atrophy resulting in formation of the fetal membrane.^{6–12}

Between the 14th and 20th weeks of pregnancy, intermediate trophoblasts invade the myometrial segments of the spiral arteries. Continued growth and enlargement of the chorion result in obliteration of the uterine cavity at around 20 weeks' gestation (Fig. 3.2). The PO_2 rises sharply at the start of the second trimester. As the villi mature, the barrier between maternal and fetal circulation is reduced.^{13–16}

A term placenta consists of 40–60 functional units. These units receive oxygenated blood from the branches of the maternal spiral arteries, which are present in the stem villi. Each lobular unit depends on its own spiral artery (Fig. 3.3). Thrombosis of the spiral arteries results in infarction of the dependent unit.¹⁷

Umbilical cord

The umbilical cord is a counterclockwise spiraled cord that usually has three vessels: two arteries, which originate from the internal iliac arteries, and one vein, which drains into the hepatic vein. Usually, 96% of umbilical arteries are either fused or connected via an anastomosis. The umbilical arteries have no internal elastic membrane, whereas the vein has an elastic sublayer.^{7,18–20} A single umbilical artery is seen in less than 1% of deliveries. Single artery cords are more common in diabetic mothers and in fetuses with chromosomal abnormalities (Fig. 3.4). Infants with a single umbilical artery have a lower birthweight and higher perinatal mortality rate.^{21–23} Closure of the umbilical cord at birth is caused by irregular constrictions of the arteries; this is mediated by serotonin, angiotensin, and oxytocin as well as by prostaglandins.^{24,25}

A normal cord is 37.7 ± 7.73 mm in diameter. A diminished size seems to be due to a reduction in Wharton's jelly, and can cause vascular occlusion.^{26–28} The length of the umbilical cord is important and can most accurately be measured in the delivery room. Short cords, defined as cords less than 32 cm long, are seen in 0.4–0.9% of pregnancies. They are often seen in conditions restricting fetal mobility, such as oligohydramnios, and crowding (multiple pregnancy) and have been linked to fetal distress. Short cords have also been seen in children with Down syndrome. In the absence of fetal anomalies, short cords have been associated with neonatal hypotonia and an increased need for resuscitation. At the extreme, there may be complete or near complete absence of the cord (acordia), associated with fetal anterior wall defects. This condition is uniformly fatal. Abnormally long cords, defined as cords longer than 80 cm according to some references or 100 cm according to others, are seen in 3.7% and 0.5% of pregnancies respectively.^{29–38} Abnormally long cords have been associated with excess knotting, torsion, encirclement around body parts, prolapsed cord, and vascular occlusions.

Table 3.1 Stages of placental development, postcoital days 1–29.

Postcoital days	Stage	Diameter (mm)	Size of embryo	Placental state
1	1 fertilized egg	0.1		
2	2–4 cells	0.1–0.2		
3	4–16 cells	0.1–0.2		
4	16 ± 64 cells	0.2		
5 to early day 6	128 ± 256 cells	0.2–0.3		Blastocyst attaches to endometrium
6 to early day 8	Prelacunar stage	0.3 × 0.3 × 0.15		Blastocyst partially implanted
Late day 8 to day 12	Lacunar or trabecular stage	0.5 × 0.5 × 0.3 to 0.9 × 0.9 × 0.6	0.1 mm	Implantation pole exhibits vacuoles (first lacunae), endometrium 0.5 mm at implantation site
13–14	Villous stage	1.2–2.1	0.2–0.4 mm, yolk sac appears	Development of primary villi
15–18	Secondary villous stage	5–8	<0.9 mm, development of notochordal and neuroenteric canals	Mesenchyme invades the villi, transforming them to secondary villi
19–23	Early tertiary villi	12–15	1.5–3.5 mm, neural tube starts to fuse	First appearance of villous capillaries
23–29	Early tertiary villi	18–21	Crown–rump length 2.5–5 mm, 21–29 closure of caudal somites, neuropore, three visceral arches, appearance of upper limb buds	First appearance of villous stems characterized by fibrous stroma

Adopted and modified from ref. 8.

Figure 3.1 Implantation site; arrow marks the tertiary villi seen in the first trimester. Lacunar stage; fetal circulation is established.

Most investigators agree that spiraling of the cord is due to fetal activity. Absence of spiraling is likely due to either disturbances of the central nervous system or the presence of chromosomal abnormalities.

True umbilical knots are reported in 0.35–0.5% of pregnancies (Fig. 3.5). True knots are associated with an overall

perinatal mortality rate of 8–11%, and acutely tightened or longstanding knots may be responsible for intrauterine or intrapartum fetal death. False knots are generally of no clinical significance.^{39–41}

Hematomas of the umbilical cord cause red–purple swelling at the fetal end (Fig. 3.6); they are usually single but may be

multiple. The perinatal mortality rate of cord hematomas is 40–50%.^{42,43}

Thrombosis of the umbilical cord is uncommon and may be associated with cord compression, abnormal coiling, knots, torsion, stricture, hematomas, funisitis, anomalous insertion,

amniotic band, or entanglements. Fetal morbidity and mortality are very high.^{44–46}

Complete cord rupture is rare. Partial rupture with the formation of hemorrhage and hematomas is more common.⁴⁷

Circulatory disorders

The placenta is a vascular organ with a dual blood supply. The integrity of both maternal and fetal circulation is essential to placental function.

Placental infarct

Placental infarcts occur when the maternal blood flow through spiral arteries is obstructed by thrombi or in the presence of a retroplacental hematoma. Small placental infarcts, usually less than 3 cm in greatest dimension, are found in approximately 25% of placentas from uncomplicated pregnancies. Multiple or large infarcts, and especially centrally located infarcts and infarcts occurring in the first and second trimester, are clinically significant (Fig. 3.7).

Clinically significant infarcts can cause neonatal asphyxia, low birthweight, and fetal death. There is a consistent positive correlation between infarcts and maternal thrombophilia, and with intrauterine growth retardation (IUGR), in both term and preterm infants.

Recurrent pregnancy loss related to acute atherosclerosis is a recognized complication in women with circulating antiphospholipid antibodies (scleroderma and systemic lupus) and in women with coagulation disorders (antithrombin III, protein C or S deficiency).^{48–64}

Figure 3.2 Continued growth and enlargement of the chorion results in the obliteration of the uterine cavity at approximately 20 weeks' gestation.

Figure 3.3 Term placenta; fetal surface is steel gray and glistening. Umbilical cord usually inserts slightly off center.

Figure 3.4 Left: underdeveloped placenta weighing 220 g at 40 weeks' gestation, below 5% of placental weight for the gestational age. Right: two-vessel umbilical cord (A, gross picture, from ref. 158, with permission; B, microscopic image).

Figure 3.7 Placental infarction involving over 70% of the placenta. The arrows indicate the area of infarction.

Figure 3.8 Retroplacental hematoma; arrow marks the area of depression secondary to the hematoma.

Maternal floor infarct

Maternal floor infarct is characterized by heavy deposition of fibrin in the region of basal villi adjacent to the decidua basalis. The fibrin extends to the intervillous space. It is reported in 0.09–5% of pregnancies and is associated with a high mortality rate (17–40%) and IUGR. It frequently recurs in successive pregnancies.^{65–67}

Retroplacental hematomas and placental abruption

Retroplacental hematomas are clots located in the decidua between the placental floor and the muscular wall of the uterus (Fig. 3.8). They may cause a characteristic depression in the placenta. Acute bleeding from a ruptured decidual artery spreads along the decidua between the placenta and the uterine wall, often resulting in complete detachment of the placenta. In these types of cases, placentas do not show any deformity.

The predisposing factors for retroplacental hematoma and placental abruption are similar. These include pre-eclampsia, trauma, essential hypertension, smoking, and chorioamnionitis. Recent studies also implicate thrombophilic states.

Small hematomas in the decidual layer can occur days or weeks before delivery, sometimes in association with a circumvallate placenta. This condition is frequently referred to as chronic abruption.

Retroplacental hematoma is related to, but not synonymous with, placental abruption. Placental abruption is an acute clinical syndrome characterized by pain, uterine tetany, fetal distress, and sometimes consumption coagulopathy. It occurs in

1.1% of pregnancies and is associated with a 20–40% fetal mortality rate. It accounts for 10% of all stillbirths and 5% of maternal deaths.

In approximately 65% of cases of retroplacental hematomas, placental abruption does not occur.^{68–77}

Placental inflammation and intrauterine infections

Placental inflammation is common. Different patterns of inflammation are associated with different routes of infection. Ascending infection, commonly caused by bacteria, induces acute inflammation of the membrane (chorioamnionitis) and umbilical cord (funisitis), and ultimately causes fetal infection. Hematogenous infections, usually caused by viruses, induce inflammation of the villous parenchyma.

Acute chorioamnionitis and funisitis

This is caused by the inflammatory response of membranes to the ascending infection (Fig. 3.9). The infection is usually caused by bacteria, including normal cervicovaginal flora such as group B β -hemolytic streptococci, *Ureaplasma urealyticum*, *Mycoplasma hominis*, *Fusobacterium*, and, rarely, *Candida* species.

In most cases, the placenta is macroscopically normal. Occasionally, the membrane may be opaque, friable, or foul smelling.

The maternal reaction is demonstrated by an accumulation of neutrophils in the decidua that migrate progressively through the chorion, amnion, and into the amniotic fluid. The

Figure 3.9 Acute chorioamnionitis (left), and funisitis (right).

fetal reaction is manifested by the migration of fetal neutrophils from the umbilical cord and chorionic plate vessels into Wharton's jelly or the chorionic plate.

The clinical significance of this placental inflammation includes preterm labor and neonatal infection. Chorioamnionitis is a major cause of premature labor. Neonatal infection can occur through the skin, eyes, nose, or ear canal or by aspiration or swallowing of infected fluid. It is commonly caused by group B β -hemolytic streptococci, *Escherichia coli*, and *Haemophilus influenzae*, and the neonate may develop bronchopneumonia, gastritis, ileitis, or gastrointestinal perforation with peritonitis and sepsis.^{78,79}

Acute and chronic villitis

Hematogenous maternal infection can affect the placenta and cause villitis (Figs 3.10 and 3.11). The inflammatory infiltrate is commonly chronic, composed of lymphocytes, histiocytes, and plasma cells (Fig. 3.10). Granulomatous inflammation,

and rarely neutrophils (Fig. 3.10), can be seen. The inflammatory infiltrate may also extend into the surrounding perivillous and intervillous space. The majority of chronic villitis cases (95%) are of unknown etiology. Table 3.2 shows the infectious agents which can cause villitis and their possible clinical manifestations.^{80–102}

Hydrops fetalis and placental hydrops

Hydrops fetalis is a state of profound generalized fetal edema, with marked accumulation of fluid in subcutaneous tissue and all body cavities. It represents the end stage of a variety of fetal diseases, including genetic anomalies, hypoproteinemia, and cardiac failure. The placenta and umbilical cord also become edematous. The placenta does not always appear grossly hydropic, but villous edema is usually evident microscopically. A hydropic placenta is often massively enlarged, soft, and friable.

Figure 3.10 Chronic villitis; arrow marks a plasma cell.

Figure 3.11 Acute villitis.

Table 3.2 Microorganisms associated with acute and chronic villitis and their clinical manifestation.

Infectious agent	Type of inflammatory response	Clinical manifestation
Cytomegalovirus (CMV)	Chronic villitis with CMV inclusion	Hepatosplenomegaly with microencephaly Late complication: mental retardation, chorioretinitis, and seizure
Herpes simplex virus	Villous necrosis, agglutination, lymphocytic villitis, and fibrinoid necrosis of vessels	Spontaneous abortion
Varicella zoster	Chronic lymphoplasmacytic chorioamnionitis Grossly visible necrotic foci of villous necrosis	Congenital malformation Wide range from completely asymptomatic to full-blown embryopathy
Parvovirus B19 (agent of fifth disease)	Large, pale placenta with edematous immature villi Fetal erythrocytes show intranuclear inclusion	Nonimmune hydrops, abortion Malformation similar to rubella
Human immunodeficiency virus (HIV)	No specific finding	Variable
<i>Treponema pallidum</i>	Large and edematous placenta with lymphoplasmacytic villitis and possible microabscesses	Abortion and stillbirth, and congenital syphilis
<i>Listeria monocytogenes</i>	Acute villitis with villous necrosis and abscess formation	Spontaneous abortion Prematurity Neonatal sepsis
<i>Toxoplasmosis gondii</i> (risk of transmission 50% during parasitemia)	Wide range (lymphocytic villitis, placental necrosis, and fibrosis)	Wide range (asymptomatic to severe damage to central nervous system and eyes)
Unknown etiology (severity of villitis correlates with the complications)	Chronic villitis	Asymptomatic to intrauterine growth retardation and increased perinatal mortality rate

Immune hydrops

Immune hydrops, also referred to as erythroblastosis fetalis, was once the most common cause of fetal hydrops. It is caused by severe hemolytic anemia, which results from the transplacental passage of maternal rhesus (Rh) antibodies to the Rh antigen-negative fetus. Hypoalbuminemia, or high output cardiac failure resulting from severe anemia, is the cause for the hydropic changes. Occasionally, other red blood cell antigens (e.g., Kell) show a similar, but usually less severe, effect.^{103–105}

Nonimmune hydrops

A heterogeneous group of conditions is responsible for non-immune hydrops. Most causes can be categorized as cardiac failure, anemia, or hypoproteinemia (Table 3.3). Homozygous α -thalassemia is a common cause of hydrops and should be considered first among ethnic Southeast Asian parents. A fetus with homozygous sickle cell disease or β -thalassemia is protected from hemolysis before birth by the presence of fetal hemoglobin. Parvovirus B19 infection, seen only in fetuses with group p antigen, is responsible for 14–18% of cases of nonimmune placental and fetal hydrops.^{105–115}

Disorders of placental development

Abnormal placental development can be caused by multiple factors, including abnormalities of placental gene expression, an abnormal maternal environment, or as a result of disruption of normal development.¹¹⁶

Disorders of membrane development

Placental membranacea

This extremely rare condition is characterized by the failure of normal membrane formation, leading to a gestational sac surrounded by chorionic villi. The placenta tends to be abnormally thin and the maternal surface is often disrupted owing to placenta accreta. Clinical features include premature separation and placenta previa, resulting in maternal hemorrhage and life-threatening fetal hemorrhage at the time of membrane rupture.^{117,118}

Circumvallation

This is the complete or partial insertion of fetal membrane into the placental disk, away from the peripheral margin, with or without a distinct ridge of degenerating blood clot. The inci-

Table 3.3 Etiology of nonimmune hydrops.

Congenital	Chromosomal aberration	Infection	Other
Hemoglobinopathies, α -thalassemia	Down syndrome	Parvovirus	Fetomaternal hemorrhage
Cardiac anomalies and cardiomyopathies	Turner syndrome	Toxoplasma	Twin–twin transfusion
Adenomatoid malformation of the lung	Trisomy 13	Syphilis	Large tumors, hemangiomas
Urinary tract malformation	Trisomy 18	Rubella	
Lysosomal storage disease			

Figure 3.12 Term placenta showing abnormal placentation with circummargination and marginal insertion of the umbilical cord.

dence in normal pregnancies is reported to be 1–7%, and these placentas tend to be smaller. Most investigators have observed that marginal venous hemorrhage is often present, which pushes the membrane inward over the chorionic plate (Fig. 3.12).

Clinical features include recurrent vaginal bleeding in all trimesters. Circumvallation can also cause placental hematomas, marginal hematomas, oligohydramnios, and placental abruption. Clinical sequelae reflect the amount of associated hemorrhage. Term infants with circumvallation or chronic marginal hemorrhage may have mild IUGR and be at increased risk of neurological impairment.^{119–124}

Disorders of uterine implantation

Placenta previa

In placenta previa, implantation is in the lower uterine segment with some tissue near or overlying the uterine cervical os. Complete previa occurs when the placenta completely covers the cervical os. Partial previa is when the edge of the placenta is within 2 cm of the os.

Placenta previa occurs in 0.3–0.5% of deliveries. Epithelial

alterations, which might have changed the extracellular matrix, may increase the risk for placenta previa. These include previous history of curettage, prior Cesarean section, or multiple vaginal deliveries, as well as abnormalities of the uterine fundus including intrauterine and submucosal leiomyomata and uterine malformations.

Clinically, placenta previa often results in premature separation of the placenta, leading to severe vaginal bleeding and premature labor, or both.¹²⁵

Placenta accreta, increta, and percreta

These conditions are caused by implantation of anchoring villi on uterine smooth muscle without intervening decidua. In placenta accreta, the villi are limited to superficial myometrium; in increta, the villi extend into the myometrium; and in percreta, the villi extend to or through the uterine serosa (Fig. 3.13).

The incidence has apparently increased in recent years and is reported to be as high as 1 in 540 pregnancies. Predisposing conditions include a maternal age greater than 35, previous instrumentation, congenital or acquired uterine defects such as uterine septa, leiomyomata, and ectopic implantation such as placenta previa or cornual pregnancy.^{126–128}

Figure 3.13 Placenta percreta with complete perforation of the uterus.

Figure 3.14 Accessory lobe.

Grossly, the maternal surface of the placenta is always disrupted. In most cases, smooth muscle cells are seen in close proximity to the anchoring villi, with fibrin and intermediate trophoblasts intervening.

Clinically, patients often present with recurrent vaginal spotting or overt hemorrhage, and occasionally with uterine rupture. Patients may also present with early or delayed postpartum hemorrhage, necessitating gravid hysterectomy.¹²⁹

Superficial implantation

A deficiency of the interstitial and endovascular intermediate trophoblasts in the decidua basalis and basal plate arteries results in superficial implantation. Superficial implantation is the underlying anatomic abnormality in preeclampsia, which affects 2.6% of all pregnancies. Other related disorders include maternal thrombophilia and placental abruption.

Superficially implanted placentas are often small for the gestational age.

Clinically, superficial implantation is related to maternal underperfusion of the intervillous space. It is not clear whether superficial implantation occurs in all cases of preeclampsia.¹³⁰

Disorders of placental migration

Accessory lobe and multilobulation

An accessory lobe and multilobulation occur when a portion of placental parenchyma is completely separated from the main placental disk by the surrounding membrane. It is found in 3–6% of placentas. Shape abnormalities occur in response to a local reduction of uterine perfusion (Fig. 3.14). Shape abnormalities are of little clinical significance except as

Figure 3.15 Chorangioma: note the well-circumscribed mass surrounded by trophoblasts and composed of tightly packed capillaries separated by fibrous connective tissue.

markers for uterine pathology. Both placenta accreta and previa are commonly associated with abnormal shape.¹²⁵

Peripheral cord insertion

Membranous insertion (velamentous insertion) and marginal insertion

In velamentous insertion, the umbilical cord terminates in the placental membrane rather than in the chorionic disk; this occurs in 1.3–1.6% of pregnancies. In marginal insertion, the cord inserts at the placental margin; this occurs in 6–9% of pregnancies.

Velamentous and marginal cord insertion are thought to occur as a result of asymmetry in the vascular supply in singletons, or competition for uterine vascular supply in twins. Abnormal insertion is more common in twin pregnancies.

Clinically, these conditions are associated with a slightly increased incidence of fetal growth retardation. The major risk is the rupture of membranous vessels at the time of membrane rupture. Twisting of the vessel can lead to progressive variable deceleration and fetal acidosis.¹²⁵

Disorders of fetal vascular development

Chorangioma

Chorangiomas are expansile single or multiple nodular lesions composed of capillary channels and intervening stroma cells surrounded by trophoblasts (Fig. 3.15). Small chorangiomas are usually incidental findings of no clinical significance; intermediate sized chorangiomas are associated with IUGR, and masses larger than 9 cm are associated with shunting of blood and multiple complications. They are thought to be induced by hypoxia.^{126,127,131}

Chorangiomatosis

This term is used when excessive capillary growth affects scattered secondary and tertiary stem villi. It is associated with preeclampsia, multiple gestation, and premature delivery. It is also associated with extreme prematurity (<32 weeks), congenital malformations, and IUGR.¹³¹

The placenta in maternal disorders

There is a great deal of disagreement and direct contradiction about the nature and significance of lesions seen in various maternal disorders.

Preeclampsia (pregnancy-induced hypertension) and eclampsia

No single or specific abnormality is found in the placentas affected by these conditions. In the majority of cases, the placenta shows the effect of low uteroplacental flow.

The placenta is smaller than those from uncomplicated pregnancies. Infarcts are more common and centrally located. The villi may show cytotrophoblastic proliferation, trophoblastic basement membrane thickening, small inconspicuous fetal capillaries, and prominence of villous stroma. The villi show accelerated maturation and are often abnormally small with increased syncytial knots (greater than 30% of the villi). The spiral arteries show a lack of adaptive remodeling features. In these women, the second wave of intravascular trophoblastic migration does not occur. The intramyometrial segment of spiral arteries retains the musculoelastic media and cannot dilate. Spiral arteries show an acute necrotizing arteropathy (see Fig. 3.9: right, upper and lower). This type

of arteropathy has also been described in other complications, including other hypertensive placentas, diabetes, systemic lupus erythromatosus, and antiphospholipid syndrome.

A smaller group of preeclamptic patients show large placentas with abundant immature trophoblasts. These patients usually have other underlying causes including diabetes, multiple gestation, or hydatidiform mole.^{132–143}

Acquired thrombophilia

Acquired thrombophilia, especially the presence of antiphospholipid antibodies, promotes intraplacental clotting. The most common inherited coagulopathies are mutations in the factor V gene (factor V Leiden), the prothrombin gene, and the methylene tetrahydrofolate reductase gene. Diabetes mellitus is also commonly associated with a hypercoagulable state.

The maternal risk is mainly venous thromboembolism, but arterial thrombosis also occurs. There is also a strong association with maternal preeclampsia. Adverse pregnancy outcomes occur in approximately 54% of women with thrombophilia. The fetus of a mother with thrombophilia is at risk for IUGR and stillbirth.^{54–60,138,144–148}

Diabetes mellitus

The gross and microscopic features of diabetic placentas vary considerably. A large study demonstrated that about one-half of the placentas of diabetic mothers had a normal weight and size. However, placentas that are abnormal are larger, thicker, more friable, and heavier than normal placentas of the same gestational age, and the umbilical cord is often notoriously thicker.

The microscopic appearance of the placenta can also be normal, but some abnormalities are distinctive when they are present. Villi commonly appear immature with stromal edema, enlarged villous diameters, and an increase in the prominence of the cytotrophoblastic cells. The decidual arteries are unremarkable except in cases of superimposed hypertension or preeclampsia.

Thrombotic vasculopathy is common. In the presence of maternal vascular disease, renal failure, or preeclampsia, the placenta may be smaller than expected with infarcts and accelerated maturation. There is generally no correlation between the severity and duration of diabetes and the severity of the placental lesions.⁵⁹

Maternal anemia

There are no specific histopathological features associated with maternal anemia. Placentas can be larger or smaller than expected for the gestational age. In maternal sickle cell anemia, placental infarctions are common with the infarcts generally showing sickled erythrocytes. Both placenta and newborn are small for the gestational age and hydropic villi

and placental abruption may occur. Uncomplicated sickle cell trait is unlikely to cause placental lesions.

Homozygous α -thalassemia produces severe fetal anemia and, consequently, hydropic changes in the placenta and fetus, as well as intrauterine fetal death or death soon after birth. In contrast, the placenta and fetus in homozygous β -thalassemia are normal at birth, but the infant soon becomes markedly anemic as the protective hemoglobin F declines.^{62,63,149}

Toxic damage to the placenta

Some of the most common toxic exposures to the placenta are initiated by smoking and cocaine use. Cigarette smoking causes low birthweight, and the placentas of women who smoke more often show necrotic damage. Women who smoke have a higher incidence of placenta previa, abnormalities of the placenta, and fetal malformations. On the other hand, the prevalence of preeclampsia is significantly lower than in nonsmokers. Both nicotine and cocaine can induce vasoconstriction of uterine vessels, causing restriction in the blood supply to the placenta. Cocaine-induced complications during pregnancy are numerous and multifactorial. These complications include placental bleeding, abruption, premature labor, and malnutrition of the developing fetus.^{63,147,149–151}

Metabolic storage disorders

On gross examination, the placenta and the fetus may be hydropic or show no specific gross findings. The accumulated metabolites in these disorders are generally soluble in water; therefore, routinely processed histological slides of the placenta may show only diffuse cytoplasmic vacuolation.¹⁵²

Chromosomal abnormalities

Certain patterns of villous morphology are suggestive of an abnormal karyotype. The incidence of chromosomal abnormalities increases with advanced maternal age. Abnormal karyotype limited to the placenta is seen in 1–3% of all first-trimester chorionic villous sampling. The clinical outcome for chromosomal abnormalities depends on the nature of the abnormality.

Multiple pregnancies

Multiple pregnancies are common, and their rate is increasing owing to assisted reproductive technology (ART). In the USA, ART accounted for 14% of all twin gestations in 2000. Multiple pregnancies are associated with a disproportionate share of complications, including higher rates of morbidity, mortality, malformation, and anomalous development and low birthweight.

Figure 3.16 Zygosity in twin placentas. Adapted from ref. 158, with permission.

Zygosity

Twins are classified as dizygous (fraternal) or monozygous (identical). Dizygous twins are the result of the fertilization of two separate ova. Monozygous twins are the result of division of a single fertilized ovum (Fig. 3.16). Monozygous twins are genetically and, usually, phenotypically identical.^{153–162}

Frequency

The frequency of monozygous twins is relatively constant worldwide (3.5 in 1000 pregnancies). There are marked geographic differences in dizygous twin pregnancies. This reflects a genetic predisposition for high follicle-stimulating hormone (FSH) levels in certain populations which results in polyovulation. The frequency also increases with advancing maternal age (greater than 35), probably as the result of increasing FSH levels with age. Approximately 30% of Caucasian twin pregnancies in the USA are monozygotic.

Placentation

Features unique to multiple gestations include the relationship of the placental disk, fetal membrane, and the pattern and degree of anastomosis of the vessels.

Placentas in twin gestations are either dichorionic or monochorionic. All dizygous twins have dichorionic placentas (dichorionic diamniotic: DiDi).

A monozygous twin gestation can show any type of placentation depending on the time of splitting of the blastocyst. If the single fertilized ovum divides before day 3, the situation is analogous to dizygous twinning. If the split occurs

between days 3 and 8 there will be a monochorionic diamniotic placenta (DiMo) (Fig. 3.17). A split after formation of the amnion (days 8–13) results in a monochorionic monoamniotic (MoMo) placenta (Fig. 3.17). The majority of monozygous twins have a monochorionic placenta. Twins with monochorionic placentas have a much higher mortality rate. Monoamniotic placentas have a fetal mortality rate of almost 50%.

Two entirely separate placentas are dichorionic. The septum in a dichorionic fused placenta is relatively thick and variably opaque owing to the presence of chorionic tissue between the two amniotic layers. The septum in monochorionic diamniotic placentas is thin and translucent, composed of only two directly opposed layers of amnion. This type of septum is easily detached from the placental surface. There is an important difference in the distribution of fetal vessels between DiDi fused placentas and DiMo placentas. In a DiDi fused placenta, the fetal chorionic vessels approach, but do not cross, the area of fusion.

Complications of multiple pregnancy

Twin–twin transfusion syndrome

Vascular communications in monochorionic placentas create the potential for blood flow between twins. Large vessel anastomoses are likely bidirectional, and arteriovenous anastomoses are likely unidirectional (Fig. 3.18).

Chronic unidirectional blood flow results in anemia and growth retardation of the donor fetus. Hypervolemia can cause hypertension, high urine output, and polyhydramnios in the recipient. A relatively selective criterion for twin–twin transfusion is a recipient heart weight that is 2–4 times that of the donor.

Figure 3.17 Diamniotic monochorionic twin placenta.

Figure 3.18 Twin–twin transfusion.

Clinically, twin–twin transfusion is manifested in the second trimester with acute hydramnios. The mortality rate is as high as 70–100%. The recipient twin can develop cardiac failure, hemolytic jaundice, kernicterus, and thrombosis. The donor twin may be severely anemic, hypoglycemic, and is at risk for ischemic lesions.

Asymmetric growth

The growth curves of twins approximate those of singletons up to 34 weeks. Thereafter, twins weigh progressively less than singletons. Twin birthweight discordance is associated with preterm labor, perinatal death, and postnatal morbidity.

Duplication abnormalities

Monozygotic twins occasionally show a marked discrepancy in size and configuration, asymmetry, and incomplete duplication. Acardiac twinning is the most common asymmetric duplication, occurring in 1% of monochorionic twins.

Cord anomalies

Anomalies of the umbilical cord are more common in multiple pregnancies. Velamentous cord insertion is nine times higher in multiple pregnancies. Single artery cords are also more common in multiple pregnancies. Monoamniotic twins are at increased risk for cord entanglement (Fig. 3.19).

Higher multiple births

The same principles of placentation and zygosity apply to triplets, quadruplets, and higher multiple births. Combinations of monozygous and polyzygous multiples are common.

Preterm labor, premature rupture of the membranes

Labor, including preterm labor, is induced by prostaglandin release, which mediates the release of cytokines. The most common cause of preterm labor is bacterial infection, with the second most common cause being vascular sequelae.

Neonatal complications include hyaline membrane disease, periventricular leukomalacia, intraventricular hemorrhage, retinopathy, necrotizing enterocolitis, and death.¹⁶³

Post-term pregnancy

Postmaturity is defined as a pregnancy of 42 or more weeks (294 days) following the onset of the last menses. It is important to note that many supposed cases of

Figure 3.19 Umbilical cord entanglement seen in a monoamniotic monochorionic component of a triplet placenta.

postmaturity result from an incorrect estimation of gestational age.¹⁶⁴

There is a marked increase in perinatal mortality in pregnancies of more than 43 weeks. The fetus can experience a combination of progressive oligohydramnios and meconium impregnation with cord compression and be at risk of pulmonary failure, possibly due to aspiration of viscous meconium.¹⁶³

Recurrent spontaneous abortion

This diagnosis is usually based on the occurrence of three or more consecutive spontaneous abortions. The probability that a recognizable cause can be demonstrated is small, but the identifiable causes are potentially significant. They include maternal thrombophilias, especially those related to autoimmune antibodies; anatomic problems such as an incompetent cervix or leiomyomata; and poorly controlled diabetes mellitus. Rare placental lesions such as maternal floor infarcts and extensive chronic villitis may cause repeated miscarriage often in the third trimester. Early gestational problems can include massive chronic intervillitis, lymphoplasmacytic deciduitis, and chronic decidual perivasculitis.^{165–167}

Intrauterine growth retardation and small for gestational age newborn

A small for gestational age (SGA) infant is a baby who has a birthweight below the 10th percentile for gestational age. Term babies born with a weight below 2500g are considered to be of low birthweight. Many of these babies are normal and healthy but small because of genetic factors such as

parental size or ethnicity. For those below the third percentile, the death rate is nearly 20 times the average population.¹⁶⁸

In addition to fetal demise, the prevalence of seizures in the first day of life, respiratory insufficiency, sepsis, hypothermia, hypoglycemia, and meconium aspiration is increased. The medical problems of the survivors persist into adulthood and include hypertension, coronary artery disease, and type 2 diabetes mellitus.^{169,170}

Maternal factors associated with IUGR are poor nutrition, hypertension, preeclampsia, chronic renal disease, tobacco, and other drug abuse. Fetal factors include chromosomal anomalies, congenital malformations, and multiple gestations.

Placental lesions associated with IUGR include maternal vasculopathy, chronic abruption, fetal thrombotic vasculopathy, large chorangiomas, villitis of unknown etiology, and maternal floor infarction.^{171,172}

Meconium staining

The passage of meconium *in utero* is due to bowel peristalsis and relaxation of the anal sphincter; it may indicate fetal distress and can be associated with meconium aspiration. It is seen in 14% of pregnancies. Meconium staining should be differentiated from the deposition of slimy green meconium across the placental surface that can be washed off by gentle rinsing with water, which indicates a normal fetus that has passed meconium shortly before delivery. True meconium staining results from exposure to meconium for several hours. Damage to the fetus increases with length of exposure to meconium. Over time, soluble meconium components diffuse into the placenta and cord, inducing vasoconstriction and resulting in fetal hypoperfusion.

Chorioamnionitis is an especially common association and may play an important role in neonatal morbidity.

Abnormal amniotic fluid volume

The presence of an excess of amniotic fluid is called hydramnios or polyhydramnios. A diminished amount is called oligohydramnios. Amniotic fluid provides the medium for free fetal movements and has a cushioning effect to prevent possible fetal injury. Secretions from amniotic epithelium and fetal urine are the main sources of amniotic fluid. The most common significant anomalies associated with hydramnios are anencephaly, spina bifida, esophageal atresia, nonimmune hydrops, and various abnormal karyotypes. The recipient twin affected by twin–twin transfusion syndrome commonly has polyhydramnios.

The most common cause of oligohydramnios is leakage of the amniotic fluid caused by premature rupture of membranes. Oligohydramnios also occurs in nearly all cases of bilateral renal agenesis and fetal urinary tract obstruction. Other associations include abnormal karyotype, IUGR, post-term pregnancies, preeclampsia, maternal hypertension, and the donor twin in twin–twin transfusion syndrome. The umbilical cord is subject to compression, especially with severe oligohydramnios, and pulmonary hypoplasia occurs secondarily. These fetuses are at risk for amniotic band syndrome.

Gestational trophoblastic disease

There is a heterogeneous group of gestational and neoplastic conditions of trophoblastic origin.¹⁷³ The incidence of gestational trophoblastic disease (GTD) varies widely among different populations. It is reported to occur in 8.3 in 1000 pregnancies in some areas of Asia and South America compared with 0.1–0.6 in 1000 pregnancies in the USA. The incidence of this disease is higher in women aged 40 or over and is also increased in those younger than 20. Other risk factors include a diet that is low in vitamin E, low socioeconomic status, and blood group A women who have children with blood group O men.

Complete and partial hydatidiform mole

Complete hydatidiform mole (CHM) results from fertilization of an empty ovum. The majority of CHMs are diploid and show a 46,XX karyotype, whereas the partial hydatidiform mole (PHM) is triploid and shows a 69,XXY karyotype. Up to 50% of gestational choriocarcinomas follow CHM.

Figure 3.20 Complete hydatidiform mole.

Figure 3.21 Partial mole. Note the presence of nucleated red blood cells indicative of fetal circulation. Partial moles are in general triploid (69,XXY).

Figure 3.22 Choriocarcinoma.

Key points

- 1 The fertilized ovum at day 1 (post coital) has a diameter of 0.1 mm. The blastocyst measures approximately 0.3 mm. The embryo grows from 0.1 mm at days 8–12 to 3.5 mm by day 23.
- 2 Steroid hormones prepare the endometrium for implantation of the blastocyst. A surge of estrogens, secreted by the ovary, triggers and induces implantation.
- 3 The fetal–placental circulation is developed by the fifth gestational week. Between 14 and 20 weeks, the trophoblast invades the myometrium, resulting in obliteration of the uterine cavity by the 20th week.
- 4 The term placenta consists of 40–60 functional units that receive oxygenated blood from the branches of the maternal spiral arteries. Each unit depends on its own spiral artery. Thrombosis of the spiral arteries results in infarction of the dependent unit.
- 5 The mean length of the umbilical cord at term is 32–45 cm. Markedly long cords (greater than 80 cm in length) have been associated with encirclement around the neck, knots, torsion, prolapse, and variable degrees of vascular occlusion. Short cords (less than 32 cm in length) may predispose to intrauterine hypoxia, cord rupture and hemorrhage, retroplacental hematomas and abruption, and uterine inversion.
- 6 Wharton's jelly acts as a cushion between umbilical cord vessels. A diminished size of cord is related to a decrease in the amount of Wharton's jelly and can cause vascular occlusion.
- 7 Small placental infarcts (<3 cm) can be found in uncomplicated pregnancies. However, large or multiple infarcts can be associated with neonatal asphyxia, low birthweight, and intrauterine fetal death.
- 8 Maternal floor infarcts are characterized by heavy deposition of fibrin around basal villi adjacent to the decidua basalis. Infarcts can be associated with perinatal death and intrauterine growth retardation.
- 9 Retroplacental hematomas are intradecidual clots between the placental floor and the myometrium. They can cause a characteristic area of placental depression. Acute bleeding from a ruptured decidual artery, spreading between the placenta and uterine wall, can cause placental detachment (abruption).
- 10 Premature rupture of the membranes is very commonly associated with preterm delivery. In the majority of cases, the reason for membranes becoming weak and rupturing is not known. Known reasons for premature rupture of the membranes are subclinical infections, hydramnios, incompetence of the cervix, retroplacental hematomas, and amniocentesis.
- 11 Acute chorioamnionitis is caused by an inflammatory response of the membranes to an ascending infection caused by bacteria, including normal cervicovaginal flora, such as group B β -hemolytic streptococci, *Ureaplasma urealyticum*, *Mycoplasma hominis*, *Fusobacterium*, and, rarely, *Candida* species. Chorioamnionitis can predispose to, and be associated with, preterm labor and neonatal infection.
- 12 Hematogenous infection of the placenta can occasionally be associated with chronic endometritis, localized maternal infection, or pelvic inflammatory disease.
- 13 Immune hydrops is caused by severe hemolytic anemia, which is mostly the result of transplacental passage of maternal Rh antibodies to the Rh-negative fetus. Rarely, other blood groups than Rh are responsible for the hemolysis (e.g., Kell). Various different conditions can cause or be associated with nonimmune hydrops fetalis. Some of these conditions are homozygous α -thalassemia, infection with parvovirus B19, and metabolic disorders.
- 14 The term placenta previa refers to a placenta that is implanted at the lower uterine segment near, or overlying, the cervical os. Placenta previa can cause premature separation of the placenta, resulting in severe bleeding and/or premature labor.
- 15 In placenta accreta, the villi are implanted into the superficial myometrium. In placenta increta, the villi invade the myometrium. In placenta percreta, the villi penetrate through the entire uterine wall.
- 16 Chorangiomas are expansile nodules composed of capillaries and stroma surrounded by trophoblasts. Small lesions are of no clinical significance, but larger lesions (>9 cm) are associated with shunting of blood and multiple related complications.
- 17 Preeclampsia is related to low uteroplacental blood flow and can be associated with other conditions such as diabetes, multiple gestation, and hydatidiform mole.
- 18 Acquired thrombophilic disorders, especially those associated with antiphospholipid antibodies, promote intraplacental clotting. The maternal risk is mainly venous thromboembolism; however, arterial thrombosis may also occur.
- 19 Assisted reproductive technology is increasing the rate of multiple pregnancies. Multiple pregnancies are associated with an increased incidence of complications related to prematurity, low birthweight, malformations, and developmental anomalies.
- 20 Excess of amniotic fluid is called polyhydramnios and is associated with anencephaly, spina bifida, esophageal atresia, nonimmune hydrops, and abnormal karyotypes. A diminished amount is called oligohydramnios. The most common cause of oligohydramnios is premature rupture of membranes. Other important causes include bilateral renal agenesis and fetal urinary tract obstruction.

Clinically, patients with CHM usually present in the first trimester with bleeding, enlarged uteri for expected gestational age, an absence of fetal parts on ultrasound, and markedly elevated β -human chorionic gonadotropin (β -hCG). Other signs include hyperemesis and toxemia during the first or second trimester.

CHM shows a diffusely edematous placenta in which the macroscopically enlarged villi lack blood vessels and have cyst-like fluid-filled cavities. Complete hydatidiform mole can also be seen in a twin gestation; in these cases, the diagnosis is often delayed. The majority of complete moles arise in uterine pregnancy, although occasional molar pregnancies are seen in ectopic pregnancies. As a comparison, PHM is composed of large and small villi, and fetal parts are present (Figs 3.20 and 3.21).

Invasive hydatidiform mole

This condition is characterized by molar villi and trophoblasts infiltrating the uterine wall, and occurs more frequently after CHM. Molar tissue may be transported to distant organs such as the lung, and may result in acute pulmonary hypertension, edema, and even death. In these cases, clinical follow-up and therapy do not differ from patients with CHM confined to the uterus.

Gestational choriocarcinoma

This is a malignant neoplasm composed exclusively of cytotrophoblasts and syncytiotrophoblasts. In the USA, the incidence is 1 in 40 000 pregnancies and correlates with the rate of CHM occurrence (Fig. 3.22). Choriocarcinoma spreads hematogenously; metastatic sites include lung (80%), vagina (30%), pelvis (20%), brain (17%), and liver (10%).

Fetoplacental perfusion and transfer of nutrients

Henry L. Galan and Frederick C. Battaglia

The technical advances in the tools that obstetricians use for the evaluation of a pregnancy have progressed faster than our basic understanding of some of the developmental aspects of fetal and placental physiology. In this chapter, we shall try to bring out those aspects of perinatal physiology that are reasonably well established.

Perfusion and placental transport

A number of concepts relating to placental perfusion and transport, most of which have considerable clinical significance, have become relatively well established. One of these is the absence of autoregulation in the uterine vascular bed. This has been shown in animal studies by the absence of reactive hyperemia after uterine artery occlusion.¹

The clinical implication of these observations is that the uterine bed in late pregnancy may be regarded as an almost fully dilated bed. Thus, it cannot easily compensate for a sudden decrease in vasodilation. From a clinical perspective, maternal hypotension must be regarded as a direct causal factor in producing a reduction in uterine and placental blood flow. Maternal hypotension should therefore be avoided, particularly in late gestation.

Another characteristic of the uterine vascular bed is the unresponsiveness of the uterine vascular vessels to changes in PO_2 or PCO_2 . Again, this has considerable clinical significance because it means that oxygen therapy for the mother does carry with it the risk of increasing fetal hypoxia by vasoconstriction of the uterine bed. It has been well demonstrated in animal studies that oxygen administration to the mother increases fetal oxygenation, lending support to the clinical approach of using maternal oxygen therapy when there are signs of fetal distress during labor and delivery. Unfortunately, as is true with many areas of physiology, we have much less information about the effects of chronic maternal oxygen therapy. Because this is such an important issue in clinical obstetrics, it is worth reviewing in some detail the animal studies that support the use of maternal oxygen therapy for

fetal hypoxia. The first study² to directly address the question of the impact of maternal oxygen administration upon uterine and umbilical blood flows and fetal oxygenation showed that there was no effect of the increased maternal PO_2 upon uterine or umbilical blood flows and that, as expected, umbilical venous PO_2 , representing the most oxygenated blood of the fetus, increased significantly.

Clinically, the first studies demonstrating an effect upon fetal oxygenation by maternal oxygen administration were based upon changes in fetal scalp PO_2 and were carried out by scalp sampling during labor. More recently, maternal oxygen administration has been used in pregnancies complicated by intrauterine growth retardation (IUGR). The beneficial effect is confirmed both by the changes in fetal blood PO_2 and saturation in blood obtained by cordocentesis, and by an apparent improvement in velocity waveform measurements upon the fetal descending aorta, suggesting a reduced placental impedance during maternal oxygen therapy.³

The relationship between fetal oxygenation and maternal oxygenation is complex because a number of factors are involved in determining the “normal” umbilical venous PO_2 in any species. These factors include:

- 1 placental oxygen consumption
- 2 uterine and umbilical blood flows
- 3 placental permeability
- 4 pattern of placental perfusion (i.e., concurrent, cross-current, countercurrent)
- 5 maternal arterial PO_2 and hemoglobin concentration
- 6 shape of maternal and fetal oxygen dissociation curves.

For a more complete discussion of the contribution of each of these factors, see references 1 and 4. In man, umbilical venous PO_2 tends to equilibrate with uterine *venous*, not arterial, PO_2 , i.e., it simulates a concurrent exchanger. With the advent of techniques to sample umbilical venous blood transabdominally (i.e., cordocentesis), data are now available describing umbilical venous PO_2 through the latter half of gestation. The umbilical venous PO_2 of the human fetus is higher in mid-gestation and decreases as gestation advances.^{5,6} However, at any gestational age, it is clear that the human fetal

umbilical venous PO_2 is very low by postnatal standards. This highlights the importance of the difference in whole blood oxygen affinity in the fetus versus the adult because the higher affinity of fetal hemoglobin insures that the bulk of the hemoglobin will be oxygenated even at the low PO_2 of fetal umbilical venous blood. The change in fetal PO_2 in late gestation does not imply increasing fetal hypoxia because, associated with this, there is an increasing hemoglobin concentration as gestation progresses. This latter change maintains the oxygen content of umbilical venous blood throughout gestation.⁷ For this reason, measurements of fetal oxygen content are particularly useful because they are independent of gestational age. Studies in the mid-gestation fetal lamb have shown a higher PO_2 and oxygen saturation in fetal vessels than in late gestation lambs.⁸

Soothill and coauthors⁹ have shown a relationship between fetal lactate concentration and fetal hemoglobin and oxygen concentration in rhesus (Rh)-isoimmunized pregnancies. Similarly, Ferrazzi and coauthors¹⁰ and Soothill and coauthors³ described lactic acidemia in association with abnormal velocity waveforms in the fetal descending aorta or umbilical artery. Several studies have shown that it is now possible to move beyond velocity measurements alone to measurements of actual blood flow in the umbilical vein.^{11,12} These studies have reported a mean umbilical blood flow of 120 mL/min/kg fetal weight in the human fetus during late gestation. The umbilical flow is markedly reduced in IUGR pregnancies.¹³

Uterine flow and placental transport

Uterine blood flow increases remarkably during late gestation. However, the increase in uterine blood flow does not keep up with the increase in uterine oxygen consumption, which causes the uterine venous PO_2 content to decrease with increasing gestational age. In human pregnancies, it has been shown that a decrease in uterine venous PO_2 leads to a lower umbilical venous PO_2 .

In terms of clinical applicability, one of the more important contributions to fetal physiology was made by the studies that described a nonlinear relationship between uterine blood flow and placental transport of oxygen and nutrients to the fetus. Wilkening and Meschia¹⁴ demonstrated that, in pregnant sheep, uterine blood flow can decrease over a fairly wide range without any effect on oxygen transport. A critical point is then reached beyond which any further reduction in uterine blood flow leads to a decrease in oxygen transport. As shown in Fig. 4.1, similar data have been obtained by the same investigators for umbilical blood flow versus placental transport.¹⁵ Although a similar study has not been carried out for other nutrients, the transport of all nutrients should share this common characteristic, namely that there is a margin of safety represented by the range within which uterine blood flow can be reduced without affecting transport. This concept has considerable clinical significance. It would appear that a critical

Figure 4.1 Changes in fetal O_2 uptake and fetal arterial blood pH in relation to the ratio of umbilical O_2 delivery to control O_2 uptake. In control periods, the ratio averaged 3.09 (O) and ranged between 2.60 and 3.62. Note that O_2 uptake and pH remained virtually constant for ratios of O_2 delivery to control O_2 uptake >1.6 .

need in obstetrics is to determine whether such relationships exist in high-risk pregnancies, i.e., critical levels of uterine perfusion beyond which reductions in uterine flow profoundly affect fetal oxygenation and fetal nutrition.

There is currently active research from many centers directed at determining the role of specific vasoconstrictors and vasodilators in normal pregnancy and in pathologic pregnancies, particularly in pregnancy-induced hypertension (PIH). However, one common path for the control of vasomotor tone is through nitric oxide production by uterine and placental endothelium. Several studies on human placental tissue by Myatt and co-workers,^{16–18} DiIulio and co-workers,^{19,20} and others^{21,22} have highlighted the importance of this area of research, particularly in terms of endothelial nitric oxide synthase expression in placental tissues. The link between these pathways and other vasodilators and constrictors is likely to remain a major focus of vascular research in perinatal medicine.

Uterine venous drainage

Uterine arterial flow has been relatively well studied in animals; however, uterine venous drainage has not received such careful attention. Maternal position has been considered to be important in clinical obstetrics, principally through the potential to relieve inferior vena caval obstruction by the pregnant uterus and increase right-sided venous return to the heart. Alleviation of signs of fetal distress have been reported

Figure 4.2 Tritiated water concentrations in both arteries and both ovarian veins of a rhesus monkey. It is clear that only one ovarian vein was carrying blood from the placenta whereas the other was draining nonexchange tissues within the uterus; the latter had a $^3\text{H}_2\text{O}$ concentration indistinguishable from the maternal artery. It should be stressed that this difference in tissue drainage could not be detected from the gross appearance of the two veins by either color or size of the vessels.²³

after positioning the mother from the supine into the left-lateral decubitus position.

Two laboratories have confirmed that, in the rhesus monkey, drainage is not predictable; occasionally, one vein carries essentially all of the placental drainage. This can put the fetus at risk, as shown in Figs 4.2 and 4.3 that were taken from the study of Battaglia and coauthors.²³ Figure 4.2 shows that tritiated water infused into the fetal rhesus monkey as a marker appeared in only one uterine vein. The other vein had a concentration similar to that of maternal arterial blood. Occlusion of this latter vein would have no repercussions upon placental function. However, as shown in Fig. 4.3, obstruction of the vein carrying all of the placental drainage leads to a rapid accumulation of tritiated water in the fetus because placental clearance is virtually zero. Such data are not available in man, but there is sufficient reason to believe that placental drainage in man is not distributed equally to the venous drainage on the two sides of the uterus. One study has shown that, when both uterine veins are sampled across the pregnant uterus during Cesarean section, there is great variability in oxygen saturation and this is independent of the position of the placenta.⁵ This suggests that there may be an unequal distribution of placental drainage to one of the other uterine veins. Thus, the question of whether uterine venous obstruction contributes to the maternal positional effects

Figure 4.3 Ligation of one ovarian vein produced rapid deterioration of the preparation, as indicated by the rapid rise of $^3\text{H}_2\text{O}$ concentration in the fetus and the inability of the system to attain a new steady state. Presumably in this animal, the principal channel for venous drainage of the placenta was the ovarian vein that was ligated.²³

upon fetal well-being is an important one that needs further investigation.

Placental transport and metabolism

The placenta is very active metabolically and has an oxygen consumption and glucose utilization rate similar to brain tissue.²⁴ One of the characteristics of its metabolism is the production of lactate and ammonia (NH_3) as the end products that are delivered into both the uterine and the umbilical circulations. Because the production of lactate and NH_3 by the pregnant uterus has been a general characteristic among species with very different placental types, it seems reasonable to hypothesize that this reflects the metabolic activity of the trophoblast as this epithelial layer persists in all placental types.

There are several studies that have examined maternal–fetal glucose relationships in human pregnancy utilizing data obtained at cordocentesis. Figure 4.4, taken from Marconi and coauthors,²⁵ compares fetal and maternal glucose concentrations over a wide gestational age range. The data demonstrate that the maternal–fetal glucose concentration difference increases as gestation advances. The increased transplacental glucose gradient is one means of accommodating the increased glucose requirements of the rapidly growing fetus. In addition, there is probably a substantial increase in placental glucose transport capacity. In fetuses with IUGR, the maternal–fetal glucose gradient is further increased and this appears to correlate with increasing severity, as shown in Figure 4.5. The question of maternal glucose utilization in pregnancy has also

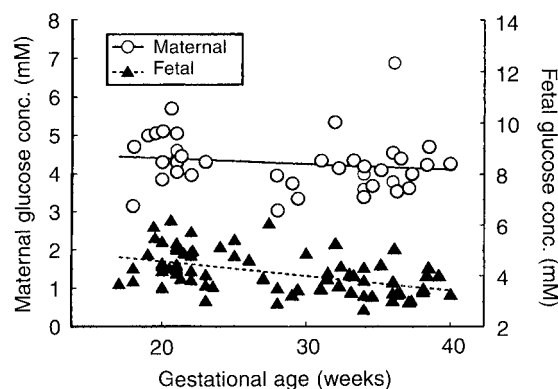

Figure 4.4 Umbilical venous glucose concentrations vs. gestational age for appropriate for gestational age (AGA) pregnancies (\blacktriangle). Maternal arterial glucose concentration vs. gestational age (\circ).

Figure 4.5 Measured mean \pm SD values of maternal arterial-umbilical venous glucose concentration (conc.) differences in AGA fetuses and fetal growth restriction (FGR) cases of groups 1, 2, and 3. The P -values refer to the significance of the differences for the intercepts of AGA compared with FGR groups (solid lines), and among groups of FGR (dashed lines) for the regression analysis of the maternal-fetal difference vs. gestational age.

been studied from the viewpoint of the increased metabolic demand placed upon the mother by multiple pregnancies. Marconi and coauthors²⁶ reported that there was a significant correlation between plasma glucose disposal rate and both the maternal glucose concentration and the mass of the conceptus. Thus, maternal glucose disposal rate is a function not only of the glucose concentration but also of the mass of the conceptus (fetus + placenta).

Amino acid transport has been studied under steady-state conditions in sheep *in vivo*^{27–30} as well as under a variety of *in vitro* conditions in small mammals and in the human pla-

centa.³¹ This is an extensive subject that has been well reviewed recently,³² but that is not covered in this chapter.

Placental growth

In all mammalian species, placental growth is much more rapid than fetal growth in early gestation. Placental growth then either stops or is at a very low rate during later gestation. Fetal growth, on the other hand, is largely exponential throughout gestation. There is a slower rate of fetal growth in late gestation but this still far exceeds placental growth. The outcome of these differences in growth rate is that the fetal-placental ratio increases markedly as gestation advances. Although the growth rate of the human placenta decreases, its maturation continues. This can be demonstrated by morphometric techniques that bring out the continued exponential increase in surface area of the placenta during late gestation when its weight is no longer increasing.³³ Physiological studies in animals support the morphometric data in that there is a marked increase in the capacity of the placenta to diffuse urea in late gestation, which parallels the changes in surface area.³⁴

Fetal growth

Key aspects of fetal growth include not only the rate of change in fetal body weight but also the change in body composition as gestation advances. This is particularly striking for the human fetus, which grows by approximately 1.5% each day. Accompanying this growth there is a reduction in total body water concentration, attributable largely to a decrease in extracellular fluid volume as a fraction of total body water, and large increases in white fat depots. There are a number of clinical implications of these changes in body composition. Water has no caloric density, whereas fat has the highest caloric density of tissues; therefore, the human fetus has a relatively high caloric accretion rate. Also, because fat consists of 78% carbon but is nitrogen free, the human fetus has a relatively low nitrogen accretion rate in late pregnancy but builds up large carbon stores in fat and glycogen.³⁵

The accumulation of large white fat depots in the human fetus has important nutritional implications. Fat depots are important storage sites for the fat-soluble vitamins and essential fatty acids, particularly the polyunsaturated, long-chain fatty acids. Intrauterine growth-retarded and very preterm infants are born with depleted fat and glycogen stores and are at risk of developing essential fatty acid deficiency relatively quickly (i.e., within days) compared with term infants (i.e., within weeks).^{36,37} Similarly, IUGR and preterm infants are at risk of neonatal hypoglycemia. Fat also helps to insulate the term infant, reducing heat and water loss through the skin – all adaptations that the premature infant does not have.

Fetal metabolism

Fetal metabolism has been fairly intensively studied in the past few years as techniques for the application of tracer methodology have become more available.

Umbilical uptake of nutrients

The net uptake of nutrients into the umbilical circulation from the placenta is an indispensable reference point for understanding fetal metabolism. The reason for this is that the net umbilical uptake represents the dietary supply of nutrients to the fetus. Although it is possible for the fetus to synthesize nutrients such as glucose or nonessential amino acids within the fetal tissues, such interconversions of compounds do not satisfy the absolute requirement for an exogenous (to the fetus) supply of carbon and nitrogen for growth and oxidation.

The main nutrients that the fetus receives include glucose, lactate, and amino acids.^{4,38} Glucose and the essential amino acids are derived from the maternal circulation.

The nonessential amino acids are a far more complicated issue. Tracer studies have clearly shown that some amino acids are produced within the placenta in large amounts, with a relatively small component coming from direct transplacental transport. The fetal requirements for some amino acids (glutamate and serine) appear to be met entirely by production within the fetus. Studies of glutamate venous–arterial differences across the human umbilical circulation at the time of Cesarean section have shown a net uptake of glutamate from the fetal circulation into the placenta.³⁹ Presumably, it is used as a metabolic fuel in the human placenta as it is in the ovine placenta.⁴⁰

Both glucose and lactate have been shown to have fairly high oxidation rates during fetal life. If their transport is increased, their contribution to oxidation will also increase, sparing the utilization of amino acids as metabolic fuels. Conversely, during maternal fasting, placental glucose transport is decreased and amino acid oxidation increased.

Quantitative information about amino acid and nitrogen transport to the human fetus is not as firmly established because it is difficult to obtain reliable data for umbilical venous–arterial differences of amino acids at the time of delivery. Several studies have measured the uptake of amino acids by the umbilical circulation at the time of Cesarean section. Because umbilical blood flow could not be measured reliably, the data were expressed per unit of oxygen uptake. These studies have shown a large uptake of most amino acids (with the exception of glutamate, which is taken up by the placenta). Amino acids are provided to the human fetus in amounts that exceed their net rates of accretion. The data supporting this interpretation come from the observation of a relatively large placental urea gradient, with fetal concentrations being higher than maternal concentrations.⁴¹ Given the large urea clearance

in the primate placenta, the urea concentration difference across the placenta implies a fairly high urea production rate during fetal life.

In addition to serving as fuels for the fetus, amino acids are used for protein synthesis. There are a number of conceptual problems in attempting to estimate the rate of protein synthesis during fetal life. However, it is clear that the rate of protein synthesis expressed per gram of fetus is higher in early gestation and decreases towards term, roughly in parallel with the changes in metabolic rate.⁴² The rate of protein synthesis exceeds the rate of net protein accretion from growth, reflecting a relatively high rate of protein turnover during normal fetal development.

Fatty acids and ketone bodies cross the placenta in man and in several other species, maintaining relatively small transplacental concentration gradients. Their fate upon entering the fetal circulation has not been well studied, although it is clear that fatty acids are used largely for carbon accretion in white fat depots and are not oxidized extensively during fetal life.⁴³ Because of their importance for brain growth, there are more studies directed at placental transport of polyunsaturated, long-chain fatty acids.

As alluded to earlier, the limitation in understanding fetal growth has been the inability to measure umbilical volume blood flow accurately. For example, endpoints of many nutritionally based studies, such as those evaluating amino acids, fatty acids, or glucose transport, have required that values be expressed by units other than rate (i.e., mL/min or mL/min/kg). Recent advances in ultrasound technology that include improved imaging and flow velocity data acquisition have given investigators the tools to accurately assess *volume* flow. Although Doppler velocimetry has been a very useful tool in assessing and managing the fetus with IUGR by obtaining information on blood flow resistance,^{44–46} determination of oxygenation and nutrient delivery is dictated by *volume* blood flow and not velocimetry. A study in 1999 demonstrated that umbilical venous flow measurements (mL/min) can be obtained in human fetuses with accuracy and precision, and that the examination can be completed on average in less than 5 min.⁴⁷ This technique involves the combined use of real-time ultrasound, color Doppler, and pulsed-wave Doppler velocimetry to obtain the necessary measurements for calculation of umbilical vein flow from the following formula:

$$\text{Umbilical vein flow (mL/min)} = \text{vessel cross-sectional area } (\pi r^2) \times \text{mean velocity (cm/s)} \times 60 \text{ s} \quad (4.1)$$

Figures 4.6 and 4.7 show the images required for accurately calculating the umbilical vein flow. Important technical aspects include maximal magnification of the vessel for diameter measurement and vertical orientation of the vessel for acquisition of the Doppler flow velocity waveform. This method of calculating blood flow has been validated in a sheep model in which a well-established technique of measuring flow (steady-state diffusion technique) confirmed the accuracy of

Figure 4.6 Magnified longitudinal image of the umbilical vein for accurate placement of calipers to measure the diameter of the vein from which the radius can be obtained.

Figure 4.7 Ultrasound and Doppler images depicting the vertically oriented umbilical vein image with color Doppler, and the 0° angle of insonation of the Doppler sample volume for obtaining the Doppler flow velocity waveform.

Figure 4.8 Graph showing the reduction of umbilical vein flow in growth-restricted fetuses compared with control subjects across gestation.¹³

Figure 4.9 Graph demonstrating that there was no difference in umbilical vein diameter adjusted for fetal weight among fetuses with IUGR compared with control subjects.¹³

measuring blood flow with ultrasound.⁴⁸ Using this ultrasound technique, absolute umbilical vein volume flow has been shown to be reduced in fetuses with IUGR compared with those growing normally (Fig. 4.8).¹³ Furthermore, when adjusted for estimated fetal weight, the reduction in blood flow volume was found to be secondary to a reduction in the velocity of blood and not to a reduction in the diameter of the umbilical vein (Figs 4.9 and 4.10). This study also showed that volume blood flow was reduced by mid-gestation in these fetuses with IUGR. This finding is important from a developmental point of view because if blood flow on a per kilogram basis is reduced by mid-gestation then this suggests that there are factors affecting normal uteroplacental vascularization and angiogenesis (branching). Thus, abnormal placental development and reduction in circulating blood volume at some point in gestation will result in insufficient nutrient delivery and aberrant fetal growth. The ability to calculate volume blood flow will provide the opportunity to better understand nutrient flux across the human placenta. It is anticipated that, with the knowledge accumulated from these types of studies, fetuses with IUGR could potentially be treated in the antepartum period and at the appropriate time.

Key points

- 1 The oxygen exchange across the human placenta is characterized by the umbilical vein PO_2 following the uterine venous PO_2 but at a somewhat lower level.
- 2 The transport of oxygen to the fetus is a function of both uterine and umbilical blood flow as well as placental permeability to oxygen.
- 3 Uterine blood flow can decrease significantly before a critical flow is reached at which oxygen delivery to the baby decreases.
- 4 Metabolism by the placenta takes place at a very high rate, as indicated by its high oxygen and glucose consumption.
- 5 There is a persistent maternal–fetal glucose concentration difference that is maintained over a very wide range of maternal glucose concentrations.
- 6 This gradient is increased in cases of fetuses with intrauterine growth retardation (IUGR).
- 7 Fetal growth in the human is characterized by a very long gestation period and by the accretion of a large mass of white fat, which accumulates in the last third of gestation.
- 8 The net umbilical uptake of nutrients represents the dietary supply to the fetus.
- 9 There is extensive interconversion of nutrients within the placenta; glucose, lactate, and amino acids represent the major sources of carbon and nitrogen for the fetal diet.
- 10 There is a net umbilical uptake of all of the essential amino acids from the maternal circulation into the fetal circulation.
- 11 The nonessential amino acids do not all show a significant transport from the maternal circulation to the fetus. There are some nonessential amino acids, e.g., glutamate and aspartate, which are taken up from the fetal circulation into the placenta.
- 12 It is important to understand the differences between measuring velocity profiles and measuring the actual blood flow, which can now be undertaken for the umbilical circulation and the uterine circulation. In normal pregnancy, umbilical blood flow, expressed per kilogram of fetal weight, decreases as pregnancy advances.
- 13 Umbilical blood flow per kilogram, as well as absolute flow in millimeters per minute, are both significantly reduced in fetuses with IUGR compared with normal fetuses.
- 14 Placental growth is characterized by a much more rapid growth rate than fetal growth in early pregnancy.
- 15 In late pregnancy, the growth rate of the human placenta slows markedly but its maturation continues.
- 16 There continues to be an exponential increase in surface area of the placenta during late gestation.
- 17 The uptake of oxygen, glucose, and amino acids in the fetal circulation has been shown to be increased when maternal concentration is increased.
- 18 Fetal lactic acid concentrations are increased in association with velocimetry changes in fetuses with IUGR.
- 19 Uterine venous PO_2 is an important determinant of umbilical venous PO_2 .
- 20 Both the maternal–fetal PO_2 gradient and the glucose gradient are increased in IUGR pregnancies.

Endocrinology of pregnancy and the placenta

Alan DeCherney, Jessica Spencer, Tim Chard, and Karen A. Hutchinson

The synthesis and role of hormones in pregnancy is a unique interplay between the three major compartments of pregnancy: the fetus, the placenta, and the mother. Some hormones are produced in the nonpregnant state and upregulated in pregnancy (quantitative hormones), whereas others are largely unique to the pregnant state (qualitative hormones). This chapter will review each of these compartments and their respective hormone products by axis, emphasizing their function and the consequences of pathological change.

The corpus luteum

The corpus luteum forms from the ovulated follicle and, in the absence of pregnancy, undergoes luteolysis at the onset of menses. Maximal activity is achieved 1 week after the luteinizing hormone (LH) surge and the normal lifespan is 14 days. The corpus luteum in early pregnancy synthesizes crucial hormones until the fetoplacental unit can take over. These include progesterone, estradiol, inhibin A, relaxin, and vascular endothelial growth factor (VEGF), all of which promote the growth and development of the embryo, inhibit spontaneous uterine activity, and suppress further folliculogenesis. The corpus luteum can also produce metalloproteases and other cytolytic enzymes that initiate luteolysis. Human chorionic gonadotropin (hCG), which is secreted by the trophoblast, inhibits this cascade and is therefore essential for rescuing the corpus luteum. This is discussed in more detail at the end of the chapter.

Estrone, estradiol, and estriol

These estrogen molecules share the same basic 18-carbon estrone nucleus and differ only in the number and arrangement of hydroxyl groups as depicted in Figure 5.1. All three estrogens increase dramatically in pregnancy. Estrone (E_1) is a precursor to estradiol (E_2) and is the predominant estrogen in menopause.

E_2 is the predominant estrogen secreted by the ovary. The endometrium contains receptors for both E_2 and progesterone,¹ creating a secretory environment that permits embryonic implantation and development.²

Estriol (E_3) is almost exclusively produced in pregnancy by the placenta, with its precursor dehydroepiandrosterone sulfate (DHEAS), produced in the fetal and maternal adrenal glands. It is believed to be the primary estrogen responsible for increased uterine blood flow during pregnancy.³ It is excreted rapidly and may provide an important route of elimination for the estrogen precursors of pregnancy. The maternal system tolerates higher levels of E_3 than more potent compounds.

Progesterone

Progestins differ in the number and arrangement of their hydroxyl groups as shown in Figure 5.2. Progesterone is clearly the more biologically active progestin.

The effects of progesterone begin early in pregnancy. The pre-implantation corona cells of the conceptus secrete progesterone and E_2 before implantation.^{4,5} En route to the uterus, the conceptus secretes progesterone, which is believed to relax uterotubal musculature. The site where ova and sperm meet, in the distal one-third of the fallopian tube, contains many progesterone receptors. It is possible that E_2 secreted by the conceptus may balance the effects of progesterone to maintain an optimal level of tubal motility and tone.^{5,6}

At the time of implantation, progesterone inhibits T lymphocyte-mediated tissue rejection. Human chorionic gonadotropin and decidual cortisol are also involved in this process.⁷ This inhibition of rejection may well offer immunological protection to the implanted conceptus and evolving placenta. In addition, progesterone decreases uterine blood flow. Progesterone and estrogens thus appear to balance one another in the maintenance of optimal blood flow to the implantation site.^{8,9}

Figure 5.1 Molecular structures of estrogens. The basic 18-carbon estrane nucleus is shared by estrone, estradiol, and estriol. Each estrogen is different as a result of the arrangement of hydroxyl groups.

The fetal allograft and maternal immune tolerance

Several changes occur in the maternal immune system and the decidual immunological environment to allow the conceptus to coexist with the mother. Normal pregnancy is characterized by a type 1 to type 2 T helper (Th1 to Th2) cytokine deviation in the mother. Pathologically, this change is not seen in preeclampsia.¹⁰ Recurrent abortion and endometriosis, both major causes of infertility, have also been linked to a Th1 cytokine deviation (tumor necrosis factor alpha, TNF- α , being the main factor).¹¹ Several studies have also demonstrated significant changes in the levels of peripheral maternal CD4⁺ and CD8⁺ cells during pregnancy. Deletion of alloreactive B cells, which are detectable in early pregnancy and which rise with each subsequent gestation, may also occur.¹²

The physical barrier which develops after implantation is composed of the outer syncytiotrophoblast layer (which is in direct contact with maternal blood) and an inner cytotrophoblast layer. This barrier is not impermeable; fetal DNA has been isolated from maternal blood¹³ and has even been detected in women 27 years after giving birth.¹⁴ On the fetal side of the barrier, major histocompatibility complex I (MHC-

Figure 5.2 Molecular structure of progestogens. The basic 21-carbon pregnene structure is shared by progesterone and 17 α -hydroxyprogesterone. These compounds differ in the number and arrangements of the hydroxyl groups.

I) is replaced by human leukocyte antigen (HLA)-G and -E, which are much less polymorphic, allowing the fetal cells to “hide” from maternal cytotoxic T lymphocytes. Interestingly, maternal serum and placental HLA-G expression appears to be reduced in preeclampsia according to one small study.¹⁵

Several studies have also implicated the Fas–FasL pathway, critical in apoptosis, as playing an integral role in deleting alloreactive T cells. Fetal cells and decidua express high levels of Fas ligand, which prevents the infiltration of cytotoxic T lymphocytes.¹²

Additionally, complement regulation at the maternal–fetal interface helps prevent complement-mediated cellular lysis. When antibodies exist in very high levels, however, such as in antiphospholipid antibody syndrome, fetal loss may occur.

The recently implicated uterine natural killer (NK) cells appear to be the dominant lymphocyte in the decidua and are concentrated most highly around the invading trophoblast. Natural killer cells seem to play a pivotal role in the acceptance of trophoblast invasion.¹⁶ Indeed, mice with deficient NK cells have been shown to have higher levels of fetal loss than their wild-type equivalent. Furthermore, rescuing their NK population with a bone marrow transplantation decreases the frequency of fetal loss.¹⁷

All of these mechanisms represent a delicate balance in cytokines, lymphocyte proliferation and apoptosis, and receptor expression, which ultimately allows the immunotolerance of the fetal allograft.

Maternal cardiovascular adaptation to pregnancy

The average blood volume in pregnant women increases by approximately 40%, peaking at 32 weeks. In contrast, the absolute red blood cell count increases by only 33%, creating a physiological anemia. This cardiovascular metamorphosis provides enough blood for the rapidly enlarging uterus, placenta, and fetus. It also safeguards the mother from blood loss in delivery, which averages 500 mL.

Angiotensin II resistance occurs in normal pregnancy causing a mild hyponatremia with a lower plasma osmolality. Several mediators including progesterone, prostaglandins, and nitric oxide also cause vasodilation. This increase in volume brings about a decrease in peripheral vascular resistance and maternal blood pressure lowers by approximately 10–20 mmHg. In contrast, maternal heart rate will increase by approximately 25%.

This characteristic volume expansion and vasodilation is pathologic in preeclampsia, when arteriolar constriction is a key feature. Leaking capillaries lead to a depletion of intravascular volume and fluid collection in interstitial spaces (e.g., liver and brain edema). Furthermore, endothelial dysfunction is characterized by higher levels of thromboxane A₂, which increases platelet activation. Corticotropin-releasing factor

and neurokinin B are additional endocrine factors that may perpetuate platelet dysfunction.^{18,19}

Nutrition and the fetus

Glucose is the primary fuel of fetal growth and its turnover in a neonate is twice that of a normal adult. The fetal glucose level is usually 10–20 mg/mL lower than in its mother, because glucose crosses the placenta by carrier-mediated facilitated diffusion. Once inside the fetus, glucose serves as a precursor for fat and glycogen. In contrast, maternal insulin and glucagon are unable to cross the placenta and are instead produced by the fetus itself. Amino acids are also actively transported by the placenta and can stimulate fetal insulin secretion. Additionally, free fatty acids cross the placenta and are esterified in the fetal liver into very low-density lipoprotein (VLDL).

This enormous maternal glucose drain favors an insulin-resistant environment that has been attributed previously to the increase in human placental lactogen (hPL) and growth hormone, progesterone, cortisol, and prolactin. Newer studies, however, have implicated TNF- α and leptin and, most recently, the so-called resistin protein, which may be the missing link between obesity and insulin resistance. Its role in pregnancy, however, has yet to be established.²⁰

Obesity is now a problem that affects over 40% of women of childbearing age. Besides its known detrimental effect on fertility (via anovulation) and the increase in miscarriage rates, obesity significantly increases a pregnant woman's chances of developing gestational diabetes and hypertensive disorders such as preeclampsia. This, in turn, increases Cesarean section rates and overall morbidity in obese women.²¹

Hypothalamic and pituitary development in the fetus

The earliest embryonic development of the brain can be identified by day 22 after conception, and the primitive diencephalon by day 35. Within the ventral portion of the diencephalon (which later develops into the hypothalamus), primitive fiber tracts and neuroblasts can be observed. By gestational day 42, the hypothalamus has coalesced beneath the third ventricle and already contains thyroid releasing factor (TRF).

Much of what we know about the development of the fetal endocrine system comes from a review by Kaplan and coauthors.²² All of the hypothalamic nuclei are differentiated by 14 weeks' gestation and the continuity of the primary and secondary plexus of the portal system is finally completed by gestational weeks 19–21.

The pituitary gland is formed at about this time and develops from the outpocketing of oral ectoderm from the floor of the diencephalon (Rathke's pouch), which gives rise to the adenohypophysis anteriorly, and neuroectoderm from the ventral

diencephalon posteriorly. Capillaries appear within the mesenchymal tissue adjoining Rathke's pouch and the diencephalon by 9 weeks' gestation. Rapid vascularization begins with the development of the primary plexus of the portal system at approximately 100 days. The anterior portion of the pituitary will differentiate into five cellular subtypes: thyrotrophs, corticotrophs, somatotrophs, gonadotrophs, and lactotrophs. The posterior pituitary will eventually produce oxytocin (Chapter 66) and vasopressin (Chapter 35), which is not discussed in this chapter. Many of the specific genes responsible for cellular differentiation in the pituitary have been elucidated and seem to be controlled by local signals that are derived from adjacent tissues.²³

Pituitary and hypothalamic-like peptides in the placenta

Pituitary-like hormones [adrenocorticotrophic hormone (ACTH), hCG, human chorionic somatomammotropin (hCS), and human chorionic thyrotropin (hCT)] have been histochemically localized to the syncytiotrophoblast.^{24–26} Hypothalamic-like hormones [corticotropin-releasing hormone (CRH), gonadotropin-releasing hormone (GnRH), somatotropin-release inhibiting factor, and thyrotropin-releasing hormone (TRH)] have been similarly localized to the cytotrophoblastic layer.^{27–30} It would appear that there is a paracrine analog within these tissues that is similar to the hypothalamic–pituitary axis. The end organ feedback within this system is not exclusively inhibitory (see below). Indeed, selective placental proteins may well have a positive feedback relationship with fetal steroids.

The endocrine axes of the fetus and placenta

GnRH, FSH and LH, and the gonads

Immunoreactive GnRH is present in the fetal hypothalamus by 10 weeks. Follicle-stimulating hormone (FSH) and LH secretion first begin at 9–10 weeks' gestation and peak at about 20–22 weeks. Unlike GnRH, which is secreted in equal concentration in the male and female fetus, the female pituitary appears to contain more FSH and LH than the male gland.²² Gonadotrope activity then gradually declines during late gestation, remaining dormant until puberty. As demonstrated in fetal sheep, this is likely due to decreased secretion of GnRH from the fetal hypothalamus as the gonadotropes are unstimulated, not inactive.³¹

At approximately 6 weeks' gestation, the structure of the fetal testes can be recognized including prominent interstitial (Leydig) cells. These cells produce testosterone, which is critical for male internal secondary sexual development. In contrast, dihydroxytestosterone (DHT), a reduced metabolite of testosterone formed in certain androgen target tissues by 5 α -reductase, is the trophic hormone for the external genitalia.

Testosterone also stimulates the production of two proteins within the adjacent Sertoli cells of the testes: müllerian-inhibiting substance (MIS) and androgen-binding protein. The former causes inhibition of müllerian duct development; the latter binds testosterone and possibly DHT within the wolffian duct system and may be involved in the transduction of androgens into their target tissues. Maximal hCG production by the placenta coincides with the time of greatest biosynthetic activity by the interstitial cells, suggesting that these events are interrelated.^{32–34}

The fetal ovary can be histologically recognized by gestational week 10. The female gonad lacks the impressive biosynthetic capacity of the testis at this point *in utero*. *In vitro* studies have demonstrated that fetal ovarian tissue has the capacity to cleave pregnenolone sulfate and further metabolize pregnenolone to the C-19 steroids dehydroepiandrosterone and androstenedione. However, ovarian production of free progesterone, testosterone, or estrogens has not been documented.³⁵

Placental GnRH, hCG, and inhibin

Placental GnRH is similar in structure to the hypothalamic decapeptide of the same name. Its activity has been localized to the cytotrophoblastic cells along the outer surface layer of the syncytiotrophoblast.³⁶ The structure and additional functions of hCG are described below (see section on human chorionic gonadotropin). Inhibin is a heterodimeric glycoprotein with α - and β -subunits and its immunoreactivity has been localized to the cytotrophoblast layer.

Syncytiotrophoblastic GnRH activity peaks at approximately 8 weeks' gestation and decreases with advancing fetal age. These changes in GnRH activity parallel those seen in placental hCG.³⁶ Information regarding inhibin variation during pregnancy is not available.

It is clear that placental GnRH stimulates the release of hCG through a dose-dependent paracrine mechanism.³⁷ *In vitro* work with first-trimester placentas has shown that GnRH has little stimulatory effect on hCG production when the latter is close to maximum.³⁶ However, in midtrimester, GnRH markedly increases hCG release. Not surprisingly, this effect diminishes in the term placenta. A complete intraplacental regulatory system can be hypothesized whereby cytotrophoblastic GnRH stimulates the production of syncytiotrophoblastic hCG, which, in turn, influences steroidogenesis. It has been postulated that placental inhibin functions also go through a paracrine mechanism to inhibit GnRH release and thereby hCG release.

TRH, TSH, and the thyroid

Immunoreactive TRH has been detected in significant levels in the fetal hypothalamus by 10 weeks. As noted with GnRH, there is not an appreciable correlation between gestational age or sex. Secretion of thyroid-stimulating hormone (TSH) *in utero* is regulated by both hypothalamic TRH and

the intact pituitary–thyroid feedback system (mature by mid-gestation).

The thyroid gland first appears at 16–17 days of gestation and the capacity of the developing follicular cells to produce thyroglobulin is established by day 29. However, the development necessary to concentrate iodide into synthesized thyroxine (T_4) is not operational until the 11th week.³⁸ Furthermore, pituitary thyrotropes are not detectable until approximately 13 weeks' gestation. Once the thyrotropes mature, iodine uptake and the synthesis of iodothyronines in the thyroid commences.

Interestingly, fetal thyroid function is not affected to any significant degree by the limited transplacental passage of TSH and iodothyronines. Indeed, the human placenta appears to contain a highly active 5-monodeiodinase that converts T_4 to the inert iodothyronine, reverse triiodothyronine (reverse T_3).³⁹

The metabolism of T_4 *in utero* differs dramatically from the situation found in adults. Not only are production and degradation rates greater in the fetus (on the basis of unit body mass), but also the specific enzymatic pathway by which T_4 is metabolized favors the formation of the inert, reverse T_3 , at the expense of the metabolically active product generally found in adults, T_3 .

Thyroxine-binding globulin (TBG) can be detected in serum by the 10th gestational week, progressively increasing in con-

centration to term. The second- and third-trimester increase in serum T_4 concentration reflects not only this increase in TBG, but also the greater secretory capacity of the fetal thyroid gland under the influence of the maturing hypothalamic–hypophyseal portal system (Fig. 5.3).⁴⁰

Somatic development *in utero* is not a phenomenon that is dependent on thyroid hormones. However, thyroid hormones do appear to be necessary for late-phase skeletal maturation and late prenatal pulmonary development, as well as the normal development of the brain and intellectual function.³⁸

Human chorionic thyrotropin

TRH has been detected in the cytotrophoblast layer of the placenta and is then called human chorionic thyrotropin (hCT). However, this molecule appears to be chromatographically different from synthetic TRH, which is a tripeptide.⁴¹ The structure of hCT is similar to pituitary TSH α -subunits, but it has negligible thyrotrophic activity³² and its role is unclear.

The excessive amount of thyroid-stimulating activity found in neoplastic trophoblast tissue is not secondary to an hCT effect. Indeed, studies in molar pregnancy have failed to identify hCT.³² The hyperstimulation of thyroid tissue that occurs in some women with molar pregnancy is attributed to the high circulating concentration of hCG which has 1/4000th of the activity of TSH.⁴²

Figure 5.3 Patterns of maturation of serum thyroid-stimulating hormone (TSH) and thyroxine (T_4) concentrations in the human fetus. (From Fisher DA, Klein AH. Thyroid development and disorders of thyroid function in the newborn. *N Engl J Med* 1981;304:702, with permission.)

Figure 5.4 Schematic representation of transplacental transport of calcium (Ca^{2+}), phosphorus (PO_4^{2-}), parathyroid hormone (PTH), calcitonin (CT), and mono- and dihydroxyvitamin D ($25(\text{OH})\text{D}$ and $1,25(\text{OH})_2\text{D}$ respectively). (From Fuchs F, Klopper A, eds. *Endocrinology of pregnancy*. Philadelphia: Harper & Row, 1983:186, with permission.)

The parathyroid and calcium homeostasis

Fetal parathyroid hormone (PTH) is detected between the tenth and thirteenth gestational weeks (Fig. 5.4). Parathyroid function, however, remains suppressed throughout most of pregnancy owing to the relatively hypercalcemic state of the fetus (secondary to the considerable placental transport of calcium, critical for bone formation). Calcitonin levels are elevated, which enhances bone development.

At term, fetal $1,25$ -dihydroxyvitamin D levels are considerably below maternal levels, supporting the concept that $1,25$ -dihydroxyvitamin D does not cross the placenta, although 25 -hydroxyvitamin D probably does cross. Direct comparisons of serum concentrations of vitamin D in mother and fetus are complicated by the fact that there are estrogen-induced changes in vitamin D-binding protein. The fetal kidney can hydroxylate 25 -hydroxyvitamin D although the placenta can synthesize $1,25$ -dihydroxyvitamin D directly. Excellent reviews of vitamin D and its metabolism have been published.⁴³⁻⁴⁵

Prolactin

Immunoreactive prolactin is present in the pituitary gland in small but measurable amounts early in gestation. However, in both males and females, the concentration increases rapidly between 20 and 30 weeks' gestation and term. Several authors have proposed that the major modulating force behind the late-trimester increase in fetal prolactin is placenta-derived estrogens. It is also possible that, developmentally, the pituitary

is functionally able to respond to tropic agents including TRF after 20 weeks' gestation.

Fetal prolactin may play a role in the regulation of normal fetal osmolality.⁴⁶ Prolactin receptors are expressed in a range of fetal tissues as early as the seventh gestational week and may play a role in bone, adrenal gland, lung, brain, and pancreatic β -cell development and function.⁴⁷ In fact, cord blood from preterm infants who develop respiratory distress syndrome has been shown to have lower mean prolactin levels.^{48,49}

GH-RH, GH, and somatostatin

The presence of growth hormone-releasing hormone (GH-RH) late in gestation is suggested by the elevated levels of plasma growth hormone (GH) in premature neonates.²² However, this peptide has yet to be identified in fetal tissues.

By 7-9 weeks' gestation, GH is present in the fetal pituitary. "Little" or monomeric GH predominates in the fetal pituitary with only a small amount of "big" GH present. This pattern is similar to that observed in adults.²² Because GH does not cross the placenta, circulating GH is entirely of pituitary origin. Peak concentrations of immunoreactive GH occur between 25 and 30 weeks' gestation, followed by a decrease in the third trimester. This coincides with maturation of hypothalamic neuroregulation (Fig. 5.5). The reader is referred to an excellent review by Gluckman and coauthors.⁴⁶

The exact role of GH in development is unknown; however, many fetal tissues express GH receptors and GH stimulates the synthesis of insulin-like growth factors (IGF-1 and -2). Fetal IGF-1 and its binding protein seem to be altered in chronic hypoxemia and malnutrition, and IGF-2 may be closely related to steroid hormone biosynthesis.⁵⁰

Growth hormone release-inhibiting hormone (also known as somatostatin) more than triples from 10 to 20 weeks' gestation.²² Studies have identified somatostatin receptors as early as 16 weeks' gestation in the hypothalamus, pituitary, and central nervous system.⁵¹ It has been suggested that the pattern of GH secretion in the fetus reflects maturational changes in the secretion of GH-RH and somatostatin.⁴⁶

Somatomedin

Somatomedin activity in umbilical cord blood increases during gestation from 24 weeks to term, although somatomedin activity can be detected in fetal sera by 14 weeks.⁴⁶ A growth-promoting function for somatomedin in the fetus is supported indirectly by the observations that cord somatomedin concentrations correlate directly with body weight,^{52,53} and infants with intrauterine growth retardation (IUGR) have lower somatomedin levels than normal newborns of a similar gestational age.^{52,54-56} Moreover, fetal chondrocytes are responsive to the growth-promoting effects of this peptide.

In the human fetus, somatomedin secretion is not GH dependent. Because a transient increase in neonatal

Figure 5.5 Schematic illustration of the proposed ontogenesis of hypothalamic neurohormonal control of fetal growth hormone (GH) secretion. GRF, growth-hormone-releasing factor; SRIF, somatotrophic release-inhibiting factor. (From Gluckman PD, Grumbach MM, Kaplan SL. The neuroendocrine regulation and function of growth hormone and prolactin in the mammalian fetus. *Endocrine Rev* 1981;2:363, with permission.)

somatomedin has been observed during the first month of life when estrogen levels are declining, it has been suggested that estrogens may serve some suppressive regulatory function *in utero*.

CRH, ACTH, and the adrenal gland

After the seventh week of gestation, the corpus luteum ceases to be the dominant steroid-producing organ and the fetoplacental unit takes over. The interdependence of the fetal adrenal cortex and the placenta reflects their incomplete, but complementary steroidogenic, enzyme systems. The characteristic steroid profile of pregnancy results from their constant exchange of steroid precursors. However, there appears to be little maternal contribution to the fetal pool of ACTH.

Bioassayable ACTH can be detected in the fetal pituitary by 8–10 weeks' gestation, peaks between 12 and 19 weeks, and then declines slowly throughout the third trimester. At mid-gestation it appears to play a critical tropic role in the developing fetal zone of the adrenal gland. However, pituitary ACTH may not provide the only stimulus for adrenal growth: placental-derived proopiomelanocortin (POMC, the precursor of ACTH and β -lipotropin) may also share this activity.

Placental CRH is structurally similar to hypothalamic CRH.⁵⁷ Both are products of the same gene located on the long arm of chromosome 8.⁵⁸ Likewise, placental ACTH appears to be structurally similar to the pituitary ACTH 1–39 peptide.⁵⁹ The activity of CRH is highest during the first trimester and diminishes as term approaches. Of note, pro-CRH mRNA has been found in the cytotrophoblast⁵⁸ and placental ACTH activity has been localized to the syncytiotrophoblast.²⁴

Similarly to their hypothalamic pituitary counterparts, there is a dose-dependent stimulation of placental ACTH by pla-

cental CRH.⁶⁰ However, a paradoxical relationship is observed between the endorgan product, cortisol, and these placental peptides (Fig. 5.6). Glucocorticoids increase placental CRH and ACTH secretion.⁶⁰ Placental CRH, once released into the maternal and fetal circulations, stimulates the respective pituitary glands and the placenta to secrete ACTH. In turn, ACTH from the maternal and fetal adrenal cortex, as well as from the placenta, stimulates more glucocorticoid secretion (see Fig. 5.6). This positive feedback mechanism may allow an increase in glucocorticoid secretion during times of stress, beyond the amount available if the woman were not pregnant.

Placental CRH and ACTH probably participate with the fetal hypothalamus and pituitary in the observed surge of fetal glucocorticoids associated with the late third trimester.⁶¹

The fetal adrenal gland

At term, the fetal adrenal glands are as large as those of adults, weighing 10 g or more. What ultimately develops into the adult adrenal cortex, the outer or definitive zone, accounts for only 15% of the fetal gland (Fig. 5.7). The unique inner or fetal zone constitutes 85% of the volume of the adrenal gland *in utero* but involutes after delivery and completely disappears by the first year of life. Work in nonhuman primates suggests that the fasciculata zone of the adult adrenal gland may stem from the fetal zone.⁶²

In late gestation, the fetal zone appears to be dependent on the fetal pituitary. This is indirectly supported by observations of fetal zone atrophy in anencephalic and apituitary fetuses, and gland atrophy and reduced DHEAS secretion subsequent to glucocorticoid treatment.^{63–65} However, before mid-gestation, the endocrine support of the pituitary appears unnecessary because anencephalic fetuses demonstrate normal adrenal growth and development up to week 20.⁶⁶ Peptides,

Figure 5.6 The fetoplacental corticotropin-releasing hormone (CRH)-glucocorticoid positive feedback hypothesis. CRH, secreted by the placental trophoblast, enters the fetal circulation via the umbilical vein and stimulates (+) fetal adrenocorticotrophic hormone (ACTH) release from the fetal pituitary. Fetal ACTH stimulates secretion of fetal adrenal cortisol, which enters the placental circulation via the umbilical artery. Cortisol further stimulates placental CRH secretion, thereby completing the positive feedback

loop. Fetal CRH, secreted from the fetal hypothalamus, may independently stimulate fetal ACTH release, and placental and fetal hypothalamic CRH may be directly stimulated by environmental stresses. In addition, placental ACTH may stimulate the fetal adrenal directly. (From Buster JE, Carson SA. Placental endocrinology and diagnosis of pregnancy. In: Gabbe SG, Niebyl JR, Simpson JL, eds. *Obstetrics: normal and problem pregnancies*. New York: Churchill Livingstone, 1991:59, with permission.)

Figure 5.7 Size of adrenal gland and its component parts *in utero*, during infancy, and during childhood. (From Bethune JE. *The adrenal cortex. A Scope Monograph*. Kalamazoo, MI: Upjohn, 1974:11, with permission.)

including hCG, prolactin, hPL, GH, and α -melanocyte-stimulating hormone (α -MSH), as well as epidermal and fibroblast growth factors, have all been proposed to play a tropic role in adrenal development.^{32,67,68}

Catecholamine production occurs in the fetal adrenal medulla, which is derived from sympathetic cell precursors from the neurocrest and neurotube. These subsequently differentiate into neuroblasts, then sympathetic ganglion cells, and eventually pheochromoblasts which invade the developing adrenal cortex by the seventh gestational week and become pheochromocytes or mature chromaffin cells. The adrenal medulla, however, is not fully developed until 3 years of age.^{69,70} Catecholamines are critical for optimal regulation of the central nervous, cardiovascular, and metabolic systems. Catecholamine release is predominantly regulated by sympathetic nerves that secrete acetylcholine.⁷¹

DHEAS

The fetal adrenal cortex is functionally deficient in the enzyme 3β -hydroxysteroid dehydrogenase, which converts preg-

nenolone and dehydroepiandrosterone (DHEA) to progesterone and androstenedione, respectively,^{72,73} the immediate precursors of the sex steroids. These enzyme deficiencies are offset by the enzyme activities of the placenta, allowing these two organs to work together to produce a range of steroids not otherwise possible (Fig. 5.8). The fetal adrenal cortex extracts LDL from the fetal circulation and converts it to pregnenolone sulfate and DHEAS.^{73,74} Pregnenolone sulfate is delivered to the placenta through the umbilical artery. The placenta, which has an abundance of 3β -hydroxysteroid dehydrogenase, converts pregnenolone to progesterone and this is then returned to the fetus for mineralocorticoid and glucocorticoid synthesis. Of note, the placenta also has the enzymatic capacity to extract LDL cholesterol and convert it to progesterone.

The fetal zone produces DHEAS in large concentrations. This reflects the restricted availability of $\Delta 3\beta$ -hydroxysteroid dehydrogenase and $\Delta 4,5$ isomerase activity necessary for the biosynthesis of progesterone, cortisol, and testosterone. The high circulating levels of progesterone and estradiol found

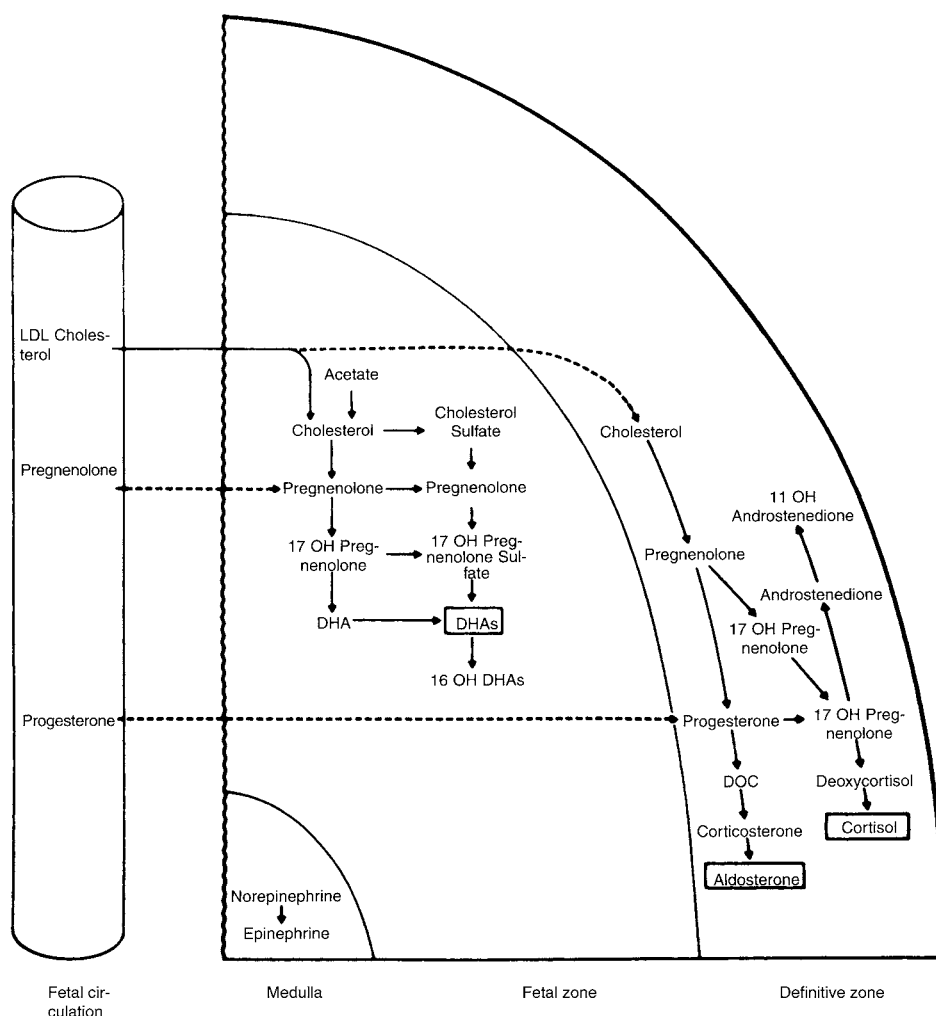

Figure 5.8 Exchange of circulating steroid intermediates between the adrenal fetal zone and placenta. Enzyme deficiencies of the fetal zone are offset by enzyme activities of the placenta, enabling the two organs to work as a mutual cooperative to produce an extensive profile of steroids not otherwise possible. The fetal adrenal cortex is functionally deficient in 3β -hydroxysteroid dehydrogenase, the enzyme that converts pregnenolone to progesterone and dehydroepiandrosterone sulfate (DHEAS) to

androstenedione. The placenta contains 3β -hydroxysteroid dehydrogenase in abundance and can make this conversion. The placenta is deficient, however, in 17α -hydroxylase and cannot make corticoids. LDL, low-density lipoprotein. (From Buster JE, Carson SA. Placental endocrinology and diagnosis of pregnancy. In: Gabbe SG, Niebyl JR, Simpson JL, eds. *Obstetrics: normal and problem pregnancies*. New York: Churchill Livingstone, 1991:59, with permission.)

Figure 5.9 Schematic illustration of generalized pathways of hormone formation in the human fetal adrenal gland. DHA, dehydroepiandrosterone; DHAS, dehydroepiandrosterone sulfate; LDL, low-density lipoprotein. (From Seron-Ferre M, Jaffe RB. The fetal adrenal gland. *Annu Rev Physiol* 1981;43:141, with permission.)

during pregnancy inhibit this enzyme complex and thereby indirectly promote DHEAS production. Maternal LDL cholesterol appears to be the major precursor of fetal adrenal DHEAS. Other steroid sulfates can also be converted to DHEAS without loss of the sulfate sidechain. DHEAS is delivered to the fetal liver, where it is converted to 16α -hydroxyandrostenedione and then further aromatized into estriol.⁷³ Estrogens are subsequently secreted into the fetal and maternal circulations.⁷³ Jaffe and Payne⁷⁵ have demonstrated that the human fetal testis has the capacity to use DHEAS *in vitro* to form active steroids.

Cortisol

Together with aldosterone, cortisol is the major steroid produced by the definitive zone (Fig. 5.9). The adrenocorticoids share the same 21-carbon pregnane structure with progesterone. However, these compounds differ markedly in their biological activity because of the additional hydroxyl and ketone groups as shown in Fig. 5.10. Low-density lipoprotein cholesterol is used as a substrate for the synthesis of cortisol via the pathways of 17α -, 21-, and 11β -hydroxylation. Prog-

esterone derived from the placental circulation can also be used within the definitive zone for the production of cortisol, deoxycorticosterone, corticosterone, and aldosterone.⁶⁶ As described below, cortisol has many roles in fetal development.

Cortisol stimulates pulmonary surfactant production by type 2 pneumocytes.⁷⁶ At approximately 34–36 weeks' gestation, cortisol, together with thyroxine, prolactin, and estrogens, stimulates choline phosphotransferase to produce dipalmitoyl lecithin, the principal surface-active phospholipid.^{77,78} This increases the lecithin–sphingomyelin ratio, characteristic of fetal lung maturity.

Corticosteroids induce the development and maturation of a number of hepatic enzyme systems necessary for carbohydrate, protein, and fat metabolism. The concentration of liver glycogen increases with advancing gestational age, and glycogen deposition appears to be controlled by cortisol.⁷⁹ This role of cortisol is critical considering the fact that glycogen availability in the newborn is necessary for its extrauterine adaptation. Indeed, during the first 24 h of life, continuous blood glucose delivery to the neonatal brain is dependent on liver glycogen stores.⁷⁷

Figure 5.10 Molecular structure of the corticoids. Cortisol and cortisone differ from progesterone in the number and arrangements of hydroxyl groups.

In nonhuman models, cortisol has also been shown to participate in the maturation of the hypothalamic–pituitary–adrenal (HPA) axis, in central nervous system growth, and the establishment of hypothalamic rhythmicity.⁷⁷ Intrauterine stressors may set this axis at an early age to favor short-term benefits such as restricting growth and increasing fuel availability, but this may have long-term adult consequences such as coronary heart disease.⁸⁰

Maternal free and bound cortisol levels increase in pregnancy, peaking in the early third trimester and then declining again. In parturition, a transient increase in cortisol is again observed. Placental CRH production has been hypothesized to initiate labor and even preterm labor. In sheep, fetal cortisol production is responsible for the initiation of labor but this has not been demonstrated in humans. However, concentrations are slightly higher in spontaneous labor than in induced labor.⁸¹

Cortisol may also play a role in the transfer from fetal- to adult-type hemoglobin. However, most of the work on the function of cortisol in the fetus has been carried out in animal models and human data are lacking.

Renin–angiotensin system

Renin secretion clearly doubles as early as the eighth week of gestation, and then increases to 32 weeks, after which no further significant changes occur. Plasma renin substrate, however, doubles by the eighth week of pregnancy, plateaus by the 20th week, and remains steady thereafter.⁸² This concurrent stimulation of enzyme and substrate levels results in a dramatic increase in plasma renin activity. The large size of renin (molecular weight 43 kDa) makes it unlikely that this molecule crosses the placenta. Not surprisingly, anephric infants have been found to have undetectable renin levels.

The circulating concentration of the octapeptide, angiotensin II, in the fetus is similar to or greater than the

maternal level, and both are higher than those observed in the nongravid state. Placental metabolism of angiotensin I into angiotensin II, or production of angiotensin II by the placenta, is suggested by the observation that venous blood from the umbilical cord has higher levels of angiotensin II than arterial cord blood. It has been suggested that these findings support a significant role of the renin–angiotensin system in the regulation of fetoplacental blood pressure.

The pattern of aldosterone secretion, as well as plasma aldosterone levels, may diverge from that of plasma renin activity in pregnancy. Although changes in plasma renin activity begin to plateau as early as 20–32 weeks, plasma and urine aldosterone continue to increase progressively throughout pregnancy. This pattern appears to closely parallel the profile of other steroid hormones, such as progesterone, E₃, and E₂.⁸³

Fetoplacental peptides

Considering the totipotent nature of the trophoblast, it is not surprising that this tissue secretes a variety of substances, including several proteins that are produced early in human pregnancy. The following discussion considers the most prominent of these and their role in gestation.

Human chorionic gonadotropin

Human chorionic gonadotropin (hCG) has a molecular weight of 36–40 kDa and is a glycoprotein that is biologically and immunologically similar to LH but with a longer half-life.^{84–86} All of the glycoprotein hormones (hCG, LH, FSH, and TSH) have a similar biological activity which is characteristic of the β -subunit component. It is because of this that hCG seems to have a stimulatory effect on the maternal thyroid in early pregnancy when hCG levels are highest. The α -subunit and carbohydrate component are required for expression of the

biological activity unique to the β -subunit. The 28–30 amino acids on the carboxy-terminal end of the β -subunit of hCG are unique compared with LH. The specific immunoreactive properties of the hCG β -subunit allow the diagnosis of pregnancy or extrapregnancy sources of hCG (i.e., gonadal tumors) with great accuracy. Even in the presence of LH, hCG is produced by the syncytiotrophoblast during pregnancy. It is also produced by all other types of trophoblastic tissue, including that derived from choriocarcinoma and hydatidiform mole.³²

The physiological role of hCG in human pregnancy has yet to be fully elucidated. As described earlier, it is known to play a luteotropic role early in pregnancy. Late in pregnancy, hCG assumes a gonadotropic role by inducing the secretion of testosterone from the fetal testes prior to the availability of LH secretion from the fetal pituitary. It may also regulate DHEAS production by the fetal zone of the adrenal gland⁶⁹ and play a critical immunosuppressive role *in vivo* by pre-

venting the rejection of the fetal allograft by its maternal host.⁸⁷ However, data from recent studies are mixed, and the relative contributions of progesterone, hCG, and cortisol to DHEAS production and immunosuppression continue to be the subject of investigation.

In spontaneous pregnancy, hCG can be detected by the ninth day after the LH surge.⁸⁴ This initial detection in maternal blood has been found to correlate with the implantation of the blastocyst and, specifically, with the moment that lacunae receive maternal blood.^{88,89} The concentration of intact hCG peaks by 60–90 days' gestation and then decreases to a plateau that is maintained throughout the duration of the pregnancy. The production of the β -subunit by the trophoblast parallels that of intact hCG throughout the first trimester.⁹⁰ During this period, free α -subunit levels are low or absent. Thereafter, the relative production of α - and β -subunits reverses and levels of the α -subunit increase until term.

Key points

- 1 The corpus luteum synthesizes crucial hormones that maintain pregnancy until the placenta can take over. These include progesterone, estradiol (E_2), inhibin A, relaxin, and vascular endothelial growth factor (VEGF) which maintain the endometrial lining, prevent contractions, and promote the growth of the embryo.
- 2 All three estrogens share the same 18-carbon nucleus. Estrone (E_1) predominates in menopause, E_2 is the major estrogen secreted by the ovary during the reproductive years, and estriol (E_3) is produced almost exclusively in pregnancy.
- 3 Physiological changes of pregnancy include:
 - physiologic anemia;
 - angiotensin II resistance and a decrease in blood pressure;
 - propensity toward insulin resistance.
- 4 The pituitary is composed of two distinctly derived parts: the anterior pituitary is derived from Rathke's pouch and secretes thyroid-stimulating hormone (TSH), adrenocorticotropic hormone (ACTH), growth hormone (GH), prolactin, follicle-stimulating hormone (FSH), and luteinizing hormone (LH), whereas the posterior pituitary is derived from neuroectoderm and produces oxytocin and vasopressin.
- 5 The α -subunits of TSH, FSH, LH, and human chorionic gonadotropin (hCG) are homologous. It is the β -subunit that confers each hormone's specificity.
- 6 β -hCG has partial thyrotropic activity and its high levels probably cause the suppression of TSH in early pregnancy and the potential hyperthyroid state sometimes observed in molar pregnancies.
- 7 Each endocrine axis of the fetus is intricately tied to the endocrine function of the placenta and the mother.
- 8 Gonadotropin-releasing hormone (GnRH) activity peaks at 20 weeks' gestation during gonadal development and then gradually becomes dormant until puberty.
- 9 Testosterone is converted by 5α -reductase to its more active form, dihydroxytestosterone (DHT). DHT is responsible for virilization of external genitalia.
- 10 The fetal adrenal cortex is mostly composed of an inner fetal zone that involutes after birth, and a smaller outer definitive zone that ultimately becomes the adult adrenal cortex.
- 11 The fetal cortex produces dehydroepiandrosterone sulfate (DHEAS) from maternal low-density lipoprotein (LDL). DHEAS serves as a precursor to multiple hormones including estrogens, testosterone, and androstenedione.
- 12 Cortisol stimulates the production of surfactant in developing fetal lungs, matures fetal liver enzymes, and may be involved in the initiation of labor.
- 13 β -hCG is produced by the syncytiotrophoblast of the placenta and maintains the corpus luteum, stimulates the testes to produce testosterone (in place of LH), and regulates DHEAS production.
- 14 β -hCG is detectable 9 days after the LH surge at the time of implantation. The level of β -hCG peaks at 2–3 months' gestation.
- 15 Human chorionic somatomammotropin (hCS, also known as human placental lactogen, hPL) shares 96% identity with GH and serves as a key stimulatory hormone for fetal growth.

Human chorionic somatomammotropin (human placental lactogen)

Human chorionic somatomammotropin (hCS), also known as hPL, is a single-chain polypeptide of 190 amino acids with two disulfide bridges. It has a short half-life and is produced in massive daily quantities by the syncytiotrophoblast layer of the placenta. Circulating levels increase 10-fold from the first trimester and plateau in the third trimester. It shares 96% identity with GH and its levels have been shown to relate to fetal and placental weight. Despite this, hCS has only 3% of the somatotrophic activity of GH. In animal studies it has been found to display 50% of the lactogenic activity of prolactin.

hCS can be detected in the urine and serum in normal and molar pregnancies, as well as in the urine of patients with trophoblastic tumors and in men with choriocarcinoma of the testes.

The major metabolic role of hCS during pregnancy is to ensure the nutritional needs of the fetus. Hypoglycemia stimulates hCS secretion. As the supply of glucose decreases during the fasting state, hCS levels rise, stimulating lipolysis over carbohydrate metabolism. The increased ketones induced by metabolism of free fatty acids are an important energy source for the fetus. During the fed state, and in response to rising glucose levels, insulin secretion increases and hCS secretion decreases, leading to glucose use and lipogenesis. Because of increasing substrate requirements by the fetus as pregnancy progresses, the functional role of hCS assumes great significance in the second and third trimesters.⁹¹

Conclusion

Endocrine influences on fetal growth and development are complex. Although there are significant gaps in our knowledge, tremendous progress has been made. The fetoplacental-maternal unit stands as a wondrous example in human biology of interrelated systems that allow for the concurrent processes of fetal progression and maternal adaptation.

Fetal Developmental Biology

6

Fetal lung development and amniotic fluid analysis

Ian Gross and Matthew J. Bizzarro

Respiratory distress syndrome (RDS) is a developmental disorder of prematurely born infants, characterized by progressive atelectasis and respiratory insufficiency. RDS occurs as a result of the structural and functional immaturity of the lung. The primary biochemical deficiency is immaturity of the surfactant system, which results in increased surface tension at the air–alveolar interface and a tendency for alveolar collapse and generalized atelectasis.

Composition and function of surfactant

Pulmonary surfactant is a complex mixture of phospholipids and proteins that is synthesized in type 2 alveolar cells. The major phospholipids in surfactant are phosphatidylcholine (PC, also called lecithin), which accounts for 80–85% of total phospholipid, and phosphatidylglycerol (PG), which accounts for 8–11%. Approximately one-half of the phosphatidylcholine is in the disaturated form (DSPC).¹ At 80–90% gestation, a marked increase in total lung phospholipid occurs, with a large increase in PC accounting for most of the change.² An increase in the surface activity of lung extracts and in lung distensibility and stability also occurs at this time.

In addition to the phospholipid components of surfactant, four surfactant-related proteins have been described and characterized. Surfactant protein A (SP-A) is a highly glycosylated protein with a molecular weight of 28–36 kDa. SP-A is a component of the innate immune system of the lung and recent studies indicate that mice deficient in SP-A are more likely to develop pulmonary and systemic infections when challenged with an intratracheal administration of bacteria, including group B streptococcus.³ Two smaller hydrophobic proteins, SP-B and SP-C, with molecular weights of 4 and 8 kDa, respectively, are important for the surface-active properties of surfactant and are present in clinically effective surfactant preparations. SP-D is a lectin-like protein and, similar to SP-A, is important for defense against infection.⁴

Regulation of lung maturation

Clinical observations

A variety of physical, chemical, and hormonal stimuli can alter lung development and phospholipid synthesis and secretion. The incidence of RDS is lower in infants who are delivered after labor, whether by vaginal delivery or Cesarean section, than in those delivered without labor at the same gestational age.⁵ Gender appears to play a role in lung maturation; at the same gestational age, males are more likely than females to develop RDS. Differences in amniotic fluid phospholipids indicate that the biochemical maturity of the female lung precedes that of the male by approximately 1 week.⁶ Maternal diabetes also influences lung maturity; there is a higher incidence of RDS in infants born prematurely to mothers with class A–C diabetes in whom there is no strict control of blood glucose. This delay in lung maturation could be due to hyperglycemia, hyperinsulinemia, excess butyric acid derivatives, or a combination of all three factors.⁷ Acute asphyxia with hypoxia and acidosis also appears to inhibit surfactant production. The incidence of RDS is higher in the second of twins, as are a variety of other problems; it is not clear whether this is related to asphyxia. Finally, there appears to be a familial tendency to develop RDS, and a history of a previous infant with RDS places a subsequent premature infant at a higher risk.

Conversely, some clinical conditions appear to accelerate lung maturation and decrease the incidence of RDS. These include long-term maternal stress, e.g., toxemia and hypertension, intrauterine growth retardation, maternal infection, class F and R diabetes, and maternal heroin exposure. Chronic low-grade maternal stress, as opposed to acute asphyxia, accelerates lung maturation by a mechanism that may involve hormones such as glucocorticoids and catecholamines.

The pharmacological acceleration of lung maturation by antenatal hormone administration will be discussed in more detail below.

Figure 6.1 Amniotic fluid phospholipid concentration vs. gestational age.

Experimental findings

Surfactant synthesis is stimulated by a variety of hormones, growth factors, and transcription factors including glucocorticoids, thyroid hormones, thyrotropin-releasing hormone (TRH), prolactin, cyclic adenosine monophosphate (cAMP), retinoic acid, epidermal growth factor, and thyroid transcription factor. Of these, glucocorticoids have been most extensively studied.^{7,8} The administration of glucocorticoids to a fetus results in morphological changes indicative of accelerated lung maturity including larger alveoli, thinner interalveolar septae, increased number of type 2 cells, and increased lamellar bodies within the type 2 cells. In addition, glucocorticoids enhance the biosynthesis of both lung phospholipids and surfactant proteins. Secretion of surfactant is also stimulated by a number of agents, including β -adrenergic agonists, such as terbutaline, and purinoceptor agonists, such as adenosine.

Evaluation of fetal lung maturity

The assessment of fetal lung maturity by the analysis of phospholipids in amniotic fluid began in 1971, when Gluck and coauthors⁹ reported on gestational changes in amniotic fluid phospholipid concentrations. In an analysis of amniocenteses from both normal and abnormal pregnancies, from 12 weeks to term, they showed that total phospholipids in amniotic fluid increased throughout gestation, but that there was a sharp increase at 35 weeks. Both lecithin (PC), which originates in the fetal lung, and sphingomyelin were measured. The concentrations of lecithin and sphingomyelin were nearly equal until approximately 32 weeks, after which lecithin concentration increased while sphingomyelin declined (Fig. 6.1). The

Figure 6.2 Lecithin-sphingomyelin (L/S) ratio vs. gestational age.

concept of the lecithin-sphingomyelin (L/S) ratio emerged from this report. The ratio between the two phospholipids was used to correct for changes in amniotic fluid volume.

This report was followed by a number of studies on the clinical utility of the L/S ratio for predicting lung maturity. In an early report, Hobbins and coauthors¹⁰ used a lecithin concentration greater than the sphingomyelin concentration as a definition of maturity and found that, regardless of birthweight, infants did not develop RDS if the amniotic fluid phospholipids indicated maturity.

An L/S ratio of 2:1 occurs at approximately 35 weeks' gestation (Fig. 6.2) and, in subsequent clinical studies,^{11,12} RDS was reported in only 2–3% of infants with a ratio of 2:1 or greater. Most of these cases of RDS occurred in infants born to women with diabetes. However, a L/S ratio of less than 2:1 was found to have a low predictive value for RDS as almost one-half of the infants with a low L/S ratio failed to develop RDS. In an effort to improve the accuracy of amniotic fluid phospholipid analysis at predicting RDS, other phospholipids such as PG were studied in normal and complicated pregnancies.^{12,13} PG was first detected at 34–35 weeks' gestation and the concentration then increased with gestational age. The presence of PG as 3% or more of total phospholipids was found to predict lung maturity. Combining the L/S ratio and PG measurements improved both the positive and the negative predictive accuracy of amniotic fluid phospholipid analysis. This was particularly important in diabetic pregnancies. Class A–C diabetics showed a delayed appearance of PG until 37–39 weeks, whereas class D, E, and R diabetics had a normal or early appearance of PG.

The L/S ratio and PG measurements (L/S-PG) have become a standard means of determining fetal lung maturity. A mature L/S with a positive PG has a negative predictive value (a mature test = clinical maturity) of close to 100%. However,

the positive predictive value (an immature test = clinical immaturity) is only around 70%. The L/S-PG test has other drawbacks as well. The test is done by the time-consuming method of thin-layer chromatography. Blood and meconium in the amniotic fluid can greatly reduce the accuracy of the L/S ratio. As a result of these limitations, other methods of determining fetal lung maturity have been evaluated. The ideal method would be reproducible, technically simple, and have a short turnaround time, and it would have both positive and negative predictive accuracy. However, to date, no ideal method has been developed.

In 1972, Clements and coauthors¹⁴ reported a rapid test for surfactant in amniotic fluid called the foam stability or shake test. This was based on the ability of surfactant to produce a stable foam in the presence of ethanol. The technique is fairly simple, requires no special equipment, and results are available rapidly: a “mature” test is indicated by the presence of foam at a 1:2 dilution of amniotic fluid; an “immature” test is indicated by the absence of foam at a 1:1 dilution. The shake test is as good at predicting maturity as the L/S ratio; however, it has a higher false immature rate.¹⁵ As with the L/S ratio, the shake test is not accurate in the presence of blood or meconium. Although it is more easily and rapidly performed than the L/S ratio, the shake test has only been used as a screen and an immature result should be confirmed with an L/S-PG test.

The concentration of lamellar bodies in amniotic fluid is directly related to its absorbance at 650nm,¹⁶ and this absorbance has been used as a rapid test for fetal lung maturity. However, this test is limited by a very high, false immaturity rate.

Amniotic fluid microviscosity, as determined by fluorescence polarization, has also been used as a fairly rapid method of evaluating lung maturity. Amniotic fluid has a high, constant viscosity until approximately 30–32 weeks’ gestation when there is an abrupt decrease followed by a steady decline to term. As with other tests, determination of microviscosity accurately predicts maturity but overestimates immaturity.¹⁷ A refinement of fluorescence polarization uses a ratio of surfactant to albumin rather than microviscosity.¹⁸ As an automated test it is simple to perform and can be carried out quickly, although it does require special instrumentation. A “mature” test correlates well with clinical maturity, but an immature test is not as good a predictor of who will actually develop RDS.

Surfactant proteins in the amniotic fluid have been examined as a way of predicting lung maturity more accurately. King and coauthors¹⁹ assayed amniotic fluid from 12 weeks to term for “surfactant-associated protein,” now known to be SP-A. Between 12 and 32 weeks of gestation essentially no protein was found; the protein titers increased from 32 to 37 weeks and then plateaued. This pattern parallels the gestational age-related increase in phospholipids. A more specific monoclonal antibody assay for SP-A was subsequently used to determine the predictive accuracy of protein assay of amniotic fluid.²⁰ Little protein was found before 32 weeks, there

Table 6.1 Predictive value of prenatal tests for lung maturity.

Test	Positive accuracy	Negative accuracy	References
L/S	0.54	0.98	11, 12, 15–18, 20
L/S-PG	0.47	0.99	20, 22
Shake test	0.12	1.0	15
A ₆₅₀	0.13	0.99	16
SP-A	0.32	1.0	20
L/S-PG + 35 kDa	0.71	1.0	20
FELMA	0.33	1.0	17
TDx-FLM	0.31	0.97	18

FELMA, microviscosity by fluorescence polarization; L/S, lecithin-sphingomyelin ratio; PG, phosphatidylglycerol; TDx-FLM, fluorescence polarization, Abbot Laboratories.

Negative test, maturity; *positive test*, immaturity; *negative predictive accuracy*, accuracy with which a mature test predicts no RDS; *positive predictive accuracy*, the accuracy with which an immature test predicts RDS.

The values above were calculated using data from the references cited. (Definitions from Feinstein AR. On the sensitivity, specificity, and discrimination of diagnostic tests. In: Feinstein AR, ed. *Clinical biostatistics*. St. Louis, MO: CV Mosby; 1997.)

was a slow increase at between 32 and 37 weeks, and a sharp increase after 37 weeks. An SP-A concentration of 3 µg/mL or greater accurately predicted clinical lung maturity but the test was much less accurate in predicting immaturity with a large false-positive rate. When surfactant protein determination was combined with an L/S-PG, the ability to correctly predict immaturity increased. Studies have also indicated that SP-A levels are decreased in amniotic fluid in diabetic pregnancies,^{21,22} but a clear clinical role for surfactant protein determination in diabetic pregnancies has not yet been established.

Table 6.1 summarizes the predictive accuracy of each of the methods discussed. The values in this table were calculated from the data in the references cited. All of the tests accurately predict lung maturity with a very low false-negative rate. This means that an infant with a mature test has a very low risk of developing RDS, which is of great value in determining the timing of delivery of a complicated pregnancy. Conversely, an infant with an immature L/S ratio has about a 50% chance of developing RDS. Using the presence of PG or surfactant protein analysis together with the L/S ratio reduces the chance of a false mature test.

Acceleration of lung development by antenatal hormone administration

Glucocorticoids

The seminal observation by Liggins that antenatal glucocorticoid administration accelerated lung maturity and improved

Figure 6.3 The effects of antenatal glucocorticoids. Modified from ref. 44. Original data from ref. 24.

viability in prematurely born lamb fetuses led to clinical trials of antenatal steroids and other agents, including TRH. In 1994, the National Institutes of Health (NIH) convened a Consensus Conference to study the impact of glucocorticoid therapy on fetal maturation and perinatal outcome.²³ The conferees relied to a large extent on Crowley's²⁴ meta-analysis of published randomized trials of antenatal glucocorticoid therapy and on the data from several "observational databases." The latter consisted of treatment and outcome information collected from five sources and involving more than 30 000 infants.

Effect on the incidence of RDS

The meta-analysis²⁴ (Fig. 6.3) revealed that antenatal glucocorticoid therapy significantly reduced the overall incidence of RDS by approximately 50%. Whereas the effect was statistically significant only in those infants who delivered from 1 to 7 days after the initiation of maternal treatment, there was a trend toward decreased RDS in infants born less than 24 h or more than 7 days after the initiation of steroid treatment. Also, treatment was effective in boys and girls.

Taken as a group, there was a significant reduction in the incidence of RDS in babies born before 31 weeks, but the effectiveness of glucocorticoids in infants born before 28 weeks of gestation was not resolved by these studies. Although

it is not clear whether the incidence of RDS was decreased, there was a benefit in terms of diminished severity of RDS, decreased mortality, and a lower incidence of intraventricular hemorrhage (IVH).

Effect on complications of prematurity

The use of antenatal steroid therapy reduces early neonatal mortality as well as two major complications of prematurity, IVH and necrotizing enterocolitis (NEC).

It is reassuring that long-term follow-up of infants exposed to antenatal glucocorticoids revealed no adverse effects on developmental outcome. Studies conducted at 12 years of age found no deficits in motor skills, cognition, or scholastic achievement despite the greater survival rate of premature infants after steroid therapy.^{25,26} The meta-analysis actually revealed a trend toward decreased neurological abnormalities at follow-up.

Effects on neonatal and maternal infection

Glucocorticoid therapy does not have a significant effect on the overall incidence of maternal or fetal infection. When steroids were administered in the presence of premature rupture of the membranes (PROM), there was a trend toward an increase in fetal and neonatal infection, but this effect was not statistically significant. The meta-analysis also indicated

that steroids decreased the incidence of RDS in the presence of PROM. Furthermore, the observational database revealed that when steroids are administered to women with PROM, there is a decrease in neonatal IVH and mortality. The advantages of using steroids in the presence of PROM appear to outweigh the disadvantages.

Complicated pregnancies

An early report²⁷ that there was increased fetal mortality when women with hypertension and proteinuria received antenatal steroid therapy has not been confirmed.^{28,29} Glucocorticoid administration, however, may adversely affect pregnant women with diabetes and the use of steroids in this situation is a matter of judgment.

Information on the use of glucocorticoids in pregnancies complicated by multiple gestation, intrauterine growth retardation, or hydrops fetalis is, at present, inadequate. Until more information is available, glucocorticoid therapy should probably be used in these situations.

Repeat courses of antenatal glucocorticoids

The incidence of RDS is not significantly decreased in newborns delivered more than 7 days after maternal glucocorticoid treatment.³⁰ As a result, some obstetricians administer repeated courses of antenatal glucocorticoids during pregnancies threatened by preterm delivery. This practice has raised major concerns. In 2000, a NIH Consensus Development Conference³¹ recommended that “because of insufficient data from randomized clinical trials regarding efficacy and safety, repeat courses of corticosteroids should not be used routinely.” The American College of Obstetricians and Gynecologists (ACOG)³² supported this recommendation in 2002. Three trials addressing this issue have now been completed^{33–35} and their data have been summarized in a systematic review.³⁶ These trials found that there is a reduction in the severity of lung disease or decreased need for surfactant therapy in patients who receive repeated doses of glucocorticoids. However, there was no statistically significant difference between groups with regard to the incidence of RDS, chronic lung disease, IVH, periventricular leukomalacia (PVL), and fetal, neonatal, or infant death.³⁶ Concern over the safety of repetitive courses of antenatal glucocorticoids stems from animal studies that have reported adverse long-term outcomes such as growth retardation,³⁷ suppression of brain growth,³⁸ and neuronal myelination,³⁹ and clinical trials that have reported suppression of adrenal function,⁴⁰ increased risk of destructive and hyperactive behavior in children,⁴¹ and increased mortality.⁴⁰ Sufficient concern has been raised by these observations to support limiting the number of courses of antenatal corticosteroids to one, as recommended by ACOG (or perhaps at most two, with the second course being administered if the patient again demonstrates threatened preterm labor, weeks after the initial course of glucocorticoid).

Betamethasone versus dexamethasone

Dexamethasone and betamethasone are structurally similar glucocorticoids that differ only in the configuration of a single methyl group, and that have equal ability to cross the placenta and influence fetal function.⁴² However, there is a growing body of evidence suggesting that dexamethasone may have more significant side-effects than betamethasone. In addition, Crowley’s systematic review indicated that there was a significant reduction in neonatal mortality in the patients treated with betamethasone compared with those treated with dexamethasone.²⁴

In 1999, Baud and coauthors⁴² retrospectively examined the effects of antenatal betamethasone, dexamethasone, or no glucocorticoid treatment on neonates of 24–31 weeks’ gestation. After adjusting for differences in gestational age, number of courses of glucocorticoids, and other possible confounding variables, they found no significant differences between the two glucocorticoids with respect to the incidence of RDS, bronchopulmonary dysplasia, IVH, or necrotizing enterocolitis. However, there was a significant reduction in the risk of cystic PVL in the group treated with betamethasone compared with the no-treatment group, whereas those neonates whose mothers had received antenatal dexamethasone had an increased risk of cystic PVL compared with the no-treatment group.

A number of theories have been put forward to account for the increased toxicity of dexamethasone. One suggestion is that it relates to sulfite preservatives which are used in dexamethasone preparations.⁴³ An *in vivo* and *in vitro* study found that there is increased neuronal death after exposure to pharmacological preparations of dexamethasone-containing sulfites or to isolated sulfites. The dose of glucocorticoid used in this study was approximately 10 times that recommended for antenatal administration. An alternative, and probably more likely, explanation is that when dexamethasone is administered intravenously or intramuscularly, it reaches higher peak blood levels than the slowly released intramuscular (i.m.) betamethasone. These high circulating levels of dexamethasone may cause the observed neuronal damage.⁴⁴ At this stage, betamethasone should be regarded as the glucocorticoid of choice.

Synergism between antenatal glucocorticoid and postnatal surfactant therapies

Animal and clinical data indicate that there is a positive interaction between antenatal glucocorticoid administration and postnatal surfactant therapy. In a clinical trial, infants who were treated with antenatal steroids and received surfactant, if indicated, had significantly less respiratory disease as well as a lower incidence of IVH or periventricular leukomalacia than infants who did not receive antenatal steroids.⁴⁵

Conclusions

The recommendations of the NIH Consensus Conference²³ are summarized in Table 6.2. It is clear that there are few situations when steroids should not be used in women with threatened preterm labor. Repeated courses of glucocorticoid, however, should not be routinely administered during pregnancy. Betamethasone is the glucocorticoid of choice.

At present, optimal management of premature infants includes assessment of fetal lung maturation, antenatal glucocorticoid administration, and postnatal surfactant therapy. This approach has been shown to be highly beneficial for the prevention and treatment of RDS and other major complications of prematurity.

Table 6.2 NIH Consensus Development Conference. Recommendations for use of antenatal glucocorticoids.

The benefits of antenatal corticosteroids “vastly” outweigh the risks
All fetuses at risk for preterm delivery between 24 and 34 weeks of gestation are candidates for treatment
This decision should not be altered by race, gender, or availability of surfactant therapy
Patients who are eligible for tocolytic therapy are also eligible for steroid therapy
Treatment should be given unless immediate delivery is expected; treatment for less than 24 h is associated with decreased mortality, RDS, and intraventricular hemorrhage
In cases of PROM at less than 30–32 weeks of gestation, treatment is recommended in the absence of clinical chorioamnionitis
In complicated pregnancies in which delivery before 34 weeks is expected, treatment is recommended unless there is evidence that it will have an adverse effect on the mother
Dosing: betamethasone, 12 mg i.m. q24 h × 2 (or dexamethasone, 6 mg i.m. q12 h × 4)

Key points

- 1 The major phospholipids in surfactant are phosphatidylcholine (PC, also called lecithin), which accounts for 80–85% of total phospholipid, and phosphatidylglycerol (PG), which accounts for 8–11%.
- 2 Surfactant protein A (SP-A) is a component of the innate immune system of the lung; mice deficient in SP-A are more likely to develop pulmonary and systemic infections.
- 3 Two smaller proteins, SP-B and SP-C, are important for the surface-active properties of surfactant and are present in clinically effective surfactant preparations.
- 4 At the same gestational age, males are more likely than females to develop RDS. Amniotic fluid phospholipid analysis indicates that the biochemical maturity of the female lung precedes that of males by around 1 week.
- 5 An L/S ratio of 2:1 occurs at approximately 35 weeks of gestation. RDS was reported in only 2–3% of infants with a ratio of 2:1 or greater.
- 6 Combining L/S ratio and PG measurements improves both the positive and the negative predictive accuracy of amniotic fluid phospholipid analysis. This is particularly important in diabetic pregnancies.
- 7 Some clinical conditions appear to accelerate lung maturation and decrease the incidence of RDS. These include long-term maternal stress, e.g., toxemia and hypertension, intrauterine growth retardation, maternal infection, and maternal heroin exposure.
- 8 The benefits of antenatal corticosteroids vastly outweigh the risks.
- 9 All fetuses at risk for preterm delivery between 24 and 34 weeks of gestation are candidates for antenatal glucocorticoid treatment.
- 10 Glucocorticoid therapy significantly reduces the overall incidence of RDS by approximately 50%.
- 11 The effect of glucocorticoid therapy on RDS is statistically significant in infants who deliver from 1 to 7 days after the initiation of maternal treatment. There is a trend toward decreased RDS in babies born less than 24 h or more than 7 days after the initiation of steroid treatment.
- 12 Although it is not clear whether glucocorticoids decrease the incidence of RDS in infants below 28 weeks' gestation, there is a benefit in terms of diminished severity of RDS, and reduced incidence of intraventricular hemorrhage (IVH) and necrotizing enterocolitis (NEC) as well as decreased neonatal mortality.
- 13 Glucocorticoid therapy does not have a significant effect on the overall incidence of maternal or fetal infection.
- 14 In cases of prolonged rupture of the membranes (PROM) at less than 30–32 weeks of gestation, treatment is recommended in the absence of clinical chorioamnionitis.

- 15 A National Institutes of Health (NIH) Consensus Development Conference and the American College of Obstetricians and Gynecologists (ACOG) recommend that repeat courses of corticosteroids should not be used routinely during pregnancy.
- 16 Administration of antenatal betamethasone has been reported to result in a significant reduction in the risk of cystic periventricular leukomalacia (PVL), whereas neonates whose mothers receive antenatal dexamethasone have an increased risk of cystic PVL.
- 17 Betamethasone is the glucocorticoid of choice for antenatal steroid therapy.
- 18 Antenatal betamethasone, if indicated, should be given unless immediate delivery is expected. Treatment for less than 24 h is associated with decreased mortality and IVH, and a trend to reduced severity of RDS.
- 19 The recommended dose of betamethasone is 12 mg i.m. q24h \times 2. If dexamethasone is used, the dose is 6 mg i.m. q12h \times 4.
- 20 Infants whose mothers were treated with antenatal steroids and who then received postnatal surfactant, if indicated, showed a significant reduction in respiratory disease as well as a lower incidence of IVH or PVL than infants whose mothers did not receive antenatal steroids.

Fetal cardiovascular physiology and response to stress conditions

Jean-Claude Fournon and Amanda Skoll

Fetal cardiovascular physiology

Functional characteristics of the fetal heart

Functional maturational processes

Significant maturational changes are observed in the structure of the myocardium prior to birth.¹ In more immature myocardial cells, the myofibrils are chaotically organized and often not oriented along the long axis of the cell. These cells are also characterized by a proportionally greater amount of noncontractile proteins than in adult cells. A maturational increase in the myofilament content of myocytes is observed progressively along with a rearrangement of these filaments into an orientation along the long axis of the cells. The nuclei and mitochondria, which were localized at the centre of the cell, are ultimately distributed in an ordered arrangement along the myofilaments. Primitive mesodermal cells lose their ability to differentiate into cardiomyocytes at approximately the time of birth; consequently, fetal cardiomyocytes may divide and increase in number, whereas mature adult cardiomyocytes can only increase in size.

The sarcoplasmic reticulum is also the site of developmental changes.^{2,3} In the mature myocardium, the sarcoplasmic reticulum serves as the site of calcium release and removal, which activates the contractile process. The process of calcium removal from troponin C, responsible for myocardial relaxation, has also been shown to be less rapid in the fetus⁴ compared with the adult myocardium. Many elements suggest that the effectiveness of the sarcoplasmic reticulum in storing and releasing calcium is quantitatively enhanced with maturation. Thus, more immature cells rely mainly on trans-sarcolemmal movement of calcium to modulate their cytosolic concentration.

In addition to these structural modifications, there are biochemical differences in fetal and adult forms of the myocardial contractile proteins myosin, actin, and the troponins, as well as in their sensitivity to cytosolic calcium concentration.^{5,6} As far as we know, cardiac myosin is made up of two heavy chains, alpha and beta. There are three known myosin

isozymes based on the distribution of these two chains. The V1 isozyme contains two alpha chains, V2 contains an alpha and a beta chain, and V3 has two beta chains. The slower V3 myosin is the predominant adult form in larger animals, including humans. Ventricles with different proportions of myosin V1 and V3 may perform similar amounts of work. However, the myocardium, with a higher proportion of V3, consumes a relatively smaller amount of oxygen and adenosine triphosphate (ATP) and, therefore, demonstrates greater efficiency. Lactate is the primary agent metabolized in the immature heart, whereas the adult myocardium preferentially consumes long-chain fatty acids.⁷ A fetal deficiency in carnitine palmitoyl transferase hampers the transport of long-chain fatty acids into the mitochondria.

Another contractile protein, titin, also known as connectin, has been shown to play a major role in myocardial mechanics.⁸ Titin is likely to be a factor in setting the lower sarcomere length limit during systole and in the elastic recoil responsible for early diastolic filling. A recent report, showing that fetal cardiac titin contains additional spring elements not found in adults, suggests that regulation of titin's spring composition may allow adjustment of diastolic filling behavior during the development of the heart.⁹

Fetal myocardial contractility

When isolated fetal muscle strips are studied, there is a significant reduction in the active tension that can be generated compared with adult samples, at all muscle lengths along the length-tension curve.¹⁰ Resting tension is, however, higher in fetal tissue. These contractile characteristics of fetal myocytes have been related to their significantly greater proportion of noncontractile protein (60% in the fetal myocardium compared with 30% in adults)¹⁰ and also to the differences in the activity of ATPase of fetal and adult myosin isoforms.⁶

Effect of changes in preload

The concept that the fetus has a stiff heart was the basis of a controversy concerning its ability to respond to the Frank-Starling mechanism. For some time, it had been accepted that

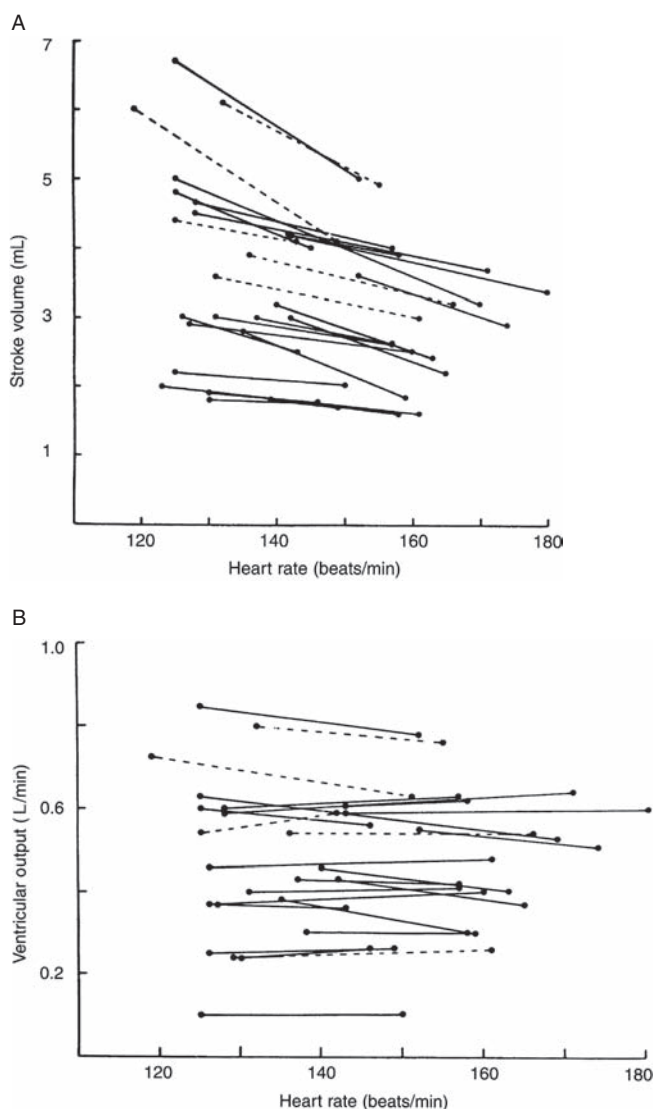

Figure 7.1 (A) Demonstration of the capacity of fetal ventricles to increase their stroke volume with a decrease in heart rate. (B) Consequently, no change is observed in ventricular outputs with bradycardia. Solid line, left ventricle; dotted line, right ventricle (reprinted with permission from ref. 14).

variation in fetal cardiac output was essentially linked to changes in heart rate.¹¹ This position was apparently strengthened by observations that volume infusion in fetal lambs did not result in any significant increase in either right or left ventricular output.^{12,13} However, because of great compliance of the umbilical placental circulation, volume infusion in the fetal circulation requires a relatively greater amount of fluid to achieve a significant change in venous return.

More recent investigations based on Doppler echocardiography have revealed that changes in fetal heart rate are not necessarily associated with alterations in cardiac output¹⁴ (Fig. 7.1). Furthermore, the Frank–Starling relationship has been

Figure 7.2 Relationship between end-diastolic volume (LVEDV) and stroke volume (SV) of the left ventricle in the fetal lamb (reprinted with permission from ref. 1).

shown to be present in the isolated fetal myocardium.¹⁰ As would be anticipated, when the relationship is plotted between muscle tension and the extent or velocity of shortening, the fetal value always falls below that of the adult myocardium. Other evidence of a functional Frank–Starling mechanism was demonstrated when the maximum rate of rise of left ventricular pressure (dp/dt max) was used to assess the effect of changes in end-diastolic volume in fetal lambs.¹ In addition, because of its relative stiffness,¹⁵ end-diastolic pressure is not a reliable index for evaluation of the Frank–Starling relationship in the fetal heart. A large change in diastolic pressure may produce relatively little change in end-diastolic volume. In fact, when ventricular dimensions are used to assess the effect of preload on fetal ventricular stroke volume, a significant positive relationship between end-diastolic volume and stroke volume is found in the fetal heart¹ (Fig. 7.2). Echocardiography permits the documentation of two clinical examples of the capacity of the fetal heart to respond to myocardial fiber stretching: first, fetuses with congenital atrioventricular block with heart rates around 60 b.p.m. show an increase in end-diastolic diameters of both ventricles without cardiac failure and, secondly, there is evidence of a postectopic increase in stroke volume in fetuses with arrhythmia. Finally, it must be remembered that, in the fetal heart, manifestations of the Frank–Starling mechanism can be hampered by diastolic–ventricular interaction. Indeed, because of the widely patent foramen ovale, any increase in right ventricular end-diastolic pressure should be transmitted to the left ventricle. The simultaneous increase in diastolic pressures on both sides of the ventricular septum should limit the

possibility of volume expansion of one ventricle and, by the same token, should impose limitations on the Frank–Starling mechanism. Similarly, extrinsic compression of the fetal heart by the chest wall, pleural pressure, and fluid-filled lungs and pericardium have also been proposed as factors constraining fetal stroke volume.¹⁶

Thus, the fetal myocardium has the ability, albeit limited, to respond to the Frank–Starling mechanism. The various components of fetal ventricular preload must be clarified, however, as they are quite different from those of extrauterine life. *In utero*, each ventricle must be considered separately. In a normal fetus, left ventricular preload will be greatly influenced not only by the size of the foramen ovale but also by approximately 30–40% of the volume flow coming from the inferior vena cava, by pulmonary venous return, and by the diastolic filling characteristics of the right side. Based on data gathered from experimental lamb preparations, it had been widely accepted that no more than 7–10% of combined cardiac output goes to the lungs, a phenomenon explained by elevated pulmonary vascular resistance during fetal life.^{17,18} More recent reports using the Doppler technique on normal human fetuses showed that pulmonary blood flow increased by almost four-fold over the period of gestation studied and amounted to a mean of 22–25% of combined ventricular output. Thus, pulmonary venous return becomes a significant component of left ventricular preload, at least during the third trimester of gestation.^{19,20} Diastolic function of the right ventricle should also influence left ventricular preload during fetal life via the widely patent foramen ovale, which allows the transmission of flow and pressure from the right to the left atrium.

On the other hand, right ventricular volume load during fetal life is normally made up of the entire volume flow coming from the superior vena cava (21% of total venous return)¹⁸ and the fraction of inferior vena cava return that does not go through the foramen ovale. Consequently, factors that will influence right to left shunting through the foramen will also modify right ventricular preload. For example, although an increase in left atrial pressure, such as that observed in left ventricular diastolic dysfunction, will have little repercussion on right atrial pressure because of secondary sealing of the foramen ovale by the septum primum, this will nevertheless cause significant volume overload of the right ventricle by rerouting the entire inferior vena cava blood toward the right ventricle.

Effect of changes in afterload

In all cardiac preparations, including those using fetal tissue, the shortening ability of the myocardium is decreased as afterload is increased.¹⁰ When the relationship between shortening velocity and afterload of the fetal myocardium is compared with that of the adult, the fetal myocardium shortens more slowly against the same relative load than does the adult myocardium. Interestingly, studies on fetal lambs have shown that, for a similar increase in afterload, a significantly greater

reduction in right compared with left ventricular stroke volume was observed.^{21,22}

Approximately 65% of the blood ejected by the left ventricle perfuses the upper body.¹⁸ Therefore, any changes in resistance or pressure of the vascular beds in this region will specifically influence afterload of the fetal left heart. On the other hand, the right ventricular outlet during intrauterine life consists of a large main pulmonary artery from which smaller left and right arteries branch off at very sharp angles. The widely patent ductus arteriosus forms a natural prolongation of the main pulmonary artery toward the descending thoracic aorta. Somewhere between 80% and 90% of blood ejected by the right ventricle flows with minimal resistance through the ductus arteriosus into the descending thoracic aorta. Because of this arrangement, fetal right ventricular afterload is essentially dictated by resistances of the various vascular beds perfused by the descending aorta. Among these vascular networks, the placenta plays a key role in establishing the level of right ventricular afterload because of its significantly lower resistance and higher volume flow.

Fetal systolic and diastolic ventricular performances

When combined right and left ventricular output/min normalized to unit fetal body weight is used to examine the ability of the developing heart to eject blood, very little difference is noted from 18 weeks of gestation to term in the human fetus, similar to that in the fetal lamb. At term, combined ventricular output of the human fetus, calculated by Doppler echocardiography, is approximately 450 mL/kg/min.^{23,24} The same value has also been found in fetal lambs by radioactive microsphere techniques.¹⁸ Likewise, right ventricular preponderance has been found in the human fetus, as described previously in sheep, and is expressed by right ventricular stroke volume approximately 20% greater than that of the left ventricle. Pressure development in the fetal left ventricle appears to be similar to that in the adult. For example, the peak first derivative of left ventricular pressure (dp/dt max) has the same range in fetal lambs as it has in adult sheep (1500–3000 mmHg/s).¹ This range is the same as that observed in the human child and adult. Likewise, the mean value of 0.36 ± 0.06 found in normal human fetuses for the myocardial performance index,²⁵ a global index of cardiac function, is similar to values for the same index in normal adults (0.39 ± 0.05).²⁶ Peak velocity and acceleration time in the ascending aorta have also been used as a Doppler index of myocardial performance. Unlike adults, in normal fetuses, acceleration time or time to peak velocity is known to be shorter in the fetal pulmonary artery than in the aorta.²⁷ This finding has been explained by the higher resistance of the fetal pulmonary vascular system. However, as mentioned previously, the right ventricle is ejecting blood toward the placenta through the widely patent ductus arteriosus. The possibility deserves investigation that, in normal fetuses, the shorter acceleration time is due to better right ventricular

Figure 7.3 Example of Doppler flow velocity waveforms through the tricuspid valve of a fetus at 22 weeks of gestation. The A waves are predominant.

performance with a higher stroke volume and a lower afterload.

In summary, the systolic performance of the fetal heart does not seem to be affected by the maturational changes observed in sarcomeres throughout gestation. In contrast, the limitations are more apparent during diastole. With the advent of Doppler ultrasound technology, it has been possible to study blood flow velocity patterns through the fetal atrioventricular valves; they are quite different from those seen during post-natal life. In extrauterine life, there is a predominance of the E wave, reflecting the major contribution of the early relaxation process causing rapid filling of the ventricles during the first part of diastole. In contrast, the fetal profile is characterized by a higher peak A than E wave²⁸ (Fig. 7.3). Throughout pregnancy, the peak velocity of the A wave does not change significantly, whereas that of the E wave rises steadily and is entirely responsible for the increase in the E/A ratio²⁹ (Fig. 7.4). This observation would support the concept of a progressive maturational change predominantly involving the active process of ventricular relaxation.

Fetal circulatory dynamics

Four basic elements characterize the dynamics of the fetal circulation: parallel arrangement of the ventricles; high resistance of the pulmonary circulation; the placental vascular system with its low resistance and relatively high flow; and the presence of shunts.

Parallel arrangement of the ventricles

In the fetus, both ventricular pumps are perfusing the same systemic circulation, the left via the ascending aorta, the right via the pulmonary trunk and the ductus arteriosus. Figure 7.5 is a schematic representation of this feature. The hemodynamic implications of this arrangement are presented in Table 7.1. In this situation, the individual ventricular outputs are not necessarily equal, and fetal cardiac output is logically expressed as combined ventricular output. Another consequence of this arrangement is that both ventricles share the same systolic ejection pressure of approximately 70–

Table 7.1 Hemodynamic implications of the parallel arrangement of the two ventricles.

Similarity of systolic pressures
Reciprocal influence of ventricular diastolic functions
Possibility of adequate perfusion by a single ventricle
Special status of the aortic isthmus

80 mmHg. Close to term, a slight increase in pressure has been reported in the pulmonary trunk compared with systemic pressure. This could be due to either greater flow through the right ventricle and/or active constriction of the ductus arteriosus. As a third consequence, there is the reciprocal influence of diastolic function of the two ventricles through a widely patent foramen ovale. The parallel arrangement of the two ventricles is also a key element in the intrauterine survival of fetuses with complex malformations; in cases of hypoplasia of one ventricle, for example, blood can be diverted toward the contralateral ventricle without significant impairment of peripheral perfusion.

Finally, the parallel arrangement of the two ventricles confers special status to the aortic isthmus. This vascular segment, localized between the origin of the left subclavian artery and the aortic end of the ductus arteriosus, establishes communication between the two parallel systems. The direction of blood flow through the fetal aortic isthmus should reflect the balance between both left and right ventricular outputs, and the vascular resistances, of the upper body on one side and the subdiaphragmatic circulation on the other side. This specific aspect will be discussed later in the chapter.

The pulmonary circulation

The fetal pulmonary arteries, offering high resistance to flow, are responsible for relatively minor pulmonary flow. This proportion, however, increases with advancing gestation. As mentioned previously, recent reports using Doppler technology found that, in term human fetuses, as much as 25% of combined ventricular output goes through the lungs.^{14,15} This

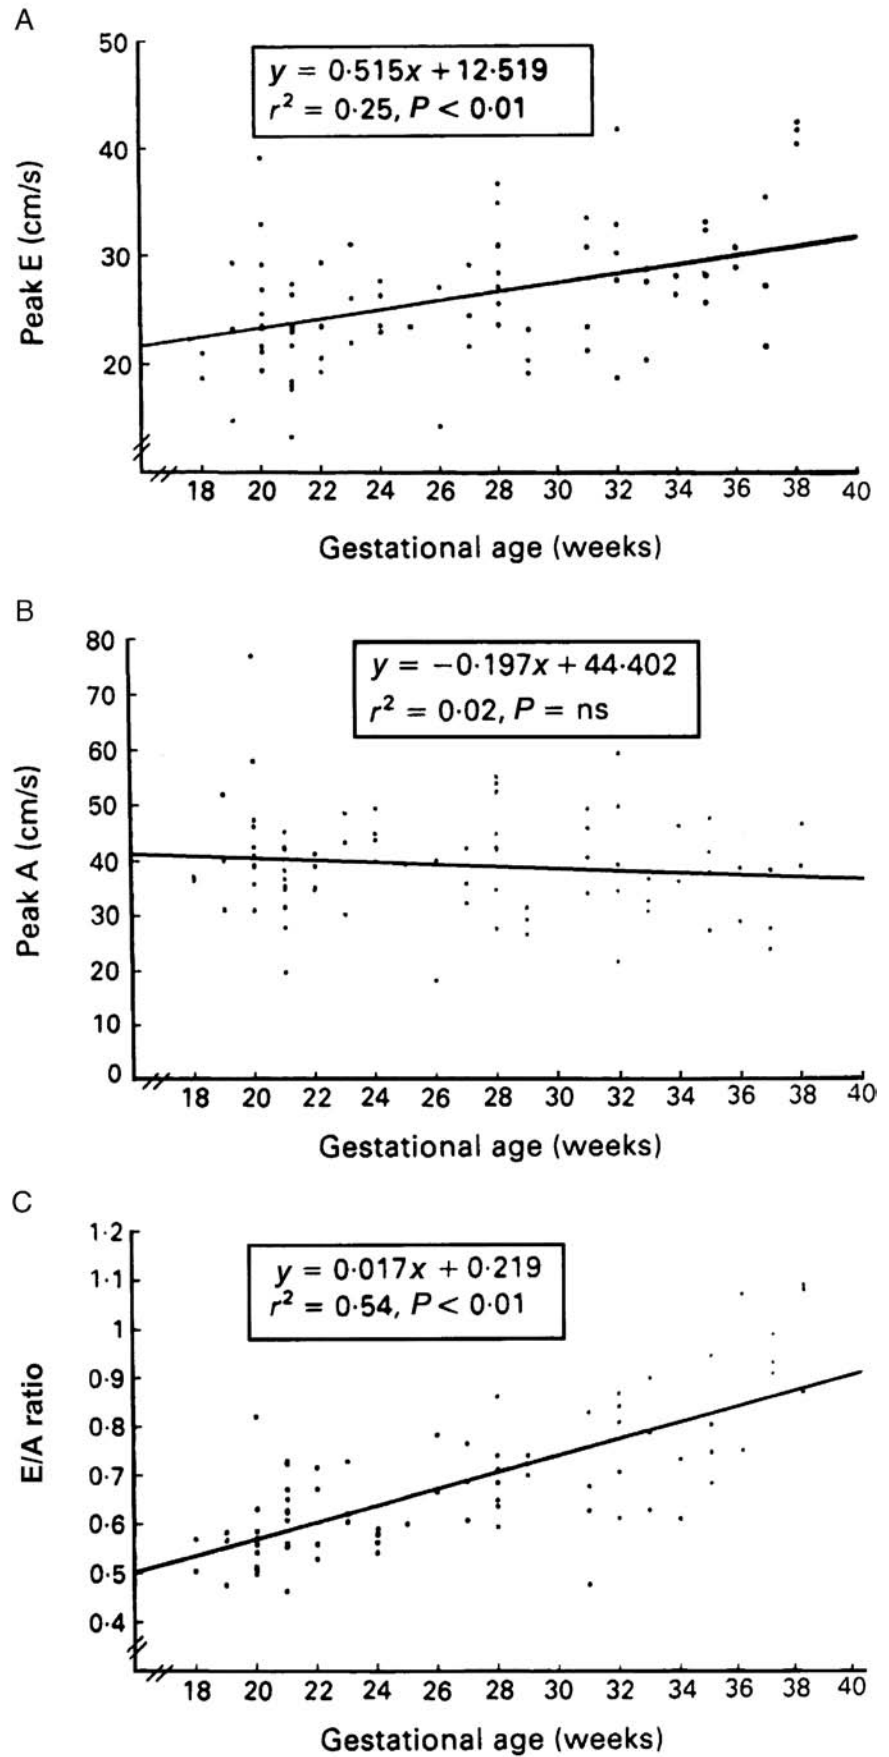

Figure 7.4 (A) With advancing gestation, the early peak velocity (E wave) of the fetal atrioventricular valves increases, while (B) the second peak (A wave) remains unchanged, resulting in (C) a progressive increase in the E/A ratio (adapted with permission from ref. 29).

Figure 7.5 Schematic representation of the fetal circulatory dynamics. The right (RV) and left (LV) ventricles are perfusing the systemic circulation in parallel. The upper part of the body receives blood exclusively from the LV. In addition to the lungs, RV perfuses the subdiaphragmatic part of the circulation via the ductus arteriosus (DA). The parallel disposition of the pulmonary (PA) and the aortic (Ao) arches is well illustrated. The isthmus represents a vascular segment connecting these two parallel systems.

unique feature of intrauterine life is related to both morphological and dynamic factors. Major developmental changes occur in the pulmonary circulation throughout pregnancy, and these changes continue after birth.^{30,31} In humans, the preacinar branching pattern of the pulmonary arteries is complete

by 20 weeks of gestation; subsequently, extensive ramification of small pulmonary arteries is observed, with these arteries increasing in number until term. Some intra-acinar arteriolar growth occurs late in gestation, but this developmental process is mainly associated with alveolar growth in the first years of life. The progressive morphological changes are responsible for a low total cross-sectional pulmonary vascular area in the first half of gestation and, at least in part, for the high vascular resistance observed *in utero*. However, a 20-fold increase in the cross-sectional area of the pulmonary vascular bed has been documented during the latter half of gestation. This growth would cause a significant drop in vascular resistance if it was not for the concomitant development of a thick muscular layer in the walls of the pulmonary arteries to the level of the terminal bronchioles. This muscular layer is the site of reactivity of fetal intrapulmonary arterial branches.

One of the main determinants of pulmonary vascular tone during fetal and extrauterine life is oxygen. Reduced pulmonary (mixed venous) and systemic arterial blood oxygen tension has been demonstrated to cause pulmonary vasoconstriction in fetal sheep.^{32,33} Normally low fetal mixed venous PO_2 (16–18 mmHg) therefore plays a major role in maintaining elevated pulmonary vascular resistance during intrauterine life. The mechanisms by which oxygen influences pulmonary vascular tone and the role played by other elements have been the subjects of extensive investigation.^{34–37} From these studies, it appears that the pulmonary circulation can be influenced not only by local changes in O_2 , but also by many other factors, acting either directly or as mediators or messengers. Among them, neurochemicals, such as alpha-adrenergic agonists and beta-antagonists, constrict whereas alpha-adrenergic antagonists and beta-agonists dilate the pulmonary circulation before and after birth. Vasoconstrictors, such as endothelin, have also been shown to be involved in the modulation of high basal pulmonary vascular resistance in normal lamb fetuses.³⁸ Another important determinant of pulmonary vascular tone is the blood pH level. Acidosis, either metabolic or respiratory, has been demonstrated to cause pulmonary vasoconstriction, and alkalosis elicits vasodilation at all stages of development.^{39,40}

The influence of the central nervous system on pulmonary vasomotor tone has been documented experimentally. In dogs, hypothalamic stimulation alters the distensibility of large pulmonary arteries, and this influence is mediated by the sympathetic nervous system.⁴¹ Electrical stimulation of the brainstem vasomotor center of the newborn piglet has been shown to cause significant increases in pulmonary artery pressure without changing pulmonary flow, indicating pulmonary vasoconstriction.⁴² The effects of eicosanoids derived from arachidonic acid (prostaglandins, thromboxane, and leukotrienes) on the fetal and perinatal pulmonary circulation have also been studied extensively. Thromboxane, leukotrienes, and prostaglandin $F_{2\alpha}$ are pulmonary vasoconstrictors.^{42–45} All the other products of cyclo-oxygenase have been found to be pulmonary vasodilators, among which prostacyclin is one of the most

Figure 7.6 Pulsed Doppler recording in the umbilical artery of a 24-week fetus. Systolodiastolic forward velocities confirm the low vascular placental resistance.

A

B

Figure 7.7 (A) Pulsed Doppler recording in the intra-abdominal portion of the umbilical vein, showing continuous low velocities. (B) In the ductus venosus, peak velocities reach 0.7 m/s. Two forward waves are seen: one during ventricular systole (S) and the other during the early part of diastole. A deceleration wave is recorded during atrial (A) contractions.

potent.^{46,47} The purine nucleotides adenosine and ATP also have significant pulmonary vasodilatory effects in fetal lambs.⁴⁸

The placental circulation

Unlike fetal lungs, the normal placenta is a vascular bed with very low resistance to flow. Consequently, approximately 50% of the combined cardiac output of lamb fetuses flows into the umbilical circulation.¹⁸ This unique feature of the fetal circulation is well illustrated by the Doppler velocimetric assessment of blood flow through the umbilical artery (Fig. 7.6); fetuses with a normal placental vasculature show Doppler flow velocity waveforms with significant diastolic forward flow, increasing as gestation progresses.⁴⁹

Many investigators have studied the mechanisms regulating placental blood flow. The absence of innervation in either the

umbilical cord or the placenta makes it very unlikely that neural control plays any physiological role.⁵⁰ Similarly, despite experimental evidence of placental vascular reactivity to some vasoactive hormones, such as angiotensin II⁵¹ and norepinephrine,⁵² administration of their respective blockers has no effect on placental vascular resistance.⁵² Prostaglandins have also been proposed as local vasoactive agents.⁵³ Intriguing evidence of maternal and fetal placental blood flow matching⁵⁴ strongly suggests some form of intrinsic regulation. For the time being, however, the mediator(s) of this physiological and important mechanism has(ve) not yet been clearly identified.

The umbilical vein drains oxygenated blood coming from the placenta into the left branch of the portal vein. Umbilical venous flow has a continuous low velocity (mean 15 cm/s) (Fig. 7.7A). Placental flow depends on the umbilical arteriovenous

gradient. The venous component of this relationship is influenced by resistance in the ductus venosus, in the liver parenchyma, and also by right atrial filling pressure.

The shunts

Three shunts are classically described within the fetal circulation. The first occurs at the level of the ductus venosus. This short venous segment links the umbilical and portal veins to the inferior vena cava, allowing a portion of blood coming from the umbilical vein to bypass the hepatic circulation and directly enter the inferior vena cava. From Doppler investigations in normal human fetuses, this shunt amounts to approximately 30% of umbilical venous return.⁵⁵ Because of its trumpet-shaped appearance, the ductus venosus functions as an important regulator of the placental circulation, protecting the fetal heart from excessive blood flow to the placenta. The continuous low velocity of umbilical venous blood is transformed within the ductus venosus into a pulsatile high-velocity jet with peak flows up to 75 cm/s, suggesting a gradient between the umbilical vein and the central venous system. The gradient has been estimated to reach a peak of 3 mmHg during atrial and early ventricular filling.⁵⁶ This flow acceleration is responsible for the preferential streaming of highly oxygenated blood across the foramen ovale into the left heart.¹⁸ Flow in the ductus venosus is normally phasic, characterized by two forward waves, one during ventricular systole, the other early in diastole. Atrial contraction causes the deceleration of blood velocities, which normally never results in complete absence of antegrade flow toward the heart (Fig. 7.7B).

A second shunt takes place at the level of the foramen ovale, which corresponds to an opening in the septum secundum between the two atria, associated with a flap valve formed by the septum primum. This valve allows blood to pass only from the right to the left atrium. Recent Doppler investigations of human fetuses estimated the shunt through the foramen ovale to drop from 34% to 18% of combined ventricular output during the period from 20 to 30 weeks of gestation.²⁰

Finally, the ductus arteriosus, which is a prolongation of the main pulmonary artery toward the descending aorta, is also usually considered as a shunt, allowing much of the blood ejected by the right ventricle to bypass the lungs. Convincing data now demonstrate that, during fetal life, the patency of the ductus arteriosus is regulated by both contractile and dilatory factors. Oxygen was the first constrictor of the ductus arteriosus to be recognized.⁵⁷ The sensitivity of the ductus arteriosus to O₂ increases during the last trimester of gestation.⁵⁸ The oxygen-constrictive effect appears to be linked to accelerated endothelin-1 production.⁵⁹ Although circulating adenosine has been suggested to be a dilator of the ductus,⁶⁰ numerous reports favor the prostaglandins (E₁ and particularly E₂) as major elements maintaining ductal patency.^{61–63}

The idea of considering the ductus arteriosus as the site of a vascular shunt is certainly valid in extrauterine life where

the two ventricles are disposed in series. In this situation, the ductus arteriosus is obviously diverting blood from the pulmonary or the systemic circulations, depending on the balance between downstream resistances of the two circulations. During fetal life, however, classification of the ductus arteriosus as a shunt must be questioned, as it is incompatible with the concept of parallel arrangement of the prenatal circulation. Indeed, because of its parallel disposition, the fetal ductus arteriosus is a segment of the pulmonary arch and does not actually divert any blood, but rather participates in combined output by channeling right ventricular output toward the systemic circulation. This is well illustrated in Figure 7.5. The concept of parallel disposition of the two ventricles implies, as a rational conclusion, that, in fetal life, the only arterial segment corresponding to the definition of a shunt would be the aortic isthmus.⁶⁴ Indeed, this vascular segment normally transfers blood from the upper body toward the lower body by connecting the two parallel systems (Fig. 7.5). Approximately 65% of the blood ejected by the left ventricle perfuses the upper body, the rest going through the aortic isthmus toward the subdiaphragmatic circulation.¹⁸ The factors influencing the direction of blood flow through the isthmus are illustrated in Figs 7.8 and 7.9. In systole, the direction of blood flow is dictated by both individual performances of the ventricles and downstream resistance of the upper and lower body vascular networks. The ventricles have opposite influences on the direction of flow: the left ventricle causes forward flow through the isthmus (Fig. 7.8A), while blood ejected by the right ventricle has a retrograde influence (Fig. 7.8B). In normal conditions, the presence of the placenta with its low vascular impedance explains the forward systolic flow observed in the isthmus.⁶⁵ With advancing gestation, however, two physiological events alter flow patterns through the isthmus: first, the fall in cerebral vascular impedance causes a reduction in the diastolic component of the waveform; secondly, the progressive preponderance of right ventricular output evokes a brief end-systolic reversal of isthmus flow; this process starts at about 30 weeks and increases progressively up to the end of gestation (Fig. 7.10). To facilitate the objective monitoring of flow patterns through the fetal aortic isthmus, an isthmus flow index (IFI) has been developed. The proposed index was obtained by dividing the sum of systolic (S) and diastolic (D) Doppler flow velocity integrals by systolic flow integrals: $IFI = S + D/S$. Positive and negative signs are assigned to antegrade and retrograde velocity values respectively. The normal reference ranges of the IFI have been published recently.⁶⁶ In cases of severe fetal left ventricular dysfunction, reverse flow is recorded even during systole through the isthmus because of the isolated influence of the right ventricle. In diastole, the two semilunar valves being closed, the direction of blood in the isthmus will be essentially influenced by downstream vascular resistance (Fig. 7.9); any significant fall in upper body vascular resistance (cerebral arteriovenous fistula⁶⁷) or increase in lower body vascular resistance (placental vascular impairment⁶⁸) should cause a reversal

Figure 7.8 Influences of individual ventricular ejection on the direction of blood flow through the aortic isthmus during systole. (A) The left ventricle (LV) causes a forward flow, while (B) blood ejected by the right ventricle (RV) has a retrograde influence.

of the diastolic component of flow velocity waveforms in the isthmus.

Fetal cardiocirculatory adjustments to stress

Abnormal loading conditions

Abnormal loading conditions of the fetal circulation can be observed in a variety of disorders, such as arteriovenous malformation, anemia or the twin–twin transfusion syndrome

(TTTS). Each of these conditions represents situations in which cardiac preload is increased but afterload varies. Furthermore, in each case, the etiology of the loading disturbance is different. The specific cardiocirculatory adjustments will, therefore, be underlined for each condition, considering separately the impact on the heart and on the peripheral circulation.

Arteriovenous malformations

A large arteriovenous shunt in the fetal circulation may occur in tumors such as sacrococcygeal teratomas, placental

Figure 7.9 In diastole, the direction of flow in the isthmus is simultaneously influenced by the downstream vascular resistances of the two parallel systems.

chorioangiomas or in the presence of cerebral vascular malformation associated with an aneurysm of the vein of Galen.

Cardiac impact

All these conditions are characterized by both elevated preload, because of increased venous return from the shunts, and reduced afterload due to arteriovenous runoff. Dramatic rises in combined cardiac output have been documented in these cases, reaching twice the estimated normal range.⁶⁹ In fetuses with cerebral arteriovenous malformations, close to 70% of the combined cardiac output comes from the right ventricle because of the increment in blood flow through the

superior vena cava going directly through the right ventricle.⁷⁰ As cardiac output increases, the fetal heart compensates by a linear augmentation in size.⁷¹ With progression of the disease, cardiac failure may develop with worsening of the degree of atrioventricular valve regurgitation and the appearance of fetal hydrops.

The peripheral circulation

During fetal life, changes in the peripheral circulation caused by localized declines in vascular impedance will be very much influenced by the parallel disposition of the two ventricles and their arterial outlets. In fetuses with arteriovenous malformations in the upper part of the body (cerebral arteriovenous fistula), retrograde diastolic flow is observed in the aortic isthmus while the flow pattern in the descending aorta remains normal.⁷⁰ The right ventricle then perfuses both the lower and the upper body. In contrast, when the arteriovenous malformation is in the lower body, both ventricles share the volume load. Antegrade flow through the aortic isthmus is then increased. Reversal of diastolic flow in the umbilical artery has also been reported, suggesting a “steal” phenomenon from the placental circulation.⁷¹

Anemia

Cardiac impact

In fetal anemia resulting from isoimmunization, left and right ventricular outputs are significantly elevated, and right cardiac output over the left ventricular output ratio is normal.^{72,73} Oxygen delivery can thus be preserved. This rise in cardiac output is related to both higher preload (decreased blood viscosity leading to increased venous return) and lower afterload (diminished blood viscosity and peripheral vasodilatation due to reduced O₂ content). Peak velocities are augmented through both semilunar valves.

The peripheral circulation

Peripheral adjustments to the stress of anemia reflect the hyperdynamic state of these fetuses. Peak velocities tend to increase in both parallel circulatory systems. An inverse correlation has been found between the rise in peak velocity in the middle cerebral artery and the level of hematocrit.⁷⁴ Venous flows are also affected, and peak velocities are elevated in the ductus venosus, which also shows less pulsatility than normal.^{73–75}

Twin–twin transfusion syndrome (TTTS)

This condition occurs in about 15% of monochorionic–diamniotic twin gestations. Vascular connections deep within the placenta cause a shift in blood volume from the donor to the recipient twin.⁷⁶ However, this classic pathophysiological background does not explain some intriguing cardiocirculatory perturbations found in TTTS.

Figure 7.10 Doppler flow velocity waveforms in the aortic isthmus. At 20 weeks of gestation, forward systolic and diastolic waves are observed. An end-systolic incisura appears at about 25 weeks and increases thereafter; late in gestation, a brief reversal of flow is observed at the end of systole. Note on the tracing recorded at 37 weeks (bottom), the superimposed velocity Doppler signals from the ductus arteriosus, demarcating the end of systole.

Cardiac impact

Although the donor twin becomes anemic, his/her hemodynamic picture is mainly marked by the consequences of his/her volume depletion. Reports of elevated blood levels of endothelin⁷⁷ and evidence of renin–angiotensin system stimulation⁷⁸ are convincing elements in favor of chronic hypotension and peripheral hypoperfusion in these fetuses. Ventricular function is usually preserved. Increased arterial pulsed wave velocity has been found in surviving postnatal donor twins, suggesting intrauterine vascular remodeling with lifelong consequences.⁷⁹

In contrast, hypertrophic cardiomyopathy is typically described in the recipient twin.⁸⁰ The progressive nature of the process and the fact that marked ventricular hypertrophy can be observed with little or no evidence of dilation strongly favor the renin–angiotensin pathophysiologic hypothesis to the detriment of a simple volume shift. Subclinical cardiomyopathy, essentially manifested by early signs of diastolic dysfunction, has also been documented and goes along well with the renin–angiotensin hypothesis.⁸¹ According to this concept, the hypervolemic recipient twin is exposed to mediators

(renin, angiotensin) released by the hypovolemic donor twin, mediators responsible for vasoconstriction and ventricular hypertrophy. In severe cases, this process can lead to ventricular dysfunction with hydrops and fetal demise. Right ventricular hypertrophy rarely evolves to pulmonary infundibular stenosis and even pulmonary atresia.⁸²

The peripheral circulation

Serial Doppler recordings in the donor twin do not reveal any significant change until the appearance of fetal distress;⁸³ at this last stage, the donor presents signs consistent with anemia (increased peak velocities), indicating a massive shift in blood volume. In the recipient twin, diastolic myocardial dysfunction causes heightened pulsatility in the ductus venosus (deep “a” waves) with umbilical vein pulsations.

Hypoxic stress

The stress encountered most frequently during fetal life is lack of oxygen. For obvious reasons, most of our information on this subject comes from experimental studies, assuming that findings in laboratories reflect what is actually occurring in the human fetus. Another problem arises from the fact that the bulk of experimental protocols are designed to provide relatively short exposure to hypoxemia; here again, assumptions have to be made about the outcome in human fetuses in whom hypoxemia is sustained for days or weeks. A third drawback is the lack of homogeneity in protocols of the experimental studies. As shown in Tables 7.2 and 7.3, the designs of studies

cited as references in this chapter vary not only in terms of the duration of the hypoxemia, but also in the way hypoxemia was created experimentally.

The advent of Doppler ultrasonography has undoubtedly opened new horizons in investigations of the human fetal cardiovascular system. This technology has been instrumental in introducing into clinical practice a fundamental notion already demonstrated in acute experiments, that is the importance of placental vascular resistance. Indeed, as the placenta offers the lowest resistances within the entire fetal vascular system, any increase in those resistances should have repercussions on both flows and pressures, which are not necessarily related to the secondary hypoxemia. The assessment of circulatory responses to fetal hypoxemia can no longer be made without first establishing the state of the placental vascular system. The two situations will, therefore, be discussed separately. Adaptive mechanisms in the presence of hypoxemia, such as increased O₂ extraction from erythrocytes⁸⁴ or reduction of fetal O₂ consumption,⁸⁵ which are not directly related to the circulatory system, will not be discussed here, despite their potential importance *in vivo*.

Hypoxemia with normal placental vascular resistances

Blood gases

In humans, this condition is usually observed in mothers suffering from chronic pulmonary or cardiac disorders or living at high altitudes, or in fetuses with acute or chronic anemia. Placental vascular resistance is usually normal in these cases. Most of our knowledge concerning this type of fetal

hypoxemia is derived from instrumented fetal lambs under hypoxemic stress created either by decreasing the O₂ concentration of the gas mixture inspired by the ewe^{86–98} or by uterine blood flow restriction^{99–105} (Table 7.2). Less frequently, hypoxia has been achieved by changing the hematocrit level by isovolemic exchange transfusion.¹⁰⁶ Except for this last condition, where the fall in blood O₂ content is related to a lack of O₂ carriers, the oxymetric feature that characterizes all the other fetuses in this group is the low PO₂ of the umbilical venous return, explaining the term “hypoxic hypoxemia” frequently assigned to the group. In these circumstances, fetal blood gases will be dependent on maternal blood gas status. As placental exchange is preserved, relatively low levels of PO₂ can be reached without significant buildup of acid metabolites in the fetus. The level of fetal PCO₂ will also depend on maternal PCO₂, which may be perfectly normal. A resultant gradual increase in fetal hematocrit serves as a compensatory mechanism to cause an elevation in arterial O₂ content.

Cardiocirculatory responses

During acute hypoxic hypoxemia, blood pressure rises and heart rate decreases, with a redistribution of cardiac output.^{87,89} Hypoxia stimulates catecholamine secretion from the adrenal medulla either directly¹⁰⁷ or, in more mature fetuses, by a reflex effect through the splanchnic nerves. The consequences of adrenal norepinephrine secretion during fetal hypoxemia can be blocked by alpha-adrenergic blockers, resulting in a return of vascular resistance and blood pressure to normal values.^{97,108} An increase in vasopressin has also been documented during fetal hypoxemia, and could be another factor contributing to the rise in vascular resistance.^{94,108} Bradycardia as well as peripheral vasoconstriction has been related to neural reflexes via both baro- and chemoreceptors in the aortic and carotid bodies.^{96,110} Animal studies have consistently shown blood flow redistribution to the brain, heart, and adrenals when hypoxic hypoxemia is induced experimentally^{87–89,102,105} (Fig. 7.11). This redistribution, mediated via

humoral and reflex mechanisms, is caused by local vasodilatation in these three organs concomitant with vasoconstriction in the lungs, digestive tract, spleen, pancreas, kidneys, carcass, skin, etc. In acute experiments, absolute flow and the proportion of cardiac output going to the brain increase.^{86,88,89} Meanwhile, placental blood flow and combined cardiac output do not change significantly. In severe hypoxia, however, the deleterious effect of acidosis on fetal heart rate and myocardial contractility will be responsible for a fall in combined ventricular output.^{87,93}

A few experimental protocols have studied chronic hypoxic hypoxemia. In these experiments, blood flow increased to the brain, myocardium, and adrenals, and remained elevated after at least 8⁹⁵ to 48 h¹⁰³ of fetal hypoxic hypoxemia. Elevated concentrations of plasma epinephrine have been found in lambs and fetuses after 28 days of hypoxemia.⁹¹ In contrast, a longer period of hypoxemia maintained by exposure of pregnant ewes to high altitude did not cause any increase in fetal cerebral blood flow¹¹¹ or changes in left ventricular function.⁹⁸ Likewise, in fetal lambs exposed to hypoxic hypoxemia for 2 weeks, right ventricular output and stroke volume fell to 30% on the third day of the experiments, but recovered to normal values in the following days.⁹⁰ One important finding documented in all studies is that the umbilical circulation is not significantly affected until severe acidemia causes a fall in combined cardiac output.

Because of the parallel arrangement of the two ventricles and the dynamic nature of vascular shunts, the fetus has the capacity to selectively adjust its arterial O₂ content. This mechanism is unique to intrauterine life, and is not available after birth. Indeed, *in utero*, arterial O₂ content is closely dependent on the redistribution of placental venous return. In normoxic conditions, approximately 30% of the umbilical venous return bypasses the hepatic microcirculation and directly enters the inferior vena cava through the ductus venosus.⁵⁵ It has been demonstrated in both fetal sheep¹⁸ and primates¹¹² that this highly oxygenated stream of blood preferentially enters the left atrium via the foramen ovale, and

is thus distributed to the upper body. In normoxemic conditions, this preferential streaming is responsible for the slightly higher arterial PO_2 of blood in the ascending aorta (~20 mmHg) compared with postductal blood in the descending aorta (~17 mmHg). During hypoxemia, an increase in the proportion of blood that bypasses the liver and goes directly to the inferior vena cava through the ductus venosus has been demonstrated repeatedly.^{112–114} This shunting pattern should reduce transit time from the placenta to the heart, favoring rapid filling of the right atrium by better oxygenated blood. What happens to the transfer of this blood through the foramen ovale is less clear. It is generally accepted that preferential shunting of ductus venosus blood across the foramen ovale does not increase during hypoxemia.¹¹²

In most cases of hypoxic hypoxemia, the O_2 content of the umbilical vein is low, but this should be compensated by the preservation of umbilical blood flow and increased cerebral perfusion. This last element, however, causes a rise in the volume of poorly oxygenated blood that returns to the right atrium through the superior vena cava. The effect of this rise in superior vena cava blood flowing into the right atrium on the shunting pattern through the foramen ovale has not been clearly established.

Doppler findings

Doppler echocardiography, which allows the indirect assessment of peripheral vascular impedance and the early recognition of circulatory adjustments, is widely integrated in contemporary fetal monitoring. Many studies have confirmed that hypoxic hypoxemia does not alter Doppler flow velocimetry waveforms in the umbilical artery^{92,115,116} or, if it does, it is only secondary to the changes in heart rate.¹¹⁶ This is in all likelihood related to the fact that placental resistance does not change significantly in this condition. In one report, 1 min of maternal abdominal aortic compression caused a 10% increase in the Doppler-derived umbilical resistance index, and a 10% fall in umbilical blood flow associated with a 20% reduction in the cerebral resistance index¹¹⁷; fetal heart rate decelerations were, however, observed during the same period. In another study in which abdominal aortic compression was also created, parasympathetic blockade with atropine prevented both fetal heart rate deceleration and Doppler velocimetric changes in the umbilical artery.¹⁰⁴

Hypoxemia with elevated placental vascular resistance

Blood gases

Uteroplacental insufficiency with secondary fetal growth restriction affects 3–7% of all deliveries and is a major cause of perinatal morbidity and mortality. Maternal blood gases are usually normal in this condition. In contrast to fetal hypoxic hypoxemia, hypoxemia due to placental insufficiency is characterized by an increase in placental vascular impedance and a secondary fall in umbilical blood flow. As a consequence of the decrease in umbilical venous return, the proportion of poorly oxygenated blood coming from the distal inferior vena

cava that reaches the right atrium increases, lowering the O_2 available to the fetus. Contrary to what was observed in the previous setting, pCO_2 tends to rise very early because of the primary disorder in placental exchange. Similarly, acid metabolites have less chance of crossing the placental barrier and, therefore, tend to accumulate in the fetus. Consequently, for the same level of hypoxemia, respiratory and metabolic acidemia should develop early, compared with the group with normal placental vascular resistance and flow. This point is important in view of the deleterious effect of acidemia on tissue O_2 extraction and myocardial contractility.

Cardiocirculatory responses

In an attempt to reproduce, at least in part, the conditions created by an increase in placental vascular resistance, various techniques have been used in fetal lambs, such as umbilical cord compression^{118–122} or embolization of the placental vascular network^{123–127} (Table 7.3). The hemodynamic characteristics created by compression of the whole cord differ somewhat from the human situation as both arterial and venous umbilical flows are impaired. Doppler investigations have shown that the pattern of umbilical Doppler flow velocities in fetuses exhibiting growth restriction due to placental insufficiency cannot be reproduced by compression of the umbilical arteries.¹²⁸ Nevertheless, in all these experiments, a drop in combined cardiac output is observed and, more importantly, cardiac output decreases linearly with umbilical blood flow.^{119,129} In experiments in which resistance to placental flow

Figure 7.11 Variation in the proportion of the combined ventricular output flowing to the heart and brain of fetal lambs according to arterial O_2 content. This proportion increases by 25% with a reduction from 6 to 1 mM (reprinted with permission from ref. 89).

was increased by selective umbilical vein compression, not only could the Doppler velocimetric pattern usually seen in growth-restricted fetuses be reproduced, but a significant drop in combined cardiac output could also be documented.¹³⁰⁻¹³²

Available reports on fetal lambs demonstrate that most of the other peripheral vascular reactions described in hypoxic hypoxemia are also present with hypoxemia caused by an increase in placental vascular resistance. Mesenteric vasoconstriction is observed as well as a decrease in flow to the skeletal muscles. Blood flow to the myocardium, adrenal glands and, particularly, the brain has been found to be augmented. This last phenomenon, documented in human fetuses with growth restriction and placental insufficiency, has been called the “brain-sparing effect.”

In the presence of hypoxemia related to changes in placental vascular impedance, arterial blood pressure is influenced by two elements acting in opposite directions. On the one hand, the increase in placental vascular resistance and hypoxemia-induced catecholamine release would tend to heighten blood pressure; on the other hand, the concomitant fall in cardiac output would tend to lower it. As a final result, blood pressure tends either to increase moderately¹²⁷ or to remain within normal limits in these cases. Heart rate is also quite variable, depending on the influence of catecholamines, baroreceptors, and direct local effects. Bradycardia is noted in the presence of severe hypoxemia with acidemia.

Myocardial function during increases in placental vascular resistance is influenced by factors that could also have opposite effects. In theory, cardiac function should be depressed both by the fall in preload (low venous return) and by the significant rise in afterload (increase in placental resistance). On the other hand, myocardial contractility should be improved by catecholamine release. Evidence of right ventricular dysfunction has been found in this group of fetuses.^{127,133} Loss of end-systolic elastance of the left ventricle has been reported in fetal sheep after repeated placental embolization.¹²⁵ Others, using the same method to create chronic fetal hypoxemia, have noted a reduction in the myocardial deoxyribonucleic acid synthesis rate that could be a contributing factor in the deterioration of fetal myocardial function associated with increased placental vascular resistance.¹²⁶ In human fetuses with severe growth restriction associated with hypoxia and acidosis, changes in ventricular diastolic filling patterns have been documented, indicating impaired diastolic function.¹³⁴⁻¹³⁶

Doppler findings

Doppler investigations have detected various degrees of alteration in blood flow velocity waveforms of the umbilical artery in human fetuses with increased placental vascular impedance. Normal forward diastolic flow decreases with the rise in placental vascular resistance, and may completely disappear. In severe cases, reverse diastolic flow can be recorded.¹³⁷ The relationship between changes in Doppler velocimetry and the fall in umbilical blood flow has been shown, however, to be

nonlinear,¹³⁸ as close to a 50% decline in umbilical blood flow must be achieved in the fetal lamb before any significant change in Doppler velocimetric indices can be seen.

Arterial redistribution and blood centralization to vital organs have been confirmed by recent Doppler investigations involving not only the cerebral arteries but also renal,¹³⁹ splenic,¹⁴⁰ brachial,¹⁴¹ coronary,¹⁴² adrenal,¹⁴³ and peripheral pulmonary arteries.¹⁴⁴ With such arterial blood redistribution, the fetus can still maintain adequate cerebral oxygenation. This corresponds to the “compensation phase” which, in the clinical setting, justifies an expectant approach and the prolongation of pregnancy. In severe cases, however, the defense system is overwhelmed, resulting in metabolic acidemia with cerebral hypoxia, and reflecting the “decompensation phase.” As mentioned previously, because of the unique position of the aortic isthmus, this vascular segment should be the best site in the entire fetal circulatory system at which even subtle changes could be detected in the balance between downstream resistances of the upper body and the subdiaphragmatic circulation. Experimental studies have shown that, when placental resistance to flow in fetal lambs is increased progressively, isthmus diastolic flow disappears quickly and becomes progressively retrograde.¹³² In these experiments, a strong correlation has been found between blood flow in the aortic isthmus and flow through the umbilical circulation (Fig. 7.12). As O₂ delivery

Figure 7.12 Relationship between aortic arch and placental flows in fetal lambs whose resistance to placental perfusion is increased by stepwise compression of the umbilical veins. A strong linear correlation is observed. (In the ovine, the aortic arch is the equivalent of the aortic isthmus in the human.) (Adapted from ref. 132.)

to the fetus is closely related to umbilical blood flow, one can extrapolate and consider that, in these circumstances, fetal O₂ delivery is also intimately linked to aortic isthmus blood flow. An inverse correlation between the isthmic blood flow velocity index and postnatal neurodevelopmental outcome has been reported recently: as the isthmic flow index diminishes, the probability of a nonoptimal neurodevelopmental outcome increases.¹⁴⁵

The authors are grateful to Mrs Nathalie Ishmael for her precious secretarial contribution.

Key points

- 1 The fetal heart is functionally immature because of differences in myofibril arrangement and a greater proportion of noncontractile proteins. Also, the fetal sarcoplasmic reticulum is less efficient at releasing calcium.
- 2 Isolated fetal cardiac muscle strips generate reduced active tension compared with the adult muscle, although they exhibit higher resting tension.
- 3 The fetal heart *does* respond to the Frank–Starling mechanism, although fetal muscle shortening is less than that of adult muscle for the same tension.
- 4 Fetal left ventricular (LV) preload is influenced by: the size of the foramen ovale; 30–40% of inferior vena cava (IVC) flow; pulmonary venous return; and diastolic filling characteristics of the right ventricle (RV).
- 5 Fetal RV preload consists of: all venous return from the superior vena cava and blood from the IVC, which does not cross the foramen ovale and the gradient between the right and left atria.
- 6 LV afterload is primarily determined by vascular resistance in the upper body. RV output – through the widely patent ductus arteriosus – is primarily directed to the placenta. Thus, RV afterload is determined by resistance at the placental level.
- 7 Combined ventricular output is fairly stable from 18 weeks of gestation at 450 mL/kg/min, with an increasing preponderance of RV stroke volume. Pressure development is similar to that of the adult heart.
- 8 It is primarily the diastolic function of the fetal heart that reflects maturational changes. Doppler flow through the atrioventricular (AV) valves demonstrates this, with a gradual increase in the E wave (resulting from active ventricular relaxation) as gestation progresses.
- 9 The fetal ventricles are arranged in parallel. However, individual ventricular outputs are not equal. Flow in the aortic isthmus represents a reflection of the relative ventricular outputs and relative resistance in vascular beds perfused by the two ventricles.
- 10 The pulmonary circulation is a relatively high-resistance, low-flow vascular bed. However, the proportion of blood flowing through this bed increases to as much as 25% of cardiac output at term.
- 11 The placental circulation is a very low-resistance, high-flow vascular bed, receiving approximately 50% of combined cardiac output.
- 12 Vascular shunts traditionally described in the fetal circulation include: the ductus venosus, which allows some of the umbilical venous flow to enter the IVC directly; the foramen ovale, which permits flow from the right atrium to the left atrium; and the ductus arteriosus. The last vascular segment actually channels RV outflow toward the systemic circulation.
- 13 The aortic isthmus, located between the origin of the left subclavian artery and the aortic end of the ductus arteriosus, is a shunt between the two parallel circulations of the LV and the RV.
- 14 The direction of flow in the isthmus is determined by the relative influences of the two ventricles and the resistance of their respective downstream vascular beds.
- 15 Arteriovenous malformations lead to increased preload and decreased afterload. There is a marked elevation in cardiac output, and then progressively in cardiac size. Failure may occur from AV valve regurgitation. Peripheral circulatory changes vary, depending on the location of the malformation (upper versus lower body).
- 16 Fetal anemia also results in increased preload and decreased afterload. Cardiac output rises, and peripheral blood velocities tend to climb.
- 17 The twin–twin transfusion syndrome is characterized by chronic hypotension and hypoperfusion in the donor twin, while the recipient develops hypertrophic cardiomyopathy potentially leading to ventricular dysfunction and hydrops.
- 18 Fetal hypoxic hypoxemia causes elevated blood pressure and decreased heart rate, with redistribution of cardiac output to the brain, heart, and adrenals. Placental blood is maintained until the progression to

severe acidemia with a fall in cardiac output. Highly oxygenated umbilical venous blood is increasingly shunted through the ductus venosus to the IVC.

- 19 Hypoxemia resulting from placental insufficiency involves heightened placental vascular impedance and decreased umbilical blood flow. $p\text{CO}_2$ increases more quickly, and acidemia develops earlier than in the setting of normal placental resistance. Blood flow is markedly redistributed to the brain, heart, and adrenal

glands. Ventricular dysfunction may develop in the face of hypoxia and acidosis.

- 20 With increased placental resistance, diastolic flow velocity in the umbilical artery (UA) decreases and may eventually become retrograde. Doppler flows in the aortic isthmus predate the changes in the UA. There is an inverse correlation between the isthmus blood flow velocity index and postnatal neurodevelopmental outcome.

Immunology of the fetus

Josiah F. Wedgwood and James G. McNamara

This chapter provides an overview of the developing fetal immune system from molecular, cellular, and functional perspectives. Many questions and issues remain unresolved, but the framework reveals a tightly regulated process of development and provides a basis for understanding future insights into the ontogeny of the immune system.

The purpose of the developing immune system is to recognize virtually all foreign pathogens (i.e., to have a very broad repertoire of responses) and yet not respond to normal host products (i.e., not react to self). This is accomplished through the innate and adaptive immune systems and the interactions between them. The generation of B- and T-cell receptor (BCR and TCR) diversity, which is critical to the adaptive immune system, has been the subject of intense investigation and has provided a number of useful models of how the developing fetus acquires functional competence. The role of changes (or lack of changes) in the innate immune system during fetal development is much less well understood. Before going further, a summary of some general concepts will allow us to consider developmental immunology issues from a common framework.

Relevant concepts in immunology

The innate immune system consists of receptors and other proteins that respond to foreign pathogens but do not change over time.¹ Table 8.1 lists the components of the innate immune system; this list will undoubtedly grow as our understanding of the innate immune system increases. In contrast with the innate immune system, the adaptive immune system uses receptors that can become more refined over time.² The two systems can cooperate in a number of ways.

All of the cells of the immune system originate from hematopoietic stem cells located in the bone marrow of adults.³ These pluripotent cells initially generate the myeloid progenitors (the precursor of granulocytes, macrophages, dendritic cells, and mast cells) and the common lymphoid pro-

genitors [the precursor of lymphocytes and natural killer (NK) cells]. Cells of the myeloid lineage mature in the bone marrow or after taking up residence in the tissues. The lymphocytes mature in the bone marrow (B cells) or thymus (T cells). After maturation, the lymphocytes circulate through the bloodstream to the peripheral lymphoid organs, where they can become exposed to antigens on dendritic cells. From the peripheral lymphoid organs, the lymphocytes enter the lymph ducts and are returned to the bloodstream. This allows the formation of immunologic memory and refinement of the receptors of the adaptive immune system.

Immunologic nomenclature

The nomenclature used in immunology can be very cumbersome and confusing. The term “clusters of differentiation” (CD) is used to describe antigens expressed by groups or subsets of cells of the hematopoietic system. More than 300 CDs have been defined.⁴ This designation is used for all species in which homologous structures have been identified. Antibodies to specific CDs are often used to enumerate important types of leukocytes by flow cytometry. Table 8.2 lists the commonly encountered leukocyte groups.

Chemokines are small secreted proteins that act as chemoattractants for leukocytes and some other cells during inflammation.⁵ Chemokines interact with specific chemokine receptors. Table 8.3 lists the chemokines, chemokine receptors, and target cells.

Cytokines are also secreted proteins that affect the behavior of other cells.⁶ Cytokines interact with specific cytokine receptors. Cytokines made by lymphocytes are sometimes referred to as lymphokines or interleukins. Table 8.4 lists the cytokines, cytokine receptors, producer cells, and cytokine actions.

Pathogen recognition in the innate immune system

The innate immune system recognizes pathogens through invariant receptors that take advantage of molecular

structures that are unique to pathogens.⁷ The system is static, although changes in the number of receptors present can occur. For example, the collectins, which include mannose-binding protein (MBP), surfactant protein A (SpA) and surfactant protein D (SpD), bind to repeating carbohydrates in particular spatial arrangements that are present only on pathogens.⁸ Binding of SpA to the respiratory syncytial virus fusion protein neutralizes this virus, and thus can prevent infection or spread of virus.⁹

Toll-like receptors (TLRs) were originally described in the fruit fly, in which they were found to confer protection from

some fungal infections.¹⁰ In humans, TLRs respond to various microbial products, including peptidoglycan, flagellin, and unmethylated CpG DNA.¹¹ Lipopolysaccharide (LPS) bound to CD14 is recognized by TLR-4. TLR-3 recognizes double-stranded RNA, which is sometimes expressed during viral infections and is not normally found in mammalian cells. Unmethylated CpG DNA is typically found in bacteria and is recognized by TLR-9. Single-stranded RNA, which is typical of many viruses, is recognized by TLR-7 and TLR-9. The activation of TLRs triggers the production of proinflammatory cytokines [IL (interleukin)-1, IL-6, IL-12, tumor necrosis factor

Table 8.1 Components of the innate immune system.

Type of system	Examples
Physical barriers	Skin, gut, and respiratory epithelium, hairs, cilia, mucin, normal flora
Host cells	Macrophages/dendritic cells, neutrophils, NK cells, mast cells, γ/δ T cells, CD5+ B lymphocytes
Antimicrobial agents	Defensins, lactoferrin, transferrin, lysozyme, myeloperoxidase, serprocidins, bacterial permeability-increasing protein
Opsonins	Complement, fibronectin
Reactive oxygen and nitrogen species	Superoxide, hydrogen peroxide, hydroxyl radical, hypochlorite ion, nitric oxide
Receptors	Collectins, conglutinin, selectins, CD14, TLR
Cytokines	IL-1, TNF- α , IL-6, IL-8, MIP, MCP, IFN- γ , IL-12, IL-15, IL-18, GM-CSF, G-CSF, M-CSF

Table 8.2 CD antigens used to define important leukocyte groups.

Leukocyte group	Description
<i>Lymphocyte subgroups</i>	
CD3+	T cells
CD4+/CD3+	Helper T cells
CD8+/CD3+	Cytotoxic T cells
CD25+/CD4+/CD3+	Regulatory T cells
CD45RA+/CD3+	Naive T cells
CD45RO+/CD3+	Memory T cells
CD19+	B cells
CD20+	B cells
IgM+/IgD-/CD19+	Immature B cells
IgM+/IgD+/CD19+	Mature naive B cells
IgM-/IgD-/CD19+	Memory B cells
<i>Other cell types</i>	
CD56+	NK cells
CD14+	Monocytes/neutrophils (myelomonocytic lineage)

Table 8.3 Chemokines.

Family*	Chemokines	Examples of other names	Human chromosome	Target cell	Specific receptor
CXCL (ELR+: chemotactic for neutrophils)	CXCL1, CXCL2, CXCL3, CXCL5, CXCL6, CXCL7, CXCL8, CXCL14, CXCL15	GRO α , GRO β , GRO γ , IL-8	4, occasionally 5	Predominantly neutrophils	CXCR1, CXCR2, some unknown
CXCL (ELR-: chemotactic for lymphocytes)	CXCL4, CXCL9, CXCL10, CXCL11, CXCL12, CXCL13, CXCL16	PF4, Mig, IP-10, I-TAC, SDF-1	4, occasionally 10 or 17	Predominantly activated T cells	CXCR3, CXCR4, CXCR5, CXCR6
CCL	CCL1–28 (some only in mouse)	MCP-1, MIP-1 α , MIP-1 β , RANTES	17, occasionally 2, 5, 7, 9, or 16	Predominantly monocytes/macrophages, also dendritic cells, T cells, eosinophils, basophils	CCR1–10, some unknown
C and CX3C	XCL1, XCL2, CX3CL1	Lymphotactin, SCM-1 β , fractalkine	1 or 16	Predominantly T cells and NK cells	XCR1, XCR2, CXCR1

*Chemokine families are characterized by the amino acid sequence surrounding the critical cysteine(s).

Table 8.4 Representative cytokines.

	Cytokine	Receptor	Producer cells	Action
Hematopoietins	Epo (erythropoietin)	EpoR	Kidney cells, hepatocytes	Stimulation of erythroid progenitors
	IL-2 (T-cell growth factor)	IL-2R (CD25 α -chain, CD122 β -chain, CD132 common γ -chain)	T cells	T-cell proliferation
	IL-4 (BCGF-1, BSF-1)	IL-4R (CD124 α -chain, CD132 common γ -chain)	T cells, mast cells	B-cell activation, IgE switch, differentiation into Th2
	G-CSF	G-CSFR	Fibroblasts and monocytes	Neutrophil development and differentiation
	GM-CSF	GM-CSFR (CD116 α -chain, CDw131 common β -chain)	Macrophages, T cells	Growth and differentiation of myelomonocytic lineage, particularly dendritic cells
Interferons	IFN- α	CD118 (IFNAR2)	Leukocytes, dendritic cells	Antiviral, increased MHC class I expression
	IFN- β	CD118 (IFNAR2)	Fibroblasts	Antiviral, increased MHC class I expression
	IFN- γ	CD119 (IFNGR2)	T cells, NK cells	Macrophage activation, increased MHC/antigen expression, Ig class switch, suppression of Th2
TNF family	TNF- α (cachectin)	CD120a, CD120b	Macrophage, NK cells, T cells	Local inflammation, endothelial activation
	TNF- β (lymphotoxin)	CD120a, CD120b	T cells, B cells	Killing, endothelial activation
	CD40 ligand (CD40L, CD154)	CD40	T cells, mast cells	B-cell activation, Ig class switch
	Fas ligand	CD95 (Fas)	T cells	Apoptosis, Ca ²⁺ -independent cytotoxicity
IL-10 family	IL-10	IL-10R	T cells, macrophages	Potent suppressant of macrophage functions
IL-12 family	IL-12	IL-12R	Macrophages, dendritic cells	Activation of NK cells, induction of CD4+ T-cell differentiation into Th1-like cells
Unassigned	TGF- β	TGF- β R	Chondrocytes, monocytes, T cells	Inhibition of cell growth, anti-inflammatory, induction of IgA switch
	IL-1 α	CD121a, CD121b	Macrophages, epithelial cells	Fever, T-cell activation, macrophage activation
	IL-1 β	CD121a, CD121b	Macrophages, epithelial cells	Fever, T-cell activation, macrophage activation

(TNF)- α] and chemokines (CXCL8 or IL-8) and the expression of co-stimulatory molecules.

TLRs are not the only pattern recognition receptors (PRRs) of the innate immune system. The nucleotide-binding oligomerization domain (NOD) proteins, which recognize mureoproteins from the bacterial cell wall, and RNA helicases, which respond to double-stranded RNA from viral infections, have recently been described,¹² and the discovery of other PRRs can be expected.⁷

Killer cell immunoglobulin-like receptors (KIRs) represent a recently described and complex series of receptors that are present on subsets of NK cells, γ/δ TCR+ T cells, and some

memory/effector α/β TCR+ T cells.¹³ In humans, the *KIR* gene family contains up to 15 genes and two pseudogenes that are closely linked on chromosome 19. The selection of varying numbers of *KIR* genes for expression appears to be a random event. The subset of expressed *KIR* genes becomes fixed by methylation of the unexpressed *KIR* genes. The KIR ligands are major histocompatibility complex (MHC) class I molecules including human leukocyte antigen (HLA)-A, HLA-B, and HLA-C proteins. Binding of KIR to these molecules is usually inhibitory, leading to suppression of cytotoxicity and cytokine secretion. The interaction of KIR with HLA-G and HLA-E may help in the maintenance of pregnancy.¹⁴ Because

NK cells are involved in vascular remodeling of the placenta, preeclampsia and spontaneous abortion may result from abnormal KIR–ligand interactions.¹⁵

The various components of the innate immune system are able to: (1) prevent infection or slow the spread of infection; (2) kill cells harboring or replicating the pathogen; and (3) recruit other components of the innate and adaptive immune systems to the site of infection.

Pathogen recognition in the adaptive immune system

By definition, mature B cells or T cells express cell-surface receptors that they use to recognize foreign antigens. The BCR is made up of a membrane-anchored immunoglobulin (two heavy chains and two light chains), together with associated signaling molecules.¹⁶ The BCR is able to recognize both membrane-associated and soluble antigens. The TCR is composed of two glycoprotein chains (α/β or γ/δ heterodimers) that are able to recognize antigens in association with MHC class I or class II molecules.¹⁷ TCRs are also associated with nonpolymorphic proteins that are involved in signal transduction.

The generation of functional BCRs and TCRs is the result of ordered rearrangements and expression of families of genes. The immunoglobulin family of genes that generate BCRs was the first to be described and became the prototype for the study of TCR genes.¹⁸ Immunoglobulin genes have coding sequences (exons) for constant regions (C), variable regions (V), joining regions (J), and, in heavy chains, diversity regions (D), which are encoded in a nonrearranged form (germline configuration) on different chromosomes: chromosome 14 for immunoglobulin heavy chains, chromosome 2 for κ light chains, and chromosome 22 for λ light chains.

The cascade of events leading up to a productively rearranged IgM heavy chain can be summarized as follows. First, a D-gene exon is transposed next to a J-chain exon, with the intervening genes being deleted as a result of the rearrangement. Then a V-gene exon is similarly transposed to form a V/D/J recombinant. This recombination alters nuclear regulatory genes and allows the transcription of the V/D/J complex as well as the downstream C exon. Subsequently, the transcribed RNA is spliced to remove the intervening sequences to produce mature messenger RNA (mRNA); this is translated to produce a functional IgM heavy chain with a hydrophobic tail, which anchors the BCR in the cell membrane. Similar events lead to the production of light chains except that no D gene is involved.

Immunologic diversity is generated through four mechanisms.¹⁹ First, a large combinatorial contribution comes from the number of different V, D, and J exons that are available to produce the heavy chain, or the different V and J exons that are available to produce the light chain. Second, junctional diversity is introduced as a result of the addition or deletion of base pairs at the time of recombination. Third, additional combinatorial diversity results from the different possible

combinations of heavy and light chains. Finally, in a process that is unique to B cells, somatic mutations, or the mutational events that occur within genes after rearrangement, occur with activation. By the process known as allelic exclusion, only one chromosomal allele at a time can be productively rearranged for each heavy- or light-chain immunoglobulin gene. Significantly, the entire process of gene rearrangements to form immunoglobulins in immature B cells occurs as an antigen-independent event. The signals that drive the initiation of this cascade, which culminates with the production of a highly sophisticated mechanism of protection, are not known.

TCRs are composed of heterodimers of α/β chains or the numerically much less common γ/δ chains (< 5% of peripheral blood T cells).²⁰ TCR diversity is generated in the same way as BCR diversity: V/D/J recombinations generate the variable region of the TCR δ -chain or γ -chain and V/J recombinations generate the variable region of the TCR β -chain or δ -chain. Similarly, the diversity of TCR antigen specificities is generated through combinatorial and junctional mechanisms; however, somatic mutation is responsible for much less receptor diversity than in immunoglobulins. As with BCR, the TCR gene rearrangement is not driven by antigen-dependent mechanisms. Generation of the TCR results in formation of a TCR excision circle (TREC) that persists until the cell undergoes mitosis.²¹ Thymic output of T cells can be assessed by determining the fraction of TREC+ T cells.

The BCR is unique in its ability to switch isotypes by recombination between the V/D/J cluster and sequences for switch sites further downstream; this brings the complex to regions encoding other heavy-chain exons, which again undergo RNA splicing to generate the final mRNA product. This process is termed “isotype switching.”²²

Clonal selection hypothesis

The random generation of BCRs and TCRs described above will lead to the generation of cells that can be expected to respond to self (auto)-antigens. Burnet’s clonal selection hypothesis includes a postulate that explains why these clones are not observed;²³ they are deleted at an early stage in lymphoid cell development. Experimental evidence has demonstrated that this hypothesis is correct.

T-cell clonal deletion in the thymus and peripheral lymphoid tissues

The development of the thymus is essential to the normal evolution of a functional immune system. Patients with the complete DiGeorge’s anomaly (triad of cardiac abnormalities, hypoparathyroidism, and absent thymus) fail to develop T-cell lymphocytes and have a severe combined immunodeficiency.²⁴

The thymus consists of numerous lobules, each of which has an outer cortical region and an inner medulla. The cortical region consists of a network of epithelial cells that provide signals to lymphoid progenitors to differentiate into T cells through the Notch1 receptor, in addition to providing other

critical cytokines which allow T-cell development.²⁵ One of the signals that is necessary for a T cell to survive is the ability of the TCR to bind to MHC self-molecules in the absence of antigen. At the time of this positive selection, the developing T cell expresses both CD4 and CD8. The selection results in CD4+ T cells, which recognize MHC class II molecules, and CD8+ T cells, which recognize MHC class I molecules. Negative selection occurs when these cells bind tightly to cortical epithelial cells expressing self-antigens that are bound to MHC molecules. A second round of negative selection occurs when developing T cells are exposed to self-antigens on dendritic cells at the corticomedullary junction. A substantial fraction of T-cell clones are removed through this selection process.²⁶

In addition to selection in the thymus, T cells are actively selected in peripheral lymphoid tissue. Repeated contact with MHC–self-peptide complexes is necessary for the continued survival of naive T cells. Negative selection of autoreactive T-cell clones also occurs in the periphery.²⁷

B-cell clonal deletion in the bone marrow and peripheral lymphoid tissues

In the bone marrow, developing B cells, which are cross-linked to BCRs by multivalent self-molecules, are either deleted or undergo additional receptor editing.²⁸ B cells that encounter soluble self-molecules in the bone marrow downregulate the μ -chain of the BCR and become anergic (unresponsive) to further exposure to antigen. Naive B cells must enter the follicular region of peripheral lymphoid tissue to receive signals to prevent cell death. Naive B cells that encounter a strongly cross-linking self-antigen also undergo clonal deletion. Again, a substantial fraction of clones are deleted through this selection process.

Immunologic memory

B cells or T cells that have not been exposed to antigen are called naive. Exposure of B cells to antigen (first signal) together with signals from activated T cells or antigen-presenting cells (APC) result in activation of the B cell, cellular proliferation, and generation of scattered somatic mutations throughout the antibody variable regions.²⁹ Somatic mutations that improve antigen binding are able to undergo additional expansion whereas mutations with diminished binding undergo apoptosis. In addition, some B cells may also undergo an isotype switch, which is regulated by T-cell-derived signals.³⁰ The resulting B cells are termed memory B cells, and are responsible for the robust secondary antibody response seen on re-exposure to an antigen. Finally, some of the B cells will mature into plasma cells and produce secreted antibody.³¹

T cells respond to antigen which has been processed by APC. Small peptides derived from the antigen are bound to class I MHC or class II MHC molecules transferred to the cell membrane.^{32,33} A second signal, usually the result of activation of the APC, is required for T-cell proliferation and maturation.³⁴ Immediately after exposure to antigen, the

number of reactive T cells increases as effector T cells are produced. Some of these cells persist and are called memory T cells.

Ontogeny of the innate immune system

The ontogeny of some components of the innate immune system has been investigated; however, further information is still required in many areas.

Physical barriers

The incomplete keratinization of the skin of premature infants is well known.³⁵ After premature delivery, accelerated maturation occurs. Studies of skin treatments to reduce infections have yielded inconsistent results.³⁶ What is clear is that there is a markedly increased absorption of topically applied compounds through the skin of newborns, which can result in toxicity (e.g., hexachlorophene, povidone–iodine).³⁷ Proponents of probiotics argue that establishing an appropriate gut flora reduces the risk of infection and necrotizing enterocolitis.^{38,39} One recent report has suggested that erythema toxicum neonatorum may be the result of the innate immune response to commensal bacteria penetrating the skin of the newborn around the hair follicle.⁴⁰

Host cells

The numbers of macrophages/dendritic cells, neutrophils, NK cells, mast cells, γ/δ T cells, and B1 lymphocytes appear normal at birth. Neonatal dendritic cellular function is impaired and may contribute to the impaired specific immune response observed in this group.⁴¹ Newborn neutrophil chemotaxis in response to chemokines is decreased when compared with adults.⁴² NK cells from newborns function poorly against herpes simplex virus (HSV)-infected target cells, which may explain the unusual susceptibility of this group to *Herpes simplex* infections.⁴³

Antimicrobial agents

Antimicrobial proteins such as defensins, bacterial permeability-increasing protein (BPI), and lysozyme are developmentally regulated and expressed in lower levels in premature infants than in term infants.^{44–46} These proteins contribute to the antimicrobial properties of amniotic fluid and vernix.⁴⁷

Opsonins

Most complement components, including C3, are decreased in newborns. Diminished C3 levels may result in an increased risk of infection as well as a diminished response to vaccination. Serum fibronectin levels are related to gestational age at birth. This may have clinical implications because fibronectin

serves as an opsonin for staphylococci and group B streptococci.

Reactive oxygen and nitrogen species

Functional comparisons of adult and newborn neutrophils give conflicting results.⁴⁸ Oxidative metabolism (H_2O_2 and O_2^- production) is normal or increased in newborn neutrophils, but chemiluminescence ($\cdot OH$ production) is diminished for many stimuli; this may be the result of decreased lactoferrin content. LPS dramatically increases oxidative metabolism and chemiluminescence in adult neutrophils but has little effect in newborns as expression of CD14, an LPS receptor, is decreased.⁴⁹ *In vivo*, the relative inability of newborn neutrophils to generate reactive oxygen and nitrogen species and hence kill bacteria is accentuated by defects in adherence to activated endothelial cells and chemotaxis,⁵⁰ defects in phagocytosis resulting from poor serum opsonization,⁵¹ and a smaller neutrophil storage pool.⁵²

Innate receptors

Many of the TLR responses of newborn cells are diminished for reasons that are not completely understood. For example, the response of cord blood monocytes to LPS exposure is diminished.⁵³ Some have argued that this is the result of decreased expression of TLR-4 on fetal and newborn monocytes, but others have noted decreased intracellular levels of MyD88, a TLR-adaptor protein.⁵⁴ Other relative defects in the TLR signaling pathway have also been described.⁵⁵ Whatever the mechanism, activation of TLRs in the newborn results in smaller amounts of proinflammatory cytokines and chemokines as well as diminished expression of co-stimulatory molecules. The predicted result of this decreased TLR function is an increased susceptibility to infection and a decreased ability to develop a robust adaptive immune response. Negative regulators of TLRs have been described but have not been studied in newborns.⁵⁶

Inflammatory cytokines

Newborn mononuclear cells produce decreased amounts of CCL3 (MIP-1 α) compared with adult cells.⁵⁷ In contrast, production of IL-8 by newborn neutrophils is increased.⁵⁸ Few studies have been conducted to evaluate other cytokines. The implications of reported differences in cytokine production for clinical practice are unclear.

Ontogeny of the adaptive immune system

Serum immunoglobulin

Term newborns have total serum IgG levels that are slightly higher than their mothers. This IgG is produced by the

Table 8.5 Serum immunoglobulin levels (mg/dL) in fetuses and newborns.

Group	IgG1	IgG2	IgG3	IgG4	IgA	IgM
17–22 weeks	0.93	0.31	0.05	0.04	0.001	–
28–32 weeks	3.7	0.93	0.19	0.21	0.002	–
Term	10.43	1.56	0.41	0.47	0.004	< 0.2
Adult	10	4	1	0.5	2.5	2

mother's immune system and is actively transported across the placenta starting in the second half of the second trimester. Transport is mediated by neonatal Fc receptors in the syncytiotrophoblast, which are able to bind IgG at the acidic pH present in the vacuoles containing pinocytosed maternal serum.⁵⁹ IgG1 is transported more efficiently than the other IgG subclasses. IgM, IgA, and IgE do not bind to the neonatal Fc receptor involved in this transport process and are virtually absent from newborn serum unless the fetal immune system has been stimulated (e.g., by a congenital infection; Table 8.5).

The presence of maternal antibodies protects the newborn (passive immunity) from some infections for several months. However, the presence of maternal antibodies also interferes with the antibody response generated by immunization.⁶⁰ Interestingly, T cells are usually primed in a normal fashion to immunogens.⁶¹ These maternal antibodies can also prevent the early replication of live viral vaccines, leading to vaccine failure.

Preterm infants have immunoglobulin levels that are similar to those seen in congenital immunodeficiency diseases involving antibody formation, which are associated with an increased risk of infections.⁶² Immunoglobulin replacement therapy in preterm infants has not been associated with decreased numbers of infections.⁶³ This may reflect alterations in complement levels, neutrophil function, and phagocytic capability, which are also present in newborns, as well as the fact that the most frequent cause of newborn sepsis is *Staphylococcus epidermidis*.

T-cell development

Pre-T cells can be identified in the fetal liver as early as 7 weeks of gestation; these cells seed the thymus at 8–9 weeks, and T cells (TCR+) appear shortly thereafter. By 18 weeks, CD4+ T cells and CD8+ T cells are present in the blood. At term, the numbers of CD4+ T cells and CD8+ T cells in blood are approximately the same as those seen in adults. However, there are some significant differences. Almost all of the peripheral blood T cells in the fetus are naive compared with 40% of the adult T cells. A much larger percentage of newborn T cells are recent emigrants from the thymus and have the DNA excision circles that are formed during the TCR recombination process. Finally, the newborn T cells have a random dis-

tribution of TCRs, whereas adult T cells have evidence of clonal expansion.⁶⁴ CD25+/CD4+ regulatory T cells are observed early in the second trimester.⁶⁵

B-cell development

In the human fetus, pre-B cells can be identified in fetal liver samples as early as 7–8 weeks' gestation.⁶⁶ B cells bearing surface IgM are first detected in fetal liver at 9–10 weeks' gestation. Shortly after this time, B cells that also express surface IgG or surface IgA can be found in small numbers, and, by weeks 12–13, surface IgD cells can also be found. Although B cells are first observed in fetal liver, they are rapidly observed subsequently in fetal bone marrow, spleen, and blood. The number of circulating B cells found in fetal blood reaches the level seen in adults by approximately 15 weeks' gestation. By the end of the first trimester, the generation of new B cells switches from the fetal liver to the bone marrow. Primary nodules develop around the follicular dendritic cells of the lymph nodes at about 17 weeks of gestation, but do not develop in the spleen until about 24 weeks.⁶⁷ Germinal centers are generally absent until after birth, probably from lack of response to antigens.

CD5+ B cells are largely T-independent and produce polyclonal antibodies that may be important in the primary immune response.⁶⁸ The percentage of CD5+ B cells is significantly elevated in the fetus and declines during gestation. At birth, most B cells are CD5+, whereas CD5+ cells represent a small fraction of the B cells found in adults. CD5+ B cells may be a distinct lineage of B cells, not a precursor of CD5– B cells.

Plasma cells secreting IgM can first be detected at 15 weeks' gestation, followed by IgG- and IgA-secreting plasma cells at approximately 20 and 30 weeks' gestation respectively.⁶⁹ As noted in the discussion above, the amount of immunoglobulin produced by these cells is very small compared with that transferred from the mother.

Functional adaptive immunity

Although the number of B cells and T cells in the fetus and newborn are similar to those observed in adults, the function of the cells is abnormal. Neonatal T cells spontaneously proliferate *in vitro*, to a small extent, and respond well to IL-7, the interleukin responsible for regulating the size of the lym-

phocyte pool. However, neonatal T cells do not proliferate well in response to activation through the TCR.

The fetus is able to develop memory CD4+ T cells to transplacental antigen exposure such as tetanus toxoid, cat dander, and dust mites;⁷⁰ generally, the response is weak. Newborns are also able to respond to immunization with bacille Calmette–Guérin (BCG) and can develop a strong antiviral response after infection.⁷¹ Still, the amount of cytokines (IL-2, IL-4, IFN- γ) secreted is lower than that seen in adults and the expression of the activation marker CD154 (CD40L), which is a second signal for B cells, is diminished.⁷² This means that fetal and newborn T cells are not as effective in helping B cells as adult T cells. The CD25+/CD4+ regulatory T cells observed in the newborn are able to suppress other T-cell functions. The functional capabilities of newborn CD8+ cytotoxic T cells have not been well studied.

Newborn B cells are able to respond to activation through the BCR and CD154 (CD40L).⁷³ Newborn B cells require higher levels of IL-4 to undergo class switch in culture.⁷⁴ The absence of germinal centers in the lymph nodes and spleen of the newborn may also play a role in the poor antibody response observed after infection or immunization.

Conclusion

The immune system develops in a highly orchestrated and integrated fashion. B- and T-lymphocyte development begins midway through the first trimester and, in many ways, achieves significant maturity (equal to that seen in the term neonate) during the second trimester of pregnancy. The early stages of lymphocyte maturation occur as the result of mechanisms that do not depend on antigenic stimulation, providing humans with an immunologic repertoire that is capable of responding to virtually any antigenic challenge. Further maturation of the immune system, such as the development of specific immunologic memory and more potent humoral and cellular effector mechanisms, occurs after exposure to the myriad environmental challenges that occur in postnatal life. Thus, the immune system is a highly responsive organ system that has its origins early in gestation, reaches maturity during the first decade of life, but continues to evolve and respond to pathogenic insults throughout life until immunologic senescence occurs.

Key points

- 1 Components of the innate immune system do not change with exposure.
- 2 The innate immune system includes pattern recognition receptors such as the toll-like receptors (TLRs).
- 3 The innate immune response can recruit other components of the innate and adaptive immune system to the site of infection.
- 4 T-cell receptor (TCR) and B-cell receptor (BCR) diversity results from recombination of multiple exons, junctional diversity, and random combinations of the two chains present in each receptor.
- 5 Self-reaction T cells are deleted primarily in the thymus.
- 6 T cells recognize small peptides bound to class I or class II major histocompatibility complex (MHC) molecules.
- 7 Repeated exposure of B cells to antigen results in somatic mutations of the antibody variable region and selection of B cells with improved antigen binding. Somatic mutation does not occur in T cells.
- 8 T-cell memory is a result of clonal expansion.
- 9 The following defects of the innate immune system are observed in newborns: incomplete keratinization of the skin; decreased neutrophil chemotaxis; decreased natural killer (NK) cell function against herpes simplex virus (HSV)-infected cells; decreased antimicrobial proteins; decreased complement C3 and fibronectin; decreased response of neutrophil oxidative metabolism to lipopolysaccharide (LPS) exposure; and a decreased neutrophil storage pool.
- 10 Many components of the innate immune system have not been studied in the fetus or newborn.
- 11 Defects in the innate immune system contribute to the susceptibility of the fetus and newborn to infection.
- 12 Maternal IgG is actively transported to the fetus during the third trimester. IgG1 is more efficiently transported than IgG2, IgG3, or IgG4. Maternal IgM, IgA, and IgE are not transported and are typically present in very small amounts.
- 13 Maternal IgG interferes with the newborn's ability to generate an antibody response to vaccination, but not a T-cell response to vaccination.
- 14 Immunoglobulin replacement therapy in preterm infants has not been associated with decreased numbers of infections.
- 15 Fetal T cells appear in the first trimester.
- 16 At birth, neonatal T cells have not undergone clonal expansion. Almost all neonatal T cells are naive.
- 17 The fetus is able to generate T-cell responses to transplacental antigen exposure.
- 18 Fetal B cells appear in the first trimester.
- 19 The fetus is able to make IgM, IgG, and IgA by the second trimester, but very little immunoglobulin is produced.
- 20 Fetal and newborn T cells have diminished expression of CD154 (CD40L), which is required to generate an appropriate antibody response.

Fetal endocrinology

Charles E. Wood and Maureen Keller-Wood

The endocrine systems of the fetus are modulators of the classical physiological organ systems. For example, the basic components of the cardiovascular system work together to transport nutrients and waste products and to perfuse the tissues with blood. However, the blood volume and osmolality is controlled via the actions of endocrine feedback mechanisms, and the distribution of combined ventricular output is affected by several hormones that are released after fetal stress. The fetal lung makes lung liquid prior to birth and serves as an organ of gas exchange after birth. However, the reabsorption of lung liquid is likely to be coordinated by several hormones that are secreted at birth. This chapter will focus on the endocrinology of the developing fetus. Because of the inherent difficulty in studying developing human fetuses, much of what we know about the developing human has its origins in the study of animal models, mostly fetal sheep; although more pertinent to the human being, less information has been obtained from primate models of fetal development. Rodents are altricial species (relatively immature at birth); however, useful information about endocrine development (especially relating to first- and second-trimester fetuses) has been obtained from developing rats and mice. There are notable exceptions, however, for example the biosynthesis of estrogens in humans and primates involves a “fetoplacental unit,” while the biosynthesis of estrogens in sheep is more straightforward. It is, perhaps, the differences among species that allow us to identify the truly basic principles of endocrine control in fetuses. This chapter is intended to be an overview of the current knowledge of several aspects of this large field, not a comprehensive review of the literature. The focus of this chapter will be the major endocrine axes of the fetus including estrogen biosynthesis, and hypothalamic and pituitary control of adrenal, gonad, and thyroid function, with special emphasis on the roles that these endocrine axes play in the development of the fetus and its adaptation to extrauterine life. We will address each of these major endocrine systems separately.

Hypothalamus–pituitary–gonadal axis

Gonadotropin-releasing hormone (GnRH) is secreted into the hypophyseal–portal blood at the median eminence, and stimulates the release of both luteinizing hormone (LH) and follicle-stimulating hormone (FSH) from gonadotropes in the anterior pituitary. At mid-gestation or before, in the sheep fetus, LH and FSH are present in gonadotropes and GnRH is present in the hypothalamus at both the mRNA and the protein level. (Prior to the maturation of the fetal pituitary, chorionic gonadotropin (CG) from the placenta stimulates fetal gonadal growth, differentiation, and secretory activity.) The levels of LH and FSH appear to be greater in female fetuses than in male fetuses and pulsatile secretion of these hormones becomes established during the fetal period. The overall activity of the hypothalamus–pituitary–gonadal (HPG) axis reaches a peak at approximately 30–40% gestation in the sheep fetus, decreasing until birth (Fig. 9.1).¹ In the rat fetus, a species that is relatively immature at birth, the protein and mRNA tissue concentrations of GnRH, LH, and FSH increase continuously until birth. GnRH neurons have been identified in the region of the organum vasculosum of the lamina terminalis (OVLT), in the medial preoptic nucleus, and in the nucleus of the diagonal band of Broca.

In the sheep fetus, testosterone secretion from the fetal gonads peaks at about the same time as the peak in plasma concentrations of gonadotropins, at approximately 30–40% gestation (Fig. 9.1). The mid-gestational peak in gonadal steroid hormone secretion appears to stimulate gonadal growth and differentiation. However, later in gestation, the placenta synthesizes increasing quantities of both estrogens and androgens, which is controlled by the fetal hypothalamus–pituitary–adrenal (HPA) axis.²

Fetal estrogen and androgen biosynthesis

The major source of androgens and estrogens in the late-gestation fetus is the placenta.³ In primate species, including humans, the biosynthesis of estrogens and androgens depends upon an intact fetoplacental unit. The placenta lacks cytochrome P450_{c17α} (CYP17), and therefore, 17α-hydroxylase and 17,20-lyase activities (Fig. 9.2). Nevertheless, the placenta

Figure 9.1 Schematic representation of the ontogeny of hCG, LH, and testosterone (T) in the plasma of a male fetus. The relationship of GnRH, FSH, LH, and T is represented in the upper right corner of the figure.

is able to synthesize large amounts of estrogen as it receives a supply of estrogen biosynthetic precursor from the fetal adrenal cortex. The *adult zone* or *definitive zone* of the fetal adrenal cortex lacks the enzyme 3β-hydroxysteroid dehydrogenase (Fig. 9.2) and cannot, therefore, convert either pregnenolone to progesterone or 17α-hydroxypregnenolone to 17α-hydroxyprogesterone. However, the *fetal zone* of the fetal adrenal cortex secretes dehydroepiandrosterone (DHEA) and dehydroepiandrosterone sulfate (DHAS) in response to adrenocorticotrophic hormone (ACTH), and these steroidogenic intermediates are taken up by the placenta and used in the biosynthesis of estrogens, bypassing the lack of CYP17 (Figs 9.2 and 9.3). Alterations in fetal HPA axis activity are reflected in changes in circulating concentrations of estrogens in maternal plasma. For example, fetal death dramatically reduces maternal plasma concentrations of estriol. In rhesus monkeys, infusion of ACTH into the fetal blood has been shown to increase the circulating concentrations of estrogens in maternal plasma, and negative feedback inhibition of fetal ACTH secretion by infusion of glucocorticoids reduces maternal plasma estrogen concentrations.⁴ Estrogen biosynthesis and release into the fetal bloodstream creates an endocrine environment that allows fetal growth and development. For example, uterine blood flow during pregnancy is critically influenced by placental estrogen biosynthesis. The estrogen environment *in utero* is also important, however, at the final stages of pregnancy; increases in estrogen biosynthesis at the end of gestation are thought to be a central feature of the events that increase myometrial contractility and initiate labor.

Hypothalamus–pituitary–adrenal axis

The endocrine hierarchy within the fetal HPA axis⁵ is similar to that of the adult (Fig. 9.2). ACTH is synthesized and

Figure 9.2 Steroid biosynthesis in the developing primate fetus. Steroidogenic enzymes are represented by the following abbreviations: P450_{c17} (17α-hydroxylase and 17,20-lyase activities); 3β-HSD (3β-hydroxysteroid dehydrogenase activity); P450_{c11b1} (11α-hydroxylase activity); P450_{c11b2} (aldosterone synthase activity); P450_{arom} (aromatase activity). The fetal zone of the fetal adrenal cortex is capable of performing the reactions in the shaded area. The overlapping box (right) represents estrogen biosynthesis by the placenta. A'dione, androstenedione.

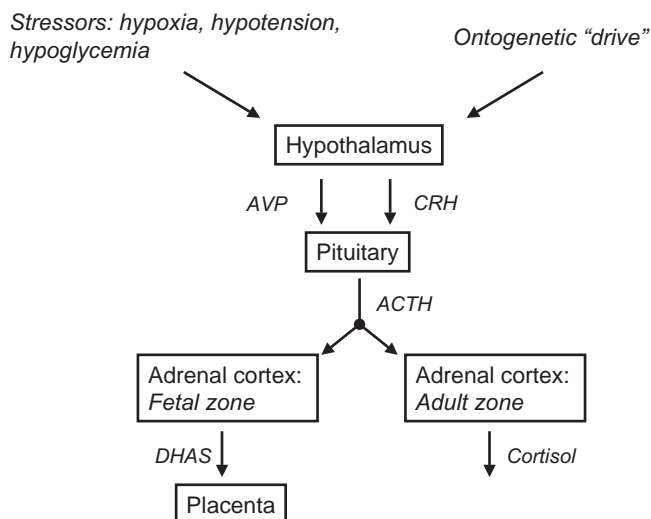

Figure 9.3 Relationship between hypothalamus, pituitary, and fetal and definitive zones of the fetal adrenal. Both zones of the fetal adrenal cortex are stimulated by ACTH secreted by the fetal anterior pituitary. The secretion of ACTH is stimulated acutely in response to stressors *in utero*, and chronically in a pattern that produces increased activity of the fetal hypothalamus–pituitary–adrenal axis independent of stressors at the end of gestation.

secreted by the corticotropes of the anterior pituitary in response to two hypothalamic releasing factors: arginine vasopressin (AVP) and corticotropin-releasing hormone (CRH). The two releasing hormones work in concert: each increases the sensitivity of the corticotrope to the other. The fetal HPA axis appears to be controlled by the paraventricular nuclei (PVN); in sheep fetuses, destruction of the PVN or implantation of dexamethasone crystals near the PVN disrupts the function of the axis.⁶

ACTH stimulates the release of glucocorticoid hormones (i.e., cortisol in the human, primate, and sheep, and corticosterone in rodents) from the *definitive zone*. This zone contains the full complement of steroidogenic enzymes that are found in the adult adrenal cortex (Fig. 9.2) and it responds to ACTH with an increase in cortisol secretion, and to angiotensin II and K^+ with an increase in aldosterone secretion. In the *fetal zone*, ACTH stimulates the release of the estrogen precursors, DHEA and DHAS. The overall size of the fetal zone increases in late gestation, reaching a peak at the time of birth and regressing thereafter.

The fetal HPA axis is activated progressively throughout the latter part of gestation as a normal consequence of ontogenetic development. This has been well documented in fetal sheep and there is good evidence that this is also true in primate fetuses. The activation of the fetal HPA axis can be seen as a semilogarithmic increase in circulating concentrations of ACTH and cortisol in nonhuman fetal blood, and DHEA, DHAS, and estrogens in human fetal blood (Fig. 9.4). In sheep fetuses, the increase in fetal HPA axis activity includes increased biosynthesis of CRH and AVP in the hypothalamus, and proopiomelanocortin (POMC) in the fetal pituitary, as well as increased abundance of steroidogenic enzymes in the adrenal cortex. The molecular processing of POMC to ACTH

is also increased in the latter stages of development (Fig. 9.5); this increased processing is in part the result of stimulation by estrogens from the placenta. Prior to term, as in the adult animal, there is an effective negative feedback mechanism by which cortisol inhibits fetal ACTH secretion. In the final few days of fetal life, however, the negative feedback mechanism is interrupted, allowing both ACTH and cortisol to increase simultaneously (Fig. 9.6); this may allow for the large increases in secretion of both hormones that occurs prior to birth.

Throughout the third trimester, the adrenal cortex increases in size and there is an increase in the sensitivity of the steroidogenic tissue to ACTH; this is a function of adrenal mass, as well as several endocrine and neural influences. For example, POMC and 22-kDa “pro-ACTH” reduce adrenal sensitivity to ACTH (Fig. 9.5), whereas splanchnic nerve stimulation increases adrenal responsiveness to ACTH. In sheep, the increases in adrenal cortisol secretion are accompanied by an increase in the binding capacity for cortisol. This effectively exaggerates the increase in fetal plasma cortisol concentration and provides an increased supply of bound cortisol in plasma.

The ontogenetic increase in fetal HPA axis activity at the end of gestation is a critical part of the process by which fetal visceral and pulmonary maturation are accelerated in preparation for extrauterine life. In sheep, the fetal HPA axis plays a critical role in the triggering of parturition.⁷ It is likely that the role is essentially similar in the human fetus because placental estrogen biosynthesis is controlled by fetal ACTH secretion in both species. There is a clear functional relationship between the fetal HPA axis and placental estrogen biosynthesis. In sheep, and likely in human fetuses, placental estrogen potently stimulates fetal HPA axis activity. At the end of gestation, the interplay between the placenta and the fetal

HPA axis functions as a positive feedback cycle, progressively increasing fetal HPA activity, thus preparing the fetus for birth.

The placenta expresses 11 β -hydroxysteroid dehydrogenase (HSD), the enzyme that interconverts cortisol and cortisone

(biologically inactive at the corticosteroid receptor). Placental 11 β -HSD-2, which predominantly converts cortisol to cortisone, partially isolates the fetus from the cortisol in the maternal circulation. As the fetus matures, the activity of 11 β -HSD is increased, perhaps itself the result of increased estrogen biosynthesis by the placenta.⁸

Primate placenta contains significant amounts of immunoreactive ACTH and CRH.⁹ It has been proposed that the release of ACTH and/or CRH into the fetal blood might be a physiologically important mechanism by which the placenta affects the timing of parturition in these species. The concentration of CRH is substantial in both fetal and maternal plasma in primates. However, CRH is partially protein bound in fetal plasma by a CRH-binding protein that is synthesized and secreted by the placental tissue. The function of the binding protein is not known; its presence in plasma suggests that the high circulating concentrations of CRH in plasma might represent spillover from sites of production and (paracrine or autocrine) action in the placenta and other sites within the peripheral circulation. In the human placenta, CRH causes the release of ACTH locally, followed by an alteration in placental steroidogenesis. It has also been proposed that the release of CRH from the human placenta into the fetal umbilical venous blood stimulates the activity of the fetal HPA axis at the end of gestation, which ultimately might initiate parturition.

Figure 9.4 Ontogeny of fetal ACTH, DHAS, and estrone (E_1), estradiol (E_2), and estriol (E_3) in the primate fetus. The relationship of these hormones is represented in the upper right corner of the figure.

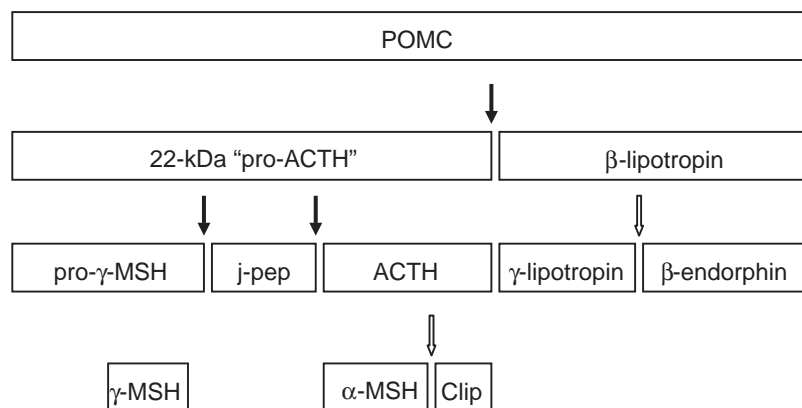

Figure 9.5 Post-translational processing of POMC. POMC is cleaved to β -lipotropin and 22-kDa "pro-ACTH" by the prohormone convertase 1/3 (PC1/3, solid arrows). β -Lipotropin is further processed to lipotropin and endorphin by prohormone convertase 2 (PC2, hollow arrow). Pro-ACTH is cleaved to ACTH, pro- γ -MSH, and joining peptide (j-pep) by PC1/3. ACTH is cleaved to α -MSH and corticotropin-like immunoreactive peptide (CLIP) by PC2. The specific peptide products of POMC are cell specific. For example, corticotropes synthesize ACTH, whereas the neurointermediate lobe synthesizes α -MSH predominantly.

Figure 9.6 Graphical representation of the efficacy of negative feedback inhibition of stimulated ACTH secretion by cortisol in fetal plasma. Negative feedback inhibition of ACTH secretion is apparent at 80% gestation, but not in the last several days of fetal life (100% gestation). The relationship between cortisol and ACTH in the fetus is represented by the inset (upper right).

Neurointermediate lobe of the pituitary

The cells of the neurointermediate lobe synthesize POMC. The major processing products of the POMC-synthesizing cells are α -melanocyte-stimulating hormone (α -MSH) and γ -MSH. One report¹⁰ suggested that neurointermediate lobe cells from fetal sheep respond to CRH and/or AVP with increased secretion of immunoreactive ACTH, whereas neurointermediate lobe cells from neonatal sheep did not respond to CRH and/or AVP. The responsiveness of the cells to CRH and/or AVP was altered by prior adrenalectomy. The authors suggested that neurointermediate lobe cells mature in late gestation, perhaps in response to cortisol in fetal plasma.

Adrenal medulla

The adrenal medulla becomes innervated by sympathetic pre-ganglionic nerves at approximately 80% gestation (in sheep), and secretes the catecholamines, epinephrine and norepinephrine,¹¹ whereas prior to innervation, the fetal adrenal is directly responsive to hypoxia. The adrenal medullary biosynthesis of epinephrine is dependent upon the expression of phenylethanolamine-N-methyltransferase (PNMT), which is, in turn, induced by cortisol. For this reason, the secretory capacity of the adrenal medulla for epinephrine increases late in gestation.

The adrenal medulla responds to various stresses such as hypoxia and hypotension with increased secretion of catecholamines. The increase in response to hypoxia is important for redistributing fetal combined ventricular output away

Figure 9.7 The ontogeny of thyrotropin, T_4 , T_3 , and rT_3 in fetal plasma. The relationship of thyrotropin, T_4 , T_3 , and rT_3 is represented in the upper left corner of the figure.

from somatic tissues and towards the umbilical-placental circulation. The adrenal medulla also plays an important role in fetal glucose homeostasis; an increase in fetal epinephrine secretion elevates the fetal plasma glucose level, which is seen, for example, following periods of fetal distress.

Hypothalamus-pituitary-thyroid axis^{12,13}

In humans, the fetal thyroid is sufficiently developed to support thyroglobulin biosynthesis by approximately 25% gestation (Fig. 9.7). Thyrotropin is present in the fetal pituitary and in fetal plasma at the beginning of the second trimester, at approximately the time of hypothalamo-hypophyseal portal system development. Thyrotropin and thyroxine (T_4) circulate in fetal plasma in increasing concentrations, starting early in the second trimester. Type 3 deiodinase (D_3), which converts T_4 to reverse 3,5,5' triiodothyronine (rT_3), is expressed leading to an abundance of rT_3 circulating in fetal plasma throughout the second and third trimesters (Fig. 9.8). Circulating concentrations of 3,5,3' triiodothyronine (T_3), however, increase only in the final stages of fetal development, suggesting late development of types 1 and 2 deiodinases (D_1 and D_2 respectively) in liver and other tissues (Fig. 9.7). In the first trimester of human pregnancy, the abundance of TRH in extrahypothalamic tissue is greater than in the fetal hypothalamus, suggesting a role for extrahypothalamic TRH in the stimulation of thyrotropin secretion from the developing anterior pituitary. In the sheep fetus, the development of the thyrotrope starts at approximately 30% gestation, followed by the development of the thyroid gland at approximately 40%

Figure 9.8 The metabolism of thyroid hormones by types 1 and 2 (D1 and D2) deiodinases, and type 3 (D3) deiodinase. Thyroxine, triiodothyronine, and reverse triiodothyronine are represented as previously defined (T_4 , T_3 , and rT_3 respectively).

gestation, and the development of hypothalamic TRH at around 50% gestation. Plasma concentrations of thyrotropin in the sheep fetus increase from approximately 30% gestation, leading investigators to speculate that extrahypothalamic TRH synthesis and release might be relevant for control of pituitary thyrotropes. True neuroendocrine control of the hypothalamus–pituitary–thyroid (HPT) axis develops near the end of human and ovine pregnancies.

The maternal and fetal HPT axes operate somewhat independently. The placenta is relatively impermeable to T_4 and T_3 because of the presence of the deiodinase that converts T_4 to rT_3 . The placenta is also impermeable to the relatively large thyrotropin and thyroid-binding globulins. On the other hand, the human placenta is relatively impermeable to TRH, a fairly small molecule (the ovine placenta is also impermeable to TRH). For this reason, there is usually a gradient of both T_4 and T_3 from maternal to fetal plasma.

Development of the HPT axis of the fetus is critically important for differentiation of the nervous system. Congenital hypothyroidism causes mental retardation in human infants. Although the infant can be treated with some success after birth, it will tend to be less responsive if the mother also suffered from hypothyroidism during pregnancy. The HPT axis also plays a role in the adaptation to extrauterine life. This has been illustrated in sheep; thyroidectomy, days before birth, causes severe neonatal hypothermia, in part because of a failure of thermogenesis in the brown adipose tissue. The effect of thyroid hormones in this process is to accelerate development of the brown adipose tissue in the last few days of gestation.

Posterior pituitary

Both AVP and oxytocin are synthesized by magnocellular neurons in the supraoptic and paraventricular nuclei. Axons from these neurons terminate in the posterior pituitary. AVP is a hormone with at least three biological activities (Fig. 9.9). The vasopressor action of this hormone is mediated by V_{1a} vasopressin receptors on vascular smooth muscle cells in the peripheral vasculature. Corticotropin-releasing activity is mediated by the V_{1b} vasopressin receptor (AVP acting as a corticotropin-releasing factor is derived from parvocellular neurons and released into the hypothalamo–hypophyseal portal blood at the median eminence). The antidiuretic activity is mediated by the V_2 vasopressin receptor. The potency of vasopressin action in the fetal kidney appears to be somewhat less than in the adult. The fetal sheep excretes a relatively large volume of dilute urine. The renal concentrating mechanisms are immature, therefore the increase in urine osmolality after exposure to vasopressin is not as dramatic as in the adult.

AVP is an important cardiovascular hormone in the fetus.¹⁴ Hemorrhage greatly increases its concentration in plasma, and pharmacologic blockade of V_{1a} receptors impairs blood pressure regulation during hypovolemia. Increases in plasma vasopressin concentration redistribute fetal combined ventricular output toward the umbilical–placental circulation, maximizing transfer of gases between the maternal and fetal circulations.

Oxytocin circulates in fetal plasma in relatively high concentrations, which increase during active labor. Immuno-

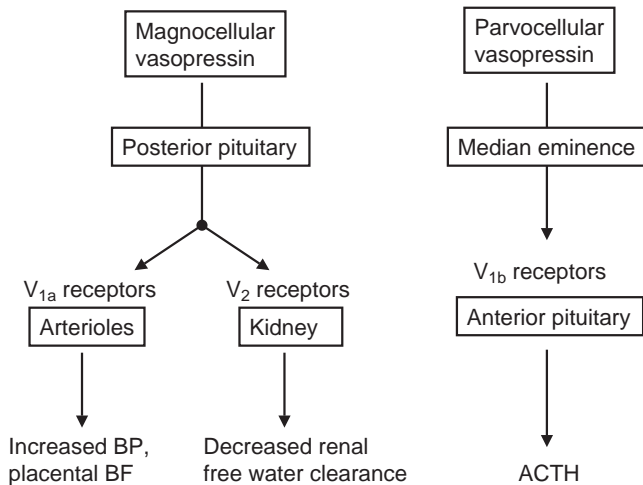

Figure 9.9 The synthesis, release, and action of AVP in the fetus. Magnocellular neurons in the paraventricular nucleus synthesize vasopressin, releasing the peptide into the bloodstream at the posterior pituitary. Parvocellular neurons in the hypothalamic nucleus synthesize vasopressin, which is released into the hypothalamo–hypophyseal portal blood at the median eminence. Portal blood vasopressin acts as a corticotropin-releasing factor at the corticotrope of the anterior pituitary.

reactive oxytocin in fetal plasma is present as a mixture of processed and unprocessed forms. As the fetus matures, the proportion of processed oxytocin in fetal plasma increases. The function of oxytocin in the fetus is not clear, although the placental barrier prevents fetal oxytocin from reaching the myometrium. It is possible that oxytocin stimulates the release of ACTH via an interaction with the V_{1b} receptor.

Figure 9.10 The fetal lung synthesizes and secretes POMC into the fetal bloodstream. This peptide is known to alter adrenal sensitivity to ACTH. It has been proposed that there is an interplay among the lung, pituitary, and adrenal that modulates fetal adrenal responsiveness to stress and the timing of parturition as the lung matures.

Ectopic hormones

In addition to the placenta, “pituitary” hormones are synthesized and released from other tissue in the fetal body (Fig. 9.10). One example of this phenomenon is the synthesis and release of POMC and POMC-related peptides by the neuroendocrine cells of the fetal lung. It has been proposed that POMC secreted by the lung might play a role in stress responsiveness, or in the timing of parturition, by altering

Key points

- 1 The fetal hypothalamus–pituitary–adrenal axis controls estrogen biosynthesis by the placenta in late gestation.
- 2 The fetal hypothalamus–pituitary–gonadal axis is a more effective controller of circulating sex steroids at mid-gestation than in late gestation.
- 3 Various hormones in fetal blood, including glucocorticoids and thyroid hormones, are either activated or inactivated at the target tissue.
- 4 The placenta synthesizes and secretes various hormones that have been proposed to modulate the activity of fetal endocrine axes.
- 5 The adrenal medulla actively secretes catecholamines and plays an important role in the fetal response to stress; however, innervation by sympathetic preganglionic nerves does not occur until late in gestation.
- 6 The posterior pituitary of the fetus actively secretes both vasopressin and oxytocin. Vasopressin plays an important role in fluid balance and blood pressure control prenatally.
- 7 Ectopic hormones, secreted by the lung and other visceral tissues, may play important roles in parturition and in other integrated physiologic processes.

adrenal sensitivity to circulating ACTH (Fig. 9.10). It is interesting that these cells, after transformation, form the basis of small cell carcinoma of the lung, a disease in which significant secretions of POMC and ACTH can produce symptoms of hyperadrenocorticism in the adult. The neuroendocrine cells of the lung synthesize many hormones in addition to POMC, such as vasoactive intestinal polypeptide (VIP) and serotonin.

Fetal hematopoiesis

Details of hematopoiesis in the newborn are well known but, because of the difficulties encountered in sampling, such is not the case with the fetus.

Blood cells are of mesenchymal origin. The mesenchyme, which stems from the cytotrophoblast surrounding the egg, forms the inner layers of the chorion and surrounds the unit created by the amniotic cavity, the embryonic button, and the yolk sac. The reunion of these two mesenchymal blades forms an embryonic film. When the first vascular elements appear, the conceptus is wholly embedded in the inner mucosa (Fig. 10.1).

First stage: mesoblastic hematopoiesis of the yolk sac

On day 19 of pregnancy, the first blood cells outside the embryo become apparent in the many vascular islets that appear in the mesenchymal wall of the yolk sac. These islets appear as dark lumps of cells. Two systems – the vascular and the hematopoietic – originate from the islets: the peripheral cells of these lumps constitute the original endothelium of the developing vascular system. Some central cells of these islets leave the vascular walls, become free in the lumen, and form the primitive blood cells, or hematocytoblasts. These cells remain nucleated throughout their functional lives. The primitive erythroblasts, or pronormoblasts, stem directly from the hematocytoblasts. The separate islets gradually connect to each other to form an irregular network enveloping the yolk sac, which will give rise to the vitelline vessels.

Toward day 22 of pregnancy, similar vascular islets begin to appear in the mesenchyme of the chorion and all along the allantoic pedicle. These vascular islets create an extraembryonic network, the chorioallantoic network, which constitutes the future umbilical vessels. In both cases, hematopoiesis is intravascular; the two vascular networks connect to the vessels formed in the embryo at a later stage. Between 6 and 8 weeks'

gestation, the vascular islets begin to regress, as does the intravascular hematopoiesis, with its large, nucleated megakaryoblasts. The first-generation erythropoietic cells disappear completely from the embryoplacental circulation at between 12 and 15 weeks' gestation.

The role of the yolk sac seems to be primary. Although the chorion's mesenchyme proves to be quantitatively greater than that of the yolk sac (which means, in theory, a greater participation in hematopoiesis), the cells of the vascular islets in the wall of the yolk sac remain undifferentiated until the fourth week. In contrast, everywhere else, the primitive vessels already contain erythroblasts.

Second stage: visceral hematopoiesis

Visceral hematopoiesis begins in the liver around 5–6 weeks' gestation and appears to reach an adequate development around 9 weeks. Nests of hematopoiesis appear in the liver sinusoids and increase rapidly. Hematopoiesis becomes extravascular. Clear morphologic differences exist between the cells formed in the liver and the earlier lineages of the yolk sac. The cells originating in the liver are smaller, and their nuclear structure is nearer the normoblast lineage of erythrocytic precursors. These are few in number when they appear in the blood around 5 weeks, becoming predominant between 8 and 9 weeks' gestation (Fig. 10.2).

Although granulocytes and platelets are found in the circulation, the fetal liver seems to be the seat of an almost pure hematopoiesis. From the third to the fifth months of pregnancy, the erythrocytic precursors represent approximately 50% of the liver's nucleated cells.

From 9 to 12 weeks, some hematopoietic activity also can be observed in the thymus, the lymph nodes, and the kidneys. Nucleated red corpuscles are also observed in the spleen.

Their presence has been interpreted in different ways. Some people think that it corresponds to local production as well as sequestration and destruction; others think it is nothing but sequestration at different stages of degeneration. In any case, the role of splenic nucleated red corpuscles is only accessory

in the human fetus. As for the yolk sac, it appears to be entirely fibrous at 11 weeks of pregnancy.

We have not been able to detect any erythrocytic activity elsewhere. Visceral, mainly hepatic, hematopoiesis reaches its highest level of production around the fifth and sixth months, gradually regressing until delivery. Visceral hematopoiesis can still be observed during the first week of postnatal life in the liver and occasionally even in the spleen.

Although it disappears almost entirely under normal conditions, extramedullary hematopoiesis is apt to increase notice-

ably in a large variety of diseases and infections in the fetus as well as in the newborn.

Third stage: medullary hematopoiesis

Medullary hematopoiesis begins at about the fourth month. Medullary spaces develop in cartilaginous portions of the long bones by a resorptive process. Toward the fifth month, medullary cellularity is still poor and predominantly leukopoietic. The erythropoietic tissues multiply rapidly, and the marrow reaches its maximal cellularity toward 30 weeks' gestation, with each lineage being adequately represented. However, the volume of marrow occupied by the hematopoietic tissue continues to rise until full term. During the last 3 months of pregnancy, the marrow is the privileged seat of blood cell formation, the whole expanding medullary space being occupied by active hematopoietic tissues. The marrow's relative volume in the fetus and the newborn, however, is smaller than that in the grown child or the adult because a large part of the fetal skeleton is cartilaginous and the bones are comparatively small.

Nonerythroid lineage

Leukocytes first develop in the wall of the yolk sac, then in the embryo. Very few circulating granulocytes are found during the first weeks of fetal life. At 8 weeks of pregnancy, some myelocytes are observed, but mature polymorphonuclear leukocytes do not appear until around 12 weeks. The circulating rate remains at less than 1000 elements/ μ L during the whole of the earlier part of pregnancy and does not increase significantly until the myeloid stage of hematopoiesis; it then increases rapidly until 28 weeks.

Lymphopoiesis begins in the lymphoid plexuses toward the eighth week and spreads first to the thymus, in the ninth week, and then to the lymph nodes from the third month on. After

Figure 10.2 Ontogenesis of the chains of hemoglobins and erythropoiesis.

they have begun to appear, the circulating lymphocytes increase rapidly, reaching a peak of 10 000 elements/ μL at 20 weeks. The level then decreases gradually to 3000 elements/ μL at birth. The megakaryocytes can be found in the wall of the yolk sac between 5 and 6 weeks and then in the liver after the visceral stage of hematopoiesis has begun. They persist there until the end of pregnancy and can be found in significant quantities in the marrow after the third month. Platelets are found in the blood from 11 weeks' gestation and, after 18 weeks, they exist in numbers equal to those in adult blood.

Origin and differentiation of the hematopoietic cells

For years, a controversy raged between the supporters of a unitary thesis and those of a pluricellular origin of the different hematopoietic lineages. The current opinion – based on experiments in animals, on clinical data in human pathology and, more recently, on the culture of hematopoietic cells from healthy subjects – is that there exists a pluripotent stem cell, the colony-forming unit, from which the various lineages stem. This pluripotent stem cell, which cannot be morphologically identified by maturation criteria, is capable of differentiation and self-renewal. It is the precursor of the erythroid, myeloid, and lymphoid lineages, and its existence was confirmed through the technique of splenic lineages described by Iscove et al.¹ We now distinguish a second generation of stem cells with a restricted differentiation potential in either the lymphoid lineage or the myeloid lineage, but their capacity for self-renewal persists. The stem cells are present in the marrow and the blood.

Kelemen et al., in their *Atlas of human haemopoietic development*,² suggest the following pattern. Everything stems from a pool of stem cells appearing on the mesenchymal wall of the yolk sac. It is the function of these first-generation intravascular stem cells, after the vascular intra- and extraembryonic networks are linked, to migrate into the embryo and multiply there. Moore and Metcalf³ demonstrated the necessity of this first migration. No hematopoiesis occurs in an embryo that has been prematurely separated from its yolk sac. The seeding of the liver gives birth to a stem cell, called a *second-generation stem cell*, which is smaller than the first and nearer to the normoblastic lineage. These pluripotent cells proliferate in the liver, becoming half as numerous as the liver's nucleated cells. Then, they migrate toward and seed other areas of the embryo (marrow, spleen, lymph nodes, and thymus) as well as the extraembryonic areas. Some vascular islets of the yolk sac especially are colonized by second-generation stem cells (the first-generation cells are short-lived, with a half-life of approximately 8–12 weeks). A third generation of pluripotent cells gives rise to all the blood cells made during pre- and postnatal life. Given what we know at present, it is difficult to speak of well-defined stages, and modification in the population of stem cells is not proved, particularly as concerns the passage from primitive to fetal erythropoiesis. The current theory is that the passage from fetal to adult erythropoiesis

represents a gradual modification of the stem cells rather than a change of population.

Purity of fetal blood samples

Fetal blood sampling under ultrasound guidance is a safe procedure that has enabled us to study fetal biology and to obtain prenatal diagnoses of an increasing variety of disorders.⁴ The first step in establishing reference values and ensuring the accuracy or diagnosis is to be sure that the fetal blood sample is not contaminated.⁵

In our samples of fetal blood, contamination can be caused by maternal blood, amniotic fluid, or sodium citrate solution. The overall incidence of contamination in our study was small (1.8%), but it must be viewed in relation to both the disorder under investigation and the type of contamination.

Each type of contamination has differing consequences, depending on the disorder under investigation. During diagnosis of fetal infection in the presence of maternal infection, contamination with maternal blood causes a false-positive result. The presence of amniotic fluid, which is often collected for culture at the same time, does not affect the results, but the hematologic parameters and specific immunoglobulin M must be evaluated with caution. Similarly, the presence of maternal blood cells in a specimen for investigation of fetal karyotype makes the specimen useless, but amniotic fluid or sodium citrate has negligible effects.

Investigation of disorders of hemostasis (platelets or coagulation factors) is severely affected by amniotic fluid contamination because amniotic fluid activates some coagulation factors and can cause platelet aggregation.

We evaluated the sensitivity of each method and measured dilutions of maternal blood, amniotic fluid, and sodium citrate. We believe that each test must be done in all cases because results differ under various conditions.

Depending on the gestational age and the indication for fetal blood sampling, we collect 2–3 mL of blood. This is divided into 500 μL anticoagulated in lyophilized ethylene-diamine tetraacetic acid [EDTA] K_2 (Sarstedt reference 32332)], 400 μL collected in 0.129 mol/L sodium citrate solution (ratio 9:n) and, if karyotype is required, 500 μL drawn into a lithium heparin dry mixture. The remaining blood is not anticoagulated.

Hematologic indexes are determined with a Coulter Counter MD II. Leukocytes, erythrocytes, platelets, hemoglobin, hematocrit, and mean corpuscular volume are measured immediately after sampling. The distributions of the volumes of leukocytes, erythrocytes, and platelets are shown in Figs 10.3 and 10.4.

Smears are obtained after leukoconcentration and stained with the May–Grünwald–Giemsa stain for the differential count. The Kleihauer–Betke test to differentiate fetal from adult red cells is performed with the Boehringer kit.

Figure 10.3 Histograms of fetal white blood cell (WBC), red blood cell (RBC), and platelet (PLT) distribution curves.

Figure 10.4 Histograms of maternal white blood cell (WBC), red blood cell (RBC), and platelet (PLT) distribution curves.

Anti-I and anti-i cold agglutinins (against erythrocyte antigens), which are active at room temperature, are used in appropriate dilution.

The levels of β -subunit of human chorionic gonadotropic hormone (β hCG) in maternal and fetal serum are determined with the enzyme-linked immunosorbent assay method using an anti-J3-hCG monoclonal antibody (Tandem Biotrol, France).

Coagulation factors IX and VIIIc are measured by a single-stage method, as described by Mibashan and colleagues⁶ adapted for automated coagulation testing (KC 10 from

Table 10.1 Fetal hemostasis expressed as a percentage (mean \pm SD) of normal adult value.

Coagulation factor	%	Inhibitor	%

Data from fetuses of 19–27 weeks' gestation.

DADE AHS, Miami, FL, USA). Factor VIII activity is tested against the World Health Organization reference plasma 80/511. Factors II and V are measured by one-stage assay by means of thromboplastin, calcium, and substrate-deficient plasma for both factors II and V. Reference levels are shown in Table 10.1.

The percentage of contamination detectable by each method is determined with fetal blood specimens by means of measured amounts of maternal blood, amniotic fluid, and sodium citrate until minimum detectable contamination is determined.

Each test is performed on all samples. Hematologic indexes are undertaken immediately as an initial screening test before the patient leaves the hospital. It is possible, depending on the clinical circumstances, to repeat the fetal blood sampling, if necessary. No individual test is infallible under all circumstances, and the reliability of each test depends on the clinical situation and the type of contamination. The percentages of contamination detectable by each method are summarized in Table 10.2.

Typical cell size distribution curves for maternal and fetal hematologic indexes are shown in Figs 10.3 and 10.4. Three major differences distinguish maternal from fetal blood. There is only one peak of leukocytes in the fetus (corresponding to lymphocytes and nucleated erythrocytes), the average erythrocyte volume is much higher in the fetus, and red cell distribution width is broader in the fetus.

In leukocytes, there are mainly lymphocytes; granulocytes appear later in pregnancy. Platelet volume is similar in mother and fetus.

In cases of maternal blood contamination, a second peak of leukocytes is usually seen with a larger volume; this peak is the granulocyte peak. The gestational age at the time of sampling must be taken into account because of the change in granulocytes toward term. Contamination of 10% or more by either amniotic fluid or sodium citrate causes a decrease in the

Table 10.2 Percentage of contamination detectable by each method.

Method	Amniotic fluid (%)	Maternal blood (%)	Sodium citrate (%)
Hematologic indexes	20	>5	20
Smear (Giemsa)	10	10	NC
Erythrocyte antigens	NC	15	NC

*Depending on the gestational age.

same ratio compared with the normal range of erythrocytes, leukocytes, and platelets.

The Kleihauer–Betke test relies on detecting differences in hemoglobins present in adult and fetal red cells. In theory, this test should be able to detect a maternal blood contamination of as little as 0.5%. In practice, although the test is rapid and simple to perform, absolutely accurate results are not possible because of the gradual appearance of hemoglobin A in fetal erythrocytes. After staining, erythrocytes containing only hemoglobin A appear as empty “cell ghosts.” Those containing mainly or exclusively hemoglobin F stain darkly, and those with both hemoglobin A and F have an intermediate level of staining. This causes difficulties and technical errors in the differentiation of immature fetal cells from maternal erythrocytes. We have never demonstrated maternal blood contamination by this method after 30 weeks.

Blood smears stained for differential count clearly show amniotic fluid squames if contamination with amniotic fluid has occurred. The presence of the squames depends on both the gestational age at the time of sampling and the percentage of contamination.

Erythrocyte antigen expression differs from fetus to adult. I antigen is present only on adult erythrocytes; i antigen is present only on fetal erythrocytes. Monoclonal antibody agglutination (anti-I and anti-i) is simple to perform and can detect a maternal blood contamination of 5%.

The β hCG is of maternal origin, has a steep gradient across the placenta, and is found in only minute quantities in fetal blood, although higher levels are found in amniotic fluid. The ratio is approximately 1:100:400 (fetal blood to amniotic fluid to maternal blood). It is probably the most sensitive method for determining whether the sample is contaminated, allowing detection of as little as 0.2% maternal blood or 1% amniotic fluid contamination. In practice, if we detect β hCG in fetal serum, the specimen is regarded as contaminated. A markedly elevated level suggests contamination by maternal blood rather than amniotic fluid, but β hCG levels do not allow differentiation between the types of contamination, so other tests must be used for clarification.

Coagulation factors V and VIII detect both amniotic fluid and sodium citrate contamination, but must be interpreted

with caution. Less than 1% contamination with amniotic fluid activates coagulation and falsely increases the activities of factors V and VIII when tested against adult reference plasma. These values need to be compared with vitamin K-dependent factors, such as IX or II, which are not activated by amniotic fluid. In contrast, a large amniotic fluid contamination (greater than 10% and detectable on blood smears) causes lower levels by dilution.

Fetal hematology

Starting from ultrasonically guided fetal blood samplings carried out between 18 and 29 weeks' gestation for various prenatal diagnoses (usually toxoplasmosis), we have been able to determine the reference values of some hematologic parameters in 2860 fetuses.⁷ The subjects' prenatal diagnosis tests were normal, and they were confirmed to be healthy at birth.

Fetal blood was sampled into EDTA tubes, and we worked with a Coulter Counter S Plus II on prediluted samples.

Table 10.3 shows the main hematologic results obtained from 2860 normal fetuses between 18 and 36 weeks of pregnancy. There is no significant increase in the number of platelets (which stays at approximately $250 \times 10^3/\mu\text{l}$). On the contrary, the red blood cell count gradually increases from 2.85 to $3.82 \times 10^6/\mu\text{l}$, and the white blood cell count increases from 4.7 to $7.7 \times 10^3/\mu\text{l}$. The concentration of hemoglobin also increases significantly during the second trimester of pregnancy. Conversely, the mean corpuscular volume decreases significantly from 131.5 to 114 fL.

Fetal cytology

The evolution of the fetal leukocyte differential according to the stage of pregnancy is shown in Table 10.4. Also shown are the distribution of polymorphonuclear leukocytes (neutrophils, eosinophils), monocytes, lymphocytes, and erythroblasts. Two reasons led us to include the erythroblasts in the leukocyte differential, even though they belong to the red cell lineage and not to the white cells: (1) erythroblasts are a normal component of fetal blood; and (2) the nuclei of these

Table 10.3 Evolution of hematologic values of 2860 normal fetuses during pregnancy (mean \pm SD).⁸

Weeks of gestation	WBC ($\times 10^3/\mu\text{L}$)	Platelets ($\times 10^3/\mu\text{L}$)	RBC ($\times 10^6/\mu\text{L}$)	Hb (g/100 mL)	Ht (%)	MCV (fL)
10–17	1.87 \pm 3.42	159 \pm 68	1.81 \pm 0.78	9.92 \pm 2.24	27.4 \pm 7.4	154.9 \pm 26.8

erythroblasts are counted as white blood cells by the Coulter Counter.

First, we found few or no basophils in the fetus. Second, a very high lymphocytosis was present from 18 weeks' gestation, along with erythroblastosis. The percentage of lymphocytes decreases from 88% at 18 weeks to 68.5% by 30 weeks, and the erythroblast percentage gradually decreases from 45% at 18 weeks to 17% at 30 weeks. This reduction in the number of erythroblasts is made up for by a gradual increase in neutrophils as fetal life advances, from 6% at 18 weeks to 23% at 30 weeks.

The importance of this evolution of the fetal differential is threefold. First, we have been able retrospectively to establish reference values related to different stages of pregnancy. Second, the blood differential is an extremely useful tool to check the purity of fetal blood. For instance, blood that contains no erythroblasts at 18 weeks, or 40% neutrophils at 20 weeks, could have been contaminated by maternal blood or by blood of placental origin. Third, we have noticed that the fetal differential varies greatly in cases of parasitic (toxoplasmosis) or viral (rubella) infections.

Fetal red blood cell antigens

We compared 72 samples of fetal blood ranging from 20 to 25 weeks of pregnancy with samples of full-term neonates (cord blood) and adults. We tested 38 red blood cell antigens, using specific antibodies:

- Polymorphic antigens: A, A₁, B, D, C, C^w, c, E, e, K, k, Kp^a, Fy^a, Fy^b, JK^a, JK^b, M, N, S, s, Lu^a, Lu^b, Le^a, Le^b, P₁, Xg^a.

- Monomorphic antigens: H, Rh17, Kp^b, Js^b, Fy³, Jk³, P, I, i, Ve^a, Ge^a, Emma.

Among these 38 antigens, identical reactions were observed in fetus, newborn, and adult, except for A, A₁, B, H, Le^a, Le^b, Lu^a, Lu^b, P₁, P, I, and i.

Table 10.5 shows that some antigens are not expressed or have hardly developed in fetuses. Test results on newborns show an intermediate expression between the fetal and adult periods.

Fetal platelet antigens

From 18 to 29 weeks, the number of platelets remains stable at around $250 \times 10^3/\mu\text{L}$. On stained blood smears (with May–Grünwald–Giemsa), fetal platelets present no particular cytologic differences from adult platelets. Fetal platelets aggregate with adenosine triphosphate (ADP), thrombin, ristocetine, collagen, arachidonic acid, but not with epinephrine.

The study of the glycoproteins of platelet membranes has made it possible to identify glycoproteins Ib, IIa/b, IIIa/b, with molecular weights of 160, 134, and 90 Da. The PLA₁ antigen is present, which explains the risk of fetal anti-PLA alloimmunization as early as the first trimester of pregnancy.

Working in cooperation with Y. Gruel, we have been able to quantify HPA-1a (PLA1a) and HPA-3a (LeK_a or Bak a) antigens, as well as the membrane glycoproteins, from 16 weeks (Table 10.6).⁸

Quantification of glycoproteins GPIIb/IIIa is similar in fetus and adult; antibody anti-GPIb (AN51) and anti-GPIb (6D1) fixed more easily in fetal platelets than in adult platelets.

Table 10.5 Percentage of reactivity of some red blood cell antigens in adult, neonate (cord), and fetus.

Antigens (%)	A	A ₁	B	H	Le ^a	Le ^b	Lu ^a	Lu ^b	P ₁	P	I	i
Adult	45	35	9	100	20	70	7	100	75	100	100	0
Birth	45	37	12	90	0	4	3	100	38	100	12	100
Fetus	36	0	11	64	0	2	1	99	17	88	0	100

Table 10.6 Platelet antigens in fetus (>16 weeks) and adult expressed as mean fluorescence values (\pm SEM).

Platelets	Immunofluorescence intensity	
	Fetus (mean \pm SD)	Adults (mean \pm SD)
Antigens		
HPA-1a	433.0 \pm 30.0	427 \pm 13.5
HPA-3a	441.5 \pm 25.0	459 \pm 15.0
Glycoproteins		
GPIIb IIIa, IgG	427.0 \pm 23.0	420.0 \pm 30.0
GPIIb IIIa, AP-2	459.5 \pm 23.0	498.0 \pm 11.0
GPIIIa, AP-3	536.0 \pm 14.0	515.0 \pm 13.0
GPIb, AN-51	491.5 \pm 14.0	426.5 \pm 9.0
GPIb, 6D1	479.0 \pm 15.0	443.0 \pm 8.7

SD, standard deviation; SEM, standard error of the mean.

Prenatal diagnostic of Glanzmann thrombasthenia (GPIIb/IIIa) or Bernard–Soulier syndrome (GPIb) is now available early in pregnancy.

Lymphocyte subpopulation

Lymphocyte count

Leukocytes are numbered while the Coulter S Plus II monitors the purity of fetal blood. The absolute number of lymphocytes is observed from the leukocyte differential performed on a blood smear stained by May–Grünwald–Giemsa stain.

Separation of the mononucleated cells

Separation of the mononucleated cells is carried out by differential centrifugation in a density gradient.

Lymphocyte phenotype

The development of hybridization techniques now permits the production of commercialized monoclonal antibodies and provides the means of investigating lymphocyte subpopulations.

The main markers of lymphocyte differentiation, as currently defined, have been characterized using Coulter monoclonal antibodies labeled with fluorescein isothiocyanate. Detection was carried out by direct or indirect immunofluorescence. It proved necessary to implement a micromethod, considering the reduced volume of fetal blood.

The following monoclonal antibodies were used:

- Coulter Clone T11 – specific for the receptor of T lymphocytes for the sheep erythrocytes and associated with an antigen that is 50 000 Da in molecular mass.
- Coulter Clone T₃ – specific for an antigen T₃ (30 000 Da in molecular mass). This antigen is present in the mature T lymphocytes of peripheral blood and on 20–30% of thymocytes.
- Coulter Clone T4 – specific for an antigen of 64 000 Da molecular mass, present on 80% of thymocytes and 60% of circulating T lymphocytes. It is associated with T lymphocytes whose target is an antigen belonging to the major system of class II histocompatibility. This antigen is stable and is not lost during T-cell activation.
- Coulter Clone T8 – specific for an antigen present in the suppressive and cytotoxic T subpopulations; it is 33 000 Da in molecular mass in its reduced state, 76 000 Da in its nonreduced state. This antigen can be found on 80% of human thymocytes and on approximately 35% of the T lymphocytes of peripheral blood.
- Coulter Clone B1 – specific for an antigen of human B lymphocytes, 35 000 Da in molecular mass. This antigen is found in the B cells of peripheral blood, of the lymphoid organs, and of bone marrow.
- Coulter Clone B₄ – specific for an antigen that is bimolecular in structure, 40 000 and 80 000 Da in molecular mass. It is expressed by the normal B lymphocytes and is present in all isolated B cells. Antigen B₄ seems to be the first antigen associated with B cells that can be detected in fetal tissues.
- E 135 – monomorphic anti-DR, kindly provided by Professor Charron (Pitié-Salpêtrière).
- Leu₇, Leu11 (Becton) – antibodies that recognize the natural killer (NK) cytotoxic cells of peripheral blood and some granulocytes. Antibody NKH1A recognizes all the cells with NK activity; anti-NKH₂ determines a population of large-grained lymphocytes with poor cytotoxic activity.
- Coulter Clone My 4 – recognizes macrophages and some granulocytes.

Results

The following is an outline of the results:

1 Lymphocyte count:

- Fetal blood (20–26 weeks of amenorrhea): $3.8 \pm 0.9 \times 10^3/\mu\text{L}$.
- Cord blood at birth: $7.1 \pm 2.3 \times 10^3/\mu\text{L}$.
- Adult blood: $2.5 \pm 0.95 \times 10^3/\mu\text{L}$.

2 Phenotyping of lymphocyte subpopulations: T-lymphocyte phenotyping is presented in Table 10.7; B-lymphocyte phenotyping is presented in Table 10.8.

The percentages of circulating mononucleated cells recognized by the Leu₁₁, NKH₁A, NKH₂ antibodies are, respectively, $21\% \pm 7\%$, $5.8\% \pm 2.3\%$, $2.5\% \pm 1.5\%$ in the fetus between 20 and 26 weeks of gestation and $13\% \pm 5\%$,

$12\% \pm 3\%$, $5\% \pm 1.5\%$ in the adult. Of fetal circulating nucleated cells, $10\% \pm 3\%$ react with Coulter Clone MY4.

The study of lymphocytes subpopulations is interesting in cases of maternofetal infection. T4/T8 is decreased in infected fetuses (toxoplasmosis or cytomegalovirus), and CD3 lymphocytes count is increased in mothers and fetus when infection is certain.

Table 10.7 Evolution of T-lymphocyte subpopulations in fetal blood, cord blood at birth, and adult, expressed as a percentage of the absolute number of lymphocytes (mean \pm SD).

Key points

- 1 Mesoblastic hematopoiesis of the yolk sac is the first stage of embryonic hematopoiesis and appears on day 19 of pregnancy.
- 2 Visceral hematopoiesis is the second stage of embryonic hematopoiesis, begins in the liver sinusoids around 5–6 weeks' gestation, and increases rapidly.
- 3 Although granulocytes and platelets are found in the circulation, the fetal liver seems to be the seat of an almost pure hematopoiesis. From the third to the fifth months of pregnancy, the erythrocytic precursors represent approximately 50% of the liver's nucleated cells.
- 4 From 9 to 12 weeks, some hematopoietic activity can also be observed in the thymus, the lymph nodes, the kidneys, and even in the spleen.
- 5 Visceral, mainly hepatic, hematopoiesis reaches its highest level of production around the fifth and sixth months, gradually regressing until delivery. Visceral hematopoiesis can still be observed during the first week of postnatal life in the liver and occasionally even in the spleen.
- 6 Medullary hematopoiesis begins about the fourth month and is initially predominantly leukopoietic. The erythropoietic tissues multiply rapidly, and the marrow reaches its maximal cellularity toward 30 weeks' gestation, with each lineage being adequately represented.
- 7 Leukocytes first develop in the wall of the yolk sac, then in the embryo. Very few circulating granulocytes are found during the first weeks of fetal life.
- 8 Platelets are found in the blood from 11 weeks' gestation, and, after 18 weeks, they exist in numbers equal to those in adult blood.
- 9 The current opinion is that there exists a pluripotent stem cell, the colony-forming unit, from which the various lineages stem. This pluripotent stem cell, which cannot be morphologically identified by maturation criteria, is capable of differentiation and self-renewal.
- 10 Investigation of disorders of hemostasis in fetal blood samplings (platelets or coagulation factors) is severely affected by amniotic fluid contamination because

amniotic fluid activates some coagulation factors and can cause platelet aggregation.

- 11 Three major differences distinguish maternal from fetal blood. There is only one peak of leukocytes in the fetus (corresponding to lymphocytes and nucleated erythrocytes), the average erythrocyte volume is much higher in the fetus, and red cell distribution width is broader in the fetus.
- 12 In leukocytes, there are mainly lymphocytes; granulocytes appear later in pregnancy. In cases of maternal blood contamination, a second peak of leukocytes is usually seen with a larger volume; this peak is the granulocyte peak.
- 13 Fetal blood sampling under ultrasound guidance is a safe procedure to study fetal biology and to obtain prenatal diagnoses of an increasing variety of disorders. The first step in establishing reference values and ensuring the accuracy of diagnosis is to be sure that the fetal blood sample is not contaminated, by detection of β hCG in fetal serum or erythrocyte antigen expression that differs from fetus to adult.
- 14 Fetal blood sampling contamination can be caused by maternal blood, amniotic fluid, or sodium citrate solution.
- 15 The red blood cell count gradually increases from 2.85 to $3.82 \times 10.6/\mu\text{L}$. The concentration of hemoglobin also increases significantly during the second trimester of pregnancy. Conversely, the mean corpuscular volume decreases significantly from 131.5 to 114fL .
- 16 The evolution of the fetal leukocyte differential according to the stage of pregnancy shows that there are few or no basophils in the fetus. A very high lymphocytosis is present from 18 weeks' gestation along with erythroblastosis, decreasing to 30 weeks.
- 17 Quantification of platelet glycoproteins GPIIb/IIIa is similar in fetus and adult; antibody anti-GPIa AN51) and anti GP-Ib (6D1) fix more easily in fetal platelets than in adult platelets.
- 18 The study of lymphocyte subpopulations is interesting in cases of maternofetal infection. T4/T8 is decreased in infected fetuses (toxoplasmosis or cytomegalovirus), and CD3 lymphocyte count is increased in mothers and fetus when infection is certain.

Variations in Embryonal and Fetal Growth and Development

Sporadic and recurrent pregnancy loss

Robert M. Silver and D. Ware Branch

Pregnancy loss is one of the most common medical problems in reproductive-aged couples, with as many as 25% of all women attempting pregnancy experiencing at least one spontaneous abortion. A miscarriage is an emotional event for most individuals, and physicians are often called on to provide insight and counseling. An estimated 0.5–1.0% of couples attempting pregnancy suffer three or more consecutive losses, and an even higher proportion have two or more consecutive losses. These couples with recurrent pregnancy loss (RPL) are often distraught and sometimes desperate, especially when childbearing has been put off until later in life. Despite the anguish associated with RPL, modern medical science has made surprisingly little progress in identifying causes or devising rational treatments. Some physicians believe there are few cost-effective evaluations and few effective treatments. At the other extreme, “pregnancy loss centers” now exist in many larger metropolitan areas, with personnel claiming special insight into the causes of RPL and offering therapies not universally accepted by mainstream medicine. The truth about RPL may lie somewhere between these two contrasting views. The purpose of this chapter is to review the known and suspected causes and management of sporadic pregnancy loss and RPL.

Terminology and frequency of pregnancy loss in humans

Traditionally, physicians have termed all pregnancy losses before 20 weeks’ gestation, *abortions*, and death *in utero* thereafter, as a *stillbirth* or *fetal death*. Advances in reproductive biology indicate that this classification is arbitrary, inconsistent with embryonic and fetal development, and not clinically useful. A more worthwhile approach is to classify pregnancy loss in terms of developmental stages of gestation. The *pre-embryonic* period lasts from conception to approximately 5 weeks after the first day of the last menstrual period. The *embryonic* period begins at 6 weeks and continues through 9 weeks’ gestation. The *fetal* period begins at 10

weeks’ gestation, or 70 days from the last menstrual period, and extends through pregnancy until delivery. Thus, from the perspective of a developmental biologist, pregnancy loss may be categorized as *pre-embryonic (anembryonic)*, *embryonic*, or *fetal*.

Fifty percent or more of human pregnancies are lost before term.¹ The majority are unrecognized pregnancy losses occurring before or with the expected next menses.² Approximately 10–12% of all clinically recognized pregnancies are lost as first-trimester or early second-trimester spontaneous abortions. The rate of fetal death after 14 weeks’ gestation is much lower than the rate of pre-embryonic and embryonic loss. If neonatal deaths due to prematurity or malformations are excluded, less than 5% of all pregnancies are lost between early second trimester and term.^{3–6} The rate of pregnancy loss is greatly influenced by a patient’s past obstetric history.⁷ Both spontaneous abortion and fetal death are more likely to occur among women with previous pregnancy losses, and less likely to occur in those with prior live births.

The vast majority of pregnancy losses are *sporadic* in nature (i.e., they occur as an isolated event in a woman whose other pregnancies are successful). *Recurrent* miscarriage, traditionally defined as the loss of three or more consecutive pregnancies, occurs in an estimated 0.5–1.0% of women. Women with two successive early spontaneous abortions have a recurrence risk similar to that of women with three previous losses.^{7–9} Thus, depending on the patient’s age and attitude, investigations into the cause of the recurrent losses may be indicated after two or three successive miscarriages. Some investigators have found that the risk of spontaneous abortion in the subsequent pregnancy increases after four or more successive abortions.¹⁰ The risk of RPL is also increased in couples with prior fetal death as opposed to early pregnancy loss.¹¹

Sporadic pregnancy loss

Sporadic pregnancy loss is perhaps the most common adverse outcome in human reproduction. In the vast majority of

sporadic spontaneous abortions, an etiology is neither readily apparent nor sought. Nonetheless, most couples who suffer a spontaneous abortion feel a sense of loss and seek an explanation.

Causes of sporadic pregnancy loss

Morphological abnormalities

Abnormalities of growth and development are the immediate cause of most pre-embryonic pregnancy losses (Table 11.1). One-half of pre-implantation conceptuses and one-third of implanted conceptuses are morphologically abnormal.¹² Many of these conceptuses are cytogenetically abnormal and are presumably destined to be miscarried around the time of the expected next menses.

Abnormalities of growth and development are also the immediate cause of most recognized pregnancy losses. Nearly one-fifth of specimens from losses occurring in the first half of pregnancy, and one-third of those occurring at 8 weeks' gestation or earlier, are anembryonic (i.e., the abortus specimen consists of an intact or ruptured gestational sac with no apparent embryo, yolk sac, or umbilical cord).¹² Approximately 35% of women presenting with symptoms of spontaneous abortion have an empty gestational sac or a gestational sac with only a yolk sac present.¹³ It is likely that such cases of "blighted ovum" or "anembryonic pregnancy" failed during the pre-embryonic or early embryonic period.

Identifiable embryos or fetuses are found in 50–60% of first-trimester or early second-trimester abortus specimens, but only one-half of these are morphologically normal.¹² The remainder exhibit disorganized growth (25%), are growth impaired (15%), or are too macerated for examination. Ultrasonographic data are consistent with these morphologi-

cal observations. Fifty percent of women presenting with symptoms of spontaneous abortion who undergo ultrasonographic examination have a dead embryo.¹³ Because failure of growth and death of the conceptus commonly precedes physically evident spontaneous abortion by one or more weeks, the gestational age at which the abortion is recognized does not necessarily indicate when pregnancy failure occurred.

Interestingly, spontaneous pregnancy loss appears to be biphasic in distribution. Using transvaginal ultrasound, Goldstein⁶ found that 13.4% of 232 women with apparently normal early pregnancies had a pregnancy loss. A total of 87% of the losses (12% of all pregnancies) occurred before 10 weeks' gestation, and all embryos that were alive at 8.5 weeks' gestation survived beyond 14 weeks. Thirteen percent of the losses (1–2% of all pregnancies) occurred from 14 to 20 weeks' gestation. Similarly, Simpson and colleagues¹⁴ reported in 1987 that only 3.2% of normal women with a live embryo seen at 8 weeks' gestation eventually suffered a pregnancy loss, and all losses occurred in the period between 10.5 and 16 weeks' gestation. Thus, embryos surviving to 8 weeks' gestation have a very low mortality rate during the next few weeks. The overall rate of pregnancy loss rises again in the early fetal period. The subsequent pregnancy loss rate is only 1% if a live fetus is seen at 14–16 weeks' gestation.¹⁴

Cytogenetic abnormalities

Overall, approximately 50% of sporadic spontaneous abortions are cytogenetically abnormal.^{15,16} Chromosome abnormalities are present in more than 90% of anembryonic abortus tissues,¹² two-thirds of malformed or growth-disorganized embryos, and one-third of malformed fetuses.¹⁷ Approximately 60% of karyotypic abnormalities in early pregnancy losses are autosomal trisomies, 20% are polyploid, and 20% are monosomy X (Table 11.2).

The autosomal trisomies found in spontaneous abortions arise *de novo* as a result of meiotic nondisjunction during gametogenesis in parents with normal karyotypes. Except for trisomy 1, all chromosomal trisomies have been reported in abortus material. The single most common trisomy seen in spontaneous abortion is trisomy 16, accounting for 20–30% of all abortus trisomies. Some autosomal trisomies are seen only in spontaneous abortions (e.g., trisomies 2, 15, 16, and 22) or very early induced abortions, whereas trisomies 13, 18, and 21 are found in spontaneous abortions and also occur in live births. The rate of chromosomally abnormal abortions increases with increasing maternal age because of an increase in the rate of trisomy abortuses.¹⁸ However, the rate of abortions with polyploidy or monosomy X decreases with increasing maternal age.

The proportion of karyotypically abnormal abortuses drops from a high of approximately 50% at 8–11 weeks' gestation to approximately 30% at 16–19 weeks' gestation according to some reports.¹⁶ However, one group of investigators noted that very early first-trimester losses (less than 8 weeks' gesta-

tion) were less likely to be karyotypically abnormal than abortuses from more advanced gestations.¹⁵ The discrepancy in these findings may be due to selection bias.

Traditional cytogenetic analysis involves metaphase analysis of successfully cultured cells. However, culture failure is common with cells obtained from products of conception, occurring in up to 40% of cases.¹⁹ This problem can be circumvented with the use of comparative genomic hybridization (CGH), a molecular genetic technique that allows for the identification of differences in copy number among chromosome regions. Indeed, CGH has been successfully used to determine karyotype in several cases of culture failure after pregnancy loss.^{20,21} The technique can even be used in cells obtained from macerated tissues or stored tissue blocks.

Medical and hormonal disorders

Diabetes and thyroid abnormalities have been associated with sporadic pregnancy loss. However, only poorly controlled diabetes, as indicated by an elevated glycosylated hemoglobin, is associated with first-trimester or early second-trimester pregnancy loss.²² Several groups of investigators have shown that women with antithyroid antibodies detected early in pregnancy have increased rates of first- or early second-trimester loss.^{23,24} Most of the affected women do not have biochemical evidence of thyroid disease, and virtually none has clinically apparent disease. It is uncertain whether or not the presence of antithyroid antibodies is specific for pregnancy loss or is simply a marker for an underlying autoimmune disorder also linked to pregnancy loss. Regardless, assessment of thyroid function or antithyroid antibodies is *not recommended* for sporadic pregnancy loss.

Infections

Case reports indicate that infections are a rare cause of some first- or early second-trimester pregnancy losses. Infectious agents such as *Treponema pallidum*,²⁵ *Borrelia burgdorferi*,²⁶ and *Listeria monocytogenes*²⁷ have been identified in first- or early second-trimester miscarriage specimens. *Chlamydia trachomatis* does not appear to be a cause of sporadic abortion.^{28,29} Although some data suggest that mycoplasmas and ureaplasmas may be associated with spontaneous abortion,^{30,31} these organisms are present in up to 70% of healthy women. Thus, screening for these organisms in women with sporadic abortion is not advised. Other organisms such as group B streptococcus, bacterial vaginosis, parvovirus, herpes simplex virus, *Toxoplasma gondii*, etc. have been linked to second- and third-trimester pregnancy loss.³² However, they are rarely associated with early losses and routine assessment is not recommended.

Other causes of sporadic early pregnancy loss

Certain drugs and chemical agents, ethanol, coffee, and cigarette smoking have been proposed as causes of sporadic early pregnancy loss. Drugs and chemicals that may cause early pregnancy loss include anesthetic gases, chloroquine, oral

hypoglycemic agents, arsenic, heavy metals, and some industrial organic chemicals. It is questionable, however, as to whether any of these is an abortifacient at typical levels of exposure. Antineoplastic agents, such as aminopterin and methotrexate, may cause miscarriage at therapeutic doses. The contention that exposure to video display terminals for more than 20 h per week is related to miscarriage has been refuted.^{33,34}

Effect of maternal age, parity, and prior pregnancy outcomes

Sporadic spontaneous abortion is influenced by maternal age and parity. In a cross-sectional study of women in a large healthcare plan,³⁵ investigators found that the ratio of observed versus expected cases of first-trimester abortion was higher in women younger than 18, lower in women aged 20–35, and rose sharply after age 35. Stein and coauthors³⁶ found that the overall spontaneous abortion rate was constant until women were in their mid-30s, when it started to rise. The rate of rise increased dramatically at about age 35. Significantly, most of the increase in the rate of spontaneous abortion in older women is not due to an increase in the rate of chromosomally abnormal conceptions.³⁶ The rate of second-trimester (fetal) loss follows a pattern similar to that of early pregnancy loss, but the increased rate seen in older gravidas begins at age 30.³⁵ Fretts and Usher³⁷ showed that approximately 1 in 440 births among women age 35 or older end in unexplained fetal death, a rate more than double that of younger women.

Several investigators have found a direct relationship between gravidity and crude abortion rates, with a noticeable increase after the second pregnancy.^{7,8,38,39} These findings are widely considered to be influenced by two factors. First, in modern Western society the third pregnancy and beyond are likely to occur in older women, allowing maternal age to influence the abortion rate. Second, because the average number of desired children in most Western countries is two, many women undertaking a third pregnancy will have experienced pregnancy loss in their prior pregnancies. These women are more likely to have another pregnancy loss than women who have never lost a pregnancy.

Women with one or two previously unsuccessful pregnancies are more likely to suffer a spontaneous loss in their next pregnancy than women undertaking a first pregnancy, or women with one or two previous live births and no abortions. The best data are from Regan's Cambridge Early Pregnancy Loss study.⁷ Women with one previous abortion had a recognized abortion rate of 11.5% in their second pregnancy, and women with two previous abortions had an abortion rate of 29.4% in their third pregnancy. By comparison, primigravidas volunteering for the study had a pregnancy loss rate of 5.6%, and women with only live births in the past had an abortion rate of 2.2% in their next pregnancy.

TORCH: toxoplasmosis, and other agents, rubella, cytomegalovirus, herpes simplex.

Fetal death

Clinicians should recognize that the etiologies of late pregnancy loss differ from first-trimester abortions. Potential causes of fetal death include chromosomal abnormalities, fetal malformations, fetal anemia secondary to alloimmunization or fetal–maternal hemorrhage, cord accidents, fetal infections (e.g., syphilis), antiphospholipid syndrome (APS), and heritable thrombophilias. Obstetric disorders such as preeclampsia, abruption, and fetal growth retardation can also lead to fetal death. At present, there is no generally accepted standard evaluation for fetal death. Studies conducted by the Multicenter Stillbirth Collaborative Research Network sponsored by the National Institute of Child Health and Human Development (NICHD) should help to clarify the issue. Meanwhile, Table 11.3 lists our suggested evaluation of patients with fetal death. Amniocentesis should be considered soon after the diagnosis of fetal demise because viable fetal cells can be difficult to obtain from macerated tissues. As CGH becomes more widely available, it will be another option for genetic analysis in cases when culture of live cells is not possible.

Evaluation and management of sporadic pregnancy loss

No specific evaluation of the mother or abortus tissue is indicated in the case of a single pre-embryonic or embryonic loss occurring in an otherwise healthy woman. It may be reassuring to tactfully inform the patient that most sporadic early pregnancy losses are the inevitable consequence of morphological or cytogenetic abnormalities of the conceptus. The clinician should also inform the patient of the high pregnancy success rate after a single spontaneous abortion, taking the

maternal age and past obstetric history into account. Recall that several studies have demonstrated that approximately 80–90% of women experiencing a single early spontaneous abortion deliver a viable live infant in the next pregnancy.^{7,40,41}

Ultrasound in the management of spontaneous abortion

Endovaginal ultrasonography can play an important role in the management of threatened abortion (Table 11.4). Traditional medical thinking holds that a patient with bleeding in the first 10 weeks of pregnancy has an approximately 50% chance of miscarriage. Ultrasonographic studies have shown, however, that the embryo is usually absent or dead at the time of presentation in patients who are destined to miscarry. In contrast, fewer than one-third of live embryos found in women with uterine bleeding before 10 weeks' gestation will abort.

Precise knowledge of gestational age can facilitate the interpretation of ultrasonographic findings in women with threat-

ened abortion. Ultrasound findings are unreliable at 3–4 weeks' gestation as the uterus usually appears to be empty. At 5–6 weeks, the diagnosis of pregnancy loss is based on yolk sac and gestational sac findings. At 7–8 weeks, gestational sac and embryo findings are germane.

The most reliable gestational sac indicator of impending abortion is abnormal sac size relative to other gestational tissue features. For example, one group of investigators have found that when the mean gestational sac diameter (MSD) minus the embryo crown–rump length (CRL) equals 5 mm or less before 9 weeks' gestation ($MSD - CRL \leq 5$), the likelihood of miscarriage is greater than 80%.⁴² Virtually definitive proof of impending pregnancy loss can be reached with high-resolution (6.25 MHz or greater probe) endovaginal scanning when one sees (1) an MSD of 8 mm or more without a demonstrable yolk sac or (2) an MSD of 16 mm or more without a demonstrable embryo (Fig. 11.1).^{43–45} The use of lower resolution equipment requires modification of these criteria.

Abnormally large yolk sac diameter is also associated with pregnancy loss, although it would be unwise to use this feature alone to diagnose pregnancy loss. As a general rule, large yolk sac diameters (6 mm or greater) are associated with abnormal pregnancies destined to miscarry (Fig. 11.2).⁴⁶

A dead embryo (i.e., without cardiac activity) is definitive for pregnancy failure. As a general rule, the presence of a normal cardiac rate in an embryo is encouraging, but there are three important caveats regarding embryonic cardiac activity. First, normal embryos with a CRL of less than 5 mm may have no ultrasonographically apparent cardiac activity. A diagnosis of embryonic death should not be made in this setting. Second, the earlier in pregnancy that embryonic cardiac activity is detected, the less likely it is to predict a successful pregnancy. Among women presenting with uterine bleeding and found to have a live embryo with a CRL of less than 5 mm, the rate of abortion is approximately 30%. After 7 weeks' gestation (CRL approx-

Table 11.4 Sonographic criteria for pregnancy loss.

Criteria diagnostic of pregnancy loss

Figure 11.2 Embryonic demise with a large (≥6 mm) yolk sac.

imately 9.5 mm), the finding of a live embryo in the setting of vaginal bleeding is associated with a 10% miscarriage rate. At 9–11 weeks’ gestation (CRL approximately 23 mm), the finding of a live embryo or fetus is associated with a 3–4% miscarriage rate. Finally, the cardiac rate provides some predictive value as to the likelihood of miscarriage.⁴⁷ At any gestational age, an embryonic heart rate of less than 80 beats per min carries a very poor prognosis. With CRLs of less than 5 mm, cardiac rates of 80–90 beats per min are associated with pregnancy loss in two-thirds of cases, and rates of 90–100 beats per min are associated with losses in one-third of cases. In embryos with a CRL of 5–9 mm, heart rates of less than 100 beats per min are ominous.

Recurrent pregnancy loss

Up to 1% of couples experience three consecutive pregnancy losses, a figure at least two or three times higher than expected based on the observed pregnancy loss rate per pregnancy in the general population. RPL is a particularly difficult clinical problem because no definite etiology is discovered in a substantial proportion of cases. In the face of this emotional and frustrating situation, both physicians and patients may feel the need to perform evaluations for uncertain or unproven “causes” and to try experimental treatments. Table 11.5 presents causes of RPL.

Causes of recurrent pregnancy loss

Genetic abnormalities

Parental structural chromosome abnormalities

In approximately 3–5% of couples with two or more spontaneous losses, one of the partners has a genetically balanced structural chromosome rearrangement.^{48,49} Balanced translo-

cations account for the largest proportion of these karyotypic abnormalities and occur as either reciprocal or robertsonian translocations. In reciprocal translocations, segments are exchanged between two nonhomologous chromosomes. In robertsonian translocations, two acrocentric chromosomes (chromosomes 13 to 15 and 21 to 22) fuse at the centromeric region and lose their short arms. Although the carrier of a balanced translocation is usually phenotypically normal, balanced translocations may cause pregnancy loss because

segregation during meiosis results in gametes with duplication or deficiency of chromosome segments. A chromosome inversion occurs when a segment of the chromosome is reinserted in the reverse order after the chromosome breaks. Inversions may result in pregnancy loss because crossovers between abnormally paired chromatids during meiosis I result in duplications or deficiencies of genetic material.

Phenotypically normal offspring do not exclude the possibility of a balanced chromosome abnormality in a couple with RPL. The recurrence risk for spontaneous abortion in a couple with a parental structural chromosome abnormality is related to many variables, the most important of which is the specific type of abnormality. Some couples may wish to consider a preimplantation genetic diagnosis and all should be offered genetic counseling. Couples with one partner who has a balanced translocation or inversion should be offered prenatal genetic diagnosis because of the increased risk of a karyotypic abnormality.

Numerical chromosome abnormalities of the conceptus

Karyotypes in consecutive abortions suggest that recurrent aneuploidy in the conceptus may be a cause of RPL. In one set of data, the karyotype of the second successive spontaneous abortion was abnormal in nearly 70% of cases in which aneuploidy was found in the first abortus, but in only 20% of cases in which the first abortus was chromosomally normal.⁵⁰ However, this observation may have been due to the age of the mothers rather than to a nonrandom event in predisposed couples.⁵¹

Molecular genetic abnormalities of the conceptus

Since the 1980s, the importance of single gene mutations as a cause of numerous human diseases has been brought to light by the development of techniques for DNA analysis. The question of whether mutations may cause RPL is now pertinent, and the potential mechanisms for such a defect to result in pregnancy loss are innumerable. For example, a mutation in genes critical for trophoblast growth and development, or blood vessel formation, could preclude successful implantation or development. There are many examples of embryonic-lethal mutations in mice but, as yet, none has been found in the human.

Hormonal and metabolic disorders

Luteal phase defect

Removal of progesterone production in early pregnancy (via resection of the corpus luteum) results in spontaneous abortion, and progesterone replacement after removal of the corpus luteum allows the pregnancy to continue. Antiprogesterins, such as RU486, reliably cause pregnancy loss when administered before 7 weeks after the last menstrual period, confirming the necessity of progesterone (and adequate progesterone response) for the maintenance of early pregnancy. Thus, it is no surprise that investigators hypothesized a role for inadequate progesterone production or effect as a cause of

pregnancy loss. Some investigators consider this condition, often referred to as luteal phase defect (LPD), to be a rather common cause of RPL, accounting for approximately 25–40% of cases.^{17,52} Nonetheless, properly controlled trials to prove that LPD is a cause of RPL are lacking.

Many authorities believe that a timed, late-luteal phase, endometrial biopsy taken from the fundal portion of the uterus is the gold standard for diagnosing LPD. The timing of the endometrial biopsy is important; it should be obtained within 3 days of the expected menstrual period. Histological interpretation is compared with the luteal phase day as established by the onset of the next menses (assuming 14 days in a normal luteal phase). The endometrium is considered to be out of phase when the histological dating lags behind the menstrual dating by two or more days. Out-of-phase endometrial histology in a single biopsy is relatively common in normal women.⁵³ For this reason, it is prudent to require that two consecutive endometrial biopsies be out of phase before a diagnosis of LPD is made. Detractors of the endometrial biopsy as a method of diagnosis point out that as many as 50% of normal women have a single endometrial histology suggestive of LPD, and 25% have abnormal biopsy findings in sequential luteal phases.⁵³ Interobserver variation in dating endometrial biopsies further limits the usefulness of the assay. In one series, more than 20% of women would have received different therapy depending on the individual interpreting the results of their endometrial biopsies.⁵⁴ Morphometric analysis of the endometrial biopsy may offer an improvement over histological analysis in the diagnosis of LPD. Using a standardized examination with morphometry, Serle and coauthors⁵⁵ identified a delay in endometrial maturation of more than 2 days in 60% of women with RPL, compared with no delay in any of the control subjects.

It would seem that measuring circulating levels of progesterone or its metabolites would be a reasonable alternative to the endometrial biopsy in the diagnosis of LPD. However, the pulsatile nature of progesterone secretion in the second half of the menstrual cycle results in wide fluctuations in circulating levels and leaves the interpretation of a single progesterone level uncertain. Many investigators use serial (daily) progesterone determinations to diagnose or exclude LPD, and the method has gained wide acceptance among infertility specialists.⁵⁶ In one well-carried out study, progesterone levels on days 1–4 of the luteal phase were compared in women with unexplained infertility and in normal fertile control subjects, and a significantly different pattern of progesterone levels was found in the infertile group.⁵⁷ Similar studies have not been carried out in women with RPL. Given the relative inaccuracies of each method, it is difficult to say whether one is superior to the other.

Notwithstanding the uncertainty as to the relationship between LPD and RPL, various treatments have been used in patients with RPL and LPD. Because most patients with RPL ovulate, it is assumed that inadequate progesterone synthesis in the luteal phase is the cause. A few patients may actually

have a progesterone-resistant endometrium. Although uncontrolled studies suggest that progesterone therapy is beneficial in achieving a successful pregnancy,⁵⁸ several controlled, randomized trials of limited numbers of patients have not confirmed this.⁵⁹ The usual treatment regimen is 25 mg of progesterone, twice a day, beginning on the third day after ovulation and administered by vaginal suppository. A reasonable alternative is 200–400 mg per day of oral micronized progesterone, taken in divided doses. Treatment is often empirical although efficacy is unproven.

Other endocrinological and metabolic disorders

Poorly controlled diabetes mellitus is a recognized cause of sporadic pregnancy loss as well as severe hypothyroidism or severe hyperthyroidism. Case reports suggest that homocystinuria and Wilson's disease are associated with pregnancy loss. However, none of these conditions is likely to present primarily because of RPL and, if they did, they would easily be detected by clinical evaluation. There is no convincing evidence that asymptomatic systemic endocrinological or metabolic disorders are a cause of RPL.^{58,60,61}

Uterine anatomic abnormalities

In total, 10–15% of women with recurrent first-trimester abortions have congenital uterine abnormalities.^{58,60,61} The rate of uterine abnormalities is higher in women with fetal deaths and deliveries of premature infants.⁶² The most common malformations associated with pregnancy loss are variations of the double uterus (bicornuate, septate, didelphys). Severe uterine synechiae (Asherman syndrome) and uterine abnormalities associated with *in utero* exposure to diethylstilbestrol (DES) may also be associated with miscarriage. An association between submucosal leiomyomata and RPL is controversial. Although not proven, pregnancy loss in patients with uterine abnormalities may be due to space constraints or poorly vascularized uterine tissues, which results in inadequate placentation.

Accurate information concerning the risks of uterine abnormalities and pregnancy loss is lacking because reported series do not include a realistic denominator. Only patients presenting for pregnancy loss or infertility are reported. Many women with uterine abnormalities have acceptable reproductive outcomes and would not be included in case series. For example, the overall reproductive performance of women with bicornuate uterus is reasonably good.⁶³ Even in highly selected series, less than one-half of prior pregnancies in women with bicornuate uterus end in abortion or premature delivery.⁶⁴ Indeed, one prospective study of three-dimensional pelvic ultrasound in relatively unselected patients demonstrated much better outcomes in women with uterine abnormalities than had been reported in retrospective cohorts.⁶⁵ Thus, a cautious, circumspect approach is warranted in ascribing pregnancy loss to uterine abnormalities and other causes must be excluded.

Uterine anatomical abnormalities are diagnosed by a variety of imaging techniques. Excellent screening techniques include hysterosalpingogram or sonohysterogram. For the hysterosalpingogram, the uterus should be deflexed using cervical traction so that an *en face* radiograph of the uterus can be obtained. Initially, only a small amount of radiopaque dye should be injected so that subtle defects are not overlooked. Pelvic magnetic resonance imaging (MRI) or hysteroscopy may provide more definitive diagnoses.

The most common congenital abnormalities among women complaining of pregnancy loss or immature delivery are septate uterus and bicornuate uterus (Fig. 11.3), which together account for at least 50% of uterine abnormalities in women with RPL. Women with septate uterus are reported to have previous pregnancy loss rates that vary widely, from approximately 25% to more than 90%.^{64,66,67} Previous pregnancy outcomes in women with septate uterus are generally worse than for women with bicornuate uterus.⁶⁸ The cause of pregnancy loss in women with septate uterus is uncertain, but diminished blood supply to the septum is often cited as a primary problem.

Surgical repair of uterine abnormalities has never been proven to improve outcome in women with RPL in properly designed studies. Nonetheless, dramatically improved outcomes have been reported in case series in women with RPL and septate uteruses undergoing hysteroscopic resection of the septum.^{69,70} Given its low morbidity and cost, we believe hysteroscopic resection of uterine septa should be considered in women with a history of RPL, a single fetal death, or marked preterm delivery. In contrast, the metroplasty required to correct abnormalities such as bicornuate uterus and uterus didelphys is considerably more morbid and expensive. Also, the link between these conditions and RPL is less convincing than for uterine septum. Today, metroplasty is rarely performed as a treatment for RPL and should be reserved for unusual and refractory cases. Treatment of Asherman syndrome or submucosal fibroids is of theoretical benefit in some women with RPL but proof of efficacy is lacking.

Cervical insufficiency (cervical incompetence) is a generally accepted cause of second-trimester loss. Diagnosis is made on clinical grounds (painless dilation of the cervix with passage of the fetus) or via sonogram. The reader is referred to chapter 62 of this book for further discussion.

Infectious causes

It remains controversial as to whether an infectious agent may cause RPL. For an infectious agent to cause multiple pregnancy losses, it would have to establish a chronic infection or colonization that could infect, or at least affect, the gestational tissues in successive pregnancies. No infectious agent has been proven to cause recurrent early pregnancy loss, although case reports and circumstantial evidence raise the possibility. In the absence of additional data, evaluation for infectious causes of RPL is ill advised.

Three or more unexplained early spontaneous abortions
 Premature birth before 34 weeks' gestation (placental insufficiency)
 Unexplained fetal death

Vascular thrombosis

Venous thrombosis
 Arterial thrombosis
 Small vessel thrombosis

Laboratory criteria

Lupus anticoagulant
 Anticardiolipin antibodies (IgG or IgM)
 Medium-high levels (antibodies must be present on two or more occasions at least 6 weeks apart)

From Wilson WA, Gharavi AE, Koike T, et al. International consensus statement on preliminary classification criteria for definite antiphospholipid syndrome: report of an international workshop. *Arthritis Rheum* 1999;42:1309.

*A diagnosis of definite antiphospholipid syndrome requires the presence of at least one of the clinical criteria and one of the laboratory criteria. No limits are placed on the interval between the clinical event and the positive laboratory findings.

Autoimmune causes

Antiphospholipid syndrome (APS) is an autoimmune disorder characterized by the presence of significant levels of antiphospholipid antibodies and one or more clinical features, including pregnancy loss, thrombosis, or autoimmune thrombocytopenia (Table 11.6). This disorder may occur as a secondary condition in patients with underlying autoimmune disease (e.g., systemic lupus erythematosus) or as a primary condition in women with no other recognizable autoimmune disease. Second-trimester fetal death is the most specific type of pregnancy loss associated with APS, but some patients present with recurrent late first-trimester or early second-trimester fetal loss.^{71,72} Overall, 5–20% of women with RPL have detectable antiphospholipid antibodies,^{71–74} but these low levels of antibodies can be found in 5–10% of otherwise normal women. Thus, APS is identified as the cause of pregnancy loss in 5–10% of women with recurrent miscarriage. Women with a previous fetal death^{75–77} and high levels of anticardiolipin IgG antibodies⁷⁷ are at greatest risk of fetal loss in subsequent pregnancies.

The two most well-characterized antiphospholipid antibodies are lupus anticoagulant and anticardiolipin. Lupus anticoagulant (a double misnomer and an unconventional name for an antibody) is reported as present or absent. Anticardiolipin antibody results are reported in semiquantitative terms (negative or low/medium/high positive). Low-positive results are of questionable significance;⁷⁸ patients with APS virtually

Table 11.7 Indications for antiphospholipid antibody testing.

Recurrent spontaneous abortion*
 Unexplained second- or third-trimester fetal death
 Severe preeclampsia before 34 weeks' gestation
 Unexplained venous thrombosis
 Unexplained arterial thrombosis
 Unexplained stroke
 Unexplained transient ischemic attack or amaurosis fugax
 Systemic lupus erythematosus or other connective tissue disease
 Autoimmune thrombocytopenia
 Autoimmune hemolytic anemia
 Livedo reticularis
 Chorea gravidarum
 False-positive serological test for syphilis
 Unexplained prolongation in clotting assay
 Unexplained severe intrauterine growth retardation

*Three or more spontaneous abortions with no more than one live birth.

always have medium- or high-positive results. Several other antiphospholipid antibodies (e.g., antiphosphatidylserine) and antibodies against β -2-glycoprotein-I (an anticoagulant protein that may be the epitope for antiphospholipid antibodies) have been reported to be associated with APS.^{79,80} However, their association with pregnancy loss remains controversial.⁸¹ Thus, we recommend testing for lupus anticoagulant and anticardiolipin antibodies when confirming the diagnosis of APS. Indications for antiphospholipid antibody testing are shown in Table 11.7.

Glucocorticoids, heparin, low-dose aspirin, and intravenous immunoglobulin (IVIG), or combinations of these medications, have been used to treat pregnant women in an attempt to improve pregnancy outcomes among women with APS and pregnancy loss. Direct comparison of these studies is virtually impossible due to differences in patient selection and treatments.⁷⁵ The two most widely used treatment regimens have been (1) a combination of prednisone and low-dose aspirin and (2) heparin, with or without low-dose aspirin. Successful pregnancy outcomes have been reported in approximately 55–85% of treated cases. Although none of these studies included appropriate control subjects and efficacy is uncertain, results of case series have been impressive. Heparin and low-dose aspirin is recommended as first-line therapy because it causes fewer side-effects than prednisone⁸² and may reduce the risk of thrombosis in women with APS. Thromboprophylactic doses appear to be as effective as anticoagulant doses and have fewer side-effects; thus, they are recommended (e.g., 7500 units twice daily). Low-molecular-weight heparins may safely be used instead of unfractionated heparin. Treatment with IVIG has generated considerable enthusiasm because obstetric outcome has been excellent in a handful of treated pregnancies in women with APS who had previously “failed” treatment with heparin or prednisone.^{83,84} However, in a small

Table 11.8 Thrombophilic disorders and risk of pregnancy loss.

Thrombophilic disorder	Prevalence in women with pregnancy loss (%) [*]	Prevalence in control subjects (%)	Risk of pregnancy loss (OR)
Factor V Leiden	8–32	1–10	2–5
Acquired APC resistance (without factor V Leiden)	9–38	0–3	3–4
Prothrombin gene mutation	4–13	1–3	2–9
Antithrombin deficiency	0–2	0–1.4	2–5
Protein C deficiency	6	0–2.5	2–3
Protein S deficiency	5–8	0–0.2	3–40
Hyperhomocysteinemia	17–27	5–16	3–7
Homozygous MTHFR C677T†	5–21	4–20	0.4–3‡
Combined thrombophilia	8–25	1–5	5–14

From ref. 100, with permission.

^{*}Variably defined as first or recurrent early and/or late pregnancy loss.

†5,10-methylenetetrahydrofolate reductase (MTHFR).

‡No significant difference in prevalence or risk in the majority of studies.

randomized trial,⁸⁵ the use of IVIG and heparin was not better than heparin alone, and cannot be recommended as primary therapy in the absence of further study because of its extremely high cost.

Some women with antiphospholipid antibodies have had successful pregnancies without specific medical treatment, but there is no way to identify these patients prospectively. At present, women with APS and a history of second-trimester fetal death or thrombosis should be considered for heparin or heparin and low-dose aspirin treatment,⁷⁶ but the empirical nature of the treatment should be discussed with the patient. The treatment of women with recurrent first-trimester miscarriage and antiphospholipid antibodies, but no history of fetal death or thrombosis, is controversial. Results of well-designed clinical trials are mixed.^{86–88}

Regardless of treatment, one-half of women with APS in one series developed preeclampsia, with more than one-fourth having severe preeclampsia.⁷⁶ Fetal distress requiring delivery developed in more than one-half of cases, and nearly one-third of liveborn infants were small for gestational age. More than one-third of surviving infants were born at, or after, 32 weeks' gestation. Finally, 5% of pregnancies were complicated by maternal thrombosis, including one case of stroke. These high-risk pregnancies demand close maternal and fetal surveillance.

Some investigators have proposed that a subclinical autoimmune condition or conditions might be associated with RPL, and several have found that some women with RPL have detectable antinuclear antibodies (ANAs). However, the proportion of recurrent unexplained miscarriage patients with positive ANAs is not statistically different from that of appropriate control subjects.^{89,90} One group found that ANAs having a titer greater than or equal to 1:80 were more frequent in women with RPL than in normal nonpregnant or pregnant women.⁹¹ Subsequent, untreated pregnancy outcomes were no different in this subset than in other women

with recurrent miscarriage. Other autoantibodies have also been associated with miscarriage (including anti-SS-A, thyroid autoantibodies) and positive results in autoantibody “profiles.” However, these studies were not convincing, or they require confirmation of their significance in women with recurrent miscarriage. Taken together, the data available at present do not support testing women with RPL for ANAs or autoantibodies other than antiphospholipid antibodies.

Thrombophilia

The histological findings of placental infarction, necrosis, and vascular thrombosis (Fig. 11.4) in some cases of pregnancy loss associated with antiphospholipid antibodies have led to the hypothesis that thrombosis in the uteroplacental circulation may lead to placental infarction and fetal death. In turn, these observations have raised the question as to whether other thrombophilic defects (Table 11.8) predispose to fetal loss. Several case series and retrospective studies reported an association between miscarriage,⁹² second-trimester pregnancy loss,⁹³ and stillbirth and deficiencies of the anticoagulant proteins antithrombin III, protein C, and protein S (Fig. 11.5).⁹⁴ Placental infarction was noted in many of these cases. Recurrent pregnancy loss has also been linked to the hypercoagulable state, hyperhomocysteinemia,⁹⁵ and deficiencies in levels of activated factor XII (Hageman factor).⁹⁶

Abnormal factor V resistance to the anticoagulant effects of activated protein C (APC resistance) has been recognized as the predominant cause of venous thrombosis and familial thrombophilia.⁹⁷ It is usually associated with the factor V Leiden mutation in the factor V gene, which is present in approximately 2–8% of the general population in the USA.⁹⁸ The second most common thrombophilia is the G20210A mutation in the prothrombin gene, occurring in 2–3% of the general population.⁹⁹ Numerous case series and retrospective cohort-control studies have linked both the factor V Leiden

Figure 11.4 Placenta demonstrating extensive infarction and vascular thrombosis taken from a pregnancy resulting in second-trimester fetal death in a patient with antiphospholipid syndrome.

Figure 11.5 Overview of hemostasis. Antithrombin III (ATIII) inhibits thrombin and factor Xa, whereas protein C (with protein S as a cofactor) inactivates factor Va and VIIIa. These proteins all inhibit thrombus formation and contribute to the maintenance of vascular patency. ADP, adenosine diphosphate; ADPase, adenosine

diphosphatase; NO, nitric oxide; PGI, prostacyclin. (From Colman RW, Marder VJ, Salzman EW, Hirsh J. Plasma coagulation factors. Chapter 1. In: Colman RW et al., eds. *Hemostasis and thrombosis: basic principles and clinical practice*, 3rd edn. Philadelphia: Lippincott, 1994, with permission.)

and G120210A prothrombin gene mutations to pregnancy loss.^{100,101} In most studies, thrombophilias were more strongly associated with losses after 10 weeks' gestation as opposed to anembryonic or embryonic losses. A recent meta-analysis indicated an odds ratio of 2 for "early" and 7.8 for "late" RPL for women with the factor V Leiden mutation, and an odds ratio of 2.6 for "early" recurrent fetal loss in those with the prothrombin gene mutation.¹⁰¹ Protein S deficiency, but not the methylenetetrahydrofolate mutation associated with hyperhomocysteinemia, protein C deficiency, or antithrombin III deficiency were associated with pregnancy loss in the meta-analysis.¹⁰¹

It is noteworthy that many heritable thrombophilias are common in normal individuals without a history of thrombosis or pregnancy loss.¹⁰⁰ Thus, although retrospective studies (and one prospective cohort)¹⁰² link thrombophilias to pregnancy loss, most individuals with thrombophilias have uncomplicated pregnancies. Indeed, two large prospective cohort studies indicated no association between the factor V Leiden mutation and heritable thrombophilias, and either pregnancy loss or obstetric complications characterized by placental insufficiency.^{103,104} It is clear that thrombophilia alone is insufficient to cause pregnancy loss and such individuals without prior obstetric complications should be reassured.

The association between thrombophilias and pregnancy loss raises the question as to whether thromboprophylaxis may improve outcome in subsequent pregnancies. Several uncontrolled studies report improved outcome in subsequent pregnancies in women with thrombophilias taking thromboprophylactic doses of low-molecular-weight heparin.¹⁰⁰ A recent prospective randomized controlled trial also supports the efficacy of low-molecular-weight heparin in women with thrombophilia and prior pregnancy loss.¹⁰⁵ Out of 80 women taking 40 mg per day of enoxaparin, 69 (86%) had live births compared with 23 out of 80 (29%) taking low-dose aspirin.¹⁰⁵ These data are compelling, but caution is advised regarding the evaluation and treatment of thrombophilias in the setting of RPL. The frequency of thrombophilias in healthy people, the excellent outcome in most women with thrombophilias, and the side-effects and cost of testing and thromboprophylaxis weigh against mass screening and treatment in the absence of additional data from properly designed studies.

Alloimmune causes

The term *alloimmune* refers to immunological differences between individuals of the same species. Allogeneic factors have been proposed as the cause of otherwise unexplained RPL, similar to allograft rejection in organ transplantation. However, there is no direct scientific evidence that alloimmune factors play a role in human pregnancy loss. This concept led to the use of immunological treatments for unexplained RPL, including leukocyte immunization (typically with paternal leukocytes) and IVIG. Although both treatments are still in use, randomized controlled trials failed to demonstrate effi-

cacy.^{106,107} These treatments are expensive, have significant adverse effects, and are not recommended at present.

Psychotherapy

Several authorities have proposed that psychotherapy or a program of emotional support and reassurance can improve pregnancy outcome in women with RPL.^{108–110} Two studies reported successful pregnancies in approximately 85% of women undergoing "tender loving care" compared with only one-third of control subjects.^{109,110} Unfortunately, none of these studies was randomized controlled trials. Nonetheless, couples are likely to benefit emotionally from additional psychological support, as well as medical and ultrasound examinations.

Unexplained recurrent early pregnancy loss

In as many as 55% of couples with RPL, an evaluation that includes parental karyotypes, hysterosalpingography or hysteroscopy, endometrial biopsy, and antiphospholipid antibody testing is negative (Fig. 11.6). Given that an alleged alloimmune cause for RPL is controversial, a substantial majority (approximately 50–75%) of couples with RPL have no diagnosis. Informative and sympathetic counseling appears to serve an important role in this frustrating situation. Livebirth rates ranging from 35% to 85% are commonly reported in couples with unexplained RPL who undertake an untreated subsequent pregnancy,^{108,109,111,112} figures that many couples view as optimistic. Good pregnancy outcomes may be achieved using a sympathetic, "tender loving care" approach in early pregnancy.^{108–110} Other couples may want to consider the experimental therapies outlined above.

Figure 11.6 Causes of recurrent pregnancy loss in 310 women evaluated at the University of Utah. Luteal phase defect (LPD) caused 16% of losses, uterine abnormalities caused 15%, genetic abnormalities caused 5.5%, antiphospholipid syndrome (APS) caused 13%, and 57.5% were unexplained. Seven percent of women with "explained" recurrent pregnancy loss had more than one diagnosis.

Conclusions and recommendations

Recurrent pregnancy loss is often a frustrating clinical problem for patients and physicians. Of the known or suspected causes, only parental karyotype abnormalities, APS, uterine malformations, and cervical incompetence are widely accepted. Except for the use of heparin and low-dose aspirin for the treatment of APS, none of the treatments for RPL has been established as efficacious by properly designed studies. A suggested routine for the evaluation of recurrent early pregnancy loss is shown in Table 11.9.

Table 11.9 Suggested routine evaluation for recurrent early pregnancy loss.

History

Pattern and trimester of pregnancy losses and whether a live embryo or fetus was present
 Exposure to environmental toxins or drugs
 Known gynecologic or obstetric infections
 Clinical features associated with antiphospholipid syndrome
 Genetic relationship between reproductive partners (consanguinity)
 Family history of recurrent miscarriage or syndrome associated with embryonic or fetal loss
 Previous diagnostic tests and treatments

Physical

General physical examination
 Examination of vagina, cervix, and uterus

Tests

Hysterosalpingogram or sonohysterogram
 Luteal phase endometrial biopsy; repeat in the next cycle if abnormal
 Parental karyotypes
 Lupus anticoagulant and anticardiolipin antibodies
 Factor V Leiden mutation
 Prothrombin G20210A mutation
 Other laboratory tests suggested by history and physical examination

Key points

- 1 Pregnancy loss is the most common obstetric complication, affecting up to 25% of women attempting pregnancy.
- 2 In total, 10–14% of clinically recognized pregnancies result in losses.
- 3 Losses before 20 weeks' gestation are referred to as abortions.
- 4 *In utero* death after 20 weeks' gestation is referred to as stillbirth.
- 5 Pre-embryonic losses occur before 6 weeks' gestation. There is an "empty sac" without a discernible embryo. This has previously been referred to as a "blighted ovum."
- 6 Embryonic losses occur between 6 and 10 weeks' gestation. An embryo without cardiac activity is noted on a sonogram.
- 7 Spontaneous pregnancy loss is biphasic in distribution. Most occur before 10 weeks' gestation. The second most common time for pregnancy loss is between 14 and 20 weeks' gestation.
- 8 Approximately 50% of sporadic spontaneous abortions have abnormal karyotypes.
- 9 The most common abnormal karyotypes in abortus specimens are autosomal trisomies.
- 10 The most common trisomy in abortus specimens is trisomy 16.
- 11 Abnormal karyotypes are more common in pregnancy losses occurring early in gestation.
- 12 Diabetes and thyroid disease may cause pregnancy loss but it is almost always in women with clinically apparent disease. Routine evaluation for diabetes and thyroid disease is not advised.
- 13 A variety of infections are rare causes of pregnancy loss. Routine evaluation for infection is not advised.
- 14 The risk of pregnancy loss is increased in women over 35 years of age and in those with two or more previous losses.
- 15 The causes of fetal death differ from those of spontaneous abortion.
- 16 Most cases of spontaneous abortion do not require evaluation.
- 17 Evaluation for possible etiologies should be offered to all women with fetal death.

- 18 Obstetric sonogram is the best way to diagnose pregnancy loss.
- 19 A total of 0.5–1.0% of couples suffer three or more losses, termed recurrent pregnancy loss (RPL).
- 20 Recommended evaluation for couples with RPL includes parental karyotype, assessment of uterine anatomy, exclusion of luteal phase defect, and testing for antiphospholipid syndrome.
- 21 Of couples with recurrent pregnancy loss, 3–5% will have one partner with a genetically balanced structural chromosome rearrangement.
- 22 Luteal phase defect (LPD) is diagnosed with endometrial biopsy or serum progesterone determination.
- 23 LPD is present in 25–40% of women with RPL. However, it is present in many women with normal obstetric outcomes, and it may vary from month to month in the same woman.
- 24 Typical treatment of LPD consists of progesterone supplementation in the luteal phase, for example 25 mg of progesterone administered by vaginal suppository twice daily, beginning on the third day after ovulation through either the onset of menses or 10 weeks' gestation. Treatment is of unproven efficacy.
- 25 In total, 10–15% of women with RPL have uterine abnormalities.
- 26 Most women with uterine abnormalities have normal obstetric outcomes.
- 27 Uterine septum is the abnormality most strongly associated with pregnancy loss. Hysteroscopic resection of uterine septa may improve outcome in women with RPL.
- 28 Antiphospholipid syndrome (APS) is an autoimmune disorder characterized by the presence of specified levels of antiphospholipid antibodies and one or more clinical features, including pregnancy loss, thrombosis, or autoimmune thrombocytopenia.
- 29 The two best-characterized antiphospholipid antibodies are lupus anticoagulant and anticardiolipin antibodies.
- 30 APS is identified as the cause of pregnancy loss in 5–10% of women with recurrent miscarriage.
- 31 Treatment with thromboprophylactic doses of heparin (7500 units twice daily) and low-dose aspirin improves obstetric outcome in women with APS.
- 32 Heritable thrombophilias have also been associated with recurrent pregnancy loss. The association is stronger for fetal death as opposed to early miscarriage.
- 33 It is noteworthy that many heritable thrombophilias are common in normal individuals without a history of thrombosis or pregnancy loss, and most women with thrombophilias have normal obstetric outcomes.
- 34 Although of unproven efficacy, improved outcome has been reported in subsequent pregnancies in women with thrombophilias taking thromboprophylactic doses of low-molecular-weight heparin.
- 35 Treatments such as leukocyte immunization and IVIG are not proven to be efficacious in the treatment of unexplained pregnancy loss.

Ectopic and heterotopic pregnancies

Arnon Wiznitzer and Eyal Sheiner

Incidence

Ectopic pregnancy, i.e., implantation of a fertilized ovum outside the uterus (Fig. 12.1), is a major health problem for women of reproductive age and is the leading cause of pregnancy-related death during the first 20 weeks of pregnancy.¹ Accurate diagnosis and treatment of ectopic pregnancy decreases the risk of death and optimizes subsequent fertility. A significant increase in the number of cases of ectopic pregnancy has occurred in the USA during the past two decades.² In 1970, the rate was 4.5 per 1000 reported pregnancies, whereas in 1992, it was approximately 20 per 1000 pregnancies.² Importantly, ectopic pregnancy accounted for around 9% of all pregnancy-related deaths. The incidence of ectopic pregnancy is higher for nonwhite women and this discrepancy increases with age. Available data do not include pregnancies managed in outpatient settings and therefore its true incidence is most likely underestimated.

Etiology

The most common denominator is tubal obstruction and injury. Previous pelvic inflammatory disease, especially when caused by *Chlamydia trachomatis*, is a major risk factor for ectopic pregnancy.³ The adjusted odds ratio (OR) for previous pelvic infectious disease was recently found to be 3.4 (95% confidence interval, CI: 2.4–5.0).⁴ Other factors associated with an increased risk of ectopic pregnancy include prior ectopic pregnancy (which increases the risk for subsequent ectopic pregnancy 10-fold), a history of infertility (and specifically *in vitro* fertilization), cigarette smoking (causing alterations in tubal motility and ciliary activity), prior tubal surgery, diethylstilbestrol exposure (which alters fallopian tube morphology), and advanced maternal age.

Controversy exists regarding the association between ectopic pregnancy and medical abortions. Whereas Bouyer and coauthors⁴ found previous, medically induced abortions

to be associated with an increased risk of ectopic pregnancy (adjusted OR = 2.8, 95% CI: 1.1–7.2), no such association was observed by Shannon and coauthors⁵ who searched MEDLINE for articles on medical abortion regimens.

Intrauterine contraceptive devices (IUDs), progesterone-only contraceptives, and sterilization protect women against developing an ectopic pregnancy.^{6–8} Nevertheless, if a woman who has been sterilized or who is a current user of an IUD or progesterone-only contraceptive becomes pregnant, her risk for an ectopic pregnancy is increased six- to 10-fold, as these methods of contraception provide greater protection against intrauterine pregnancy than against ectopic pregnancy.^{6–8} The first 2 years after sterilization carry the greatest risk of pregnancy in general and ectopic pregnancy in particular.⁹ Sterilization reversal also increases the risk of ectopic pregnancy owing to possible obstruction and abnormal tube anatomy.

The risk of ectopic pregnancy is increased among women who are undergoing assisted reproductive technology and, specifically, *in vitro* fertilization (IVF). The risk is particularly high for women with underlying tubal disease. Hormonal alterations during ovulation induction can cause alterations in tubal function and peristalsis.¹⁰ Other possible explanations include placement of the embryo in embryo transfer high in the uterine cavity (deep fundal transfer), and fluid reflux into the tubes.¹¹

Other less common causes of ectopic pregnancy include salpingitis isthmica nodosa (anatomic thickening of the fallopian tube with epithelium leading to multiple lumen diverticula), and possibly vaginal douching and multiple sexual partners (both leading to a higher risk of pelvic infections).^{12,13}

Signs and symptoms

Clinical manifestations of ectopic pregnancy are varied and depend on whether rupture has occurred. The classic symptom triad of ectopic pregnancy includes amenorrhea, irregular bleeding, and lower abdominal pain. However, it is present in

Figure 12.1 Ultrasound image of a well-defined ectopic pregnancy (cornual pregnancy of 15 weeks' gestation).

only one-half of patients and most commonly when rupture has occurred.¹⁴ The most common complaint is sudden severe abdominal pain, which is present in more than 90% of patients.

Any physical examination should include measurements of vital signs. Abdominal and pelvic tenderness, especially cervical motion tenderness, is common when rupture has occurred (and present in approximately 75% of patients). However, pelvic examination before rupture is usually nonspecific, and a palpable pelvic mass on bimanual examination is established in less than one-half of cases.¹⁴ The accuracy of the initial clinical evaluation before rupture is less than 50%, and additional tests are required in order to differentiate ectopic pregnancy from early intrauterine pregnancy (Fig. 12.2).

Laboratory assessment

β-Human chorionic gonadotropin measurements

The first stage in the evaluation of women with a suspected ectopic pregnancy is to determine if the patient is pregnant. The β-human chorionic gonadotropin (β-hCG) enzyme immunoassay, with a sensitivity of 25 mIU/mL, is an accurate screening test and is positive in virtually all cases of ectopic pregnancy.¹⁵

The levels of β-hCG increase during gestation and reach a peak of approximately 100 000 mIU/mL at 6–10 weeks; they then decrease and remain stable at approximately 20 000 mIU/mL.¹⁶ Many studies have evaluated the increase of β-hCG in normal and abnormal pregnancies. The level of β-hCG in normal pregnancies doubles every 2 days (48 h), and thus, at present, clinicians rely on a normal “doubling time” to characterize a viable gestation. A 66% rise in the β-hCG

level over 48 h represents the lower limit of normal values for a viable intrauterine pregnancy.¹⁵ Indeed, there is a consensus that the predictable rise in serial β-hCG values in a viable pregnancy is different from the slow rise or plateau of an ectopic pregnancy.^{15–20} However, Barnhart and coauthors¹⁶ recently showed a slower rise in serial β-hCG values for women with viable intrauterine pregnancies. The slowest rise for a normal viable intrauterine pregnancy was 24% at 1 day and 53% at 2 days. Approximately 15% of normal pregnancies are associated with a less than 66% increase in β-hCG, and 17% of ectopic pregnancies have normal doubling times.¹⁵ Thus, limitations of serial β-hCG testing include its inability to distinguish a failing intrauterine pregnancy from an ectopic pregnancy and the inherent 48-h delay. As there is no definitive laboratory level of β-hCG permitting distinction between an ectopic pregnancy and an intrauterine pregnancy, a more conservative approach toward interventions in abnormal pregnancies is mandatory.¹⁶

Serial β-hCG levels are usually required when the initial ultrasound performed fails to demonstrate either intra- or extrauterine pregnancy. At β-hCG levels of approximately 2000 mIU/mL, a viable intrauterine pregnancy should be seen by vaginal ultrasound.²¹ If the β-hCG values fail to decline by 15% after uterine curettage for suspected nonviable intrauterine pregnancy, the possibility of ectopic pregnancy should be kept in mind and treatment may be indicated.²²

Serum progesterone

Measurement of serum progesterone levels has been shown to be useful in evaluating the chances of early pregnancy failure.^{23–25} Serum progesterone levels increase during pregnancy.²⁶ A baseline serum progesterone level of <20 nmol/L

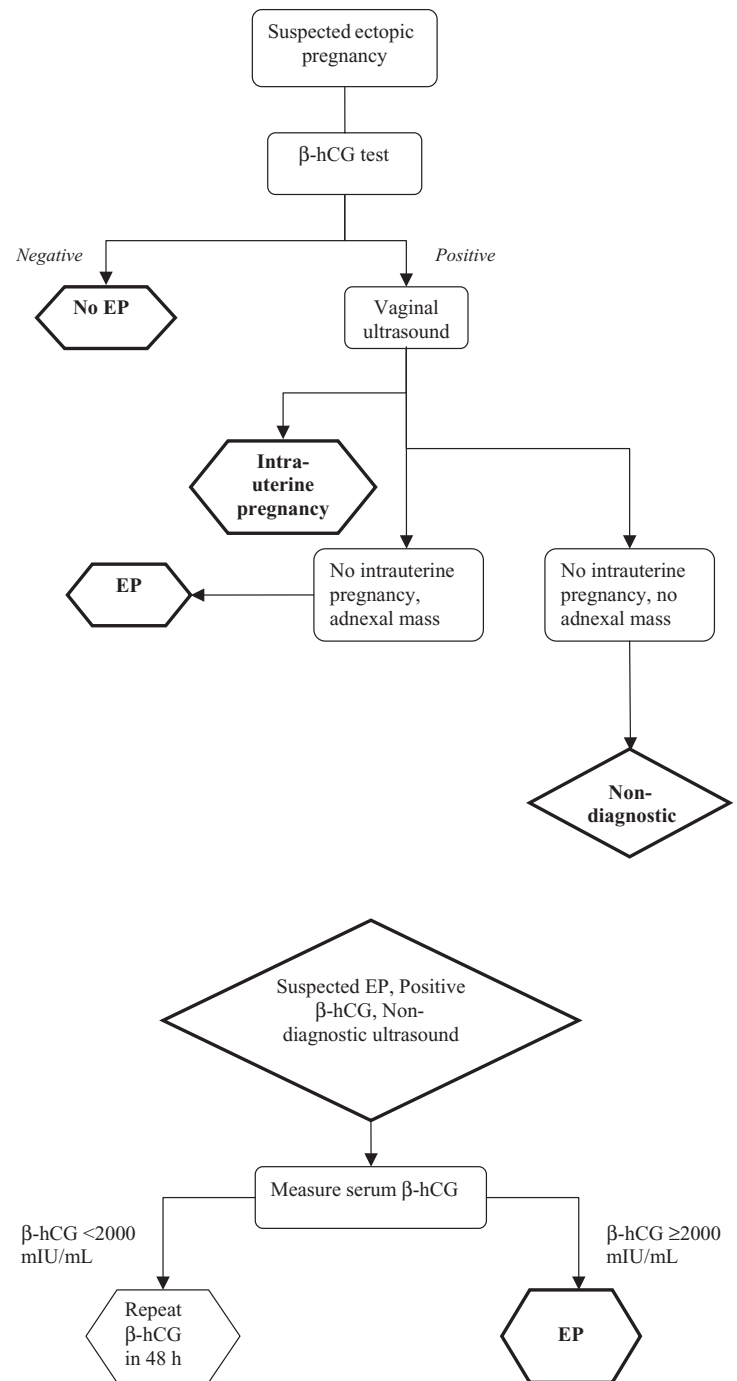

Figure 12.2 Diagnostic management of ectopic pregnancy.

can be used to identify abnormal pregnancy (either intra- or extrauterine) with a positive predictive value (PPV) of $\geq 95\%$.²⁴ Of pregnant patients with serum progesterone values of $< 5 \text{ nmol/L}$, 85% have spontaneous abortions, 0.16% have viable intrauterine pregnancies, and 14% have ectopic pregnancies.²⁷ Most ectopic pregnancies are associated with serum progesterone levels that are lower than 20 nmol/L .²⁸ On the contrary, the chances of an ectopic pregnancy in patients with serum progesterone levels of 20 nmol/L and above are less than 5%.

However, serum progesterone levels cannot distinguish ectopic pregnancy from spontaneous abortion.²⁵ Thus, progesterone levels at defined times can be used to predict the immediate viability of a pregnancy, but cannot be used reliably to predict its location.²³

Ultrasonography

The best diagnosis of ectopic pregnancy is based on the positive visualization of an extrauterine pregnancy (Fig. 12.1) but it is not seen in all cases. Approximately 90% of ectopic pregnancy may be visualized using transvaginal sonography within 5 weeks of the last menstrual period.^{29–31}

A viable intrauterine pregnancy should be seen by transvaginal ultrasound^{21,32} at $\beta\text{-hCG}$ levels of between 1000 and 2000 mIU/mL or at 5.5 weeks' gestation, as the sensitivity of ultrasound to detect a normally developing intrauterine pregnancy approaches almost 100%.^{21,32–34} When the $\beta\text{-hCG}$ level exceeds the transvaginal discriminatory zone (1000–2000 mIU/mL of $\beta\text{-hCG}$), the absence of an intrauterine gestational sac is suggestive of ectopic pregnancy, but the differential diagnosis includes failed intrauterine pregnancy. The reported sensitivity of transvaginal ultrasonography for identifying ectopic pregnancy ranges from 20.1% to 84% with a specificity of 98.9–100%.³⁵ The combination of positive $\beta\text{-hCG}$ and transvaginal ultrasound has a PPV of 95% for an ectopic pregnancy.³⁶

If an intrauterine pregnancy is detected, this is taken to exclude a diagnosis of ectopic pregnancy because coexistent intra- and extrauterine pregnancies (heterotopic) following spontaneous cycles are rare, with an estimated incidence of 1 in 30 000 normal pregnancies.¹ However, the incidence of heterotopic pregnancy is increased by the use of assisted reproductive technology, with an incidence of up to 1 in 100 normal pregnancies.³⁷

The early sonographic appearance of a normal gestational sac is characterized by the double decidual sac sign, i.e., two concentric echogenic rings separated by a hypoechogenic space. The double sac is believed to be the decidua capsularis and decidua parietalis. The double decidual sign is useful to the physician for early diagnosis of intrauterine pregnancy and for the exclusion of ectopic pregnancy. Chiang and coauthors³⁸ found recently that the sensitivity of the diagnosis of intrauterine pregnancy based on the decidual sign increased

when $\beta\text{-hCG}$ levels were equal to or greater than 2000 mIU/mL or the mean sac diameter was equal to or greater than 3 mm. However, the appearance of an intrauterine sac can be seen in some cases of ectopic pregnancy owing to intrauterine fluid or blood collection, i.e., a pseudosac. A pseudosac is a uterine sac without a double decidual ring or a yolk sac. Indeed, the report of a pseudosac is significantly associated with a false-positive diagnosis of ectopic pregnancy.³⁹ Ahmed and coauthors³⁹ concluded that a diagnosis of pseudosac should not be interpreted as indicative of an ectopic pregnancy as radiological differentiation between an early intrauterine pregnancy failure and an ectopic pregnancy is not possible. Color flow Doppler may aid in the differentiation between a pseudosac and a normal intrauterine sac; however, it requires advanced technical skills.^{40–42}

Dilation and curettage

When serial $\beta\text{-hCG}$ levels do not rise or fall appropriately, an abnormal gestation exists. When the pregnancy has been confirmed to be nonviable and when ultrasound is not sufficient, a uterine dilation and curettage can be performed to distinguish between an ectopic pregnancy and a miscarriage.^{22,43–45} Once tissue is obtained by curettage, it can be added to saline in order to investigate if it floats. Because floating of the material is not 100% accurate, histological verification (frozen section is possible) or serial $\beta\text{-hCG}$ measurements are needed. Visualization of villi in the tissue obtained indicates the occurrence of spontaneous intrauterine abortion. The absence of chorionic villi in the curettage specimen indicates the possibility of an ectopic pregnancy. However, a decrease in $\beta\text{-hCG}$ levels of 15% or more, 12 h after the curettage, indicates a complete abortion. A plateau or a rise in the $\beta\text{-hCG}$ levels is diagnostic for ectopic pregnancy. Once the possibility of an abortion is excluded, medical or surgical treatment for ectopic pregnancy is pursued.^{22,43–46}

Culdocentesis

Culdocentesis was used as a diagnostic technique for ectopic pregnancy before the widespread availability of the vaginal ultrasound and $\beta\text{-hCG}$ assay. Culdocentesis is positive in around 80% of women with ectopic pregnancy who have hemoperitoneum. In the remaining 20% of cases, the results are nondiagnostic. A nondiagnostic finding cannot be used to exclude ectopic pregnancy, and the test alters management only when it is positive. Thus, it is rarely indicated and is performed only in places where facilities for pregnancy testing and ultrasound are limited.⁴⁷

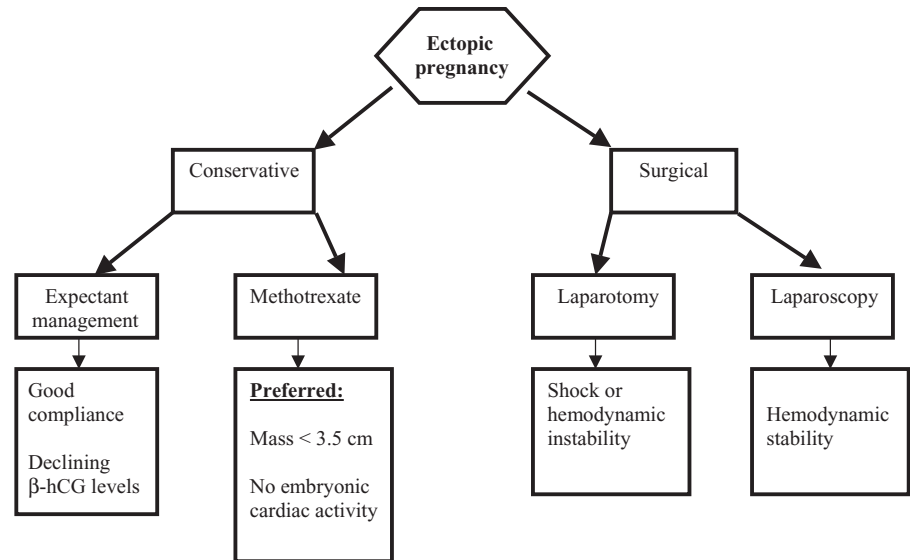

Figure 12.3 Treatment of ectopic pregnancy.

Treatment of ectopic pregnancy

The minority of patients with ectopic pregnancy (less than 10%) present with a surgical abdomen and signs of hypovolemia and shock.⁴⁸ They present no diagnostic problem and require no specific intervention besides fluid and blood resuscitation, and immediate operation. Delayed hospital admission and treatment leads to maternal mortality. Indeed, in developing countries, maternal mortality was almost 1% during the year 2000,⁴⁹ approximately 100 times higher than that reported in industrialized countries.^{50,51} Cases of ectopic pregnancy can be treated by medical (methotrexate), surgical (laparoscopy or laparotomy), or even expectant management alone (Fig 12.3). The choice depends on the medical condition, available resources, and the site of ectopic pregnancy involved.

Surgical treatment

Laparoscopy versus laparotomy

The standard operative procedure for the treatment of ectopic pregnancy in the developed world is laparoscopy (Fig. 12.4). Almost all tubal pregnancies in hemodynamically stable women can be removed laparoscopically, without the need for laparotomy. The excellent benefits of laparoscopic treatment include less blood loss, less analgesia, less postoperative pain, shorter recovery period, and decreased hospital costs.^{52–55}

The laparoscopic treatment of ectopic pregnancy and mainly tubal pregnancies has proven to be safe, but not entirely complication free.^{56–60} In a recent meta-analysis, the average laparoscopy resolution rate was above 90%, with an average rate of 2% for intraoperative complications and 9% for postoperative complications.⁶¹

Figure 12.4 Laparoscopy picture of tubal ectopic pregnancy.

Because of lower peri- and postoperative morbidity, lower cost, and equivalent efficacy, laparoscopy is preferred to laparotomy for the treatment of ectopic pregnancy. The only absolute contraindication for laparoscopy is shock or hemodynamic instability.^{48,52,55}

Salpingectomy, salpingotomy, salpingostomy, and milking

The most commonly performed procedures (by either laparoscopy or laparotomy) are radical salpingectomy (removal of the affected tube – Fig. 12.5), or salpingotomy (tubotomy that is closed) and salpingostomy (tubotomy that is left open) that preserve the tube. Salpingectomy is preferred in cases of ruptured ectopic pregnancy with uncontrolled bleeding, extensive tubal damage, recurrent ectopic pregnancy in the same tube, and sterilization.⁶² Higher rates of intrauterine pregnancy have been reported following conservative surgery than with radical surgery.⁶³ Thus, salpingectomy for

Figure 12.5 Radical salpingectomy (removal of the affected tube) for ruptured ectopic pregnancy.

an unruptured ectopic pregnancy is rarely performed and linear salpingostomy is the procedure of choice. Moreover, linear salpingostomy was found to be as effective as segmental resection with reanastomosis, and is technically easier with a shorter operative time. The ectopic pregnancy is removed through a linear incision of 10–15 mm made into the tube on its antimesenteric border. The products will extrude from the incision and can be flushed out and evacuated. Both livebirth rates and recurrent ectopic pregnancy rates after a tubotomy were similar, regardless of whether the incision was closed (salpingotomy) or left open to heal by secondary intension (salpingostomy).^{55,64} Because no differences in prognosis with or without suturing were found, laparoscopic salpingostomy is the preferred surgical procedure for an unruptured ectopic pregnancy.⁵⁵

Manual expression or milking of the tube in order to effect a tubal abortion is possible only in cases of fimbrial pregnancy. The present consensus among tubal surgeons is that milking should be abandoned as it is associated with an inordinately high recurrent rate of ectopic pregnancies, regardless of whether the procedure is performed by laparoscopy or laparotomy.⁶⁵

Medical treatment with methotrexate

Methotrexate is a folinic acid antagonist that inactivates dihydrofolate reductase resulting in the depletion of tetrahydrofolate, a cofactor essential for deoxyribonucleic acid and ribonucleic acid synthesis. It thus interferes with DNA synthesis, repair, and cellular replication.⁶⁶ Actively proliferating tissue, such as trophoblast cells of an ectopic pregnancy, is generally more sensitive to these effects of methotrexate.⁶⁶ In a meta-analysis study,⁶¹ methotrexate was proven to be a cost-saving treatment for ectopic pregnancy, which is nonsurgical

Table 12.1 Relative and absolute contraindications for methotrexate treatment.

Absolute contraindications	Relative contraindications
Shock, hemodynamic instability	Embryonic cardiac activity
Known sensitivity to methotrexate	Gestational sac of 3.5 cm or more
Breastfeeding	
Immunodeficiency	
Alcoholism	
Hepatic, pulmonary, renal, or hematological dysfunction	
Blood dyscrasias	
Peptic ulcer disease	

and spares the fallopian tube. Moreover, receiving methotrexate treatment does not subject patients to surgical intervention and the possible associated complications. Thus, at present, methotrexate is considered to be the treatment of choice for ectopic pregnancy.¹

Candidates for medical therapy

Hemodynamically stable patients without active bleeding or signs of hemoperitoneum are candidates for medical therapy^{1,67} and they should comply with follow-up care. Contraindications for methotrexate treatments are summarized in Table 12.1. Absolute contraindications to medical therapy include breastfeeding, immunodeficiency, alcoholism, hepatic/pulmonary/renal/hematological dysfunction, known sensitivity to methotrexate, blood dyscrasias, or peptic ulcer disease.¹ Relative contraindications for methotrexate treatments include embryonic cardiac activity and a gestational sac of 3.5 cm or more.¹

Because of its potential toxicity, patients receiving methotrexate should be followed up carefully. Patients using this drug should be aware of the potential side-effects and signs of toxicity. During treatment, patients should be counseled to promptly report any signs and symptoms associated with tubal rupture such as abdominal pain, dizziness, weakness, and syncope. Sexual intercourse, alcohol use, and nonsteroidal anti-inflammatory drugs, as well as folic acid supplements and prenatal vitamins, are prohibited until serum β -hCG is undetectable.¹

It is clear that the main factor in successful medical treatment is rigorous patient selection. Several parameters aimed at the suitable choice of patients have already been assessed, such as the presence of fetal cardiac activity, size of the ectopic pregnancy, initial levels of β -hCG, and endometrial thickness.⁶⁸⁻⁷⁰ Interestingly, a history of previous ectopic pregnancy was found to be another independent risk factor for methotrexate failure.^{71,72}

Treatment protocols

Presently, there are two commonly used protocols for the administration of methotrexate in the treatment of an ectopic pregnancy. Most commonly, methotrexate can be administered using a single-dose method, based on 50 mg/m² of body surface area, without the need for leucovorin rescue. Otherwise, methotrexate can be given using a multidose regimen of 1 mg/kg intramuscularly, alternating with 0.1 mg/kg of leucovorin intramuscularly, for up to four daily doses of each drug.^{67,73} Both protocols have been demonstrated to have good success rates in the treatment of ectopic pregnancy.⁷³⁻⁸⁰ The single-dose protocol is easier to administer and monitor, and results in fewer side-effects.⁸¹ However, a recent systematic meta-analysis of the published literature comparing the two regimens found that the single protocol was associated with a higher failure rate. The crude OR was 1.7 (95% CI: 1.04-2.82), and the OR adjusted for β -hCG values and for the presence of embryonic cardiac activity was 4.7 (95% CI: 1.77-12.62).⁸¹

Direct injection of methotrexate has lower efficacy than systemic administration, and is not considered as a therapeutic alternative for ectopic pregnancy.⁸²

Monitoring efficacy of therapy

The overall success rate of methotrexate treatments is almost 90%.^{61,73,81} Before treatment with methotrexate, blood analysis is required to establish baseline laboratory values for β -hCG and for renal, liver, and bone marrow function. Blood type should be determined because all patients with ectopic pregnancy who are Rh negative require 50 μ g of Rh(D) immunoglobulin.

During treatment, outpatient observation is preferred for its cost-effectiveness and for patients' convenience. However, if there is any question of safety, hospitalization is mandatory. Patient monitoring continues until β -hCG levels are nondetectable. It usually takes a month or longer until β -hCG

levels disappear from plasma.^{73,83-87} With the single-dose treatment, levels of β -hCG generally increase during the first week after treatment and peak 4 days following injection.¹ Levels should decline 1 week after injection.⁷³ If a response is observed and the fall in β -hCG levels is greater than 15%, weekly serum β -hCG determinations should be measured until undetectable β -hCG levels are documented. Failure of the β -hCG level to decline requires a second dose of methotrexate.^{73,83,88} An additional dose of methotrexate may also be given if β -hCG levels plateau or increase in 1 week.^{73,85,86} Ultrasound examination may be repeated to evaluate significant changes in clinical status, such as increased pelvic pain, bleeding, or inadequate decline of β -hCG levels.^{73,84-87} Persistent ectopic mass or hemoperitoneum may lead to surgery.

Side-effects

Methotrexate has the potential for serious toxicity and, indeed, high doses can cause bone marrow suppression, hepatotoxicity, stomatitis, pulmonary fibrosis, alopecia, and photosensitivity.^{89,90} Toxic effects are usually related to the amount and duration of therapy. Nevertheless, most side-effects during regular treatment for ectopic pregnancy are minor and self-limited, and generally limited to an increase in hepatic transaminases, mild stomatitis, and gastrointestinal disturbances.^{81,83-87} This is probably due to the lower dosage and shortened duration of treatment compared with dosages used in treating malignancies. Undoubtedly, the use of the single-dose protocol is associated with fewer side-effects than the multidose regimen.⁸¹

One of the known problematic side-effects of methotrexate treatment is acute abdominal pain which can be difficult to distinguish from the intra-abdominal hemorrhage of a tubal rupture.^{81,84,85} Thus, patients should be counseled regarding this possible side-effect and the continuing risk of tubal rupture during treatment. In such cases, hospitalization is frequently needed for careful surveillance. Interestingly, the presence of side-effects was recently found to be associated with higher rates of resolution of the ectopic pregnancy without surgical intervention.⁸¹

Reproductive outcome after methotrexate treatment

Recently, Gervaise and coauthors⁹¹ found that within 1 year of seeking to become pregnant, 57.5% of women previously treated with methotrexate for ectopic pregnancy conceived and had ongoing pregnancies. The cumulative intrauterine pregnancy rate was 66.9% after 2 years. The cumulative ectopic pregnancy rate was 15.4% after 1 year and 23.7% after 2 years.⁹¹ Higher conception rates of 79.6%, with a mean time to conception of 3.2 months, were also documented,¹⁰ with 12.8% of the conceptions being recurrent ectopic pregnancies. Similarly, when investigating reproductive outcome following laparoscopic treatment, the intrauterine pregnancy rate was 54% with a recurrent ectopic pregnancy rate of 13%.⁹² It seems that fertility depends more on the patients'

previous medical history (i.e., a history of infertility) than on her treatment for ectopic pregnancy.⁹¹

Expectant management

For years, gynecologists have stressed the need for early diagnosis and treatment of ectopic pregnancy in order to reduce morbidity and mortality. However, some patients experience spontaneous resolution of their ectopic pregnancy and in such patients, an expectant management is optional in order to avoid unnecessary treatment. After clear demonstrations that select cases of ectopic pregnancy resolve without therapy, several studies of patients with ectopic pregnancy have been conducted with consistent, reassuring results.^{93–95} Candidates for successful expectant management must be asymptomatic with a clear indication of resolution (generally manifested by declining levels of β -hCG). In addition, they should be willing to accept the potential risks of tubal rupture and hemorrhage.¹ Certainly, fetal cardiac activity, adnexal mass of greater than 4 cm, and β -hCG levels greater than 2000 mIU/mL are considered to be contraindications for expectant management. Patients with early, small tubal gestations with lower (β -hCG < 200 mIU/mL) and falling β -hCG levels are the best candidates for expectant management.¹

A serum β -hCG of less than 1000 mIU/mL, accompanied by a small adnexal mass (<4 cm), predicts spontaneous resolution in 75% of cases, whereas falling levels of β -hCG predict resolution in around 90% of ectopic pregnancies.^{93,94} However, failure of β -hCG levels to decline and suspected tubal rupture due to abdominal pain warrant immediate intervention and abandonment of the expectant management.

Recently, Elson and coauthors⁹⁶ have conducted a prospective observational study in which clinically stable women with nonviable pregnancies and no signs of hemoperitoneum were managed expectantly, on an outpatient basis, until their serum β -hCG declined to <20 mIU/mL. Women who developed pelvic pain and those with nondeclining serum β -hCG levels were offered surgery. A total of 107 out of 179 (59.8%) tubal ectopic pregnancies were considered to be suitable for expectant management. Ectopic pregnancy resolved spontaneously in 75 out of 107 (70%) women. Initial serum β -hCG level was the best predictor for the successful outcome of expectant management.⁹⁶

Persistent ectopic pregnancy

Incomplete removal of trophoblastic tissue after conservative surgery leads to persistent ectopic pregnancy. Several studies have reported a higher incidence of persistent ectopic pregnancy after laparoscopic surgery than after laparotomy.^{97–101} The reported frequency of persistent ectopic pregnancy following conservative laparoscopic surgery varied between 5% and 15% of cases.^{102–105}

Management includes methotrexate treatment or sometimes further surgery. Hoppe and coauthors¹⁰² successfully treated all patients with persistent ectopic pregnancy with a single-dose systemic administration of methotrexate. In an attempt to define patients at increased risk of having persistent ectopic pregnancy, β -hCG levels as well as the size of the ectopic pregnancy have been suggested as possible markers. Interestingly, women with a small ectopic pregnancy size (of 8 mm or less), detected by preoperative ultrasound, were at an increased risk for residual tissue.^{106,107}

Heterotopic pregnancy

Incidence

Coexistent intrauterine and extrauterine pregnancies are referred to as a heterotopic pregnancy.¹⁰⁸ The occurrence of a heterotopic pregnancy following spontaneous cycles is rare, with an estimated incidence of 1 in 30 000 normal pregnancies.¹ It was calculated by multiplying the rate of ectopic pregnancy (0.37%) by that of dizygous twinning (0.8%), thus producing a hypothetical approximation. However, the incidence is increased to around 1% by the use of assisted reproductive technology.³⁷ It is particularly high among women who are undergoing ovulation induction with gonadotropins, and among women undergoing *in vitro* fertilization, as it has become standard practice to transfer at least two embryos.¹⁰⁹

Clinical features

Heterotopic pregnancy poses a diagnostic dilemma. Serial β -hCG levels are not helpful because of the intrauterine pregnancy. Routine ultrasound detects only one-half of cases; in cases of viable intrauterine pregnancy, it is more likely that the intrauterine pregnancy will be detected in the course of workup and the ectopic pregnancy dismissed. In cases of nonviable intrauterine pregnancy, the presence of chorionic villi in the curettage specimen serves consistently to delay the correct diagnosis. Indeed, 50% of patients suffer from late diagnosis and arrive at hospital after rupture.¹¹⁰ There are no specific features to guide the physician to make an accurate, early diagnosis of heterotopic pregnancy other than a general awareness of such a possibility. This is particularly important in cases of abdominal pain and tenderness accompanying normal intrauterine pregnancy, or following uterine curettage for a nonviable intrauterine pregnancy among patients who conceived following assisted reproductive technology. Also, in cases of persistent or rising β -hCG levels following uterine curettage for a nonviable intrauterine pregnancy, the possibility of heterotopic pregnancy should be considered.

Reece and associates¹⁰⁸ performed a review on combined intrauterine and extrauterine pregnancies, which included 589 cases. Approximately 94% were tubal and the rest were ovarian pregnancies. However, combined intrauterine and cervical pregnancies from *in vitro* fertilization and embryo

Figure 12.6 Sites of ectopic pregnancy.

transfer were also reported.^{111,112} Abdominal pain was found to be the most frequent presenting symptom occurring in more than 80% of patients.¹⁰⁸ A combination of symptoms including abdominal pain, adnexal mass, peritoneal irritation, and an enlarged uterus was the most significant finding in support of a diagnosis of heterotopic pregnancy.

Treatment of heterotopic pregnancy

Treatment consists of removal of the ectopic pregnancy by surgery, and avoidance of intrauterine instrumentation and systemic methotrexate treatment in cases when the pregnancy is desirable (especially following assisted reproductive technology). In hemodynamically unstable patients, an explorative laparotomy is necessary. Expectant management is problematic as β -hCG levels cannot be monitored effectively owing to the intrauterine pregnancy. The prognosis for the intrauterine pregnancy is excellent, and the majority are carried to term.¹¹³

Treatment is complex in cases of heterotopic cervical pregnancy accompanied by a desirable intrauterine pregnancy. In such cases, hysteroscopic resection of the cervical gestation sac has been tried and the intrauterine pregnancy continued uneventfully until term.¹¹⁴ The use of cervical Shirodker cerclage as an elective procedure for the management of a heterotopic cervical pregnancy with intrauterine pregnancy has also been described.¹¹⁵ It resulted in a normal, uneventful term vaginal delivery. Local injection of KCl has been considered as an alternative to methotrexate to avoid exposure of the coexisting intrauterine pregnancy to chemotherapeutic agents.

In most reported cases, the intrauterine pregnancy was preserved leading to delivery of liveborn infants.¹¹⁶⁻¹¹⁸

Nontubal ectopic pregnancy

The most common site of ectopic pregnancy implantation is the fallopian tubes, accounting for around 98% of all ectopic pregnancies. The majority of ectopic pregnancies are in the ampullary part of the fallopian tube (79.6%), with 12.3% in the isthmus, 6.2% in the fimbria, and 1.9% in the interstitial part. However, in rare cases implantation can occur in other ectopic sites, including the ovary, uterine cervix, and abdomen (Fig. 12.6).

Interstitial (cornual) pregnancy

The interstitial part of the fallopian tube is the proximal portion that lies within the muscular wall of the uterus. Interstitial implantation of the blastocyst is the rarest form (1.9%) of tubal ectopic pregnancy.¹¹⁹ Late diagnosis and treatment are the main contributing factors to the poor outcome traditionally linked to these ectopic pregnancies.^{120,121} The mortality rate of interstitial pregnancy is about twice that of other ectopic pregnancies.

There are some unique signs in a sonogram that characterize an interstitial ectopic pregnancy. They include the following: an empty uterine cavity with an eccentrically located or a lateral gestational sac, the presence of myometrium between the sac and the uterine cavity, the gestational sac covered with

Figure 12.7 Cornual pregnancy of 15 weeks' gestation, after cornual resection.

thin myometrial fold, and no visible sac above the level of the internal os.¹²² Recently, Tulandi and Al-Jaroudi¹²³ summarized 32 cases of interstitial pregnancies reported to the registry of the Society of Reproductive Surgeons and found ultrasound diagnosis of interstitial pregnancy to be accurate in 71.4% of cases, thus allowing conservative treatment.

Important risk factors for interstitial pregnancy include previous ectopic pregnancy (40.6%), ipsilateral salpingectomy (37.5%), *in vitro* fertilization (34.4%), sexually transmitted disease (25.0%), and ovulation induction (3.1%).¹²³

The traditional treatment of interstitial pregnancy was hysterectomy or cornual resection by laparotomy.¹²⁰ These patients tend to present later in gestation than other tubal pregnancies mainly because the myometrium (cornual part) is more distensible than the fallopian tube (Figs 12.1 and 12.7). However, the progress in diagnostic techniques has led towards conservative management with methotrexate, laparoscopic treatment including cornual resection, cornuostomy, salpingostomy or salpingectomy, and even hysteroscopic removal.^{123–127} However, if uncontrolled hemorrhage occurs, hysterectomy might be the preferred treatment.¹²⁰

Abdominal ectopic pregnancy

Abdominal pregnancy occurs in approximately 1 in 8000 normal births and represents 1.4% of ectopic pregnancies.¹¹⁰ The prognosis is generally poor, with an estimated maternal mortality of 5.1 per 1000 cases (7.7 times higher than other ectopic pregnancies).¹²⁸

Abdominal pregnancies are classified as primary (primary peritoneal implantation) or secondary reimplantation. The latter are more common, resulting from tubal abortion or rupture. Distinction between the two is problematic but treat-

ment is given according to the clinical presentation. Diagnosis is best made by ultrasound.

The incidence of abdominal pregnancy is increased following *in vitro* fertilization, induced abortions, recurrent pelvic infections, previous ectopic pregnancy, and endometriosis.^{129,130} There are several reports on abdominal pregnancies reaching near term and their viability. In such cases the survival of the newborns is above 60%, although these pregnancies are associated with a high rate of congenital anomalies (20–40%).¹³¹ Such anomalies, attributed to oligohydramnios, include bone and joint deformities, and central nervous system and skull anomalies.

Laparotomy was considered to be the treatment of choice with removal of the pregnancy, with or without (if impossible) the placenta.^{132,133} The placenta can be detached if its vascular supply can be recognized and ligated. If the vascular supply cannot be identified, the cord is ligated and the placenta is left. In cases where the placenta was left in place, complications such as sepsis, abscess formation, hemorrhage, and intestinal obstruction were noted.¹³¹ However, although removal of the placenta may reduce morbidity, it is associated with a high risk of hemorrhage and subsequent visceral damage.¹³² Thus, alternative regimens, including the use of methotrexate or selective embolization of the vessels feeding the placenta prior to definitive surgery, have been successfully tried.^{134–137} Laparoscopic management of an early primary abdominal pregnancy has also been reported.¹³⁸

Ovarian pregnancy

Ovarian pregnancy is an infrequent variant of ectopic pregnancy with an incidence of 0.5–3% of all ectopic pregnancies.^{139–143} It is likely, however, that the frequency is

underestimated as some of the suspected tubal pregnancies that were treated conservatively with methotrexate were in fact early ovarian pregnancies. Also, several cases were only retrospectively confirmed by the pathologist as they had been mistakenly considered as ruptured corpus luteum. Recent improvements in ultrasonography and operative laparoscopy should lead to an earlier and a more accurate diagnosis of these pregnancies.¹³⁹

Risk factors for ovarian pregnancies include multiparity and the use of an IUD.^{139,142–144} Interestingly, in two large series, 68–90% of the women with ovarian pregnancies had used this form of contraceptive device.^{139,143}

Clinical findings are similar to those encountered in tubal pregnancy. The major presenting symptom (present in almost all patients) is abdominal pain.¹³⁹ Other findings include

vaginal bleeding and amenorrhea.^{142,143} Owing to the increased vascularity of the ovarian tissue, hemodynamic instability and rupture occurs in around 30% of patients.¹⁴³

Historically, oophorectomy was considered as the treatment of choice for ovarian pregnancies. However, improvements in operative laparoscopic skills and instrumentation have led to a more conservative approach, so that laparoscopic wedge resection (Fig. 12.8) and ovarian cystectomy have become the preferred treatment. Successful treatment with methotrexate has also been reported.^{145,146} In patients with circulatory collapse, however, immediate laparotomy is mandatory.

Cervical pregnancy

Cervical pregnancy, which results from implantation of the blastocyst within the cervical canal, is a rare complication of pregnancy. Its incidence varies from 1 in 2400 to 1 in 50000 normal pregnancies.¹⁴⁷ Appropriate early diagnosis and treatment has led to the remarkable reduction of maternal mortality from 50% in 1911¹⁴⁸ to under 5% in 1983.¹⁴⁷

A close relationship was found between therapeutic abortions with sharp curettage (dilation and curettage), previous Cesarean sections, *in vitro* fertilization, and cervical pregnancy.^{148–150}

Presenting symptoms include painless vaginal bleeding which may be accompanied by abdominal pain and urinary problems.¹⁵⁰ On physical examination, the cervix is usually enlarged, global (barrel shaped), and distended. Occasionally, the external os is dilated.

Accurate diagnosis can be performed by vaginal ultrasound and magnetic resonance imaging, demonstrating an intracervical ectopic sac below a closed internal cervical os (Fig. 12.9). Transvaginal demonstration of an intact part of the cervical

Key points

- 1 Ectopic pregnancy (EP) accounts for approximately 9% of all pregnancy-related deaths.
- 2 The most common denominator is tubal obstruction and injury.
- 3 The β -hCG levels in normal pregnancy double every 2 days (48 h), and thus, at present, clinicians rely on a normal “doubling time” to characterize a viable gestation.
- 4 The accuracy of the initial clinical evaluation before rupture is less than 50%, and additional tests are required in order to differentiate ectopic pregnancy from early intrauterine pregnancy.
- 5 The risk of EP is increased among women undergoing assisted reproductive technology and specifically *in vitro* fertilization.
- 6 The most common complaint in EP is sudden severe abdominal pain.
- 7 Pelvic examination before rupture is usually nonspecific, and a palpable pelvic mass on bimanual examination is established in less than half of the cases.
- 8 A baseline serum progesterone level of <20 nmol/L can be used to identify abnormal pregnancy (either intra- or extrauterine) with a positive predictive value of $\geq 95\%$. However, serum progesterone levels cannot distinguish ectopic pregnancy from spontaneous abortion.
- 9 The best diagnosis of ectopic pregnancy is based on the positive visualization of an extrauterine pregnancy outside the uterus.
- 10 At hCG levels between 1000 and 2000 mIU/m, or at 5.5 weeks’ gestation, a viable intrauterine pregnancy should be seen by transvaginal ultrasound.
- 11 Coexistent intra- and extrauterine pregnancies (heterotopic) following spontaneous cycles are rare, with estimated incidence of 1 in 30 000 normal pregnancies.
- 12 Methotrexate is a cost-saving, nonsurgical fallopian tube-sparing treatment for EP.
- 13 Absolute contraindications to methotrexate include breastfeeding, immunodeficiency, alcoholism, hepatic, pulmonary, renal, or hematologic dysfunction, known sensitivity to methotrexate, blood dyscrasias, or peptic ulcer disease.
- 14 The overall success rate of methotrexate treatments is almost 90%.
- 15 Candidates for successful expectant management must be asymptomatic with an objective evidence of resolution (generally manifested by declining levels of hCG).

canal between the endometrium and gestational sac is suggestive of cervical pregnancy.

Conservative medical management (with systemic methotrexate) has been reported to be successful, obviating the need for surgical treatment, which entails a risk of hysterectomy. Dilation and evacuation, followed by cervical tamponade, was successfully applied using Foley catheter

tamponade.¹⁵⁰ Methotrexate is the most commonly used chemotherapy for cervical pregnancies, with a success rate of around 80%.^{150–154} Other treatment regimens include arterial embolization and even Shirodkar cerclage placement in order to reduce bleeding. However, in cases of massive and uncontrolled vaginal bleeding, abdominal hysterectomy is necessary (Fig. 12.10).¹⁴⁷

Multifetal pregnancies: epidemiology, clinical characteristics, and management

Michelle Smith-Levitin, Daniel W. Skupski, and Frank A. Chervenak

Background

Incidence and epidemiology

In the past, the overall incidence of twins worldwide was about 1 in 80 pregnancies (1.13%), and high-order multiples were rare. During the last 30 years, the incidence of multiple births has been steadily increasing. In the USA, the number of twin births has increased by over 60% since 1980, giving a twin birth rate of 31.1 per 1000 live births. Higher order births increased by 500% for a higher order birth rate of 1.84 per 1000 live births.¹ More than 90% of the increase is estimated to result from the more widespread use of assisted reproductive technologies (ART).^{2,3} Patients who conceive after treatment with ovulation-inducing agents or *in vitro* fertilization procedures do so with a multiple gestation 7–50% of the time.^{3,4} Recent trends toward delayed childrearing in developed countries have probably contributed to the increase in multiple births as well, as there is a naturally occurring greater incidence of twins among older women.^{1,3–5}

Prior to the introduction of ART, the frequency of monozygotic (MZ) twins was relatively constant throughout the world. The incidence was 4 per 1000 births with a 2:1 ratio of DZ:MZ pairs.^{6,7} In contrast, the incidence of naturally occurring dizygotic (DZ) twins varies and is affected by maternal race, parity, age, nutritional status, and family history.^{6,8} This may be related to higher baseline levels of gonadotropins in certain groups of women.^{6,8} For example, the highest incidence of DZ twinning has been found in black women, who have been shown to have larger pituitary glands and higher serum hormone content than other women.^{6,8}

Pathogenesis/embryology

Multiple gestations can be either monozygotic (arising from the fertilization of one ovum by one sperm leading to fetuses with an identical genotype) or multizygotic (arising from the fertil-

ization of two or more ova each with one sperm leading to genotypically unique fetuses that happen to share the uterus at the same time). In describing them, one should avoid the terms “identical” and “fraternal”, which refer only to phenotypic likeness. Nonetheless, identical generally implies monozygosity, and fraternal generally implies dizygosity.

Monozygous gestations can be diamnionic–dichorionic (DC), diamnionic–monochorionic (MC), or monoamnionic–monochorionic (MA) depending on when the zygote splits (Fig. 13.1).^{6,8,9} The zygote splits soon after fertilization resulting in DC placentation in about 30% of MZ twins.^{6,8,9} Remnants of blood vessels, ghost villi, and decidual debris can be seen between the four layers of membranes (two amnions and two chorions). The chorions are almost always fused, as seen by a characteristic ridge at the center of the placental mass. If the zygote splits between the third and the eighth days, the resulting single placenta will be MC, which occurs in 70% of MZ twins.^{6,8,9} The dividing membranes (two amnions and one chorion) are thin and translucent. Rarely (less than 1%), MZ twins will be MA if the zygote splits after the amnion has formed at about days 9–12.^{6,8,9} If the twinning process occurs even later, after the yolk sac has formed, the MZ pair will be conjoined.^{6,9} Beyond the 17th day, a singleton gestation will develop.

Interestingly, the rate of zygotic splitting and, therefore, of monozygotic twins appears to be higher following all ART procedures.^{3,7,10,11} There is some evidence that it may be related to biochemical or mechanical trauma to the zona pellucida.^{10,11} If the timing of events outlined in Fig. 13.1 is correct, one would expect to see only DC multiples in this setting as ART procedures involve manipulation of the zygote within 2 days after ovulation. This has not been the experience.

Multizygotic gestations are generally assumed to be the result of multiple ovulation, as evidenced by their high rate after ovulation induction with sonographically and biochemically confirmed ovulation of multiple ova. All DZ twins have separate DC placentas. Higher order multiple gestations can contain any combination of monozygotic (DC, MC, and MA) and multizygotic (DC) fetuses.

Figure 13.1 The embryology of monozygotic twinning. From Benirschke K, Kim CK. Multiple pregnancy. *N Engl J Med* 1973;288:1276.

Diagnosis

Ultrasound has become indispensable for the identification, assessment, and management of multiple gestations (Table 13.1).¹² An awareness of the risk factors for multiple gestation and the clinical indicators is still important, however, as ultrasound is not routine worldwide.

Risk factors/clinical indicators of multiple gestations

Risk factors for conceiving a multiple gestation include a family or personal history of spontaneous twins and the use of ovulation induction or gamete or zygote transfer procedures. The most common clinical signs or symptoms suggestive of twins include uterine size that is greater than expected for dates, hyperemesis gravidarum, auscultation of two or more fetal heart rates, and accelerated maternal weight gain. Higher levels of biochemical pregnancy markers such as β -human chorionic gonadotropin (β hCG), progesterone, estriol, estradiol, and maternal serum alpha fetoprotein (MSAFP) can also be suggestive of a multiple gestation, although none is specific enough to make the diagnosis of more than one fetus without an ultrasound examination.^{6,13}

Ultrasound

At a minimum, patients with the above risks should have a diagnostic ultrasound because outcomes are much better for multiple gestations that are diagnosed early. Although multiple sacs can be seen as early as 4–5 weeks using a transvaginal probe, it is prudent to reserve the diagnosis of twins (or more) until several weeks later when fetal poles with cardiac

Table 13.1 The use of ultrasound in multiple gestations.

First trimester

Diagnosis of multifetal pregnancy
Determination of chorionicity and amnionicity
Accurate pregnancy dating (crown–rump length)
Screening for some anomalies (nuchal translucencies)
Guidance for chorionic villus sampling and multifetal pregnancy reduction

Second trimester

Screening for fetal anomalies
Guidance for amniocentesis
Determination of chorionicity and amnionicity
Determination of placental cord insertion
Biometry to screen for early fetal growth restriction or discordance
Assessment of cervical length

Third trimester

Biometry to screen for fetal growth restriction or discordance
Assessment of cervical length
Fetal status assessment
Amniotic fluid volume
Biophysical profile
Doppler flow studies
Fetal presentation

Intrapartum

Fetal presentation
Guidance for external cephalic version of the second twin

activity are seen, because there is a high frequency of embryonic “disappearance” in patients with a presumed multiple gestation who are scanned in early pregnancy.¹⁴ The prevalence of this “vanishing twin” phenomenon has been reported to range between 22% and 54% of patients with twins or more scanned in the first trimester.¹⁴ Furthermore, a diagnosis of a multiple gestation should not be made simply on the basis of visualization of more than one fluid-filled cavity as a subchorionic hematoma, excessive transducer pressure, or a septate uterus can all mimic a multiple gestation.^{12,15}

Determination of chorionicity

There are several ways to determine the placentation in multiple gestations, but the most accurate is assessment in the late first or early second trimester. The visualization of a dividing membrane at any time excludes a diagnosis of a MA pair. Lack of visualization, however, is not necessarily diagnostic of a MA pair as the dividing membrane may be difficult to see until 10–12 weeks in MC multiples (Fig. 13.2). If two fetal poles but only one yolk sac is present, the pregnancy is most likely MA.¹⁶ After the first trimester, the membrane may be completely apposed to a twin with severe oligohydramnios. In this situation, the fetus is trapped or “stuck” against the uterine wall and will not move over time or with maternal position change.⁶ A truly MA pair will move away from the uterine wall, and cords will often be visibly entangled.

If the ultrasound reveals separate placental discs, particularly if on opposite uterine surfaces, or fetuses of opposite gender, the pregnancy is DC. If the placentas are close together, attention should be turned to the dividing membranes. A MC

membrane will be thin and wispy (Fig. 13.3B), whereas a DC membrane will be thick and more easily visualized (Fig. 13.3A). MC membranes have two layers, and DC membranes have four visible layers. In DC placentas, the “twin peak” sign is a triangular projection of placental tissue from the chorionic plate into a cleft between the layers of the intertwin membrane (Fig. 13.3A).¹⁷ In contrast, a T-shaped junction will be present in an MC placenta (Fig. 13.3B).¹⁸ Assessment of the Y-shaped ipsilon zone can aid in the determination of chorionicity in triplet gestations (Fig. 13.3C).¹⁹ These methods correctly identify chorionicity in the majority of patients who are scanned in early pregnancy.^{19,20}

The early determination of chorionicity does not always establish the zygosity of multiple gestations as an MZ set can have an MC or DC placenta. More sophisticated methods of zygosity determination can be performed, such as DNA fingerprinting from amniocytes, when the information is needed for antenatal management.²¹ It is important to confirm chorionicity and zygosity after birth for the parents and for the future medical care of the children. For example, an MZ twin has a higher chance of developing some medical conditions if the co-twin is affected, and an MZ twin can accept tissue from the co-twin as an isograft. Examination of the placenta after birth, blood grouping, and DNA mapping techniques are methods that are used to determine the zygosity.⁶

Fetal complications

Perinatal morbidity and mortality

Multiple gestations contribute significantly to perinatal morbidity and mortality, although they still account for a relatively small percentage of live births.^{4,6,22,23} Twins alone account for 12.6% of the perinatal mortality, although they account for only 3% of live births.^{1,22} The overall perinatal mortality rate for twins in developed countries is approximately 50 per 1000 births.^{5,15,22} The risk of perinatal death is three- to 10-fold higher for a twin than for a singleton,^{15,22} and the risk of cerebral palsy is four times greater.⁷ The corrected perinatal mortality rates for triplets and higher order gestations are more striking. The crude perinatal mortality rate for triplets is 121 per 1000 births.²⁴ Twenty percent of triplets have a major handicap and a triplet is 17 times more likely to have cerebral palsy than a singleton.⁷

Prematurity

The relatively high incidence of perinatal mortality and morbidity is largely due to complications of prematurity. Fifty-eight percent of twins and 92% of triplets are born prior to 37 weeks, because of preterm labor, preterm premature rupture of membranes, or fetal or maternal complications, compared with 10% of singletons.¹ The average length of gestation decreases inversely with the number of fetuses present (Table 13.2). Twelve percent of twins, 36% of triplets,

Table 13.2 Gestational age and birthweight in multiple gestations.

	Twins	Triplets	Quadruplets
Average gestational age (weeks)	35.3	32.2	29.9
Average birthweight (g)	2347	1687	1309

Adapted from ref. 1.

and 60% of quadruplets are born prior to 32 weeks, and a significant percentage deliver prior to 28 weeks.^{7,25} Furthermore, prematurity results in babies being born at low birthweight, and birthweight has been shown to be the most important factor for predicting morbidity and mortality in twins.^{7,23,26} The risk of being born at a low birthweight (< 2500g) is ninefold higher for a twin than for a singleton and 15-fold higher for a triplet.^{1,22,27} The risk of being born at a very low birthweight (< 1500g) is also 10-fold higher for a twin than for a singleton and is 31-fold higher for a triplet.^{1,22,27} Twenty-five percent of twins, 75% of triplets, and all quadruplets are admitted to the neonatal intensive care unit.^{7,24,28–30}

Fetal growth

The biometrical parameters that are used to assess fetal growth in singletons have been shown to be accurate in multiple gestations as well. Although femur length measurements between singletons and twins tend to be similar throughout gestation, abdominal circumferences and biparietal diameters tend to be smaller.^{31,35} Estimated fetal weights in twins should be determined using formulas that incorporate at least femur length and abdominal circumference.^{32–33}

Multiple gestations are at increased risk of being small for gestational age, which also leads to perinatal morbidity and mortality.^{6,7,15,23,26} Twins who are born at the same gestational age but who weigh less than 2000g have a 10-fold greater risk of an adverse outcome compared with twins weighing more than 2000g, and the risk decreases by 40% for every 250-g increase in birthweight.²³ Fetal growth restriction (FGR) complicates as many as 60% of multiple gestations.^{6,7,31,34,35} The degree of FGR tends to increase with increasing numbers of fetuses.³⁶ The factors that influence growth in multiples are unclear. Theories range from phenomenon that occur early, such as limited vascular supply after the implantation of more than one embryo, to uterine conditions occurring later, such as fetal crowding or limited decidual area for placental

growth. Experience with patients undergoing multifetal pregnancy reduction, which reveals correlation between rates of FGR and the starting number of viable embryos, indicates that first-trimester events may play a role.^{35,37} However, the fact that fetal growth in the majority of pregnancies, regardless of fetal number, follows the same trajectory until approximately 28–32 weeks when multiple gestations begin to fall behind singletons, and the fact that rates of FGR among multiples increases exponentially with increasing gestational age, suggests that the third-trimester environment is also significant (Fig. 13.4).^{6,12,15,31,36,40,41}

The definition of FGR in the setting of multiple gestations is problematic. Some believe that it should be defined as an estimated fetal weight below the 10th percentile at a given gestational age based on specific growth curves for twins or triplets.^{31,33,36} Others believe that the use of singleton nomograms is valid and should, in fact, be used, as multiple gestations, at least multizygotic sets, have the same genetic growth potential as singletons.^{35,39,40,41} As the validity and accuracy of published twin and triplet growth curves have not been established, singleton curves continue to be used as the gold standard.

Another growth problem seen in multiple gestations is discordance between the fetuses, which complicates at least 15% of twins and up to 54% of triplets.³⁴ This is associated with even higher morbidity and mortality compared with concordantly grown pairs, especially for the smaller twin or triplet.^{7,12,13,42–45} Although discordant growth is not always the result of a pathologic process, it is often due to placental insufficiency or abnormal placentation of one twin, twin–twin transfusion syndrome, or a congenital anomaly of one twin.^{12,23,36,46} A combination of some or all of the ultrasonographically detectable indices listed in Table 13.3 identify discordant sets.^{12,31,32,47} As with FGR, measurement of abdominal circumference seems to be the most sensitive marker for significant growth discordance.⁴⁷

Congenital anomalies

The incidence of congenital anomalies in multiple gestations is one and a half to three times higher than in singletons.^{5,6,28} There is a higher incidence of structural defects seen in MZ

twins, some of which are unique to twins and may be due to the twinning process itself.⁴⁸ There is also a higher incidence of chromosomal abnormalities, which is related to the older age, in general, of woman conceiving multiples and to the increased probability that a woman carrying more than one fetus will have at least one that is aneuploid at a younger maternal age than if she were carrying a singleton.^{7,49–51}

Conjoined twins

Schinz et al. describe three helpful categories to organize the anomalies encountered in multifetal pregnancies.⁴⁸ The first are midline structural defects that are felt to be a consequence of the “teratogenic” event of twinning such as sirenomelia, holoprosencephaly, exstrophy of the cloaca, and neural tube defects.^{48,52} Conjoined twins, which are specific to multiple gestations, also fall into this category. The incidence of conjoined twins is 0.2–0.6 per 10 000 births or 40 per 10 000 twin births.^{53,54} They can also occur in the setting of a higher order multiple gestation.¹² The twins may be joined by minor, superficial attachments, attachments of major body parts including internal organs, or in the most severe forms (dupl-cata incompleta), there may be complete union except for duplication of just one body part. Conjoined twins are classified by the most prominent site of union (Table 13.4).^{53,54} They can now be diagnosed relatively early in gestation with ultrasound and adjuvant use of three-dimensional ultrasound.^{53–55} The signs include lack of a dividing membrane, a fixed position relative one to the other that does not change over time, a bifid appearance to the first-trimester fetal pole, inability to distinguish two complete fetal borders, the appearance of more than three vessels in the umbilical cord, and detection of other anomalies.^{13,53–55}

Acardia

The second category of anomalies results from vascular interchanges that occur in most monochorionic placentas.^{46,56} Such vascular anastomoses can often be demonstrated by perfusing the placentas after delivery with colored water or milk (Fig. 13.5).^{6,46,56,57} The most severe form, acardia or twin reversed arterial perfusion (TRAP), is believed to arise when arterial–arterial and venous–venous anastomoses exist without any arterial–venous connections.^{8,9,58,59} As a result, there is uncompensated reversed flow, which is thought to impair development of the heart and often the head (Fig. 13.6). The “pump” twin becomes hydropic, and the “recipient” twin has multiple anomalies, often appearing only as an amorphous mass of tissue.^{6,13,58} This anomaly only affects approximately 1 in 35 000 infants or 1 in 100 monozygotic twin pregnancies.⁵⁸

Twin–twin transfusion syndrome

A less severe, but much more common, form of vascular interchange between fetuses leads to the twin–twin transfusion

Table 13.3 Sonographic criteria for discordance.

syndrome (TTTS) or polyhydramnios–oligohydramnios sequence. It is thought to occur when deep arterial–venous connections are uncompensated, leading to a one-way shunt between the fetuses (Fig. 13.7).^{8,12,46,56,57,60} The exact incidence is unknown as severe forms may present as a “vanished twin” in the first trimester or as the full syndrome later in gestation, and milder forms may be evident only at birth or not at all.⁵⁸

Figure 13.6 Example of twin reversed arterial perfusion (TRAP). The fetus on the left has no head or upper limbs (acardiac), while the fetus on the right is structurally normal. From Ref. 46.

Although it has been reported in fused dichorionic placentas, it is largely a complication of monochorionic placentation, probably occurring in 5–15% of such pregnancies.^{58,60} The recipient twin becomes hypervolemic and polycythemic, which eventually leads to polyhydramnios, congestive heart failure, and hydrops, while the donor becomes hypovolemic and anemic, which leads to decreased renal perfusion, oligohydramnios, and FGR, and can also eventually lead to heart failure.^{12,58,61} An antepartum diagnosis can be made with reasonable certainty using ultrasound. The criteria include a strong suspicion of monochorionicity, oligohydramnios (maximum vertical pocket less than 2 cm) around the smaller twin (often severe enough to make it appear “stuck”) with a small or absent urinary bladder on serial scans and polyhydramnios (maximum vertical pocket > 8 cm) around the larger

Figure 13.7 The pathologic arteriovenous connection in the twin transfusion syndrome. Redrawn from Benirschke K. Twin gestation: incidence, etiology and inheritance. twin (sometimes with evidence of high-output heart failure), with a distended urinary bladder on serial scans.^{12,13,58}

In addition to the vascular connections that can occur in the placentas of multiple gestations, other abnormalities of the placenta, membranes, and umbilical cords that can cause fetal complications occur. MA gestations, although rare, are associated with a high perinatal mortality, which often results from entanglement of the two umbilical cords.^{46,58,62,63} Bivascular cords (single artery)^{8,46} and velamentous cord insertions are also much more common in twin and higher order placentas.⁴⁶ The portion of cord that is unprotected is susceptible to thrombosis, compression, or rupture, particularly if it is a vasa previa.⁸

The third group of anomalies that Schnizel et al. described are those resulting from intrauterine crowding. Examples are minor foot deformities, skull asymmetry, and dislocation of the hip.^{15,48}

Intrauterine fetal demise

As discussed previously, a vanishing twin early in pregnancy may be a common event that does not usually lead to further problems.^{58,64,65} However, death of one fetus later in a multiple gestation, which complicates 4–8% of twins^{58,65} and 11–17% of triplets,^{58,66} is associated with an increased risk of preterm delivery, FGR, and perinatal mortality in the survivors.^{58,64} The risk of fetal demise is at least twice as high in MC as in DC pregnancies,^{58,64,65} and there is a 20% risk of organ damage such as microcephaly, hydranencephaly, multicystic encephalomalacia, intestinal atresia, aplasia cutis, or limb amputation in the survivor.^{13,48,58,64,67} There is at least a 12% risk of severe neurologic handicap in children who survive the death of a MC co-twin even as early as 18 weeks.^{13,58,67} The pathogenesis of such damage is not fully understood, but the most likely theory is hypotension along with hypoxemia and anemia occurring in the survivor due to exsanguination of the survivor into the dead twin's relaxed vascular bed.^{8,13,58}

Maternal medical complications

Women carrying multiple fetuses are at greater risk of medical and obstetrical complications than women carrying a singleton because of the increased average maternal age and the increased physiologic demands of multiple fetuses and greater placental mass (Table 13.5). Some of the problems that seem to be more common with multiple gestations are discussed below.

Gastrointestinal

Hyperemesis gravidarum

Nausea and vomiting early in pregnancy complicate almost 50% of multiple gestations.²⁸ This is probably due to the higher levels of β hCG and steroid hormones. Although there is likely a higher incidence of hyperemesis gravidarum, as well, the exact incidence in multiple gestations has not been quantified.

Cholestasis of pregnancy

There is a higher incidence of intrahepatic cholestasis of pregnancy in multiple gestations, particularly in genetically susceptible populations, in which it occurs in 21% of twins compared with 10% of singletons.⁶⁸ As in singletons, intrahepatic cholestasis of pregnancy in multiples usually presents with generalized pruritis and mild jaundice in the third trimester. The recurrence rate is reported to be as high as 70.5%.⁶⁸ The differential diagnosis includes viral hepatitis, acute fatty liver of pregnancy, and cholelithiasis. The bile acids (cholic acid, deoxycholic acid, and chenodeoxycholic acid) are increased 10–100 times over normal levels, and should be at least three times normal levels to confirm the diagnosis. The management of intrahepatic cholestasis of pregnancy in a multiple gestation is the same as in a singleton, which must include careful antepartum fetal monitoring and probable early delivery as the condition is associated with adverse perinatal outcome.

Acute fatty liver of pregnancy

Acute fatty liver of pregnancy (AFLP) is a very rare condition; yet, 16.7% of the cases occur in twin pregnancies.⁶⁹ AFLP is a fulminant disease that causes jaundice, nausea, and vomiting in the third trimester. It has historically been associated with poor maternal and perinatal outcome and, if undiagnosed or untreated, may result in somnolence, coma, liver rupture, liver failure, hypoglycemia, disseminated intravascular coagulation (DIC), oliguria, renal failure, metabolic acidosis, multisystem organ failure, maternal death, fetal distress, and fetal demise. Although earlier recognition and treatment of AFLP have decreased maternal mortality, it is still up to 20%.⁷⁰ Therefore, the diagnosis must be considered and serum chemistries obtained in symptomatic patients. Important tests include liver transaminases, complete blood count, serum ammonia (all increased), and serum glucose (markedly decreased). Management of AFLP in a multiple gestation is the same as for a singleton.^{7,69,70}

Hematologic

The increased demands of a multiple gestation often lead to iron and folate deficiency, and there is more “dilutional” anemia due to the exaggerated increase in plasma volume.⁶ Anemia (hemoglobin <10 g/dL or hematocrit <30%) has been reported twice as often in mothers with twins compared with those with singletons.^{5,71} It has also been found in 20–70% of triplets and higher order multiples.^{13,25,38} Severe anemia can be defined as a hematocrit <22%, an anemia that requires blood transfusion, or an anemia associated with cardiorespiratory symptoms or decompensation. It is suspected, but has not been shown, that severe anemia is also increased in multiple pregnancy. Thromboembolism is also more common in women carrying a multiple gestation.⁷²

Gestational diabetes

It is unclear whether carbohydrate metabolism is affected significantly by the added demands of a multiple gestation.⁵ However, it is logical that gestational diabetes (GDM) would be increased in multiples because of the increased human placental lactogen and circulating steroid hormones that are seen in these pregnancies.^{38,73,74} The higher incidence observed in triplets (~25%) compared with twins (~5%) supports this logic.^{7,74,75} Diabetes education, particularly as it relates to diet, must take into account the increased baseline caloric requirement for women with a multiple gestation and GDM.

Urinary tract infections

Ureteral changes in women carrying a multiple gestation are likely to be exaggerated. Decreased peristalsis from the high progesterone levels or compression at the pelvic brim from the overdistended uterus may lead to increased stasis and more urinary tract infections. Urinary tract infections have been found more commonly in twins than in singletons,^{5,71} and in triplets than in twins.²⁸ However, it is not clear whether the incidence of frank pyelonephritis is increased among multiple gestations.⁵

Cardiovascular complications

The expected physiologic changes in the cardiovascular system are exaggerated in women pregnant with a multiple gestation.^{713,76–78} There is an even greater drop in diastolic blood pressure in the second trimester, followed by a greater rise before delivery.^{6,13,78} There is a 10–20% greater increase in plasma volume (approximately 500 mL extra) compared with singletons.^{6,13,78} As a result, total concentrations of serum proteins and electrolytes are reduced more than expected for singletons. Total intravascular protein mass, however, is unchanged, as are serum sodium, potassium, chloride, and osmolality. Greater increases in stroke volume and heart rate lead to greater increases in cardiac output than singleton

pregnancies.^{77,78} Most healthy women can adapt to these changes, but women with underlying medical problems and a multiple gestation may be at increased risk of serious consequences.

Preeclampsia/eclampsia

The incidence of gestational hypertension and preeclampsia is significantly increased in women carrying a multiple gestation compared with women carrying a singleton.^{5,71,79,80} The average incidence in twins across studies performed from 1982 to 2003 is 16.7% (8.9–37%).^{5,15,28,34,70,71,79,80–82} Women carrying triplets have greater placental mass and even higher rates of hypertensive complications, averaging 24.6%.^{25,34,38,70,81,83–86} The reported incidence of preeclampsia among patients carrying more than one fetus would undoubtedly be even higher if more of these patients delivered closer to term.^{70,80} The onset of preeclampsia is often earlier and the severity and complications are greater in women carrying a multiple gestation compared with a singleton.^{15,25,70,80,81,83–85,87} For example, Lynch and colleagues found severe disease in 26% of their cohort of twins presenting with preeclampsia at an average gestational age of 34 weeks.⁸⁷ In a series of 100 triplets, 73% of the patients with preeclampsia had severe disease at a mean gestational age of 32.8 weeks.²⁵ Life-threatening complications such as eclampsia, hemolysis, elevated liver function, and low platelets (HELLP) syndrome, and AFLP occur more often among twins and triplets.^{25,28,70,71,79,80,87} For this reason, we recommend obtaining uric acid, transaminases, serum creatinine, and complete blood count with platelets early in pregnancy and again early in the third trimester. Patients with borderline blood pressures or a low platelet count and a multiple gestation are assumed to have a potentially serious hypertensive complication and are evaluated frequently in order to avoid maternal and neonatal morbidity and mortality from missed or delayed diagnosis.⁷⁰ A woman with a multiple gestation and preeclampsia is more susceptible to volume overload and pulmonary edema because of the combination of increased afterload (caused by the vasospasm seen in preeclampsia), increased preload (caused by the baseline increase in plasma volume), and decreased baseline colloid oncotic pressure.⁸⁸ Therefore, management of preeclampsia in multiple gestations, although similar to management in singletons, must include extra precautions to control blood pressure and to avoid excessive intravenous fluid administration as well as closer monitoring for evidence of life-threatening complications.^{70,79,83} There may be a role for expectant management of HELLP syndrome in multiple gestations to avoid a significantly preterm delivery of multiple fetuses using high-dose dexamethasone to improve platelet counts and suppress liver function abnormalities.^{70,89}

Psychologic

The psychosocial effects of a multifetal pregnancy and birth can also be significant.^{29,85,90–93} Families experience a great deal

Table 13.6 Loss scenarios in multiple gestations.

First- and second-trimester miscarriage of all fetuses
First-trimester loss of some fetuses (vanishing twin/triplet)
Multifetal pregnancy reduction (MFPR)
Later intrauterine demise of some or all fetuses
Selective or complete termination for anomalies
Expectant management with one or more anomalous fetuses
Complications of monochorionic twins
Intrapartum demise
Delivery at limits of viability
Sudden infant death syndrome (SIDS) (twice as common in twins as in singletons)
Accidental death (more common in multiples)

Adapted from ref. 92.

Table 13.7 A few management pearls for perinatal bereavement after multiple pregnancy loss.

Offer private experiences such as viewing, holding, bathing, and dressing with multiples individually and together (including deceased with survivors)
Offer prenatal mementos (i.e., ultrasound pictures) and matching mementos for each neonate
Offer photos of multiples alone, together, and with parents or other family members: color, black-and-white, digital, or 35 mm
Suggest computer-manipulated photos (Fig. 13.13), sketches, or pastels
Clarify parent preferences for the survivor's crib label (i.e., "twin A" or just "baby Jones")
Clarify parent desires to refer to survivors by the original or the remaining number of babies
Offer multiple-specific grief information and support resources (i.e., Center for Loss in Multiple Birth – www.climb-support.org)

Adapted from ref. 92.

of stress including feelings of isolation, depression, frustration, and marital difficulties when caring for even healthy, full-term multiples. These feelings are compounded when the infants are preterm, often with handicaps or special needs.^{90,91,94}

The complex ethical and bereavement issues that often arise in a multiple gestation (Table 13.6) require a particularly knowledgeable and sensitive approach. Couples often mourn not only for the lost fetus (or baby) or fetuses (or babies) but also for the unique celebrity status that being a parent of multiples confers. With subtotal loss, conflicting feelings of grief and joy can interfere with normal bonding to survivors, a fact that is commonly overlooked by healthcare providers and social supports.⁹² In some situations, such as with multifetal pregnancy reduction (MFPR), couples experience grief reactions even when they are comfortable with their decision and do not regret it.^{95,96} A detailed discussion of the reactions and responses to loss in the setting of multiple gestations is beyond the scope of this text, but a few pearls for healthcare providers are listed in Table 13.7.

Economic

The cost of giving birth to multiple babies is significant for the healthcare system and for the families.^{7,30,66,97,98} The expense does not increase linearly with the number of fetuses.^{97,98} One study in the USA found the total charges for a triplet delivery to be almost threefold higher than for a twin delivery and 11-fold higher than for a singleton delivery.³⁰ The lifetime costs of feeding, clothing, and educating multiple children of the same age have not been quantified. Families often lose valuable income when the woman, pregnant with a multiple gestation, is forced to give up her job due to pregnancy complications or to the demands of caring for the children.

Obstetrical complications

Preterm labor

Preterm labor is markedly increased in multiple gestations, with an incidence ranging from 20% to 90%, depending on the study, the definitions used, and the number of fetuses.^{7,28,66,71,85,97} The standard treatments for preterm labor have decreased margins of safety in multiple gestations because of the physiologic changes in the cardiovascular system of these women.^{7,13,71,78} For example, the combination of pregnancy, multiple gestation, labor, and the administration of tocolytic agents can more than triple cardiac output compared with nonpregnant levels. Intravenous tocolysis, particularly with beta-mimetic agents, but also with magnesium sulfate, is associated with a host of serious cardiovascular and metabolic side-effects that are exaggerated in patients carrying a multiple gestation.^{6,7,78,88,99} Volume overload is commonly a precipitating factor in the development of pulmonary edema in patients receiving tocolytics as well as hydration for treatment of preterm labor and, as mentioned previously, patients with a multiple gestation are at higher risk on account of their increased plasma volume.⁷⁸ Indeed, multiple gestation appears to have been a predisposing factor in over 19% of the reported cases of pulmonary edema occurring after the use of beta-sympathomimetic agents.⁷⁸ In addition, patients with a multiple gestation may be at higher risk for myocardial ischemia and arrhythmias while receiving intravenous beta-sympathomimetics. Maternal death, in this setting, has been reported to have occurred in at least three patients with a multiple gestation.¹⁰⁰

Preterm premature rupture of membranes

Preterm premature rupture of membranes (PPROM) complicates approximately 14% of twin pregnancies^{28,34} and 20% of triplet pregnancies.^{25,28,34} The treatment for PPRM, which usually involves prolonged strict bedrest in the hospital, puts the mother at risk of infection, deep venous thromboses, and deconditioning, and is costly.

Hemorrhage

An increased rate of both antepartum and postpartum hemorrhage has been reported for multiple gestations.^{28,71} Abruptio placentae, which occurs three times more often in twins than in singletons, is the major reason for the increased risk of antepartum hemorrhage.¹³ Placenta previa, other than vasa previa, has not been shown to occur at higher rates in twins.⁵ The risk of postpartum hemorrhage is twofold higher for women giving birth to twins,⁷¹ and it occurs in up to 15% of women delivering triplets.^{13,25} The average blood loss for a twin vaginal delivery is 500 mL higher than for a singleton.⁶ Uterine atony due to overdistention from the multiple gestation is the major etiology. Therefore, patients need to be watched closely for the first 24–48 hours, and treatment, which is the same as in singletons, should be instituted promptly.

Cesarean delivery

More than 50% of twins, 75% of triplets, and almost all higher order multiple gestations are delivered by Cesarean section, often with a classical incision, primarily because of malpresentation.^{6,28,66,71,101} There are numerous maternal complications that are increased in incidence in patients undergoing Cesarean delivery compared with patients having vaginal delivery. These include, but are not limited to: puerperal infection (endometritis, pelvic abscess, wound infection, and septic pelvic thrombophlebitis), wound dehiscence and evisceration, deep venous thrombosis, ileus, bowel obstruction, bladder catheter drainage, intraperitoneal or retroperitoneal hemorrhage, and increased need for transfusion of blood products. In a controlled study comparing twin with singleton pregnancies undergoing Cesarean delivery, endometritis was increased nearly threefold (13.1% versus 4.7%) and abdominal wound infections nearly twofold (5.6% versus 3.0%).¹⁰²

Uterine rupture

One retrospective study found a 0% incidence of uterine rupture in patients with twins undergoing a trial of labor after a previous Cesarean section (vaginal birth after Cesarean section; VBAC).¹⁰¹ A newer, multicenter, retrospective study confirmed the overall safety of attempted VBAC in twins with uterine rupture rates that are comparable to singletons.¹⁰³ Until a larger, prospective study is completed, a trial of labor is justifiable for patients with twins as long as they are monitored closely during the antepartum and intrapartum periods, and signs or symptoms of uterine rupture, such as repetitive severe variables or prolonged decelerations, are taken seriously.

Antepartum management

Multifetal pregnancy reduction

Multifetal pregnancy reduction (MFPR), which was introduced in the late 1980s, has proven to be a safe and effective procedure to reduce the maternal and perinatal morbidity and mortality associated with high-order multiple gestations.^{34,37,50} It is most commonly performed by transabdominal or transvaginal injection of potassium chloride into the fetal thorax under ultrasound guidance late in the first trimester. The uppermost or technically easiest embryo is chosen for reduction unless one has a smaller crown–rump length or increased nuchal translucency, which can be an early indicator of an anomaly.^{104,105} The overall pregnancy loss rates after the procedure are reported to be approximately 3.3–11.7%, depending on the starting and finishing number.^{37,50} This must be compared with the background loss rates for high-order multiple gestations prior to viability, which range from 8% to 20%.^{13,28} Although there is clear improvement in both maternal and fetal outcome for women with four or more fetuses who undergo the procedure, the medical benefit, although present, is less striking for women pregnant with triplets.^{34,74} However, because there is clearly some improvement in outcome for triplets that undergo MFPR to twins, and some women may have compelling economic or psychological reasons for desiring the procedure, we believe that all mothers discovered to have more than two fetuses should be offered the procedure with appropriate counseling.^{13,34} The final number of fetuses can safely be left at two or one depending on the woman's medical and emotional background.^{37,50} There also appears to be some residual effect of the starting number of fetuses, as the overall pregnancy loss rates and incidence of complications, such as subsequent preterm labor and delivery, and fetal growth restriction, seem to increase in proportion to the starting number.^{35,37} MFPR now gives women who find themselves pregnant with a high-order multiple gestation, often after years of emotionally, financially, and physically exhaustive infertility treatments, a chance of a good pregnancy outcome, but the availability of the procedure is not a substitute for judicious monitoring of ovulation induction and the use of advanced reproductive technologies. Patients need to be thoroughly counseled about the likelihood of conceiving multiple fetuses and the risks involved in carrying such a pregnancy before embarking on infertility therapies.

Prenatal diagnosis

Women with multiple gestations frequently have indications for prenatal diagnosis due to the higher incidence of congenital anomalies, the frequency of advanced maternal age, and the increased risk of aneuploidy in at least one fetus at younger ages.^{7,13,50,51} The modalities that are available in multiple gestations are similar to those for singletons,

although prenatal diagnosis in multiples has some unique problems.^{7,50} The noninvasive modalities are ultrasound and biochemical marker screening. The ultrasound markers in twins are similar to those in singletons. As many multiple gestations are scanned early, there is an opportunity to diagnose some anomalies such as anencephaly even in the first trimester. A nuchal translucency thickness greater than 2.5 mm in the first trimester has been shown to be present in a large number of trisomic twin fetuses, as in singletons.¹⁰⁵ It has value, especially when combined with maternal age, as a noninvasive screen for Down syndrome.^{13,105} A comprehensive fetal survey should be performed on each fetus at 18–20 weeks to rule out structural anomalies that are not detectable in the first trimester. Biochemical markers, as a screen for aneuploidy, have unproven validity in the setting of multiple gestations, particularly in those of high order, as the normal distributions for both first- and second-trimester proteins have not been established.^{13,49} For example, a MSAFP of greater than 2.5 MoM, which is considered abnormal in singletons, occurs in 20–30% of patients with twins.¹⁰⁶ Elevations greater than 4 MoM in a twin gestation, however, are indications for further evaluation.⁴⁹ Thus, MSAFP screening alone does have some use in detecting open neural tube and abdominal wall defects in twins that are not the result of MFPR, where the levels are elevated due to the remains of one or more fetuses.

The three invasive methods available for prenatal diagnosis in singletons, chorionic villus sampling (CVS), amniocentesis, and percutaneous umbilical blood sampling (PUBS), are also available for multiple gestations, even those of high order. CVS has been shown to be safe and effective in multiples with loss rates (2–3%) that are similar to those with amniocentesis.⁵⁰ The potential problems include inadvertent sampling of the same fetus twice, contamination of one sample with villi from another, and inability to identify the fetus with an abnormal karyotype at a later date.^{7,49,50} Some of these problems can be solved by using a combined transcervical and transabdominal route to sample different placentas and by careful ultrasound guidance.⁴⁹ The advantages, such as earlier diagnosis, and the disadvantages, such as forgoing amniotic fluid AFP analysis, are the same as for CVS in singletons. An additional use for CVS in high-order multiples is prior to MFPR procedures where it has been used without increasing loss rates from the procedure.^{49,50} This saves couples the potential tragedy of finding out later that one of their remaining fetuses has a karyotypic abnormality when embryos that may have been normal were the ones chosen for reduction.

Standard amniocentesis for analysis of karyotype and AFP can be done in multiple gestations at 15–18 weeks with reported loss rates prior to 28 weeks of 2.8%, which are not significantly different from the background loss rates for twins.^{49,107,108} Each fetus should be sampled as a separate procedure. To insure that the same fetus is not sampled twice, 1–3 mL of dilute indigo carmine can be injected into the first sac after the fluid is withdrawn.⁴⁹ If the second tap produces

blue fluid, the same sac has been entered. It is not recommended that methylene blue or other agents be used because of some reports of fetal damage after their use.⁴⁹

PUBS can be performed in twin gestations for the same indications as in singletons. The procedure can be technically difficult, and the cord of one fetus may not be accessible without traversing the sac of another. Although the exact risks of the procedure are not well defined in multiple gestations, the procedure has been performed safely, and there is experience in using it successfully for *in utero* fetal therapy in twins, such as for management of isoimmunization. Whichever method of prenatal diagnosis is chosen by the patient, it is imperative that fetal positions are clearly mapped, preferably by a drawn diagram that identifies the locations of the sacs, placentas, and fetuses, at the time of the procedure, and that the specimens are labeled accordingly. This will decrease the risk that the 'wrong' fetus will be chosen for termination if the parents elect such a procedure at a later date.

Selective termination

Once a fetal abnormality is diagnosed, management options will depend on the severity of the anomaly, the gestational age at the time, and the chorionicity. In the past, patients could either terminate the entire pregnancy, sacrificing the other normal fetus or fetuses, or expectantly manage the pregnancy. Currently, patients have the additional option of selective termination of the abnormal fetus only.^{109,110} The procedure is similar to MFPR in which potassium chloride or another cardiotoxic agent is injected directly into the affected fetus's heart under direct ultrasound guidance. Loss of the entire pregnancy occurs in 5–6% of cases if the procedure is done in twins prior to 13 weeks and in 7–9% if the procedure is performed after 13 weeks.¹⁰⁹ Loss rates are slightly higher when the procedure is performed in triplets (12.5%).^{109,110} Ongoing pregnancies generally have good outcomes for the remaining fetus or fetuses.¹⁰⁹ It is essential that the abnormal fetus be properly identified prior to the procedure, and a specimen of amniotic fluid or fetal blood should be sent for confirmation in cases of karyotype abnormalities. This injection procedure is not safe in MC gestations discordant for an anomaly because of morbidity and mortality in the survivors similar to that seen with spontaneous death of a monochorionic twin *in utero* (see discussion above). However, a selective termination can still be performed if the ultimate vascular connection between the two fetuses is interrupted by an umbilical cord ligation.^{13,111} This can be accomplished using a percutaneous endoscopic technique and is most commonly done using bipolar coagulation.^{112–114}

Antenatal care

Specialized clinics

The antepartum care of women carrying more than one fetus requires knowledge of all the maternal and fetal complications

that can occur in these pregnancies. In addition, special attention to nutrition, preterm birth prevention, and fetal surveillance has been shown to decrease the perinatal morbidity and mortality that is seen with multifetal pregnancies.¹¹⁵ In order to provide the most effective care, some have advocated the use of specialized multidisciplinary twin clinics or at least applications of vigilant management protocols.^{15,116} The following discussion outlines the interventions that have been recommended to improve outcomes for multiple gestations.

Weight gain/nutrition

Patients pregnant with twins or more have extra nutritional demands.^{117,118} It is recommended that supplemental iron (60–80 mg/day) and folate (1 mg/day) be given from the time of diagnosis in addition to standard prenatal vitamins.^{15,118} Patients will also need additional calcium, especially in the third trimester, to support the developing skeletons of more than one fetus.^{29,99,117} We advocate liberal use of calcium supplements as most patients have difficulty meeting the 1500–2000 mg/day requirement with diet alone. Zinc and magnesium supplementation may be beneficial as well. Increased fluid intake (at least 2 L/day) is necessary to support the expanded plasma volume, amniotic fluid volume, and metabolic demands of multiple gestation. Patients need a diet that is rich in protein (300–400 g/day) and calories (at least 1000 kcal/day) over the requirements for a singleton. Adequate maternal weight gain, especially in the first and second trimesters, has been associated with higher birthweights and better outcomes in multiple gestations.^{15,116,118,119} It is currently recommended that women with twins gain 35–45 pounds (16–20 kg), or more if underweight or carrying more than two fetuses.^{116–119} Counseling by a certified nutritionist, early in the first trimester, can help patients meet their body mass index (BMI)-based weight gain goals. Screening for gestational diabetes should be performed at 24–26 weeks. Strong consideration should be given to repeating a normal screen at 32 weeks in women with a multiple gestation.

Prevention of prematurity

Prevention, diagnosis, and treatment of preterm labor must be a major focus in the antepartum care of women carrying a multiple gestation as preterm birth is the leading cause of morbidity and mortality in this group. Education and interventions must begin early because most of the mortality (50–80%) occurs before 32 weeks, and the critical period of gestation appears to be between 26 and 29 weeks and between 600 and 900 g. Many methods of preventing premature birth have been explored, with varying levels of success, but little progress has been made. For example, the average gestational age of delivery for triplets (~33 weeks) has not improved since the 1940s.¹ Outcomes have vastly improved, but this is likely due to improvements in neonatal management. It becomes clear as we review current methods that are used to combat prematurity that further clinical investigation is needed.

Identification of patients at risk

The first step in preventing preterm birth is to identify those patients at greatest risk so that they can be targeted for intervention. This process should start with intensive education of the patient regarding the dangers of prematurity, the signs and symptoms of preterm labor, and easy access to a healthcare provider at all times. A cervical length of <25 mm at 24 weeks in twins is strongly predictive of preterm delivery.^{15,120–122} A midtrimester short cervix has also been shown to be an increased risk for preterm delivery in triplets.¹²³ Therefore, the next steps in identifying patients with a multiple gestation who are even more likely to deliver prematurely are a knowledgeable risk assessment combined with serial cervical examinations, both manually and with transvaginal ultrasound.¹²³ Cervical lengths of at least 3.5 cm at 24 weeks in twins are associated with less than a 5% risk of delivery at less than 34 weeks.¹²⁴ Assessments should be made at least every 2 weeks starting in the second trimester in order to be effective. A suspicion of shortening or funneling on a transabdominal sonogram or a digital examination should be followed immediately by a transvaginal sonogram.

Many practitioners use costly home uterine activity monitoring (HUAM) in attempts to identify patients at risk for premature labor. This noninvasive modality is based on the knowledge that baseline uterine activity is increased in twin pregnancies, that there is an increase in the frequency of contractions as early as several weeks before the development of preterm labor, with an even greater rise 24 hours before,¹²⁵ and that women with twins are less likely to perceive their contractions.¹⁵ However, the data showing the efficacy of HUAM are limited, even in multiple gestations, and some of the apparent benefit may be from the frequent nursing education and contact that accompanies the programs and not from the use of the monitor *per se*.^{15,126}

The detection of fetal fibronectin (fFN) on a simple culture swab from the cervicovaginal secretions, which is commercially available, is a modality that identifies patients at risk for delivering in the near future. The best positive predictor is in twins with serially positive fFN and a short cervix.¹²⁰ The high negative predictive value of the test has been confirmed in multiple gestations.^{120,127} Unnecessary interventions may be avoided in a patient with increased uterine activity but no cervical change and a negative fFN.¹²⁴

Preventative measures

Cerclage

The placement of a purely prophylactic cerclage in all patients with a multiple gestation is not currently recommended. No benefit from the procedure has been demonstrated in twins without evidence of cervical incompetence.^{6,13,121,128} Even in twins with a sonographically short cervix (≤ 2.5 cm), rescue cerclage placement does not clearly improve outcomes.¹²¹ There is potentially more value to prophylactic cerclage in high-order multifetal pregnancies where the increased weight of the uterine contents may lead to cer-

vical incompetence in patients who have no other risk factors for the condition. Although there are some data that support its use in the management of triplets and quadruplets,¹²⁹ there are no randomized clinical trials, and substantial data exist that show no benefit.^{29,38,85} Prophylactic cerclage is not an intervention with proven benefit in patients pregnant with more than two fetuses and no history of incompetent cervix.¹³

Bedrest

Bedrest is one of the most commonly prescribed interventions to prevent prematurity in multiple gestations; yet, its efficacy is uncertain. For twins, in fact, prophylactic hospitalized bedrest appears to have no benefit, and it is costly and disruptive to families.^{15,28,130,131} There are no randomized trials in higher order pregnancies, but modern management in the USA has essentially abandoned routine hospitalization for these pregnancies as well.^{15,29,86,97} The value of prophylactic bedrest at home has not been formally studied, but it is part of the management in most studies of high-order multiple gestations.^{28,29,86,97} Modification of normal activity and increased rest periods throughout the day may prolong gestation and decrease the incidence of other complications such as hypertension and FGR, even in twins.^{15,86} It is the author's opinion that recommendations to women carrying multiple fetuses regarding lifestyle modifications must be individualized depending on additional risk factors for pregnancy complications and the patient's home and work environment, and that strict bedrest and hospitalization be prescribed only when complications occur that warrant it.

Prophylactic tocolytic therapy

The use of currently available tocolytic agents as a prophylactic means to prevent preterm labor in multiple gestations is not supported by the literature.^{15,7,132} Furthermore, there is significant risk associated with their use, which is exaggerated in multiple gestations, as discussed above.

Treatment of preterm labor

Tocolytics

Once preterm labor has been diagnosed, however, tocolysis is indicated. The medications, routes of administration, and contraindications are the same as in singleton pregnancies. Unfortunately, multiple gestation is frequently an exclusion criteria in studies that have evaluated the efficacy of tocolysis. Despite the paucity of scientific evidence in multiple gestations, experience has shown that tocolytic agents decrease uterine activity and prolong gestation by at least 24–48 hours in these pregnancies^{15,133} and, thus, we believe they should be used to halt (or slow down) labor occurring prior to 34 weeks' gestation. Of course, these agents must be used with extra caution and monitoring in women with multiple gestations because of the increased risk of complications detailed above.^{6,78,88}

Figure 13.8 A simultaneously reactive twin nonstress test.

Steroids

The administration of betamethasone or dexamethasone within several hours to 7 days of birth between 24 and 34 weeks' gestation clearly decreases the incidence of respiratory distress syndrome, intraventricular hemorrhage, and necrotizing enterocolitis in singleton gestations.¹³⁴ The benefit in multifetal pregnancies has not been studied extensively, and there is some question as to whether the currently recommended doses are adequate, given the altered pharmacokinetics in these women.^{134,135} However, no harm has been demonstrated, and it is therefore recommended that they be used liberally in multifetal pregnancies for the same indications as in singletons.¹³⁴ The efficacy and safety of weekly, prophylactic administration of antenatal steroids has not been demonstrated and is not currently recommended.¹³⁴

Fetal surveillance

Ultrasound

The important uses of ultrasound in multiple gestations are outlined in Table 13.1. As discussed previously, an early sonogram is necessary to confirm the diagnosis, assess chorionicity, and establish good dating.¹² Another sonogram should be performed at 18–20 weeks to screen for anomalies, confirm the chorionicity, and assess the cervix. Frequent sonograms should be performed thereafter (every 3–4 weeks in an uncomplicated multiple gestation) to assess fetal growth, amniotic fluid volume, and cervical length.^{15,136} If complications arise, or in particularly high-risk multiple pregnancies, sonograms should be performed more frequently and be done by sonologists experienced in the management of such complications.

Nonstress test

All multiple gestations are at some increased risk for unexplained demise and uteroplacental insufficiency, and they should therefore undergo antepartum fetal testing.^{7,137} However, the gestational age at which tests of fetal well-being should be initiated, the frequency of testing, and the modality

or combination of modalities that should be used varies depending on the presence of additional maternal or fetal risk factors.^{7,15,136} At most centers, the nonstress test (NST) is the primary method, and it is performed at a minimum of weekly from 36 weeks in uncomplicated dichorionic multiples.^{15,136} It has been proven to have the same validity in multiple gestations as in singletons and has some of the same problems, such as a high false-positive rate.^{15,138} Monitors are available that allow simultaneous testing of multiple fetuses, which shortens testing time and allows for study of the *in utero* behavioral interactions between twins (Fig. 13.8).^{136,139} The general principle that an abnormal screening test should be followed immediately by a more sensitive and specific test, such as vibroacoustic stimulation or biophysical profile, applies to multiples as well, but the interpretation and management of nonreassuring testing in a multiple gestation can be much more complex than in a singleton, particularly when the fetuses have discordant test results. Management recommendations must take into account the impact of immediate, often preterm, delivery on the healthy fetus, and the prognosis, which may be poor even with immediate delivery, of the fetus with concerning testing.

Contraction stress test

Although a contraction stress test (CST) may be performed safely in some cases of multiple gestation, this form of fetal surveillance is rarely used. Often, multiple pregnancies are complicated by conditions for which the CST is contraindicated, such as premature labor, abnormal placentation, or abnormal bleeding. If a spontaneous CST arises during a period of antepartum fetal heart rate testing, its interpretation may be of value.¹³⁶

Biophysical profile

The fetal biophysical profile (BPP) is also a reliable method of fetal surveillance in multiples, even in those of high order, with comparable sensitivity and specificity to testing in singletons.^{15,136,139} An advantage of using the BPP as an adjunct to the NST in multiple gestations is the ability to assess amniotic

fluid volume which, if increased or decreased, may be the first sign of a problem, such as FGR or a twin–twin transfusion. Monochorionic multiple gestations, women with additional risk factors for uteroplacental insufficiency, and fetuses who are already known, from ultrasound, to have a growth problem should have at least an amniotic fluid volume assessment weekly.

Doppler ultrasound

The umbilical artery systolic/diastolic (S/D) ratio in twins is the same as the value in singletons throughout gestation.^{12,13} Similar controversies exist regarding the use of umbilical artery Doppler velocimetry as a screening modality for fetal well-being in twins as in singletons. Some have shown that abnormal or discordant values can be detected 4–8 weeks earlier than other evidence of growth problems,^{12,13,136,140} and that they are good predictors of poor perinatal outcome.^{136,141} It has also been shown to be of use in the surveillance of the twin–twin transfusion syndrome.^{12,136,141} However, the utility of Doppler velocimetry in concordant multiples has not been proven, and we feel that its use should be limited to those pregnancies at highest risk. Abnormal results may indicate more frequent surveillance, but other interventions should only be undertaken if a combination of all available test results warrants it.

Timing of delivery

Much controversy exists regarding the timing of delivery in multiple gestations. There is no evidence that fetuses “mature” faster just because they are sharing the same womb. For this reason, uncomplicated twins should not be electively delivered prior to 38 weeks, and there is no contraindication to expectant management until close to the due date as long as there is reassuring testing.^{7,15} There is some evidence that twins have higher stillbirth rates and higher than expected rates of FGR after 38–39 weeks.^{6,137} The elective delivery of higher order pregnancies, which is almost always by Cesarean section, can be justified slightly earlier, at 36–37 weeks. Many multiple gestations, however, are at higher risk as gestation progresses. Consideration should be given to earlier delivery in these situations, only after confirmation of fetal lung maturity, unless there is an absolute fetal or maternal indication for delivery. As in singletons, the presence of phosphatidylglycerol or a lecithin–sphingomyelin ratio ≥ 2.5 in amniotic fluid is indicative of fetal lung maturity. In at least 50% of twins, there is intersac discordance in lung maturity, so both sacs should be sampled if possible.^{6,13,15,142}

Antepartum management of fetal complications

Monoamniotic gestations

Monoamniotic twins were traditionally associated with a mortality rate of 50%, which is predominantly the result of cord entanglement.^{13,58,62,63} This occurs in at least 70% of cases

and can happen at any time.⁵⁸ Contemporary management protocols that involve early diagnosis, ultrasound looking for evidence of cord compression and to evaluate fetal growth, frequent antepartum fetal testing with nonstress tests and continuous fetal monitoring for frequent variable decelerations, and delivery by Cesarean section for nonreassuring testing have decreased the mortality to 20%.^{13,58,62,63} Most advocate delivery, usually by Cesarean section, as soon as fetal lung maturity is documented, usually around 34 weeks when mortality is low.^{13,58,53} There is some justification for planned Cesarean delivery at 32 weeks.¹⁴³

Conjoined twins

If the diagnosis of a conjoined twin is made early, the option of pregnancy termination should be offered. If the patient declines or if the diagnosis is made later, serial ultrasound and further evaluations such as echocardiography and magnetic resonance imaging (MRI) should be performed to help determine whether extrauterine life is possible, and if there is any chance of successful separation after birth. Management will depend on such assessments.^{53,54} If conjoined twins have a possibility of survival, the best perinatal outcome will be achieved with Cesarean delivery, close to term, at a specialized tertiary care center.⁵⁴ Abdominal delivery is sometimes necessary, even for nonviable or demised conjoined twins, to avoid maternal trauma. Postnatal prognosis will depend on the site and degree of union, the presence or absence of any other major anomalies, and the degree of prematurity.⁵⁴

Acardiac twins

The mortality for the pump twin in cases of acardia is greater than 50% and is universally lethal for the recipient.^{13,59} The *in utero* treatment modalities that have been attempted include medical therapies, selective delivery, and umbilical cord blockade.^{13,58,111} The most promising seems to be fetoscopic umbilical cord ligation, which has a relatively low failure rate but a high risk of preterm delivery due to rupture of membranes and preterm labor.^{13,111} There is also a role for expectant management when the weight of the acardiac twin $[-1.66(\text{length}) + 1.21(\text{length}^2)]$ divided by the weight of the normal twin (using standard biometry), the twin-weight ratio (TWR), is more than 70%.^{58,59} The pump twin needs close surveillance for evidence of cardiac failure and most likely will require early delivery.

Twin–twin transfusion syndrome

When a “stuck twin” is visualized on ultrasound, a fetal anomaly of that twin or a severe growth abnormality with placental insufficiency must be considered. Similarly, if isolated polyhydramnios is seen around one twin, an anomaly or infection may be the etiology. A diagnosis of TTTS should be reserved for those cases that demonstrate the multiple criteria discussed earlier. Once the syndrome is diagnosed with reasonable certainty, prognosis depends on the gestational age and the severity, but the mortality is generally well above 50%

without treatment.⁵⁸ A staging system based on the appearance of the bladder in the donor, Doppler values, and the presence of hydrops has some value in patient counseling and comparison of treatment protocols.¹⁴⁴ Four treatment options have been investigated. The first is decompression amniocentesis, whereby large quantities of amniotic fluid are serially removed from the recipient's sac.¹⁴⁵ This serves to decrease maternal respiratory embarrassment and preterm labor from the often massive polyhydramnios, and may reduce compressive forces on the umbilical cord leading to reversal of the shunt. Although some have reported improved outcomes with the procedure (78% survival), there is a question of abnormal neurologic outcome in a significant percentage of the survivors.¹⁴⁵ Another option is amniotic septostomy, which has outcomes similar to serial amniocentesis. There is the possibility of enlargement of the hole in the septum, resulting in an iatrogenic MA pair with its associated risks.¹⁴⁶ A more invasive modality is fetoscopic laser ablation of the anastomotic placental vessels, which has been reported to achieve a 60% survival rate with low neurologic morbidity in the survivors.^{60,147–149} By ablating the vascular connections between the fetuses, the now functionally DC pair is probably less susceptible to neurologic injuries that can occur as a result of hypotension or other vascular alterations in a co-twin.¹³ Two randomized trials have been performed, one demonstrating no difference in survival between serial amniocentesis and amniotic septostomy,¹⁵⁰ and one showing a significant benefit to laser therapy over serial amniocentesis.¹⁴⁸ The prognosis, including the potential for damage to the survivor in the event of a demise, should be discussed with the patient after the diagnosis is made when deciding between various management options. After therapy, weekly ultrasound and intensive fetal surveillance will be needed. The option of termination of pregnancy needs to be discussed due to the poor prognosis, even with therapy. Delivery should be undertaken as soon as fetal maturity is confirmed or for nonreassuring fetal testing.

Fetal growth restriction of one or more fetuses

When FGR afflicts one or more fetuses, management is similar to that of FGR in a singleton. If it is detected early in pregnancy, an anomaly should be ruled out by careful sonography and karyotype analysis. If it is secondary to uteroplacental insufficiency, the risks of prematurity must be weighed against the risks of continued stress *in utero*. Close fetal surveillance should ensue, with ultrasound examinations every 2 weeks to assess fetal growth, frequent nonstress and biophysical profile testing, and Doppler velocimetry. Delivery of the growth-retarded fetus should await fetal lung maturity of all the fetuses unless the testing is nonreassuring or the affected fetus fails to demonstrate any growth over time.

Growth discordance

The finding of discordant growth among fetuses in a multiple pregnancy is not necessarily pathologic or associated with poor outcome.^{36,23,36,42–44} However, severe growth discordance

(25–30%), particularly when there is evidence of FGR, is associated with increased morbidity and mortality.^{36,42–44} Once etiologies for the discordance, such as TTTS or anomalies of one twin, are dismissed, it is difficult to predict which pairs are truly at risk. For this reason, multiples that are found to be discordant on ultrasound should be followed more frequently for fetal growth and undergo more frequent and earlier fetal testing.^{17,13,42,151} As long as each fetus follows its own growth curve and testing is reassuring, there is no indication for early delivery.^{6,13,43,151} Early intervention should be undertaken, however, even if premature, if there is progressive growth discordance or signs suggestive of immediate fetal danger.

Single fetal death *in utero*

The management of multiple gestation complicated by the death of one fetus depends on the gestational age at which the loss occurs, the potential cause of the demise, and the chorionicity. If the demise is caused by a pregnancy complication that is likely to affect the survivor, such as uncontrolled diabetes, maternal hypertension, or other medical problems, delivery should be strongly considered even if the fetus will be premature.¹⁵² If the demise is caused by a problem that is unlikely to affect the survivor, such as a known fetal anomaly, expectant management with close surveillance is warranted.^{57,58,152} With monochorionic gestations, there is a significant risk to the survivor, as discussed previously.^{7,58,64,67} Even immediate delivery may not prevent neurologic deficits. If demise occurs prior to 32 weeks, intensive fetal surveillance should be performed with counseling regarding the substantial risk of morbidity in the survivor that may or may not be detectable on ultrasound or heart rate monitoring.^{13,58} Ideally, delivery should be undertaken, even in the face of prematurity, if a complicated MC twin is likely to die shortly.¹³ Maternal coagulation profiles should be followed periodically after a single fetal demise, although the risk of maternal DIC is low.^{6,7,58,65}

Intrapartum management

Asynchronous birth

Most deliveries of multiple fetuses occur in close proximity to each other. There is a role, however, for delaying delivery of some fetuses after a very premature delivery of one. The criteria for attempting expectant management of the remaining fetuses include reasonable evidence of fetal well-being by heart rate monitoring and ultrasound, absence of signs of abruption or chorioamnionitis, and dichorionic placentation.¹⁵³ Although some have had success with the liberal use of antibiotics, tocolysis, and cerclage placement shortly after delivery,^{153,154} these interventions are controversial.¹⁵⁵ Indocin, for 48–72 hours after delivery, does appear to work well as a tocolytic in this setting.^{153,154} There is a reasonable chance (~50%) of achieving the delivery of a surviving infant or infants weeks after the loss of one in carefully selected patients who have been counseled about the potential risks.^{153–155}

Figure 13.9 The relative occurrence rates of the possible combinations of twin presentations. From ref. 156.

Mode of delivery

The delivery of all multifetal pregnancies, even the seemingly most uncomplicated, has the potential for serious complications including unanticipated malpresentations, cord accidents, abruptions, and postpartum hemorrhage. For this reason, women with more than one fetus should be delivered in centers with capabilities for intrapartum fetal monitoring both electronically and by real-time ultrasound, for immediate Cesarean delivery, and for neonatal resuscitation. Any meaningful discussion of the intrapartum management of twins should consider the relative presentations of twin A and twin B (Fig. 13.9).¹⁵⁶ The possible combinations are varied, but three broad categories provide a working classification: vertex-vertex, vertex-nonvertex, and nonvertex twin A (Fig. 13.10). The authors' management plan is illustrated in Figure 13.11.

Twin A vertex, twin B vertex

There is widespread agreement that vaginal delivery of vertex-vertex twins is appropriate.^{13,155-157} Throughout labor, twin A can be monitored with a scalp electrode, once membranes have been ruptured, and twin B can be monitored with an external cardiotocograph. After delivery of twin A, electronic or sonographic monitoring of the fetal heart rate of twin B is carried out until its delivery. Further labor should bring the vertex of twin B into the pelvis, whereupon amniotomy is performed and vaginal delivery is accomplished. If labor has not resumed within 10 min after the delivery of twin A, careful oxytocin augmentation should be used.¹⁵⁸ Although the time

Figure 13.10 The relative occurrence rates of the three broad categories of twin presentations: vertex-vertex, vertex-nonvertex, and twin A nonvertex.

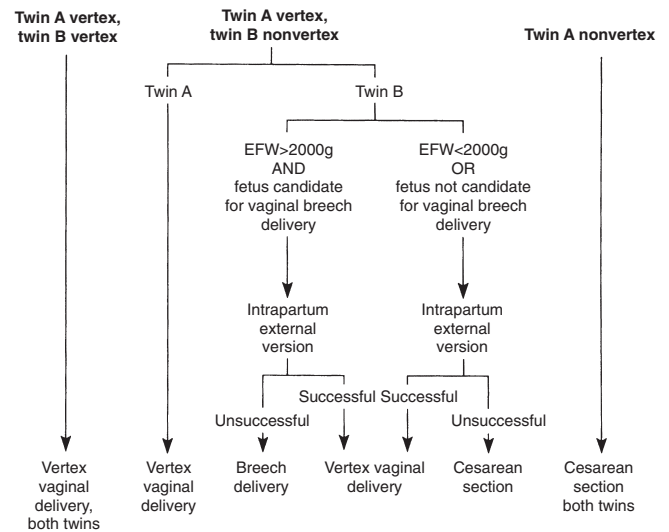

Figure 13.11 Outline of proposed intrapartum management of twin gestation. From ref. 156.

interval between delivery of twins is not a critical factor in obtaining a successful outcome, as long as the well-being of the second twin is continuously assessed, there is a higher incidence of an umbilical cord pH less than 7.00 with longer intervals.¹⁵⁶⁻¹⁵⁸ Cesarean delivery of either or both twins should be undertaken for the same indications as in singletons. The safety of internal podalic version with total breech extraction for a second vertex twin who is in distress has not been demonstrated and, therefore, cannot be recommended.¹⁵⁵

There is some controversy regarding the mode of delivery for very low birthweight infants, even if they are vertex-vertex.¹⁵⁵ However, there is an absence of data demonstrating that Cesarean section is beneficial.^{13,156,157}

Twin A vertex, twin B nonvertex

There is no definitive conclusion at this time regarding the optimum management of the vertex-nonvertex twin gestation. One option is that of elective Cesarean delivery because of the possibility of birth trauma and birth asphyxia to the vaginally delivered nonvertex twin.¹⁵⁷ The preponderance of evidence, however, indicates that this is not necessary.^{6,155,159-162} Two other options exist after vaginal delivery of the first twin: external cephalic version with subsequent vaginal delivery from the vertex presentation or total or assisted breech extraction.

Several series report a 70% success of external cephalic version for the second twin with good maternal and fetal outcomes.^{155,156,160} When considering this option, sonographic assessment of the size of both fetuses should be made and, if twin B is much larger than twin A, the option of elective Cesarean section should be considered. If the patient is a candidate for labor, she should be strongly encouraged to have epidural anesthesia as abdominal wall relaxation will greatly aid attempts at version or breech delivery. The specific maneuver is shown in Figure 13.12. As the first twin is being delivered, the presentation and heart rate of the second twin should be evaluated with real-time ultrasound. Gentle pressure, either with the transducer or with one's hands, is used to guide the vertex toward the pelvis. The shortest arc between the vertex and the pelvic inlet should be followed initially. The version can be accomplished as either a forward or a backward roll, but undue force must be avoided in all patients. When the vertex is brought to the pelvic inlet, the membranes are ruptured and delivery is accomplished, with oxytocin augmentation as needed. If the version is unsuccessful, vaginal breech delivery or Cesarean section is performed depending on

whether the fetus is a candidate for breech delivery (see below) and whether the status is reassuring.

Vaginal breech delivery of the second twin is the other option to avoid routine abdominal delivery of vertex-nonvertex twins.^{155,156,159,162} For twins weighing more than 1500 g, several studies have had up to 95% success rates without any differences in outcome compared with second breech twins delivered by Cesarean section or second vertex twins delivered vaginally.^{155,156} In fact, one study showed improved outcomes and lower hospital charges for the breech extraction group.¹⁶² Even in second breech twins weighing less than 1500 g, there is no evidence that Cesarean section is beneficial.^{161,163} We recommend that vaginal breech delivery be performed for the second twin, after a failed version attempt, if the standard criteria for a vaginal breech are met. These include an adequate maternal pelvis, a flexed fetal head, and an estimated fetal weight of 1500–3500 g, and size that is not significantly larger than twin A.^{113,155,159,163} If these criteria are not met, or if there is evidence of fetal distress, immediate Cesarean delivery should be performed.

Twin A nonvertex

Cesarean delivery is usually recommended for twins when the first is not vertex because the safety of vaginal delivery in this setting has not been established, and there is the potential complication of interlocking fetal heads.¹⁵⁵ Some have shown, however, that, if the criteria are met for vaginal delivery of a breech singleton, vaginal delivery of a breech first twin may be just as safe as abdominal delivery for the pair.¹⁶⁴

Higher order births

There are some studies, albeit with small sample sizes, that report good outcomes for triplets that were allowed to deliver vaginally.^{165,166} These studies clearly do not provide sufficient evidence to suggest that this is safe, especially given the skill that is required to perform such a delivery, and the increased perinatal mortality inherent with triplet and higher order gestations. Most still recommend Cesarean delivery for all high-order multiple gestations,^{7,13,29,155} but the option should be available for motivated patients without other indications for elective Cesarean delivery.

Conclusion

The complexity of both maternal and fetal problems seen with multiple gestation argues for management of the antepartum and intrapartum periods by a multidisciplinary team of experienced personnel, including those skilled in prenatal diagnosis, obstetrical ultrasound, nutrition, prematurity assessment and prevention, and delivery (spontaneous, operative vaginal, and Cesarean deliveries). If complications arise at any time, it is particularly important to have physicians available who are experienced in the management of complications of multiple gestations to optimize successful outcomes and minimize morbidity and mortality.

Key points

- 1 Widespread use of assisted reproductive technologies has led to dramatic increases in the incidence of twins and higher order multiple births.
- 2 Multiple gestations can be dizygotic (all diamnionic–dichorionic) or monozygotic (30% diamnionic–dichorionic, 70% diamnionic–monochorionic, or < 1% monoamnionic–monochorionic), or any combination.
- 3 Ultrasound is indispensable for the identification, assessment including determination of chorionicity, and management of multiple gestations.
- 4 Multiple gestations contribute significantly to perinatal morbidity and mortality.
- 5 The majority of twins and most higher order multiple gestations are born prematurely as a result of premature labor, preterm rupture of membranes, or fetal or maternal complications.
- 6 The risk of being born at a low and very low birthweight is much higher for a multiple because of both prematurity and fetal growth restriction, both of which contribute to morbidity and mortality.
- 7 Fetal complications such as growth restriction, intrauterine fetal demise, and congenital anomalies and complications unique to multiples, such as discordant growth and twin–twin transfusion syndrome, also lead to significant morbidity and mortality.
- 8 Maternal medical complications are exaggerated when carrying a multiple gestation.
- 9 Hyperemesis gravidarum, cholestasis, acute fatty liver of pregnancy, anemia, gestational diabetes, urinary tract infections, and cardiovascular complications occur more frequently and more severely in women carrying a multiple gestation.
- 10 The incidence of gestational hypertension and preeclampsia is several fold higher in women pregnant with a multiple gestation, and life-threatening complications occur more frequently and at earlier gestational ages.

- 11 Complex ethical and bereavement issues often arise in a multiple gestation, and psychological stress can be overwhelming.
- 12 The expenses associated with multiple birth increase exponentially with the number of fetuses.
- 13 Obstetrical complications such as preterm labor, preterm rupture of membranes, hemorrhage, and Cesarean delivery occur at high rates in multiple gestations, and their management poses additional risks to the mother.
- 14 Multifetal pregnancy reduction and selective termination are safe options for women who are pregnant with a high-order multiple gestation or who are found to have an anomaly in one fetus.
- 15 Both noninvasive modalities for prenatal screening such as nuchal translucency as well as invasive modalities for prenatal diagnosis such as CVS, amniocentesis, and cordocentesis are feasible and safe in multifetal pregnancies.
- 16 Antepartum care for women pregnant with a multiple gestation must focus on good nutrition with adequate supplementation, weight gain, and fluid intake as well as on preterm birth prevention with close surveillance for cervical change and fetal and maternal complications.
- 17 Antepartum fetal surveillance for multiple gestations must include serial sonograms for fetal growth and cervical length and tests of fetal well-being such as nonstress tests and biophysical profiles.
- 18 Multiple gestations should not be delivered “early” without documentation of fetal lung maturity unless specific maternal or fetal complications warrant it.
- 19 Therapeutic interventions such as laser ablation of anastomotic vessels and umbilical cord ligation in complicated monochorionic twins can improve outcomes.
- 20 Most twins presenting with A vertex can safely be delivered vaginally utilizing external cephalic version or total breech extraction when the second is nonvertex; however, the safest route of delivery for most higher order multiple gestations is by Cesarean section.

Biology of normal and deviant fetal growth

Andrée Gruslin and the late Carl A. Nimrod

Fetal growth is the result of a complex interplay of various factors, which include genetic, environmental, maternal, nutritional, placental, and endocrine influences. Over 40 specific factors have been shown, through animal studies, epidemiological, and observational data, to influence fetal growth.¹ The importance of identifying the determinants of fetal growth is highlighted by the fact that fetal growth restriction remains the second leading cause of perinatal mortality, and is further enhanced by the association between low birthweight (LBW) and adult-onset diseases.² Epidemiologic studies have demonstrated that individuals born with a LBW have an increased risk of cardiovascular diseases and diabetes in adulthood. Conversely, there has also been a positive association reported between high birthweight and breast cancer risk as, for instance, women who weighed more than 4000 g at birth have been shown to have a risk of breast cancer 3.5 times higher than those who weighed less than 3000 g.^{3–5} These associations between birthweight and adult-onset diseases support the hypothesis that *in utero* events may result in alterations in the programming of the fetus itself or of its metabolic milieu, thereby resulting in significant adult diseases. Increasing laboratory and epidemiologic evidence of the *in utero* origins of these diseases makes it necessary that we understand the factors involved in fetal growth regulation and examine how they may interact as they carry long-term consequences for future health. This chapter will focus on the current literature describing the influences of maternal, genetic, environmental, endocrine, and placental factors on fetal growth, and will examine how these factors are involved in aberrant growth patterns such as growth restriction and macrosomia.

Genetic influences

Elements from both the maternal and the paternal genome are required for normal fetal growth and development. Recent data have demonstrated that, for certain genes, only one allele is functional. This is referred to as genetic imprinting, an epigenetic mechanism by which one of the two alleles of a gene

is expressed according to its parental origin. The allele that is silenced is called imprinted. In the murine model, over 60 imprinted genes have been identified, and the majority influence fetal growth directly. This has led to the suggestion that imprinting may also be an important regulatory factor in human fetal growth. In fact, recent human studies have demonstrated that most maternally imprinted genes act as growth suppressors (e.g., H19, p57), whereas paternal ones act as growth promoters (e.g., insulin-like growth factor 2, IGF-2).⁶ It has been postulated that imprinting occurs because of conflicts between the maternal and paternal genome and nutrient transfer to the fetus from the mother. Thus, paternally expressed genes result in fetal growth promotion at the expense of the mother, whereas genes that are maternally expressed would have the opposite effect. The most striking evidence of the importance of this mechanism lies in the influence of IGF-2 imprinting and its disorder on human fetal growth (Table 14.1). It has been shown that biallelic expression of IGF-2 leads to overgrowth of the fetus, which is recognized clinically as Beckwith–Wiedemann syndrome (Fig. 14.1), characterized by large birthweight, organomegaly, macroglossia, and neonatal hypoglycemia.⁷ Conversely, in the mouse, deletion of the paternal IGF-2 allele has been shown to cause fetal growth restriction.⁸ The mechanisms by which imprinting is altered include chromosomal deletion/duplication, point mutations, and uniparental disomy (UPD). The last refers to a situation in which chromosome fragments originate from a single parent. Murine studies have shown that, for some specific fragments, abnormal fetal growth occurred, suggesting that this portion of the chromosome carried an imprinted gene.^{6,9,10} There are several examples of human imprinted genes associated with UPD. In humans, UPD has been observed for most chromosomes, although only a few are associated with an abnormal phenotype (often growth restriction), again suggesting that these carry an imprinted gene.⁷ Specific examples include Prader–Willi syndrome, Angelman syndrome, and Silver–Russell syndrome (see Table 14.2).

There is evidence from the literature of an influence of maternal genotype on fetal growth. These genetic influences

Table 14.1 Evidence of a role for the IGF system in human fetal growth.

Homozygous deletion of exons 4 and 5 in the IGF-1 gene results in severe intrauterine growth restriction (IUGR) and postnatal growth failure
Biallelic expression of the IGF-2 gene leads to Beckwith–Wiedemann syndrome
Both IGFs are present in the fetal circulation very early and expressed in the placenta
Positive correlation between cord serum IGF-1 concentration and fetal size
Birthweight positively correlated with IGFBP-3 and negatively with IGFBP-1
Human IUGR associated with increased IGFBP-1 and -2 and decreased IGFBP-3
↑ IGFBP-1 at decidual–placental interface in severe preeclampsia/IUGR
↑ Circulatory levels of IGFBP-1 up to six times in severe preeclampsia
↑ IGFBP-1 in IUGR at term and antenatally (cordocentesis)
↓ PAPP-A leads to ↓ birthweight (PAPP-A protease of IGFBPs)

Summary of various evidence from human studies supporting the role of the IGF system in the regulation of fetal growth. This includes the involvement of IGF-1 and -2 as well as their binding proteins and the proteases, which themselves modulate these binding proteins. IGFBP, insulin-like growth factor binding protein; PAPP-A, pregnancy associated plasma protein A.

Figure 14.1 Infant with Beckwith–Wiedemann syndrome. Note the obvious macrosomia related to overexpression of IGF. From Wiedemann HR, Kunze J. *Clinical syndromes*, 3rd edn. Mosby-Wolfe Publishers; 1997:148–149.

are likely those involved in maternal size determination and metabolism, as evidenced by the fact that maternal height is correlated with birthweight and probably reflects its influence on uterine size and perhaps blood flow.¹¹ What is however becoming clear is that maternal phenotype, which results in

physical constraints, probably plays an even more important role in fetal growth regulation.¹² This is evidenced by the cross-breeding studies between horses and ponies in which it was shown that, given the same fetal genotype, growth was greater when occurring in a large animal compared with a

Table 14.2 Clinically relevant outcomes of uniparental disomy in the human.

UPD	Outcome
Maternal UPD2	IUGR
Paternal UPD6q24	Diabetes (transient neonatal)
Maternal UPD7	Silver–Russell syndrome
Paternal UPD11p15	Beckwith–Wiedemann syndrome
Maternal UPD14	IUGR
Paternal UPD14	Short-limbed dwarfism
Maternal UPD15	Prader–Willi syndrome
Paternal UPD15	Angelman syndrome
Maternal UPD16	IUGR
Maternal UPD20	IUGR

Uniparental disomy represents one mechanism that can influence gene imprinting and therefore fetal growth.

small one.¹³ Furthermore, studies of outcomes from assisted reproductive technologies using ova donation clearly demonstrated that birthweight correlated with the height and weight of the birth mother and not the donor.¹⁴ From an evolutionary standpoint, this represents an adaptive mechanism preventing fetal overgrowth and the resulting maternal and fetal complications. This also suggests to the clinician that the interplay between maternal genotype and phenotype that influences birthweight must be recognized as a significant confounding variable in the interpretation of data from pregnancies that are the result of assisted reproductive technologies.

Conversely, paternal factors are thought to have very little influence over fetal growth. Human pedigree studies have demonstrated very little effect of paternal factors on birthweight. Studies of paternal height and weight have also concluded that only a very small effect on fetal weight was present. In a more recent report, paternal height was related to birthweight, with a small effect, an increase of 10 g/cm increase in paternal height, being apparent.¹⁵ This therefore accounted for a very small amount of the variation in birthweight. As paternal weight and body mass index (BMI), which are acquired characteristics, did not influence birthweight, it was suggested that it was paternal genotype (a determinant of height) that played a small role in fetal growth. Again, the fact that this effect is small is highly desirable from an evolutionary standpoint as it prevents fetal overgrowth in mothers whose physical determinants would not allow it.

Fetal genotype, on the other hand, is an important regulator of growth. This is supported by the aberrant birthweight seen in chromosomally abnormal fetuses. Indeed, the average birthweight of fetuses with trisomy 13 is 2400 g; for those with trisomy 18, it is 2240 g and, finally, for trisomy 21, 2894 g.¹⁶ This is believed to be mediated by a decrease in cellular proliferation leading to generalized hypoplasia. The cell cycle of trisomic fetuses has been shown to be slower, with a 50%

reduction in the G2 phase and a generally decreased rate of DNA synthesis.¹⁷ Other evidence of the importance of fetal genotype lies in the fact that fetal gender influences birthweight, as male fetuses are approximately 175 g heavier than females at term. Confined placental mosaicism (CPM) results from a chromosomal error located only in the placenta and has been shown to increase the risk of fetal growth restriction. It has been reported that up to 20% of cases of fetal growth restriction are associated with CPM, which can itself be associated with UPD.¹⁴ Therefore, in cases of unexplained fetal growth restriction, a placental examination looking for CPM may provide useful information.

Maternal influences

Various maternal factors affect fetal growth. These include maternal anthropometry, overall health, nutritional status, and genotype as described above. Several studies have clearly demonstrated correlations between birthweight and maternal height, prepregnant weight, and weight gain during gestation.^{11,18} However, the absence of a correlation between maternal weight gain and birthweight in very obese patients is noteworthy. This also applies to women with gestational diabetes possibly resulting from decreased maternal insulin sensitivity. In addition, birthweight has also been shown to increase with increasing parity, perhaps secondary to the cumulative effects of previous pregnancies on maternal metabolism.

Good maternal health is essential for proper placental implantation and normal fetal growth and development, as it allows the woman to respond and adapt appropriately to changes related to the establishment and maintenance of pregnancy.

In a recent review of the effect of exercise in pregnancy, Clapp¹⁹ demonstrated that, in healthy, fit pregnant women, exercise (particularly regular, weightbearing, strenuous) was associated with improved maternal and fetal outcomes. It was proposed that regular physical activity improved placental growth as well as the normal physiologic changes of pregnancy. Furthermore, as exercise resulted in intermittent decreases in uterine blood flow along with a very small decrease in nutrient supply, those fetuses were leaner at birth but more tolerant of the physiologic stresses of pregnancy and labor.

Conversely, maternal health factors limiting oxygen and nutrient delivery to the fetus do have a significant negative impact on fetal growth. For instance, women with cyanotic heart disease, preeclampsia, or significant pulmonary diseases tend to have smaller infants as well as an increased risk of LBW infants. One of the most common maternal medical conditions worldwide that alters fetal growth is anemia.^{20–22} In a recent study involving 629 women, 313 of whom were anemic, the risk of LBW and intrauterine growth restriction (IUGR) was increased by 2.2 times and 1.9 times

respectively.²⁰ This is consistent with many other studies in which severe anemia was associated with a 200- to 400-g decrease in birthweight. Several mechanisms have been proposed to explain this association²³ including:

- Norepinephrine/cortisol: others have shown that iron deficiency anemia increases norepinephrine release, which can stimulate CRH and cortisol, known to have a negative effect on fetal growth. Furthermore, norepinephrine infusion in the sheep model results in a reduction in fetal protein synthesis and accretion.
- Chronic hypoxia: severe anemia may result in a reduction in oxygen transfer to the fetus, thereby impacting on fetal growth.
- Increased oxidative stress: through this mechanism, oxidative damage to erythrocytes could result as well as endothelial dysfunction, further impeding fetal growth.
- Increased infection; iron deficiency anemia has been shown to have a negative influence on B and T cells, neutrophils, and natural killer (NK) cells, thereby increasing susceptibility to infection. Maternal infection itself has been shown to activate the fetal hypothalamic–pituitary axis, as evidenced by increased cord blood concentrations of cortisol and dehydroepiandrosterone sulfate, thereby again negatively affecting fetal growth.

Maternal nutrition is responsible for the availability of nutrients for the fetoplacental unit. Its importance is highlighted by the fact that fetal growth restriction is seen as a result of severe maternal undernutrition in many developing countries and that the incidence of LBW is higher in women with eating disorders.^{1,24} Women exposed to the Dutch famine of 1944–1945 delivered LBW infants, but only if exposed in the third trimester of pregnancy. Placental growth was also reduced with the same exposure, but was increased in women exposed to the famine during their first trimester. This suggested that the influence of maternal nutrition on fetal growth depends upon the severity of the insult and its timing, as well as its influence on placental growth. Human and animal studies of maternal undernutrition have shown significant alterations in placental size and development, thereby affecting fetal growth directly. For instance, human maternal undernutrition has been associated with decreased placental volume, chorionic villous area, fetal capillary surface area, and volume density of trophoblasts.^{25,26} These changes all correlated with LBW and thus represent a mechanism by which fetal growth is altered. Furthermore, in a recent study of maternal food restriction in the guinea pig model, a decrease in the total surface area of the placenta available for substrate exchange was demonstrated.²⁷ This correlated with fetal weight, suggesting that impaired placental transfer of nutrients to the fetus is involved in the process of growth restriction. In addition, the same study also reported an increase in the thickness of the placental barrier for diffusion, also contributing to altered growth through a decrease in substrate transfer to the fetus. It has been suggested that some of these changes may

be mediated through alterations in growth factors such as IGF-2.^{26,28}

At this time, it remains unclear whether nutritional deficiencies in specific dietary components have a greater impact on fetal growth compared with an overall deficiency. What is becoming more evident, however, is the importance of micronutrient intake on fetal growth and the role that nutrient–gene interactions may have in this process.²⁹ Some of the more important micronutrients studied to date include folate, zinc, iron, copper, as well as vitamins E and A. Of these, zinc has been shown to be critical for insulin packaging and secretion, and its deficiency has resulted in fetal growth restriction.^{24,30} Both copper and iron can alter fetal development by the generation of free radicals, whereas their deficiency results in an accumulation of antioxidant enzymes. Vitamin E, an important regulator of insulin sensitivity, also contributes to fetal growth regulation, whereas vitamin A's role is through the stimulation of growth hormone postnatally and possibly of placental growth hormone prenatally.²⁹ Although this last mechanism is not entirely clear, the effects of vitamin A deficiency on prenatal growth are supported by its association with asymmetrical fetal organ growth as well as reductions in the relative masses of fetal lungs, heart, and liver in animal models.²⁹ The influence of micronutrients on human fetal growth has recently been investigated in a study of 797 pregnant women in rural India.³¹ The authors showed that supplementation of their diet with micronutrient-rich foods such as green leafy vegetables, fruits, and milk was associated with improved birthweight. Interestingly, the intake of green leafy vegetables and fruits at 28 weeks correlated with birthweight, whereas a positive correlation with birthweight was shown for fat and milk intakes at 18 weeks. This suggests that there are likely different nutrient requirements for fetal growth at different stages of development, possibly owing to developmentally regulated tissue growth.

Interestingly, more evidence is accumulating suggesting an interaction between gene expression during fetal growth and nutrient availability.^{1,32} For instance, folate deficiency leads to a decrease in remethylation of homocysteine to methionine. As *S*-adenosylmethionine is a methyl donor, its absence or decrease results in dysregulation of important developmental genes (imprinting defects) and defective DNA synthesis. This is further supported by animal studies including that by Gluckman and Pinal et al.²⁴ in which methyl-supplemented diets fed to pregnant mice altered the expression of an imprinted gene specific to the coat color of their offspring. As DNA methylation is important in the regulation of gene imprinting, it is likely that folic acid, through this process, is involved in fetal growth determination.

Several studies have also examined the influence of maternal fish and seafood consumption on fetal growth.^{33–35} This potential association originated from the observation that birthweights tend to be higher in regions of the world such as the Faroe and Orkney Islands where there is a high maternal

intake of marine foods. It has been proposed that the n-3 fatty acids from fish and seafood might enhance fetal growth by improving placental perfusion through an increase in the ratio of prostacyclins to thromboxanes, which itself reduces blood viscosity.³⁵ To date, two large epidemiological studies (Denmark and Faroe Islands) have shown a positive correlation between fish intake and birthweight.³⁶ In agreement with this, a more recent report from south-west England revealed a decrease in the incidence of fetal growth restriction with increasing fish consumption, but failed to show an association between birthweight and fish intake after adjusting for confounding variables.³⁵ Conversely, others have shown either no effect or even a reduction in birthweight associated with fish consumption.³³ These conflicting reports may be explained by the lack of adjustments for confounding variables, and may also result from the presence of pollutants in marine foods from certain regions. Indeed, fish is known to be a major source of polychlorinated biphenyls (PCBs), which have been shown to lead to fetal growth restriction in animal models.³³ Research in this area is therefore required and needs to take into account all the variables affecting fetal growth such as smoking, as well as evaluating the presence of pollutants in fish and seafood.

Finally, in the context of maternal influences on fetal growth, caffeine intake has also been examined with much discrepancy between studies.^{37,36} This again often resulted from difficult and imprecise evaluation of maternal intake and failure to control for other important variables. The effect of caffeine on fetal growth is supported by the fact that it can cross the placental barrier and has a slow metabolism in pregnancy with a half-life of 10 hours at 17 weeks increasing to 18 hours in the third trimester. Finally, the fact that neither the placenta nor the fetus can metabolize caffeine further supports its negative influence on fetal growth. Although the exact mechanism by which this might occur has not been fully elucidated, it is likely that it involves a reduction in intervillous blood flow³⁷ and possibly an increase in oxygen consumption, as noted in preterm infants treated with caffeine for apnea.³⁶ Although, again, more information is needed on the impact of maternal caffeine intake, it appears so far that at least moderate consumption does not significantly decrease fetal growth, but that a negative impact could be seen with maternal consumption of over 600mg daily.³⁷ The literature also suggests synergism between caffeine and cigarette smoke, as evidenced by a more significant influence of caffeine in women who smoke.³⁷

Growth factors

IGF family

Adequate fetal growth is dependent upon a balanced interplay of positive and negative regulators originating from the fetal, placental, and maternal compartments. Of these, the IGF

family plays an important role. The components of this family include IGF-1 and IGF-2, as well as two receptors (type 1 and 2) and six high-affinity binding proteins (IGFBP 1–6) and their proteases (e.g., PAPP-A), which ultimately regulate the bioavailability of these two growth factors. IGF-1 and -2 are peptides, produced mostly by the adult and fetal livers. They are both potent mitogens and important regulators of tissue growth and differentiation.^{1,24} However, they are developmentally regulated in a different manner and have different actions. For instance, IGF-2 is an imprinted gene, expressed from the paternal allele, and is important for embryonic as well as placental growth and likely involved in cellular differentiation of specific organs such as the fetal pancreas. Biallelic expression of IGF-2 leads to overgrowth syndromes such as Beckwith–Wiedemann, whereas deletion of IGF-2 in the mouse is associated with decreased placental and fetal growth.⁹ In the murine model again, Constancia et al.⁸ have demonstrated that deletion of the placental transcript of IGF-2 resulted in decreased passive permeability of nutrients, leading to restricted placental and, subsequently, fetal growth. More recently, the same model was used to demonstrate that the placental IGF-2 gene is directly involved in the regulation of the diffusional characteristics of the placenta. The authors suggested that decreased IGF-2 expression might indeed be responsible for cases of idiopathic fetal growth restriction that are characterized by decreased placental diffusion capacity.²⁸

Conversely, IGF-1 regulates fetal growth in the later part of pregnancy. It has been shown that IGF-1 promotes fetal substrate uptake, inhibits catabolism, and alters placental metabolism through an inhibition of lactate production, thereby improving placental transfer of nutrients.²⁴ The importance of IGF-1 in human fetal growth regulation is highlighted by a report of an infant born with homozygous deletions of exons 4 and 5 in this gene. This resulted in severe fetal growth restriction as well as postnatal growth failure.³⁸ In addition, deletion of IGF-1 in the mouse has also been shown to lead to fetal growth deficiency which persists postnatally, contrary to animals with IGF-2 deletions that are born at 60% of the size of wild-type controls but whose postnatal growth normalizes.⁸ This suggests that IGF-2 is the dominant regulator during early intrauterine life, whereas IGF-1 influences the process later in gestation and postnatally.

Several factors influence IGF's actions, including their binding proteins and associated proteases, their receptor status, the presence of other hormones and, most importantly, maternal nutrition. Indeed, fetal IGF-1 is sensitive to fetal insulin levels, which are regulated by glucose concentrations (Figs 14.2 and 14.3). This is well illustrated by a series of sheep experiments in which maternal undernutrition was associated with a decrease in fetal IGF-1 and resulted in absent fetal growth. However, upon glucose or insulin infusion, fetal IGF-1 levels returned to normal.²⁴ In addition, it has been demonstrated in numerous studies that a positive correlation exists between cord blood IGF-1 levels and birthweight and

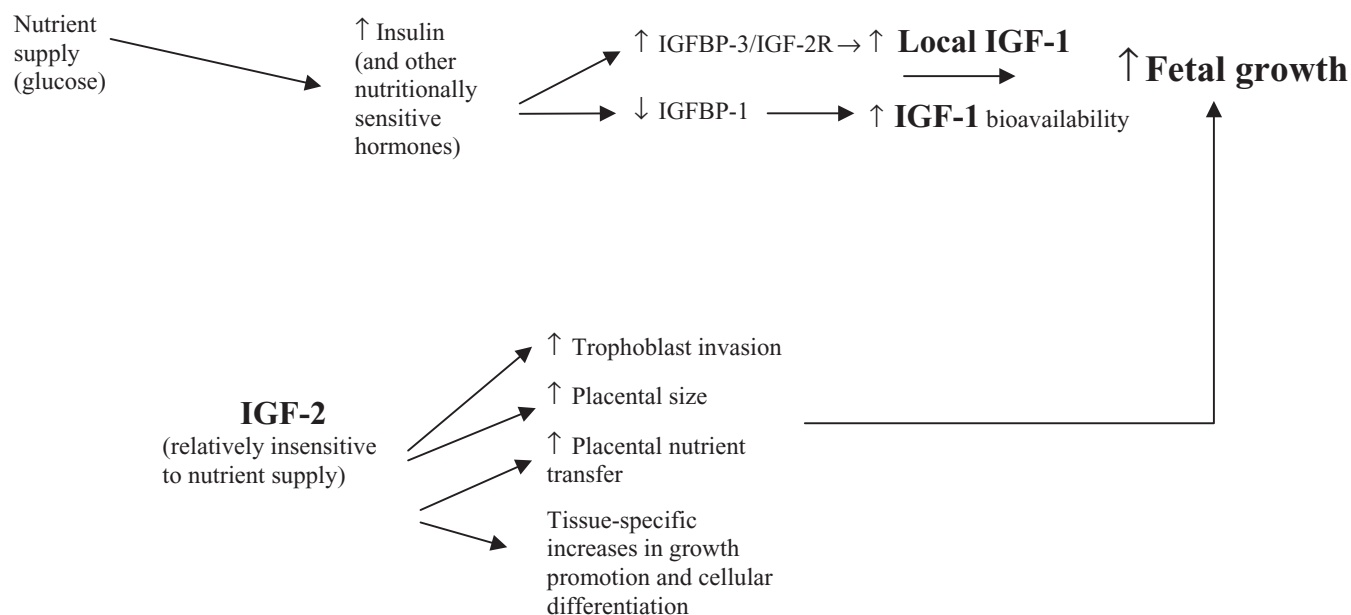

Figure 14.2 Simplification of the mechanism by which the IGF system regulates fetoplacental growth during development. As seen here, nutrient supply, although a direct influence on insulin (which itself regulates binding proteins and IGF-2 receptor), results in an

increase in IGF-1, thereby promoting fetal growth. Conversely, IGF-2 is relatively insensitive to nutrient supply and plays a role in placental growth and development as well as promoting cellular differentiation in specific tissues.

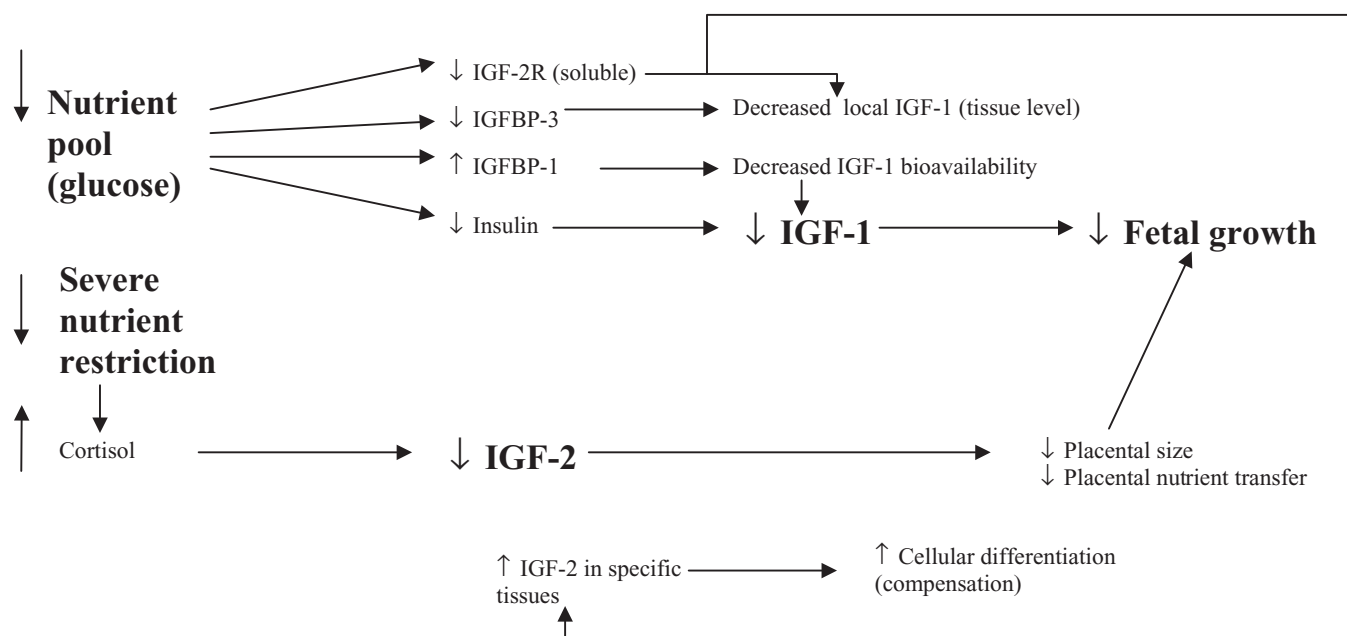

Figure 14.3 Simplified mechanism involving the IGF system in the induction of fetal growth restriction following decreased nutrient and oxygen supply. The lower glucose concentration results in several alterations including ↓ insulin with modulation in receptor concentration and binding proteins status, which all lead to decreased IGF-1 and therefore decreased fetal growth. With ongoing severe nutrient restriction and associated hypoxemia, cortisol

concentration increases and IGF-2 decreases, which leads to a decrease in placental growth and function, further impeding fetal growth. Note that the decrease in IGF-2 receptor (IGF-2R; soluble form) results in a local increase in IGF-2 concentration in specific tissues. This is believed to promote cellular differentiation and provide some positive stimulus for fetal growth in order to attempt to compensate for the above changes.

that fetuses small for gestational age display lower IGF-1 concentrations.^{39–42} This is consistent with an influence of insulin (as stimulated by glucose) over IGF-1 release in the fetus. As no correlation existed between maternal concentrations of IGF-1 and cord levels or birthweight, this suggested that IGF-1 in cord blood originated from the fetoplacental unit and that there was no placental transfer of maternal IGF-1 to the fetus. Conversely, IGF-2 expression is much less sensitive to nutrient supply. Indeed, it has been shown to be reduced only under circumstances of severe malnutrition. In the IUGR fetus, IGF-2 levels vary from organ to organ and have been noted to be elevated in brain and lungs, for example, likely in an effort to promote differentiation and maturation in the context of inadequate growth (see Figs 14.2 and 14.3).

Finally, placental production of IGF-1 should also be noted; although its exact role at this point has not been clearly elucidated, it is likely to be largely intraplacental as described in the above experiments in the murine model.

IGFBPs modulate the actions of IGFs by altering their half-life or simply through their transport to specific tissues. Of these proteins, IGFBP-1 has been shown to be negatively correlated with birthweight in humans.^{40,43} There is increasing evidence to support an important role for IGFBP-1 in fetal growth.^{44,45} For instance, it has been shown that trophoblast invasion, a step crucial to normal placentation and therefore fetal growth, is inhibited by IGFBP-1.⁴⁵ Furthermore, human fetuses that are growth restricted have been shown to display higher blood concentrations of IGFBP-1.⁴¹ Interestingly, another study has demonstrated an inverse relationship between cord blood pO_2 and IGFBP-1. Taken together, these data suggest that hypoxia may stimulate fetal IGFBP-1 production, which decreases IGF-1 bioavailability, thereby minimizing fetal growth when supply is clearly limited.⁴⁶

Compartmentalization of nutrients is essential to the maintenance of fetal growth. This process requires that fetal nutrient supply be maintained as a priority over maternal and even placental demands. Indeed, by secreting placental growth hormone (GH-v) and prolactin, a state of relative maternal insulin resistance is created in which glucose is preferentially transported across the placenta while maternal lipolysis is facilitated in order to respond to the demands of the mother.²⁴

Leptin

Leptin is a product of the *ob/ob* gene located on chromosome 7. It is synthesized by adipocytes as well as placenta (trophoblast and amnion), stomach, bone cartilage, and teeth.¹ It is an important regulator of body weight, and its effect is mediated through a negative feedback mechanism between adipose tissues and specific satiety receptors located in the hypothalamus. Its production has been shown to be stimulated by various hormones including cortisol and insulin.⁴⁷ Under conditions of starvation, leptin levels decrease, which results in induction of food-seeking behavior as mediated by the hypothalamus. It is therefore not surprising that, in adults,

leptin concentrations have been shown to be related to fat mass.

What is less clear is the role that this protein plays in fetal growth. Leptin is known to be produced by the maternal, fetal, and placental units, but whether or not it can cross the placenta has yet to be determined clearly.¹ Current studies have provided conflicting results when examining correlations between leptin concentrations and birthweight.^{48,49} There is evidence for a positive correlation between cord blood leptin and birthweight in appropriately grown fetuses; however, this same relationship could not be consistently demonstrated in small for gestational age (SGA) fetuses and was also influenced by the presence or absence of maternal diabetes. Others have reported a significant decrease in fetal leptin levels in IUGR neonates, consistent with their marked reduction in fat tissue.⁴⁹ However, at this time, the exact mechanism by which fetal weight and fat mass are regulated and how leptin is involved in this process remains unclear.

Placental influences

The placenta influences fetal growth through its functional size, capacity to transport oxygen and nutrients, and its own metabolism. Placental growth is crucial to fetal growth. This is supported by the fact that, throughout gestation, placental growth closely parallels fetal growth. In addition, it has been demonstrated recently that placental volume measured at 14 weeks was directly related to fetal anthropometric measurements at 35 weeks.¹¹ Furthermore, placental villous area (the functional area) continues to increase throughout gestation along with vascularization of terminal villi and thinning of the syncytial layer, which optimizes exchange at the fetoplacental level.

Transport capacity

Fetal growth relies on glucose as a major fuel and, as there is no significant gluconeogenesis in the fetus, it must be obtained from maternal blood directly. Placental transfer of glucose depends on the total surface area of the syncytium available for exchange, the thickness of the placental barrier, the placenta's own metabolic needs, the concentration gradient of glucose between maternal and fetal blood, maternal blood supply and, finally, the presence of transporters.⁵⁰ Indeed, as the syncytial membrane is not very permeable to glucose, the placenta facilitates this process with the synthesis of specific transporters that are members of the GLUT gene family of facilitated diffusion transporters, which are located in the microvillous and basal membranes. Of these, GLUT3 is likely to be the major functional transporter in early pregnancy, whereas GLUT1 is more important near term.⁵⁰ The inverse relationship shown *in vitro* between extracellular glucose concentration and the presence and activity of GLUT1 suggests that glucose itself may be involved in the regulation of

GLUT1. However, it has been shown that, despite the consistent findings of low glucose in IUGR fetuses, their transporter density was not affected. How this applies to the human fetus remains to be elucidated as it is likely that glucose transfer *in vivo* is very complex and relies on various mechanisms.

The fetus also requires amino acids for protein synthesis, interconversion to other substrates, and oxidation. The transfer of amino acids is also a complex process and involves significant placental metabolism as the placenta can use, produce, and interconvert several amino acids.⁵¹ However, in contrast to glucose, which is transferred across a gradient, amino acids are actively transported across the placenta, as supported by their higher concentrations in the fetus compared with the mother. This involves the presence of several transport systems that are all distinct from each other but exhibit some overlapping substrate specificity.^{51,52} The importance of amino acid transport for fetal growth is highlighted by the observations made in IUGR. These fetuses display a decrease in amino acid concentration, an impairment of some transport systems, a decrease in surface area for exchange, decreased placental perfusion, and specific demonstrations of decreased transfer of taurine, phenylalanine, and leucine.⁵²

Placental substrate delivery is also dependent on perfusion. As fetal nutrient demands increase throughout gestation, there is a 20-fold increase in maternal flow into the intervillous spaces. This process depends in part on adequate invasion of spiral arteries by trophoblasts, as supported by the marked reduction in transformed spiral arteries seen in IUGR,¹ which may result from impaired release of nitric oxide and carbon monoxide (two vasoactive substances) by trophoblasts.¹ Normal placental development also requires an early change from a relatively hypoxic to a relatively normoxic environment, resulting from spiral artery transformation and exposure of villi to maternal blood. Failure of this process leads to aberrant expression of several important growth factors involved in trophoblast migration, survival, and proliferation, function, and overall placental growth. Invasion may also be altered by external factors such as maternal smoking, which we have demonstrated to result in increased apoptotic cell death of first-trimester trophoblasts⁵³ and impairment of growth factor/cytokine-mediated trophoblast migration such as epidermal growth factor (EGF). It also requires adequate vascularization of villi, a complex mechanism that appears to be mediated partly by angiogenic factors that may include vascular endothelial growth factor (VEGF) and placental growth factor (PIGF).^{54,55} IUGR fetuses have been shown to have decreased branching angiogenesis in villi, therefore supporting the importance of this process for fetal growth (Fig. 14.4). Finally, factors that alter maternal blood flow to the uteroplacental unit are also of significance in fetal growth. For instance, vessel obliterations have been demonstrated in placentas of mothers with antiphospholipid antibody syndrome, leading to restricted flow and potentially restricted fetal growth regulation. Similarly, women with significant cardiac or vascular disease also have altered uteroplacental blood flow

Figure 14.4 Placenta from a patient with fetal growth restriction and absent/reverse end-diastolic flow in the umbilical arteries. Note the unusually long, poorly branched terminal villi resulting from hypoxemia. From Bernishke, Kaufmann, eds. *Pathology of the human placenta*, 4th edn. Springer; 1999:457.

as a result of decreased output or uterine and placental vascular lesions.

Placental growth hormones

The IGF family plays multiple roles in placental growth and development including an influence of IGF-2 in trophoblast invasion, a step crucial to adequate placentation and to the establishment of maternofetal exchange.¹⁴ In addition, as discussed earlier, placental IGF-2 is involved in placental growth and transport.

GH-v gradually replaces maternal pituitary growth hormone throughout the first trimester. It exerts its biologic effects on the mother and placenta, as it is not detected in the fetus. It has high somatogenic and low lactogenic activities and has been shown to modulate maternal metabolism by stimulating gluconeogenesis, lipolysis, and anabolism.⁵⁶ The end result is to increase nutrient supply to the fetus and therefore indirectly influence fetal growth. It is responsive to changes in

glucose concentration in the maternal circulation and is a key regulator of maternal IGF-1 as well as a mediator of insulin resistance in the mother, thereby having an important role in compartmentalization.

Conclusion

Fetal growth regulation is a complex process influenced by a multitude of factors, some of which have been explored here (Table 14.3). To date, we only have a limited knowledge of what these factors are and how they interact to influence growth *in utero*. Our incomplete understanding of this process in the human partly explains our current difficulties in identifying adequate therapeutic approaches for those fetuses that suffer from growth anomalies such as restriction and

macrosomia. The adult consequences of these aberrant growth patterns *in utero* further highlight the importance of understanding the mechanisms behind fetal growth regulation.

Table 14.3 Determinants of fetal growth.

Maternal	Genotype (maternal height)	+++
	Physical constraints	+++++
Paternal	Genotype (paternal height)	+
	Paternal weight	No effect
Fetal	Genotype	+++
Placental	Size	++
	Transport capacity	++
	Metabolism	++

Key points

- 1 Abnormal fetal growth is associated with adult-onset diseases. Growth restriction increases the risk of cardiovascular diseases and diabetes, whereas fetal macrosomia appears to result in an increase in the incidence of certain types of cancer in the adult.
- 2 Genetic imprinting is a mechanism by which one of the two alleles of a gene is expressed according to its parental origin. Insulin-like growth factor (IGF)-2 is an example of an imprinted gene that plays an important role in fetal growth. Biallelic expression of IGF-2 results in fetal overgrowth (Beckwith–Wiedemann syndrome).
- 3 Uniparental disomy (UPD) is a situation in which chromosome fragments originate from a single parent. In the human fetus, UPD has been observed to be associated with aberrant growth (e.g., Prader–Willi syndrome).
- 4 Maternal phenotype is a very important determinant of fetal growth and, therefore, when evaluating this process, the interplay between maternal phenotype and genotype must be taken into consideration. There is a suggestion that paternal genotype plays a very small role in fetal growth.
- 5 Trisomic fetuses have a decrease in cellular proliferation leading to generalized hypoplasia.
- 6 Exercise in fit, pregnant individuals may improve placental growth. Fetuses tend to be leaner at birth but appear to be much more tolerant of the stresses of labor.
- 7 Maternal anemia is one of the most important medical conditions worldwide that is associated with fetal growth restriction. The mechanism involved may include increased catecholamines, hypoxia, increased oxidative stress and/or infections.
- 8 The influence of maternal undernutrition on fetoplacental growth depends on the severity and timing of the insult.
- 9 Micronutrients such as folate, zinc, iron, copper, and vitamins A and E play a role in the regulation of fetal growth.
- 10 It is controversial at the present time whether n-3 fatty acid consumption from marine foods promotes fetal growth.
- 11 Moderate consumption of caffeine does not significantly alter fetal growth. However, there appears to be synergism between caffeine intake and cigarette smoke resulting in inadequate fetal growth.
- 12 IGFs (IGF-1, -2) are important mitogens and play important roles in growth of the placenta and the fetus.
- 13 IGF-2 is important in embryonic growth and is involved in promoting cellular differentiation. Placental IGF-2 plays a role in the regulation of diffusion capacity and, therefore, in fetal growth.
- 14 IGF-1 regulates growth in the latter part of pregnancy and is partly regulated by insulin (as mediated by glucose). It is highly sensitive to nutrient supply.
- 15 Leptin is produced by the maternal, placental, and fetal units. Its cord concentrations are positively correlated with birthweight. However, the exact mechanism by which fetal fat mass may be regulated by leptin remains unknown.

- 16 The placenta influences fetal growth through its functional size, transport capacity, and metabolism.
- 17 Glucose is the major fuel for fetal growth. Specific transporters such as GLUT1 and 3 are expressed in the placenta and facilitate glucose transport to the fetus.
- 18 Amino acid transfer in the fetus relies on a variety of different placental transport systems. Growth-restricted fetuses have a decrease in amino acid concentration along with an impairment in some of these transport systems.
- 19 Normal fetal growth partly depends on placental growth, which itself initially requires adequate trophoblast invasion. Failure of this process may lead to abnormal expression of important growth factors, which may result in poor placental growth and function.
- 20 Placental growth hormone gradually replaces maternal pituitary growth hormone. It appears to be involved in the promotion of nutrient supply to the fetus through modulations in maternal metabolism.

Fetal Infections and Teratogenesis

Developmental toxicology, drugs, and fetal teratogenesis

Robert L. Brent and Lynda B. Fawcett

Reproductive problems encompass a multiplicity of diseases including sterility, infertility, abortion (miscarriage), stillbirth, congenital malformations (resulting from environmental or hereditary etiologies), fetal growth retardation, and prematurity. These clinical problems occur commonly in the general population and, therefore, environmental causes are not always easy to corroborate (Table 15.1). Severe congenital malformations occur in 3% of births; according to the Center for Disease Control, they include those birth defects that cause death, hospitalization, and mental retardation, and those that necessitate significant or repeated surgical procedures, are disfiguring, or interfere with physical performance. This means that each year in the USA, 120 000 babies are born with severe birth defects. Genetic disease occurs in approximately 11% of births, and spontaneous mutations account for approximately 2–3% of genetic disease. This spontaneous mutation rate presents difficulties when determining the proportion of mutations that are induced from preconception exposure to environmental mutagens.

There have been dramatic advances in our understanding of the causes of human birth defects. In earlier times, superstition, ignorance, and prejudice played a major role in explaining why birth defects occurred. Reproductive problems have been viewed throughout history as diseases of affliction, along with cancer, psychiatric illness, and hereditary diseases. The stigma associated with birth defects has primitive beginnings and persists today; in the minds of many, even the most sophisticated, a birth defect is felt to be some form of punishment for previous misdeeds.^{1–4} Ancient Babylonian writings recount tales of mothers being put to death because they delivered malformed infants. In the seventeenth century, one George Spencer was slain by the Puritans in New Haven having been convicted of fathering a cyclopean pig; the Puritans were unable to differentiate between George Spencer's cataract and the malformed pig's cloudy cornea.¹ More recently, the situation has been reversed and the responsibility for reproductive problems such as congenital malformations, infertility, abortions, and hereditary diseases is often blamed on others, for

example, environmental agents dispensed by healthcare providers or utilized by employers.^{1,2}

Reproductive problems alarm the public, the press, and scientists to a greater degree than many other diseases. Severely malformed children are disquieting to healthcare providers, especially if they are not experienced in dealing with such problems; no physician will be comfortable informing a family that their child was born without arms and legs. The objective evaluation of the environmental causes of reproductive diseases is clouded by the emotional climate that surrounds these diseases, resulting in the expression of partisan positions that either diminish or magnify the environmental risks. These nonobjective opinions can be expressed by scientists, the laity, or the press.^{5,6} It is the responsibility of every physician to be aware of the emotionally charged situation when a family has a child with a birth defect; an inadvertent comment from medical staff attending delivery can have grave consequences for the physician and the family. Comments such as, "Oh, you had a radiograph during your pregnancy," or "You did not tell me that you were prescribed tetracycline while you were pregnant," can direct the patient's family to an attorney rather than to a teratology or genetic counselor.

At present, the etiology of congenital malformations can be divided into three categories: unknown, genetic, and environmental. Unfortunately, the largest group (65–75%) has an unknown etiology, whereas the most common known cause is genetic (15–25%).^{7–9} Environmental factors account for 10% of congenital malformations. Over 50 teratogenic environmental drugs, chemicals, and physical agents have been described^{9–12} by clinical dysmorphologists using modern epidemiological tools.^{13–19} The basic science and clinical rules for evaluating teratogenic risks have been established.²⁰ The purpose of this chapter is to inform clinicians about environmental drugs, chemicals, and physical agents that have been documented to produce congenital malformations and reproductive effects, and to indicate that the multitude of teratogenic agents accounts for only a small proportion of malformations.

Table 15.1 Background reproductive risks in pregnancy.

Reproductive risk	Frequency
Immunologically and clinically diagnosed spontaneous abortions per million conceptions	350 000
Clinically recognized spontaneous abortions per million clinically recognized pregnancies	150 000
Genetic diseases per million births:	110 000
Multifactorial or polygenic genetic environmental interactions (i.e., neural tube defects, cleft lip, hypospadias, hyperlipidemia, diabetes)	90 000
Dominantly inherited disease (i.e., achondroplasia, Huntington's chorea, neurofibromatosis)	10 000
Autosomal and sex-linked genetic disease (i.e., cystic fibrosis, hemophilia, sickle-cell disease, thalassemia)	1 200
Cytogenetic (chromosomal abnormalities) (i.e., Down syndrome (trisomy 21), trisomies 13 and 18, Turner syndrome, 22q deletion, etc.)	5 000
New mutations*	3 000
Severe congenital malformations† per million births (resulting from all causes of birth defects: genetic, unknown, environmental)	30 000
Prematurity per million births	40 000
Fetal growth retardation per million births	30 000
Stillbirths (> 20 weeks) per million births	2000–20 900
Infertility	7% of couples

Modified from ref. 11.

*The mutation rate for many genetic diseases can be calculated; this can be readily performed with dominantly inherited diseases when offspring are born with a dominant genetic disease and neither parent has the disease.

†Congenital malformations have multiple etiologies including a significant proportion that are genetic.

Basic principles of teratology

To label an environmental agent as teratogenic it is necessary to characterize the dose, route of exposure, and stage of pregnancy when the exposure occurred. A 50-mg dose of thalidomide administered on the 26th day post conception has a significant risk of malforming the embryo. The same dose taken during the 10th week of gestation will not result in congenital malformations, and 1 mg of thalidomide taken at any time during pregnancy will have no effect on the developing embryo. X-ray irradiation can be teratogenic;^{21–23} however, if the dose is too low or the X-ray does not directly expose the embryo, there is no increased risk of congenital malformations.³ Therefore a list of teratogens indicates only teratogenic potential; evaluation of the dose and time of exposure may indicate that there is no teratogenic risk or that the risk is significant.

Physicians must be careful to carry out a thorough evaluation of the risks faced by a woman exposed to drugs and chemicals during pregnancy, and before alleging that a child's malformations result from exposure to an environmental agent. Clinical teratology and genetics is not emphasized in medical schools and residency education programs. However, clinicians have a multitude of educational aids to assist them in their evaluations; these include consultations with clinical teratologists and geneticists, the medical literature, and the Online Mendelian Inheritance of Man (OMIM) website.²⁴

The analysis of human and animal studies on the reproductive effects of environmental agents should be guided by

the basic principles of teratology and developmental biology;³ these principles are outlined in Table 15.2.^{25–32}

The etiology of congenital malformations

As mentioned earlier, the etiology of congenital malformations can be divided into three categories: unknown, genetic, and environmental (Table 15.3). A significant proportion of congenital malformations of unknown etiology are likely to have an important genetic component. Malformations with an increased recurrent risk such as cleft lip and palate, anencephaly, spina bifida, certain congenital heart diseases, pyloric stenosis, hypospadias, inguinal hernia, talipes equinovarus, and congenital dislocation of the hip fit into the category of multifactorial disease as well as that of polygenic inherited disease.^{33,34} The multifactorial/threshold hypothesis postulates the modulation of a continuum of genetic characteristics by intrinsic and extrinsic (environmental) factors.

A significant percentage of spontaneous errors of development can occur without apparent abnormalities of the genome or environmental influences; these are due to the statistical probability of errors in the developmental process, similar to the concept of spontaneous mutation, and mean that we may never achieve our goal of eliminating birth defects. It is estimated that the majority of all miscarriages occur early in pregnancy, many within the first 3 weeks of development. The World Health Organization estimated that 15% of all clinically recognizable pregnancies end in spontaneous abortion,

Table 15.2 Basic scientific principles of teratology.

Principle	Description
Exposure to teratogens follows a toxicological dose–response curve	There is a threshold below which no teratogenic effect will be observed. As the dose of the teratogen is increased, both the severity and frequency of reproductive effects will increase (Fig. 15.1)
The embryonic stage at which exposure occurs will determine what effects, if any, a teratogen will have	Some teratogens have a broad period of embryonic sensitivity while others have a very narrow period of sensitivity
Most teratogens have a confined group of congenital malformations referred to as the syndrome of the agent's effects	Known teratogens may be presumptively implicated by the spectrum of malformations they produce. It is easier to exclude an agent as a cause of a birth defect than to definitively prove it was responsible because of the existence of genocopies of some teratogenic syndromes
No teratogen can produce every type of malformation	The presence of certain malformations can eliminate the possibility that a particular teratogenic agent was responsible because those malformations have not been demonstrated to be part of the syndrome caused by the teratogen, or because production of the malformation is not biologically plausible for that particular alleged teratogen

Based on concepts from ref. 20.

Table 15.3 Etiology of human congenital malformations observed during the first year of life.

Suspected cause	Percent of total
Unknown	65–75
Polygenic	
Multifactorial (gene–environment interactions)	
Spontaneous errors of development	
Synergistic interactions of teratogens	
Genetic	15–25
Autosomal and sex-linked inherited genetic disease	
Cytogenetic (chromosomal abnormalities)	
New mutations	
Environmental	10
Maternal conditions: alcoholism, diabetes, endocrinopathies, phenylketonuria, smoking and nicotine, starvation, nutritional deficits	4
Infectious agents: rubella, toxoplasmosis, syphilis, herpes simplex, cytomegalovirus, varicella zoster, Venezuelan equine encephalitis, parvovirus B19	3
Mechanical problems (deformations): amniotic band constrictions, umbilical cord constraint, disparity in uterine size and uterine contents	1–2
Chemicals, prescription drugs, high-dose ionizing radiation, hyperthermia	< 1

Modified from ref. 8.

many (50–60%) resulting from chromosomal abnormalities.^{35–38} Finally, 3–6% of offspring are malformed, which represents the background risk for abnormal human development (Table 15.1).

Factors that affect susceptibility to developmental toxicants

A basic tenet of environmentally produced malformations is that teratogens or a teratogenic milieu have certain character-

istics in common and follow certain basic principles. These principles determine the quantitative and qualitative aspects of environmentally produced malformations.

Embryonic stage

The risk of an exposure to a developmental toxicant resulting in morphological anomalies or intrauterine death depends on the dose and the embryonic or fetal stage at which exposure occurs. The period when an exposure occurs will determine which structures are most susceptible to the deleterious effects

Table 15.4 Developmental stage sensitivity to thalidomide-induced limb reduction defects in the human.

Days from conception for induction of defects	Limb reduction defects
21–26	Thumb aplasia
22–23	Microtia, deafness
23–34	Hip dislocation
24–29	Amelia, upper limbs
24–33	Phocomelia, upper limbs
25–31	Preaxial aplasia, upper limbs
27–31	Amelia, lower limbs
28–33	Preaxial aplasia, lower limbs; phocomelia, lower limbs; femoral hypoplasia; girdle hypoplasia
33–36	Triphalangeal thumb

Modified from ref. 4.

of the drug or chemical and to what extent the embryo can repair the damage. The period of sensitivity may be narrow or broad, depending on the environmental agent and the malformation in question. Limb defects produced by thalidomide have a very short period of susceptibility⁴ (2 weeks; Table 15.4), whereas microcephaly, produced by radiation, has a long period of susceptibility (weeks 8–15 of pregnancy).³

The embryo is most sensitive to the lethal effects of drugs and chemicals during the period of embryonic development, from fertilization through the early postimplantation stage. Surviving embryos have malformation rates that are similar to those of control subjects because significant cell loss or chromosome abnormalities at these stages has a high likelihood of resulting in embryonic death, not because malformations cannot be produced at this stage. Because of the omnipotentiality of early embryonic cells, surviving embryos have a high probability of having malformation rates that are similar to embryos that have not been exposed.

The period of organogenesis (from day 18 through about day 40 post conception in the human) is the period of greatest sensitivity to teratogenic insults and when most gross anatomic malformations can be induced. Most environmentally produced major malformations occur before the 36th day post conception in the human. The exceptions are malformations of the genito-urinary system, the palate, and the brain, or deformations due to problems of constraint, disruption or destruction.

The fetal period is characterized by histogenesis involving cell growth, differentiation, and migration. Agents that result in cell depletion, vascular disruption, necrosis, specific tissue or organ pathology, physiological decompensation, or severe growth retardation have the potential to cause deleterious effects throughout gestation. The fetus is most sensitive to the

induction of mental retardation and microcephaly at the end of the first and the beginning of the second trimester. Other permanent neurological effects can be induced in the second and third trimesters. Effects such as cell depletion or functional abnormalities, not readily apparent at birth, may give rise to changes in behavior or fertility which are only apparent later in life. The last gestational day on which certain malformations may be induced in the human is presented in Table 15.5.

Dose or magnitude of the exposure

The quantitative correlation between the magnitude of the embryopathic effects and the dose of a drug, chemical, or other agent is referred to as the dose–response relationship. This is extremely important when comparing effects among different species because the use of mg/kg doses are, at best, rough approximations. Dose equivalence for drugs and chemicals between humans and other species can be accomplished only by performing pharmacokinetic studies, metabolic studies, and dose–response investigations, whereas ionizing radiation exposures in rads or sieverts (Sv) are similar in most mammalian species.³ The response should be interpreted carefully. For example, a substance given in large enough amounts to cause maternal toxicity is also likely to have deleterious effects on the embryo such as death, growth retardation, or retarded development. Also, it is unlikely that progesterone or its synthetic analogues are involved in congenital teratogenesis because the steroid receptors that are necessary for naturally occurring and synthetic progestin action are absent from nonreproductive tissues early in development.^{7,39–41} Several considerations affect the interpretation of dose–response relationships and these are outlined in Table 15.6.

Threshold dose

The threshold dose is the dose below which the incidence of death, malformation, growth retardation, or functional deficit is not statistically greater than that of control subjects (Fig. 15.1). The threshold level of exposure usually varies between less than one and up to two orders of magnitude below the teratogenic or embryopathic dose for drugs and chemicals that kill or malform one-half of the embryos. An exogenous teratogenic agent, therefore, has a no-effect dose compared with mutagens or carcinogens, which have a stochastic dose–response curve (Table 15.7, Fig. 15.1). The incidence and severity of malformations produced by all exogenous teratogenic agents that have been appropriately studied have exhibited threshold phenomena during organogenesis.⁷ The threshold concept stems from the principle that manifestations of developmental toxicity occur because the processes of repair and regeneration have been overwhelmed by a particular exposure to a developmental toxicant. It does not predicate that no effect occurs at lower exposures, just that there is no deleterious or irreversible effect.

Table 15.5 Estimated outcome of pregnancy vs. time from conception.

Time from conception	Percent survival to term*	Percent loss during interval*	Last time for induction of selected malformations†
<i>Pre-implantation</i>			—
0–6 days	25	54.55	—
<i>Postimplantation</i>			—
7–13 days	55	24.66	—
14–20 days	73	8.18	—
3–5 weeks	79.5	7.56	22–23 days: cyclopia, sirenomelia, microtia 26 days: anencephaly 28 days: meningomyelocele 34 days: transposition of great vessels
6–9 weeks	90	6.52	36 days: cleft lip 6 weeks: diaphragmatic hernia, rectal atresia, ventricular septal defect, syndactyly 9 weeks: cleft palate 10 weeks: omphalocele; 12 weeks: hypospadias
10–13 weeks	92	4.42	—
14–17 weeks	96.26	1.33	—
18–21 weeks	97.56	0.85	—
22–25 weeks	98.39	0.31	—
26–29 weeks	98.69	0.30	—
30–33 weeks	98.98	0.30	—
34–37 weeks	99.26	0.34	—
38+ weeks	99.32	0.68	38+ weeks: CNS cell depletion

*An estimated 50–70% of all human miscarriages occur in the first 3 weeks of gestation.^{36,72}

†Modified from ref. 60.

Table 15.6 Considerations that affect the interpretation of dose–response relationships.

Concept	Description	Example
Active metabolites	Metabolites may be the proximate teratogen rather than the administered drug or chemical	The metabolite phosphoramidate mustard and acrolein may produce abnormal development resulting from the metabolism of cyclophosphamide
Duration of exposure	A chronic exposure to a prescribed drug can contribute to an increased teratogenic risk	Anticonvulsant therapy; in contrast an acute exposure to the same drug may present little or no teratogenic risk
Fat solubility	Fat-soluble substances can produce fetal malformations for an extended period after the last ingestion or exposure because they have an unusually long half-life	Polychlorinated biphenyls (PCBs). Etretinate may present a similar risk but the data are not conclusive

Pharmacokinetics and metabolism of the drug or chemical

Physiological alterations during pregnancy as well as the bioconversion of compounds can significantly influence the teratogenic effects of drugs and chemicals by affecting absorption, body distribution, the active form(s), and excretion of the compound. Tables 15.8 and 15.9 outline the pregnancy-related physiological alterations in the mother and fetus, respectively, that affect the pharmacokinetics of drugs.^{42–44}

Although other organs, including the placenta, can be involved in the metabolism of drugs or chemicals, the major site of bioconversion of chemicals *in vivo* is likely to be the maternal liver. Placental P450-dependent monooxygenation of xenobiotics will occur at low rates unless induced by compounds such as those found in tobacco smoke.⁴⁵ However, the rodent embryo and yolk sac have been shown to possess functional P450-oxidative isozymes capable of converting proteratogens to active metabolites during early organogenesis.⁴⁶ In addition, P450-independent bioactivation has been

Figure 15.1 Dose-response relationship of reproductive toxins comparing preconception and postconception risks.

Table 15.7 Stochastic and threshold dose-response relationships of diseases produced by environmental agents.

Relationship	Pathology	Site	Diseases	Risk	Definition
Stochastic phenomena	Damage to a single cell may result in disease	DNA	Cancer, mutation	Some risk exists at all dosages; at low exposures the risk is below the spontaneous risk	The incidence of the disease increases with the dose but the severity and nature of the disease remain the same
Threshold phenomena	Multicellular injury	High variation in etiology, affecting many cell and organ processes	Malformation, growth retardation, death, chemical toxicity, etc.	No increased risk below the threshold dose	Both the severity and incidence of the disease increase with dose

Modified from ref. 73.

Table 15.8 Pregnancy-related physiological alterations in the mother that affect the pharmacokinetics of drugs.

Alteration	Effect on drug pharmacokinetics
Decreased gastrointestinal motility; increased intestinal transit time	Results in delayed absorption of drugs in the small intestine owing to increased stomach retention and enhanced absorption of slowly absorbed drugs
Decreased plasma albumin	Alters the kinetics of compounds normally bound to albumin
Renal elimination	Generally increased but is influenced by body position later in pregnancy
Increased plasma and extracellular fluid volumes	Affects concentration-dependent transfer of compounds
Inhibition of metabolic inactivation in the maternal liver	Increases half-life of drug in plasma
Variation in uterine blood flow	May affect transfer across the placenta (although little is known concerning this)

Based on concepts from refs 42–44.

Table 15.9 Pregnancy-related physiological alterations in the fetus that may affect the pharmacokinetics of drugs.

Alteration	Effect on drug pharmacokinetics
Amount and distribution of fat	Affects distribution of lipid-soluble drugs and chemicals
Lower plasma protein concentrations	Results in a higher concentration of unbound drug in the fetal circulation
Functional development of pharmacological receptors	Likely to proceed at different rates in the various tissues of the developing fetus
Extent of amniotic fluid swallowing	Drugs that are excreted by the fetal kidneys may be recycled through the fetus via swallowing of amniotic fluid

Based on concepts from refs 42–44.

suggested; for example, there is strong evidence that the rat embryo can reductively convert niridazole to an embryotoxic metabolite.⁴⁷

Bioconversion of xenobiotics has been shown to be important in their teratogenic activity. There is strong evidence that the reactive metabolites of cyclophosphamide, 2-acetylaminofluorene, and nitroheterocycles (niridazole) are the proximate teratogens.⁴⁸ There is also experimental evidence suggesting that other chemicals undergo conversion to intermediates that have deleterious effects on embryonic development, for example, phenytoin, procarbazine, rifampicin, diethylstilbestrol, some benzhydrylpiperazine antihistamines, adriamycin, testosterone, benzo(a)pyrene, methoxyethanol, caffeine, and paraquat.^{45,48}

Juchau⁴⁸ has defined several experimental criteria to suggest that a suspected metabolite is responsible for the *in vivo* teratogenic effects of a chemical or drug (Table 15.10). These criteria may explain why there are marked qualitative and quantitative differences in the species response to a teratogenic agent.

Placental transport

It has been suggested that the placental barrier is protective and that harmful substances do not reach the embryo; however, it is now clear that there is no “placental barrier” *per se*. The package inserts on many drugs state that “this drug crosses the placental barrier”⁶ and the uninitiated may infer from this statement that this characteristic of a drug is both unusual and hazardous. However, most drugs and chemicals cross the placenta, and only selected proteins, whose actions are species specific, will cross the placental barrier in one species but not another.

The role that the placenta plays in drug pharmacokinetics has been reviewed by Juchau and Rettie⁴⁵ and involves: (1) transport; (2) the presence of receptor sites for a number of endogenous and xenobiotic compounds (β -adrenergic agents, glucocorticoids, epidermal growth factor, IgG-Fc, insulin, low-density lipoproteins, opiates, somatomedin, testosterone, transcobalamin II, transferrin, folate, retinoid);⁴⁹ and (3) the bioconversion of xenobiotics.

The factors which determine the ability of a drug or chemical to cross the placenta and reach the embryo include molecular weight, lipid affinity or solubility, polarity or degree of

Table 15.10 Criteria to suggest that a suspected metabolite is responsible for the *in vivo* teratogenic effects of a drug or chemical.

The chemical must be convertible to the intermediate
The intermediate must be found in, or have access to, the tissue(s) affected
The embryotoxic effect should increase with the concentration of the metabolite
Inhibiting the conversion should reduce the embryotoxic effect of the agent
Promoting the conversion should increase the embryotoxicity of the agent
Inhibiting or promoting conversion should not alter the target tissues
Inhibiting the conversion should increase the embryotoxicity of the agent

Based on concepts from ref. 48.

ionization, protein binding, and receptor mediation. Compounds with a low molecular weight and lipid affinity, non-polarity, and without protein-binding properties will cross the placenta rapidly and with ease. For example, ethyl alcohol reaches the embryo rapidly and in concentrations equal to or greater than the level in the mother. High-molecular-weight compounds like heparin (20 000 daltons) do not cross the placenta readily and, therefore, during pregnancy, heparin is used instead of warfarin-like compounds for the treatment of hypercoagulation conditions. Rose Bengal does not cross the placenta at all. In general, compounds with molecular weights of 1000 daltons or more do not readily cross the placenta, whereas those less than 600 daltons usually do; most drugs are 250–400 daltons and do cross the placenta.⁵⁰

Genetic differences

The genetic constitution of an organism is an important factor in the susceptibility of a species to a drug or chemical. More than 30 disorders of increased sensitivity to drug toxicity or effects in the human result from an inherited trait.⁵¹ Maternal and fetal genotypes determine the types of bioconversion route, the rate at which bioconversions take place, and the extent to which a compound is metabolized.

Environmental agents resulting in reproductive toxicity following exposure during pregnancy

Table 15.11 lists environmental agents that have resulted in reproductive toxicity and/or congenital malformations in humans. The list should not be used in isolation because many other parameters must be considered when analyzing reproductive risks in individual patients. Many of these agents represent a very small risk while others may represent substantial risks; the risks will vary with the magnitude, timing, and length of exposure. Further information can be obtained from more extensive reviews or summary articles. Table 15.12 lists agents that have had concerns raised about their reproductive effects but which, after a careful and complete evaluation, have not been found to represent an increased reproductive risk.^{41,52–55} References for the environmental agents can be found in review articles and texts on teratogenesis.^{13,18,24,38,51,56–61}

Interpretation of animal study data for assessment of reproductive risks in humans

As human studies are expensive and take years to complete, scientists have investigated the issue of whether appropriate animal models can be used to evaluate the reproductive and toxicological risks of environmental agents in humans (teratogenesis, growth retardation, pregnancy loss, stillbirth, and infertility). Whole animal teratology studies are helpful in raising concerns about the reproductive effects of drugs and chemicals;

however, negative animal studies do not guarantee that these agents are free from reproductive effects in humans. There are examples in which drug testing was negative in animals (rat and mouse), but was teratogenic in the human (thalidomide).²⁷ Similarly, there are examples in which a drug was teratogenic in an animal model but not in humans (diflunisal). Therefore, while chemicals and drugs can be evaluated for their toxic potential by utilizing *in vivo* animal studies and *in vitro* systems, it should be recognized that these testing procedures are only one component in the process of evaluating the potential toxic risk of drugs and chemicals. Well-performed epidemiology studies still represent the best methodology for determining the risks and effects of environmental toxicants on humans. Indeed, most human teratogens have been discovered by alert physicians or during epidemiology studies, not animal studies.⁶² *In vitro* studies play an even less important role, although they are helpful in describing the cellular or tissue-specific effects of drugs and chemicals.

One useful aspect of animal studies is in corroborating findings reported in epidemiological studies. Attempts at risk assessment can be made by utilizing toxicokinetic data that have been obtained in an animal model, and exposure levels of the alleged toxicant and its metabolites that have been determined in humans. Studies to elucidate whether the mechanism of action of a drug or chemical in the animal model is the same as that in humans would further add to the toxicologist’s ability to estimate human risks. This is not a simple process and explains why good-quality epidemiological studies are so valuable in determining human risks and toxicity.

Clinicians are given little training in medical school and during residency training on how to interpret animal toxicology studies. This is probably more true of reproductive

Table 15.11 Proven human teratogens or embryotoxins: drugs, chemicals, milieu, and physical agents that have resulted in human congenital malformations.

Reproductive toxin	Alleged effects
Aminopterin, methotrexate	Growth retardation, microcephaly, meningomyelocele mental retardation, hydrocephalus, and cleft palate
Androgens	Along with high doses of some male-derived progestins, can cause masculinization of the developing fetus
Angiotensin-converting enzyme (ACE) inhibitors	Fetal hypotension syndrome in second and third trimester resulting in fetal kidney hypoperfusion and anuria, oligohydramnios, pulmonary hypoplasia, and cranial bone hypoplasia. No effect in the first trimester
Antituberculous therapy	The drugs isoniazid (INH) and paraaminosalicylic acid (PAS) have an increased risk for some CNS abnormalities
Caffeine	Moderate exposure not associated with birth defects; high exposures associated with an increased risk of abortion but data are inconsistent
Chorionic villus sampling (CVS)	Vascular disruptive malformations, i.e., limb reduction defects
Cobalt in hematemic multivitamins	Fetal goiter
Cocaine	Very low incidence of vascular disruptive malformations, pregnancy loss
Corticosteroids	High exposures administered systemically have a low risk for cleft palate in some epidemiological studies; however, this is not a consistent finding
Coumarin derivative	Exposure during early pregnancy can result in nasal hypoplasia, stippling of secondary epiphysis, and intrauterine growth retardation. Exposure in late pregnancy can result in CNS malformations as a result of bleeding

Table 15.11 *Continued.*

Cyclophosphamide and other chemotherapeutic and immunosuppressive agents, e.g., cyclosporine, leflunomide	Many chemotherapeutic agents used to treat cancer have a theoretical risk of producing fetal malformations, as most of these drugs are teratogenic in animals; however, the clinical data are not consistent. Many have not been shown to be teratogenic but the numbers of cases in the studies are small; caution is the byword
Diethylstilbestrol	Genital abnormalities, adenosis, and clear cell adenocarcinoma of the vagina in adolescents. The risk of adenosis can be quite high; the risk of adenocarcinoma is 1:1000 to 1:10000
Ethyl alcohol	Fetal alcohol syndrome (microcephaly, mental retardation, growth retardation, typical facial dysmorphogenesis, abnormal ears, and small palpebral fissures)
Ionizing radiation	A threshold greater than 20 rad (0.2 Gy) can increase the risk of some fetal effects such as microcephaly or growth retardation. The threshold for mental retardation is higher
Insulin shock therapy	Microcephaly and mental retardation
Lithium therapy	Chronic use for the treatment of manic depressive illness has an increased risk for Ebstein's anomaly and other malformations, but the risk appears to be very low
Minoxidil	Hirsutism in newborns (led to the discovery of the hair growth-promoting properties of minoxidil)
Methimazole	Aplasia cutis has been reported*
Methylene blue intraamniotic instillation	Fetal intestinal atresia, hemolytic anemia, and jaundice in the neonatal period. This procedure is no longer utilized to identify one twin
Misoprostol	Low incidence of vascular disruptive phenomenon, such as limb reduction defects and Mobius syndrome, has been reported in pregnancies in which this drug was used to induce an abortion
Penicillamine (D-penicillamine)	This drug results in the physical effects referred to as lathyrism, the results of poisoning by the seeds of the genus <i>Lathyrus</i> . It causes collagen disruption, cutis laxa, and hyperflexibility of joints. The condition appears to be reversible and the risk is low
Progestin therapy	Very high doses of androgen hormone-derived progestins can produce masculinization. Many drugs with progestational activity do not have masculinizing potential. None of these drugs has the potential for producing congenital malformations
Propylthiouracil	Along with other antithyroid medications can result in an infant born with a goiter
Radioactive isotopes	Tissue- and organ-specific damage is dependent on the radioisotope element and distribution, i.e., high doses of ¹³¹ I administered to a pregnant woman can cause fetal thyroid hypoplasia after the 8th week of development
Retinoids, systemic	Systemic retinoic acid, isotretinoin, and etretinate can result in an increased risk of CNS, cardio-aortic, ear, and clefting defects, microtia, anotia, thymic aplasia and other branchial arch and aortic arch abnormalities, and certain congenital heart malformations
Retinoids, topical	This is very unlikely to have teratogenic potential because teratogenic serum levels are not achieved from topical exposure
Streptomycin	Streptomycin and a group of ototoxic drugs can affect the eighth nerve and interfere with hearing; it is a relatively low-risk phenomenon. Children are even less sensitive to the ototoxic effects of these drugs than adults
Sulfa drug and vitamin K	Hemolysis in some subpopulations of fetuses
Tetracycline	Bone and teeth staining
Thalidomide	Increased incidence of deafness, anotia, preaxial limb reduction defects, phocomelia, ventricular septal defects, and GI atresias during susceptible period from the 22nd to the 36th day post conception
Trimethoprim	This drug was frequently used to treat urinary tract infections and has been linked to an increased incidence of neural tube defects. The risk is not high, but it is biologically plausible because of the drug's lowering effect on folic acid levels. This has also resulted in neurological symptoms in adults taking this drug
Vitamin A (retinol)	Very high doses of vitamin A have been reported to produce the same malformations as those reported for the retinoids. Dosages sufficient to produce birth defects would have to be in excess of 25 000 to 50 000 units per day
Vitamin D*	Large doses given in vitamin D prophylaxis are possibly involved in the etiology of supravalvular aortic stenosis, elfin facies, and mental retardation
Warfarin (coumarin)	Exposure during early pregnancy can result in nasal hypoplasia, stippling of secondary epiphysis, and intrauterine growth retardation. Exposure in late pregnancy can result in CNS malformations as a result of bleeding
<i>Anticonvulsants</i>	
Carbamazepine	Used in the treatment of convulsive disorders; increases the risk of facial dysmorphology

(Continued)

Table 15.11 *Continued.*

Diphenylhydantoin	Used in the treatment of convulsive disorders; increases the risk of fetal hydantoin syndrome, consisting of facial dysmorphology, cleft palate, ventricular septal defect (VSD), and growth and mental retardation
Trimethadione and paramethadione	Used in the treatment of convulsive disorders; increases the risk of characteristic facial dysmorphology, mental retardation, V-shaped eyebrows, low-set ears with anteriorly folded helix, high-arched palate, irregular teeth, CNS anomalies, and severe developmental delay
Valproic acid	Used in the treatment of convulsive disorders; increases the risk of spina bifida, facial dysmorphology, and autism
<i>Chemicals</i>	
Carbon monoxide poisoning*	CNS damage has been reported with very high exposures, but the risk appears to be low
Gasoline addiction embryopathy	Facial dysmorphology, mental retardation
Lead	Very high exposures can cause pregnancy loss; intrauterine teratogenesis is not established
Methyl mercury	Causes Minamata disease consisting of cerebral palsy, microcephaly, mental retardation, blindness, and cerebellum hypoplasia. Endemics have occurred from adulteration of wheat with mercury-containing chemicals that are used to prevent grain spoilage. Present environmental levels of mercury are unlikely to represent a teratogenic risk, but reducing or limiting the consumption of carnivorous fish has been suggested in order not to exceed the Environmental Protection Agency's (EPA's) maximum permissible exposure (MPE), which is far below the toxic effects of mercury
Polychlorinated biphenyls	Poisoning has occurred from adulteration of food products (cola-colored babies, CNS effects, pigmentation of gums, nails, teeth and groin, hypoplastic deformed nails, intrauterine growth retardation, abnormal skull calcification). The threshold exposure has not been determined, but it is unlikely to be teratogenic at the present environmental exposures
Toluene addiction embryopathy	Facial dysmorphology, mental retardation
<i>Embryonic and fetal infections</i>	
Cytomegalovirus	Retinopathy, CNS calcification, microcephaly, mental retardation
Herpes simplex virus	Fetal infection, liver disease, death
Human immunodeficiency virus (HIV)	Perinatal HIV infection
Parvovirus B19 infection	Stillbirth, hydrops
Rubella virus	Deafness, congenital heart disease, microcephaly, cataracts, mental retardation
Syphilis	Maculopapular rash, hepatosplenomegaly, deformed nails, osteochondritis at joints of extremities, congenital neurosyphilis, abnormal epiphyses, chorioretinitis
Toxoplasmosis	Hydrocephaly, microphthalmia, chorioretinitis, mental retardation
Varicella zoster virus	Skin and muscle defects, intrauterine growth retardation, limb reduction defects, CNS damage (very low increased risk)
Venezuelan equine encephalitis	Hydranencephaly, microphthalmia, CNS destructive lesions, luxation of hip
<i>Maternal disease states</i>	
Corticosteroid-secreting endocrinopathy	Mothers with Cushing's disease can have infants with hyperadrenocortism, but anatomical malformations do not appear to be increased
Iodine deficiency	Iodine deficiency can result in embryonic goiter and mental retardation
Intrauterine problems of constraint and vascular disruption	Defects such as club feet, limb reduction, aplasia cutis, cranial asymmetry, external ear malformations, midline closure defects, cleft palate and muscle aplasia, cleft lip, omphalocele, and encephalocele. More common in multiple-birth pregnancies, pregnancies with anatomical defects of the uterus, placental emboli, and amniotic bands
Maternal androgen endocrinopathy (adrenal tumors)	Masculinization
Maternal diabetes	Caudal and femoral hypoplasia, transposition of great vessels
Folic acid insufficiency in the mother	Increased incidence of neural tube defects (NTDs)
Maternal phenylketonuria	Abortion, microcephaly, and mental retardation. Very high risk in untreated patients
Maternal starvation	Intrauterine growth retardation, abortion, NTDs
Tobacco smoking	Abortion, intrauterine growth retardation, and stillbirth
Zinc deficiency*	NTDs

*Controversial.

Table 15.12 Agents erroneously alleged to have caused human malformations.

Agent	Alleged effect
Doxylamine succinate (Bendectin)	Alleged to cause numerous types of birth defects including limb reduction defects and heart malformations
Diagnostic ultrasonography	No significant hyperthermia, therefore no reproductive effects
Electromagnetic fields (EMF)	Alleged to cause abortion, cancer, and birth defects
Progestational drugs	Alleged to cause numerous types of congenital birth defects, including limb reduction defects and heart malformations
Trichloroethylene (TCE)	Alleged to cause cardiac defects

toxicology studies than of any other area of animal testing. For physicians the best source of information concerning animal testing comes from the drug package insert or the Physicians' Desk Reference (PDR).⁶³ The PDR utilizes the Food and Drug Administration's (FDA's) classification of reproductive risks (categories A, B, C, D, and X), which is partly based on animal testing. Category A includes drugs that present no risk of reproductive effects. Category B, C and D drugs show increasing risks and category X includes drugs such as methotrexate, isotretinoin (Acutane), or thalidomide that should not be used in pregnant women or women of reproductive age who are not taking contraceptives. However, these categories are often more misleading than helpful. Teratologists, obstetricians, and other clinicians who counsel pregnant women have been very critical of the FDA's classification⁶ because it ignores the basic principles of teratology³ and the importance of modern pharmacokinetics in evaluating animal studies.²⁹ In 1990, an article was published which indicated that of the 200 most frequently prescribed drugs, none represented a significant teratogenic risk.⁶⁴ However, only a small proportion of these drugs was placed in category A by the FDA, the most important reason being the misapplication of animal testing results. When a new drug is marketed or a new environmental toxicant is discovered, however, often the only information that is available are the animal data.

Evaluating animal studies to determine the potential risk in humans

When utilizing animal data to assess the potential risk of a drug or chemical exposure in humans, it is important to critically evaluate the studies using the basic principles of teratology guidelines (Table 15.2). As discussed previously, one of the most critical factors for consideration is the dose or magnitude of the exposure, and the concept of the threshold-dose effect for reproductive toxicants. A major shortcoming in many studies is the use of weight (mg/kg) as a measure of dose, as dose comparisons based on mg/kg doses are, at best, rough approximations. Instead, testing in animals could be improved if drugs and chemicals were administered to achieve pharmacokinetically equivalent serum levels in the animal and human. Dose equivalence between species can be accomplished only by performing pharmacokinetic studies, metabolic studies, and dose-response investigations in the human and the species

being studied. Dose equivalence must also be determined for the drug-specific effects at the cellular level, to account for species differences in the molecular targets of chemicals or drugs. An excellent example of the importance of the use of pharmacological, rather than weight-based, dose equivalence in interpreting animal study data is illustrated by animal and epidemiological studies performed on leflunomide.³²

Leflunomide is a relatively new drug (1998) which is used to treat rheumatoid arthritis. It contains a warning for reproductive effects (teratogenesis) and has been placed in category X. This classification was based on animal studies as there were no human data available at the time of marketing.

Leflunomide is a novel isoxazole immunomodulatory agent that has antiproliferative activity. It inhibits mitogen-stimulated proliferation of human peripheral blood mononuclear cells (PBMCs) in a dose-dependent fashion. It has been demonstrated that the active metabolite binds to, and is a potent inhibitor of, dihydroorotate dehydrogenase (DHODH), an enzyme important for DNA synthesis in the *de novo* pyrimidine synthesis pathway. Together, these data suggest that at serum concentrations achievable in patients, leflunomide inhibits *de novo* pyrimidine synthesis in activated lymphocytes and other rapidly dividing cell populations, resulting in reversible cell cycle arrest.

In oral embryotoxicity and teratogenicity studies in rats and rabbits, leflunomide was embryotoxic (growth retarding, embryo-lethal, and teratogenic). The no-effect level for embryotoxicity and teratogenicity in rats and rabbits was 1 mg/kg body weight, which resulted in serum levels of 3.7 and 4.1 µg/mL respectively. In patients being treated with leflunomide, the active metabolite (the pyrimidine antagonist), is maintained at a blood level of 40 µg/mL. The decision to label leflunomide as having a teratogenic risk was based on the fact that the human serum level was in the range of the teratogenic blood level in the animal models, and, therefore, the initial labeling was an appropriate precaution to prevent birth defects.

After 4 years of treating rheumatoid arthritic patients with leflunomide there was no indication of an increase in teratogenesis in a very small group of pregnant patients who continued their pregnancy to term. The animal data were, therefore, reanalyzed as follows (referred to as the method of action (MOA) approach). The most likely mechanism of leflunomide teratogenicity is the suppression of DNA

synthesis and cell proliferation by the inhibition of pyrimidine synthesis. This is based on the assumption that, at the same serum levels of the active metabolite of leflunomide, suppression of DNA synthesis, pyrimidine synthesis, and cell proliferation is equal in the rat, rabbit, and human. There would then be concurrence and the risks would be determined to be identical in all three species; this was the basis of the X-category labeling. However, *in vitro* studies on the active metabolite of leflunomide revealed that the rat was 40 and 328 times more sensitive to the suppression of DHODH and cell proliferation, respectively, than the human.³² This means that if enzyme suppression or antiproliferative activity is the mechanism (MOA) of teratogenicity in the rat, then the clinical use of leflunomide in pregnant women would probably not be teratogenic. It is important that this drug is subjected to ongoing epidemiological surveillance to confirm these findings. This is an example of how modern pharmacokinetic studies can improve risk assessment, making it easier to understand the epidemiological studies.

Examples of *in vivo* animal studies

In the past 2 years, many excellent *in vivo* animal studies have been carried out. Two particular studies demonstrate the importance, differences, and the usefulness of animal studies as well as the difficulties inherent in drawing inferences from animal studies to describe human risk. Dam and coauthors⁶⁵ used an *in vivo* animal model to study the effect of chlorpyrifos (CPF), an organophosphate insecticide whose domestic use has been curtailed in the USA because of concerns about its neurotoxicity, on gene expression. Newborn animals were injected subcutaneously with one of two different doses of CPF on postnatal days 1–4 or 11–14. Studies of the forebrain using molecular biological techniques revealed a significant elevation in one protein that persisted for 5 days after cessation of the exposure regimen. This is an interesting study; however, the results are of little use in determining the human risks of CPF for the following reasons:

- 1 CPF exposure in humans does not occur via subcutaneous injection but by ingestion or skin absorption of contaminated food or water.
- 2 The serum concentration of CPF was not determined for the two different exposures used.
- 3 There was no discussion of the range of levels of CPF that have occurred in human populations.
- 4 The threshold dose and the no-observed adverse effect level (NOAEL) were not determined.
- 5 The authors performed toxicogenomics without toxicokinetics.

In contrast, the *in vivo* study by Tyl and coauthors⁶⁶ on the reproductive toxicity of dietary bisphenol in rats is considered to be a modern, animal toxicology study for the following reasons:

- 1 The bisphenol was placed in the diet *ad libitum*.

- 2 There were seven exposure groups.

- 3 The exposures were listed in ppm and mg/kg.

- 4 The range of exposures used was very large: 0.001–500 mg/kg or a 500 000-fold range.

- 5 The following were not affected at any of the lower exposures although some effects were observed in the 500 mg/kg group: mating, fertility, gestational indices, ovarian primordial follicle counts, estrous cyclicity, precoital interval, gestational length, offspring sex ratios, postnatal survival, nipple/areolae retention in pre-weanling males, epididymal sperm number, motility, and morphology, daily sperm production, and efficiency of production

- 6 The adult NOAEL was 5 mg/kg/day and the reproductive NOAEL was 50 mg/kg/day. There was a reduction in total body weight and some reduction in organ weight at the higher exposures.

To perform a risk analysis for bisphenol in the human population, some additional information is required that was not reported in this study but which is available in other studies. Yamada and coauthors⁶⁷ obtained bisphenol exposure data in humans from the mother and amniotic fluid. The average concentration of bisphenol was 0.32 ng/mL of serum, with a range of 0.0–1.6 ng/mL, levels which appear to be far below the threshold exposure determined by Tyl and coauthors. However, Tyl and coauthors did not obtain the same pharmacokinetic data in the rat that Yamada and coauthors reported in the human, and therefore the serum concentration of bisphenol in the rat at the threshold exposure is not known. Furthermore, it is not known whether the metabolism and effects of bisphenol are similar in the human and the rat.

These studies^{66,67} on the risk analysis for bisphenol in the human population indicate the difficulties that can be faced in achieving an accurate and complete interpretation of the data. Combining such studies may appear to be a rare occurrence in the field of risk analysis; fortunately, however, it is occurring more often.⁶⁸

In vitro testing

In vitro tests can be utilized for preliminary screening procedures, and to study the mechanisms of teratogenesis and embryogenesis. However, *in vitro* studies will never be able to predict human teratogenic risks at particular exposures without additional data obtained from whole animal and epidemiological studies.^{25,29,31,60} In spite of the advances in *in vitro* and *in vivo* testing for teratogenicity, human epidemiological surveillance by various methodologies is, and will continue to be, our most powerful tool for discovering human reproductive toxins and teratogens. It may be difficult for experimental teratologists to accept the fact that alert physicians and scientists have been the most prominent contributors to the discovery of the environmental causes of birth defects.²⁶

The role of the physician in counseling families regarding the etiology of a child's congenital malformation

The clinician must be cognizant of the fact that many patients believe that most congenital malformations are caused by a drug or medication taken during pregnancy. Counseling patients about reproductive risks requires a significant degree of knowledge and skill. Physicians must also realize that erroneous counseling by inexperienced health professionals may result in nonmeritorious litigation.²

Unfortunately, it has sometimes been assumed that if a drug or chemical causes birth defects in an animal model or *in vitro* system at a high dose, then it has the potential for producing birth defects at any dose.^{27,29} This may be reinforced by the fact that many teratology studies reported in the literature investigate the effects of several doses but do not determine the no-effect dose.

Ignoring the basic tenets of teratology appears to occur most commonly in the evaluation of environmental toxic exposures when the exposure is very low or unknown, and the agent has been reported to be teratogenic at a very high dose or a maternally toxic dose. In most instances, the actual population exposure is orders of magnitude below the threshold dose, the doses that were used in animal studies, or those received during toxic exposures in the population. This has been the case with 2,4,5-trichlorophenoxyacetic acid (2,4,5-T), polychlorinated biphenyls (PCBs), lead, cadmium, arsenic, pesticides, herbicides, veterinary hormones, and industrial exposures.

Unfortunately, there are examples where environmental disasters have been responsible for birth defects or pregnancy loss in exposed populations (methyl mercury in Japan, PCBs in the Far East, organic mercury in the Middle East, and lead poisoning in the nineteenth and early twentieth centuries) and examples where teratogenic drugs have been inadvertently introduced (Table 15.11). Therefore, it is not possible to determine whether a chemical or drug is safe or hazardous unless the magnitude of the exposure is known.

Scholarly evaluation

The physician should respond to a parent's query into the cause of a child's birth defect using the same professional and methodical approach that would be used in a differential diagnosis for any clinical problem. Physicians have a protocol for evaluating complex clinical problems, for example, "fever of unknown origin," "failure to thrive," "congestive heart failure," or "respiratory distress." If a mother of a malformed infant had some type of exposure during pregnancy, for example, medication or a diagnostic radiological examination, the consulting physician should not support or suggest the possibility of a causal relationship before performing a com-

plete evaluation. This is also true if a pregnant woman is exposed to a drug, chemical, or physical agent. As mentioned previously, only a small percentage of birth defects result from exposure to prescribed drugs, chemicals, and physical agents^{12,64} (Table 15.3). Even when the drug is listed as a teratogen, to exert a teratogenic effect it has to be administered during the sensitive period of development for that drug, and above the threshold dose. Furthermore, the malformations in a child should be the same as the malformations in the teratogenic syndrome produced by that particular drug. It should be emphasized that in a recent analysis of the 200 most prescribed drugs in the USA, none were found to have measurable teratogenic potential.⁶⁴

After a complete examination of the child and a review of the genetic and teratology medical literature, the clinician must decide whether the child's malformations are genetic or result from exposure to an environmental toxin or agent. It may not be possible to definitively or presumptively conclude the etiology of the child's birth defects. This information must then be conveyed to the patient in an objective and compassionate manner. A similar situation exists if a pregnant woman has been exposed to a drug, chemical, or physical agent, as the mother will want to know the risk of the exposure to her unborn child. A formal approach is recommended to determine whether a particular environmental drug, chemical or physical agent is a reproductive toxicant; this should include, where possible, data obtained from a number of investigative approaches (Table 15.13²⁰) including: (1) epidemiological studies,^{25,26} (2) secular trend or ecological trend analysis, (3) animal reproductive studies,²⁷⁻³¹ (4) dose-response relationships and pharmacokinetic, toxicokinetic, pharmacodynamic, and toxicodynamic studies comparing human and animal metabolism, (5) MOA studies that pertain specifically to the agent and include receptor affinity, cytotoxicity, genotoxicity, organ toxicity, neurotoxicity, etc.,^{25,28,30,32} (6) biological plausibility.

Some typical analyses of the reproductive risks of doxylamine succinate (Bendectin), sex steroids, diagnostic ultrasound, and electromagnetic fields demonstrate the usefulness of an organized approach to determine whether an environmental agent has been demonstrated to be a reproductive toxin.^{41,52-55,69}

Clinical evaluation

There are many articles and books that can assist the physician with the evaluation of the medical literature and the clinical evaluation of the patient,^{13,18,24,38,51,56-61} although training programs do not usually prepare generalists to perform sophisticated genetic or teratology counseling. In addition to the usual history and physical evaluation, the physician has to obtain information about the nature, magnitude, and timing of the exposure. The physical examination should include descriptive and quantitative information about the physical

Table 15.13 Proof of developmental toxicity in humans.*Epidemiological studies*

Controlled epidemiological studies consistently demonstrate an increased incidence of a particular spectrum of embryonic and/or fetal effects in exposed human populations

Secular trend data

Secular trends demonstrate a positive relationship between the changing exposures to a common environmental agent in human populations and the incidence of a particular embryonic and/or fetal effect

Animal developmental toxicity studies

An animal model that mimics the human developmental effect at clinically comparable exposures can be developed. Because mimicry may not occur in all animal species, animal models are more likely to be developed once there is good evidence for the embryotoxic effects reported in the human. Developmental toxicity studies in animals are indicative of a potential hazard in general rather than the potential for a specific adverse effect on the fetus when there are no human data on which to base the animal experiments

Dose-response relationship (pharmacokinetics and toxicokinetics)

Developmental toxicity in the human increases with dose (exposure), and the developmental toxicity in animals occurs at a dose that is pharmacokinetically (quantitatively) equivalent to the human exposure

Biological plausibility

The mechanisms of developmental toxicity are understood, and the effects are biologically plausible

Modified from refs 20 and 74.

characteristics of the child. While some growth measurements are routine, many measurements taken by specialized counselors are not part of the usual physical examination, e.g., palpebral fissure size, ear length, intercanthal distances, and total height-to-trunk ratio. Important physical variations in facial, hand, and foot structure as well as other anatomical structures may be suggestive of known syndromes, either teratological or genetic.

Evaluation of the reproductive risk or cause of a child's malformation after an environmental exposure during pregnancy

The vast majority of consultations involving pregnancy exposures conclude that the exposure does not change the reproductive risks for that pregnancy. In many instances, the information that is available is so vague that the counselor cannot reach a definitive conclusion about the magnitude of the risk. The following information is necessary to evaluate any risk:

- 1 What was the nature of the exposure?
- 2 Is the exposure agent identifiable? If so, has it been definitively identified as a reproductive toxin with a recognized range of malformations or other reproductive effects?
- 3 At what stage during embryonic and fetal development did the exposure occur?
- 4 If the agent is known to produce reproductive toxic effects, was the exposure above or below the threshold for these effects?
- 5 Were there other significant environmental exposures or medical problems during the pregnancy?

6 Is this a wanted pregnancy or is the family ambivalent about carrying this baby to term?

7 What is the medical and reproductive history of the mother with regard to prior pregnancies and the reproductive history of the family lineage?

After obtaining this information, the counselor is able to provide the family with an estimate of the reproductive risks of the exposure. Some examples of consultations that have been referred to our clinical teratology service are listed below.

Patient 1

A 34-year-old pregnant laboratory worker dropped and broke a reaction vessel containing a mixture of chemical reagents. She proceeded to clean the floor with paper towels and later became concerned about the potential harmful effects of the exposure. This was a planned, wanted pregnancy; she was in the sixth week of pregnancy and, therefore, the embryo was in the period of early organogenesis. The chemicals in the spill were tetrahydrofuran (70%), pyridine (20%), and iodine (1%). It was not possible to quantitatively estimate the exposure to these agents, but the laboratory worker experienced no symptoms from the exposure. There have been no epidemiological studies of tetrahydrofuran and pyridine in pregnant women but iodine has been shown to interfere with fetal thyroid development; in this situation, however, the exposure would have been inconsequential because, at this stage of pregnancy, the thyroid is not yet present. No other exposure to reproductive toxins occurred in this pregnancy and the family history for congenital malformations was negative. The woman was advised that it would be very unlikely that her

teratogenic risk would be increased because the exposures to the embryo would be extremely low. She was told that she still faced the background risks for birth defects and miscarriage and, therefore, her reproductive risks would be the same as that of the general population (Table 15.1).

Patient 2

A 26-year-old pregnant woman was in an automobile accident in the 10th week of her pregnancy and sustained a severe concussion. Although she did not convulse post injury, the treating neurosurgeon prescribed 300 mg of diphenylhydantoin during her first 24 h in hospital. Fortunately, she recovered from the injury without any sequelae but her primary physician was concerned that she had received an anticonvulsant associated with a teratogenic syndrome. No other exposure to reproductive toxins occurred in this pregnancy and the family history for congenital malformations was negative, except for an uncle with neurofibromatosis. The primary physician requested a consultation with regard to the teratogenic risk. While diphenylhydantoin administered chronically throughout pregnancy has been associated with a low incidence of characteristic facial dysmorphogenesis, reduced mentation, cleft palate, and digital hypoplasia, there are no data to indicate that 24 h of therapy would cause any of these features. In addition, the development of the lip and palate are complete by the 10th week of pregnancy. This was a wanted pregnancy and the mother chose to continue her pregnancy; she delivered a normal 3370-g boy at term.

Patient 3

A 25-year-old woman was seen in the emergency service of her local hospital with nausea, vomiting, and diarrhea, on return from a cruise on which a number of the passengers became ill with similar symptoms. The emergency-ward physician ordered a pregnancy test followed by a flat-plate radiograph of the abdomen as there was evidence of peritoneal irritation; however, both of these tests were negative. One week later she missed her menstrual period and a subsequent pregnancy test was positive. Her obstetrician was concerned because she had been exposed to a radiological examination at a time when she was pregnant; he referred the patient for counseling after obtaining an ultrasound that indicated that the embryo was approximately 7 days post conception at the time of the examination. The patient advised the counselor that she was ambivalent about the pregnancy because of the “dangers” of the X-rays to her embryo. The estimated exposure to the embryo was less than 500 mrad (0.005 Sv), an exposure that is far below that known to affect the developing embryo. Also, the embryo was exposed during the first 2 weeks post conception, a time that is less likely to increase the risk of teratogenesis, even at much higher exposures.^{3,70} After an evaluation of the family history and after receiving counseling about the risks of the radiological examination, the woman decided to continue the pregnancy; she delivered a normal 3150-g baby.

Evaluation of the cause of a child's congenital malformations: unknown, genetic, or environmental

Patient 4

The mother of a 30-year-old man born in the Azores in 1960 with a congenital absence of the right leg below the knee had pursued compensation for her son because she was certain that she must have received thalidomide during her pregnancy.⁴ The German manufacturer of thalidomide refused compensation, claiming that thalidomide had never been distributed in the Azores. The mother fervently believed that thalidomide was responsible for her son's malformations and asked for my opinion; she sent me the radiograph studies of his hips and legs and his complete evaluation performed at the local hospital in the Azores. He had none of the other stigmata of thalidomide embryopathy (preaxial limb defects, phocomelia, facial hemangioma, ear malformations, deafness, crocodile tears, ventricular septal defect, intestinal or gallbladder atresia, and kidney malformations) and, most importantly, his limb malformations were not of the thalidomide type; he had a unilateral congenital amputation with no digital remnants at the end of the limb, his pelvic girdle was completely normal, and his limb defect involved only one leg with the other leg being normal. In this particular case, the man had a congenital amputation probably resulting from vascular disruption of an unknown etiology (known causes of vascular disruptive malformations are cocaine, misoprostol and chorionic villous sampling). It is difficult to determine whether any amount of appropriate counseling will give closure to this mother.

Patient 5

The family of a malformed boy claimed that the antinausea medication doxylamine succinate (Bendectin),^{52,53,71} taken by the mother during pregnancy, was responsible for the child's congenital limb reduction defects. Bendectin was taken after the period of limb organogenesis; however, some limb malformations can be produced by teratogens after this time. The boy's malformation was the classical split-hand, split-foot syndrome, which is dominantly inherited; it was unaccompanied by any other dysmorphogenetic effects. Although significant number of cases of this syndrome result from a new mutation, neither parent manifested the malformation and this suggested that a new mutation had occurred in the sex cells of one of the parents. Therefore, the risk of this malformation occurring in the offspring of this boy would be 50%. It was concluded that Bendectin was not responsible for this child's malformation; however, in spite of the obvious genetic etiology of the birth defect, a legal suit was filed. A jury decided for the defendant, namely, that Bendectin was not responsible for the child's malformation.

Patient 6

A woman visited a hospital emergency ward with severe lower abdominal pain; as she had had a previous ectopic pregnancy

that necessitated the removal of her ovary and fallopian tube, she was seen by an obstetrical resident. A pregnancy test was positive and she returned to the obstetrical clinic a week later when her chorionic gonadotropin level was retested. It had not changed from its previous level and, without performing an ultrasound, a diagnosis of ectopic pregnancy was made; in order to preserve the patient's reproductive potential, it was decided to treat the ectopic pregnancy with methotrexate rather than remove the remaining fallopian tube and ovary. However, following the administration of methotrexate, a laboratory report was received which indicated that the gonadotropin level had increased fivefold, and a subsequent ultrasound revealed a normally implanted embryo; the laboratory report received earlier in the day was found to be a copy of the original report performed a week earlier. The mother was counseled that the baby was at an increased risk of having congenital malformations because of the exposure to methotrexate; however, she refused to abort the pregnancy. The obstetrical department therefore offered to provide care for the pregnancy and delivery that included a number of ultrasound examinations. At 28 weeks, the patient went into labor and delivered a premature liveborn infant, and during infancy, the child was diagnosed with hydrocephalus, developmental delay, and spastic cerebral symptomatology. The family filed a lawsuit against the doctors and hospital and I was asked to evaluate the allegation that the abnormalities in the child were due to the administration of methotrexate. Methotrexate has been reported to cause growth retardation, microcephaly, developmental delay, and hydrocephalus, but not prematurity. The clinical care provided by the resident doctor was unfortunate; however, the provision of care by the obstetrical department turned out to be fortunate for the defendants in this case. A review of the records revealed two important findings: first, an ultrasound examination taken a week before the premature delivery revealed that there was no evidence of hydrocephalus and, second, the birthweight was appropriate for the gestational stage. Therefore, the exposure to methotrexate was not responsible for the serious problems in this infant; the hydrocephalus and neurological symptoms resulted from a central nervous system (CNS) bleed in the postnatal period as a complication of the prematurity.

These examples show that it is not a simple process to determine the reproductive risks of an exposure during pregnancy or to determine the etiology of a child's congenital malformations. It requires careful analysis of the medical and scientific literature on the reproductive toxic effects of exoge-

nous agents in humans and animals, as well as an evaluation of the exposure and biological plausibility of an increased risk or a causal connection between the exposure and a child's congenital malformation. It also involves a careful physical examination, and a review of the scientific literature regarding the genetic and environmental causes of the malformations in question. Abridged counseling, based on superficial and incomplete analyses, is a disservice to the families involved.

Conclusion

Approximately 10% of human malformations are due to environmental causes and fewer than 1% are related to prescription drug exposure, chemicals, or radiation. However, malformations caused by drugs and other therapeutic agents are important because these exposures may be preventable. Advances in animal research and epidemiology have enabled scientists to gain a better understanding of the mechanisms of teratogenesis.

Concerns about environmental chemicals and physical agents are clearly justified because, in most cases, not enough information is available on the potentially differential effects on the fetus and child. Such information, for example, the population exposure and the NOAEL, can only be obtained from high-quality human and animal toxicology and epidemiological studies which include toxicokinetic and toxicodynamic data and, therefore, it is essential that we expand our research programs in these areas. Ecological studies that do not measure exposures in the human population are more confusing than helpful in determining human risks, and studying exposures to groups of agents, e.g., solvents and pesticides, does not allow a risk assessment for individual toxicants.

All chemicals and drugs have the potential for developmental toxicity if the exposure is high enough; it would therefore be beneficial if humans were not exposed to chemicals in the workplace or home, or if chemicals were not dispersed into the environment. To address this problem now, and in the future, an extensive program of monitoring, reducing, and eliminating the delivery of chemicals to the environment and the exposure of populations to chemicals is needed. Introducing or banning chemicals that expose the human population is an extremely difficult task that needs to be carefully planned on the basis of risks and benefits.

Key points

- 1 Severe congenital malformations (including those birth defects that cause death, hospitalization, and mental retardation, and those that necessitate significant or repeated surgical procedures, are disfiguring, or interfere with physical performance) occur in 3% of all births.
- 2 Only a small percentage of birth defects are due to prescribed drugs, chemicals, and physical agents. Even when a drug is listed as a teratogen, it has to be administered during the sensitive period of development for that drug, and above the threshold dose for producing teratogenesis. Environmental causes account for approximately 10% of human birth malformations, and fewer than 1% of all human malformations are related to prescription drug exposure, chemicals, or radiation.
- 3 The etiology of congenital malformations can be divided into three categories: unknown (65–75%), genetic (15–25%), and environmental (10%).
- 4 Reproductive problems alarm the public, press, and some scientists, to a greater degree than most other diseases.
- 5 Physicians must recognize the consequences of providing erroneous reproductive risks to pregnant women exposed to drugs and chemicals during pregnancy, or of alleging that a child's malformations are caused by an environmental agent without performing a complete and scholarly evaluation.
- 6 Labeling an environmental exposure as teratogenic is inappropriate unless one characterizes the exposure with regard to the dose, route of exposure, and stage of pregnancy when the exposure occurred.
- 7 The application of the basic scientific principles of teratology is extremely important in evaluating studies on the reproductive effects of an environmental agent. These principles include the following criteria: exposure to teratogens follows a toxicological dose–response curve; the embryonic stage at which exposure occurs determines what effects (if any) a teratogen has; most teratogens have a confined group of congenital malformations (syndrome of agent's effects) and; no teratogen can produce every type of malformation.
- 8 The risk of morphological anomalies or intrauterine death resulting from exposure to a developmental toxicant varies depending on the dose and the embryonic or fetal stage at which exposure occurs.
- 9 The threshold dose for an environmental toxicant is the dose below which the incidence of death, malformation, growth retardation, or functional deficit is not greater than that of control subjects. The severity and incidence of malformations produced by every exogenous agent that has been appropriately studied have exhibited threshold phenomena during organogenesis.
- 10 Teratogens follow a threshold dose–response curve, whereas mutagens and carcinogens tend to follow a stochastic dose–response curve.
- 11 Physiological alterations in pregnancy and the bioconversion of compounds can significantly influence the teratogenic effects of drugs and chemicals by affecting absorption, body distribution, active form(s), and excretion of the compound.
- 12 Interpretation of dose–response relationships for teratogens must take into account the active metabolites, when metabolites might be the proximate teratogen rather than the administered drug or chemical, the duration of the exposure (chronic versus acute), and the fat solubility of the agent.
- 13 The role that the placenta plays in drug pharmacokinetics involves transport, the presence of receptors for a number of endogenous and xenobiotic compounds, and the bioconversion of xenobiotics.
- 14 The genetic constitution of an individual is an important factor that affects the susceptibility of a species to a drug or chemical.
- 15 Animal teratology studies are helpful in raising concerns about the reproductive effects of drugs and chemicals, but negative animal studies do not guarantee that these agents are free from reproductive effects.
- 16 Well-performed epidemiology studies represent the best methodology for determining the human risk and the effects of environmental toxicants.
- 17 *In vitro* tests can be used to study the mechanisms of teratogenesis and embryogenesis, and for preliminary screening procedures. However, *in vitro* studies cannot predict human teratogenic risks at particular exposures without the benefit of data obtained from whole animal studies and epidemiological studies.
- 18 The clinician must be cognizant of the fact that many patients believe that most congenital malformations are caused by a drug or medication taken during pregnancy.
- 19 Ignoring the basic tenets of teratology appears to occur most commonly in the evaluation of environmental exposures when the exposure was very low or unknown and the agent has been reported to be teratogenic at a very high dose or maternally toxic dose.
- 20 The evaluation of the toxicity of drugs and chemicals should (when possible) use data obtained from investigative approaches including: (1) epidemiological studies, (2) secular trend analysis, (3) animal reproductive studies, (4) dose–response relationships, (5) mechanisms of action (MOA) studies that pertain specifically to the agent and include receptor affinity, cytotoxicity, genotoxicity, organ toxicity, and neurotoxicity, and (6) biological plausibility.

Drugs, alcohol abuse, and effects in pregnancy

Stephen R. Carr and Donald R. Coustan

Determining the developmental toxicity of a drug or chemical requires an understanding of the mechanism of action and pharmacology of the substance as well as an understanding of embryology. Drugs, both legal and illicit, exert fetal developmental effects that are dependent on the dose, route of administration, physiologic handling by both the pregnant woman and the fetus, genetic predisposition, and the timing of the exposure in the pregnancy. The type of abnormality seen following drug exposure during pregnancy may give valuable clues about when in the pregnancy that drug had its effect. Thalidomide is perhaps the best known example of a substance with a very narrow window of toxic effect in developing humans.¹ Exposure of human fetuses to thalidomide between days 22 and 36 after conception is associated with characteristic limb reduction defects, as well as other structural anomalies. Complete understanding of the above-named factors may not in many cases be possible, so providers who care for pregnant women must rely on published experience of the agent in question. In the course of a busy practice, exhaustive research is neither practical nor possible but, fortunately, there are convenient alternatives including the Physician's Desk Reference (PDR), online resources such as Reprotox, traditional texts, and those for portable use on a personal digital assistant (PDA). When agents are new to the pharmacopeia, caution is necessary. Data in animal models may not present the full spectrum of toxicity in human pregnancy. Responsible pharmaceutical companies sponsor registries to more rapidly amass clinically significant data concerning the fetal impact of drug exposure during pregnancy. Even given that, frequently it is many years after the introduction of an agent before any degree of certainty about the appropriateness of an agent for use in pregnancy can be established. These registries benefit from being part of an organized effort to present comprehensive information concerning legal medications. Such organized registries are rare for illicit drug use and, as a result, practitioners rely on animal models and analyses of case series.

In spite of well-intentioned efforts at education, prevention, and intervention, the use and abuse of drugs, both legal and illicit, continue to cause maternal and fetal problems during pregnancy.

Alcohol

Ethanol is a social drug that offers no apparent benefit to the pregnant woman or her fetus. In spite of this, more than 500 000 fetuses per year in the US are exposed to ethanol *in utero*.² In total, infants born with fetal alcohol syndrome (FAS) cost approximately US\$40 billion yearly (in 1998 dollars), or approximately US\$2 million as a lifetime cost per individual.³ The term FAS was coined to describe 11 children of alcoholic mothers with characteristic features (Table 16.1).^{4,5} In 1980, specific criteria for FAS were proposed by the Fetal Alcohol Study Group of the Research Society on Alcoholism, requiring that at least one feature from each of the three categories be present for the diagnosis to be made.⁶ More recently, the Institute of Medicine defined five categories of alcohol-related birth effects⁷ (Table 16.2). The average IQ of children with FAS is 70.⁸ The original FAS children were followed for 10 years, and their growth deficiency and mental handicaps persisted.

It is difficult to estimate the prevalence of FAS or construct a dose-response curve for levels of alcohol exposure necessary to produce this problem, because it is difficult to accurately quantify alcohol intake; the amount of alcohol used is invariably underestimated. In addition, specific features of FAS may be caused by exposure to alcohol at different times in gestation. Craniofacial anomalies may occur during embryogenesis, disorders of central nervous system function may be brought about later in gestation, and growth disturbances may reflect alcohol exposure over a broad range of gestational ages.

The prevalence of FAS among offspring of heavy drinkers ranges from 2.5% to 10% in prospective studies.⁹ Recent work estimates FAS prevalence in the US at 0.3–0.4 per 1000 live births.¹⁰ Although it is difficult to obtain more specific data, it is clear that all cases of full-blown FAS occurred in chronic alcoholic mothers who drank heavily throughout pregnancy. It is also clear that binge drinking increases the risks of affected children having IQs in the mentally retarded range.¹¹ Studies have attempted to identify a threshold level of maternal ethanol ingestion above which effects are seen, and below which effects are not seen, without notable success. One analysis of the Spanish Collaborative Study of Congenital

Table 16.1 Alcohol and the fetus.

<i>Fetal alcohol syndrome</i> – at least one from each of the following categories:
Growth restriction, either prenatal or postnatal in onset
SGA/IUGR
Failure to thrive/short stature
Craniofacial abnormalities
Small eyes
Epicanthal folds
Long philtrum
Midface hypoplasia
Central nervous system abnormalities
Microcephaly
Developmental delay
Mental retardation
Learning disabilities
Alcohol-related birth defects – any of the preceding problems in the offspring of an alcoholic individual

SGA, small for gestational age; IUGR, intrauterine growth restriction.

Table 16.2 Categories of alcohol-related birth defects.

FAS: with confirmed maternal alcohol use and a characteristic pattern of malformations
FAS: without confirmed maternal alcohol use, but with the characteristic pattern of malformations
Partial FAS: with confirmed maternal alcohol use and some components of the characteristic malformations
Alcohol-related birth defects: the presence of congenital anomalies resulting from prenatal alcohol exposure
Alcohol-related neurodevelopmental disorder (ARND): central nervous system neurodevelopmental abnormalities, neurological hard or soft signs, or behavioral/cognitive abnormalities not consistent with background or environment

Malformations determined that even low and sporadic alcohol ingestion during pregnancy increased the risk of congenital anomalies.¹² Recent work has demonstrated increased neurodegeneration via apoptosis during synaptogenesis,¹³ defects in neuronal migration and decreased numbers of neurons in the mature cortex,¹⁴ and effects on myelination leading to decreases in white matter volume.¹⁵

The pathophysiologic mechanism for the adverse effects of alcohol on the developing fetus is poorly understood. Ethanol levels in maternal and fetal blood are identical in sheep, and studies in sheep demonstrate a time lag before ethanol's appearance in amniotic fluid.¹⁶ A similar time lag has been found in the appearance of ethanol in human amniotic fluid.¹⁷ There are increased c-myc protein levels and decreased growth-associated protein 43 levels after exposure of neural cell lines to ethanol.^{18,19} Normal cellular morphologic differentiation requires decreases in c-myc and increases in growth-

associated protein 43. Ethanol effects the production of these differentiation modulators and inhibits normal neuronal growth and differentiation. These studies describe changes in neuronal development/migration, apoptosis, and myelinization that are likely to be at the root of the neurobehavioral changes seen in children exposed to ethanol *in utero*. Acetaldehyde, a toxic metabolic product of ethanol, behaves similarly with respect to the amniotic fluid. Alcohol is metabolized via a number of different systems, including alcohol dehydrogenase in the cytosol fraction of the liver, the hepatic microsomal ethanol-oxidizing system, and the peroxisomal catalase system. There are genetic differences in some of these enzymes, and different individuals may induce them at different rates when exposed to the same concentrations of ethanol. Differential enzyme induction may lead to differential susceptibility to cell injury or disruption by other agents.²⁰ Alternatively, ethanol or acetaldehyde may interfere with placental transport of vital nutrients such as amino acids, leading to fetal malnutrition.²¹ Either interference with normal cellular development or fetal malnutrition may result in the 150-g lower birthweight of babies exposed to one to three drinks per day seen in a study of 10 539 women.²²

Alcohol ingestion by the gravida decreases fetal breathing movements but not gross body movements or fetal heart rate.²³ Alcohol withdrawal effects have been described, even in infants without the stigmata of FAS.²⁴ The fetal effects of alcohol appear to be multifactorial.

There is no treatment or cure for FAS or alcohol-related birth effects. One study suggested a protective effect of antioxidants (alpha-tocopherol and N-acetylcysteine) in the rat model, but this has not been confirmed in humans.²⁵ The best strategy is prevention, and the first component of prevention is education, so that women of childbearing age are aware of the risks of drinking during pregnancy. Educational campaigns have been carried out in the US at all levels. An epidemiologic study in Seattle reported that any alcohol use in early pregnancy fell from 81% in 1974–75 to 42% in 1980–81, and this was attributed to educational programs.²⁶ Although the prevalence of heavy drinking (defined in this study as 30 mL or more of absolute alcohol per day) before the discovery of pregnancy was unchanged at 6–7% during each time period, such use after pregnancy was discovered fell from 2.3% to 0.8%. In a population-based study in Finland from 1983 to 1985, 55% of women drank at least 2 oz of absolute alcohol during the week in which conception occurred, and only 16% were totally abstinent during the first trimester.²⁷ By 32 weeks, 50% were totally abstinent and, by term, 80% took no alcohol at all.

To prevent FAS, it is first necessary to identify mothers at risk. The CAGE²⁸ (Table 16.3), T-ACE²⁹ (Table 16.4), and TWEAK³⁰ (Table 16.5) questionnaires are all brief and effective. Several basic questions are asked in each of these questionnaires. Two or more positive answers on the CAGE questionnaire indicate a high probability of being a risk drinker. In the T-ACE questionnaires, the ability to hold a

Table 16.3 CAGE.

-
1. Have you ever felt the need to Cut down drinking?
 2. Have you ever felt Annoyed by criticism of your drinking?
 3. Have you ever had Guilty feelings about drinking?
 4. Have you ever taken a morning “Eye-opener”?
-

Table 16.4 T-ACE.

-
1. How many drinks can you hold? (Tolerance)
 2. Have you ever felt Annoyed by criticism of your drinking?
 3. Have you ever felt the need to Cut down drinking?
 4. Have you ever taken a morning “Eye-opener”?
-

Table 16.5 TWEAK.

-
- Tolerance: how many drinks does it take before you feel the effects of alcohol? (2 points for ≥ 3 drinks)
- Worry: have close friends or family worried or complained about your drinking in the past year? (2 points for yes)
- Eye-opener: do you sometimes take a drink in the morning when you wake up? (1 point for yes)
- Amnnesia: are there times when you drink and afterwards can't remember what you said or did? (1 point for yes)
- Cut down: do you sometimes feel the need to cut down on your drinking? (1 point for yes)
-

six-pack of beer or a bottle of wine scores two points on the tolerance question; affirmative answers on the others each score one point. A cumulative score of more than 2 indicates a high probability of being a risk drinker. A total of ≥ 2 points on the TWEAK questionnaire also indicates a high probability of problem drinking. One of these questionnaires should be administered to every patient when obtaining a history.

Recent research suggests that meconium fatty acid ethyl esters are a sensitive and specific marker for suspected but unreported maternal alcohol abuse in pregnancy.³¹ This remains to be confirmed in clinical practice.

Once the individual at increased risk for having a child with alcohol-related birth defects is identified, attention should be turned to intervention. Rosett and co-workers³² found that 67% of 49 pregnant problem drinkers reduced their alcohol intake when enrolled in a counseling program. Work in both the US and Finland found that cessation of heavy alcohol intake before the third trimester benefits the fetus.^{33,34} A randomized trial, although not specific to pregnancy, demonstrated that two brief (10–15 min each using scripted advice and educational information) interventions decreased both chronic and binge drinking.³⁵

Disulfiram use to increase the motivation of alcoholics to avoid consumption of alcohol is generally contraindicated in pregnancy.³⁶ Not a proven teratogen, disulfiram, when taken in combination with alcohol, leads to very high circulating acetaldehyde concentrations.

Table 16.6 Reported effects of cocaine on the fetus and pregnancy.

-
- Placental abruption
 - Intrauterine growth restriction
 - Preterm labor
 - Premature rupture of the membranes with meconium
 - Spontaneous abortion
 - Intrauterine cerebral infarctions
 - Genitourinary tract anomalies
 - Neurobehavioral disorders
-

Pregnant women should be advised to avoid alcohol, but this advice should not be construed as suggesting interruption of pregnancy when a history of alcohol consumption has been elicited; the risks of low-level alcohol consumption, or even occasional binges of marked consumption, have not been clearly quantified to date.

Cocaine

Pharmacology

Cocaine is an alkaloid³⁷ and can be administered intranasally, orally, vaginally, sublingually, rectally, and by intravenous, subcutaneous, or intramuscular injection.

At one time, the most popular form of administration was the intranasal route. Use of “crack” cocaine, an inexpensive, pure, and portable form of cocaine that gives an immediate effect, has superseded snorting. Cocaine is detoxified by cholinesterases, and cocaine and its metabolites are excreted in the urine, where they may be present for up to 3 days. Cocaine blocks the presynaptic reuptake of norepinephrine and dopamine, with accumulation of these neurotransmitters at postsynaptic receptor sites. Vasoconstriction, hypertension, myocardial irritability, and seizures may result. Euphoria results from the accumulation of dopamine, a mechanism that may also be responsible for addiction. In the pregnant ewe, cocaine induces vasoconstriction, decreased uterine blood flow, maternal and fetal hypertension, and fetal hypoxemia due to impaired oxygen transfer.^{38,39}

Adverse effects on the mother

Medical complications reported with cocaine include acute myocardial infarction, cardiac arrhythmias, aortic rupture, subarachnoid hemorrhage, strokes, ischemic bowel damage, and various other problems.³⁷ These same complications occur in pregnant women, and a report of intracerebral hemorrhage during the postpartum period confirms that expectation⁴⁰ (Table 16.6). The altered hormonal milieu of pregnancy may provide a setting in which the cardiovascular effects of cocaine are exaggerated.⁴¹

Adverse effects on pregnancy

Acker and associates⁴² in 1983 reported two cases of abruptio placentae occurring 30 min to a few hours after intravenous or intranasal administration of cocaine. Although it is likely that the acute vasoconstrictive effects of cocaine are responsible for causing abruptions, a chronic effect also exists. Chasnoff et al.⁴³ found that women who used cocaine only in the first trimester demonstrated a high rate of abruption (9%), as did women who used the drug throughout gestation (15%). They suggested that cocaine alters the placental or uterine vasculature early in pregnancy, with adverse effects showing up near term. Other reports of perinatal morbidity in cocaine users have appeared. Morbidities include IUGR, preterm labor and delivery, premature rupture of membranes, and spontaneous abortion.^{44–48} Cerebral infarcts occurring *in utero* have been reported in the offspring of cocaine users.⁴⁹ The major methodologic problem of these studies has been the issue of polydrug abuse. The majority of substance-abusing individuals abuse multiple substances, any one of which can adversely affect fetal growth and development. As a result, it is difficult to know whether a given effect is the result of abuse of a given substance or the abuse of a combination of substances. The teratogenic effects of cocaine have, as a result, proved difficult to evaluate, and patterns of cocaine use during the time of organogenesis are difficult to document. One study found major malformations (mostly cardiac anomalies) in five offspring of 50 cocaine users, compared with seven of 340 drug-free pregnancies ($P < 0.01$).⁵⁰ Chavez et al.⁵¹ and Ferris et al.⁵² found increased odds ratios for urogenital malformations among cocaine-abusing gravidae compared with noncocaine-abusing gravidae. A meta-analysis of 45 investigations into cocaine's teratogenic effects found a nonsignificant trend toward an increase in all malformations [odds ratio (OR) 4.08; 95% confidence interval (CI), 0.70–23.6] and cardiovascular malformations (OR 2.36; 95% CI, 0.83–6.74), but a significant increase in genitourinary malformations (OR 4.97; 95% CI, 1.05–23.6).⁵³ The proposed mechanisms by which cocaine exerts its teratogenic effects include vasoconstriction and reperfusion directly³⁹ and the generation of oxygen free radicals during the reperfusion that follows vasoconstriction.⁵⁴

Adverse effects on the neonate

Withdrawal has been reported in neonates exposed to cocaine,^{43,55,56} as well as electroencephalogram (EEG) abnormalities and abnormal visual evoked potentials.^{56,57} The confounding effects of polysubstance abuse make it difficult to determine whether it is the unique effects of cocaine or the effects of cocaine acting in concert with other drugs that generate the effects seen. Overall, however, studies have not generally found that cocaine adversely affects mental and motor outcomes.^{58,59} Recent work suggests that, while fetal cocaine exposure is associated with abnormalities in arousal, attention, and neurologic and neurophysiologic function, the effects

appear to be short-lived phenomena seen in infancy and early childhood, and are correlated with other factors, including prenatal exposure to alcohol, tobacco, and marijuana.^{60,61}

Cocaine use among pregnant women varies widely depending on the study. Two reports found that cocaine use was seen in 8–24% of pregnant women.^{62,63} Better birth outcomes for cocaine-abusing gravidae can be achieved by a combination of specialized prenatal care and drug treatment.⁶⁴ Prenatal care by itself is associated with a marked decrease in the rate of low birthweight (less than 2500 g; 34.3% versus 52.3%, $P < 0.05$) and very low birthweight (less than 1500 g; 5.2% versus 18.2%, $P = 0.01$). Stopping cocaine after the first trimester appears to decrease some (low birthweight, preterm delivery) but not all of the risk.⁴³ The challenge remaining is to insure that these women continue to have access to care.

Heroin

Pharmacology

Heroin's effects are similar to those of morphine, except that it appears to cross the blood–brain barrier more quickly. This is an effect of the greater lipid solubility of heroin. Heroin is hydrolyzed to monoacetylmorphine and morphine, and is excreted in the urine. Its effects are similar to those of other opioids, and physical dependence leading to abstinence-related withdrawal symptoms is induced with chronic use. Gynecologic problems such as galactorrhea–amenorrhea have been reported in female heroin addicts.⁶⁵ Although cocaine use has shifted attention away from perinatal heroin addiction, this problem remains a challenge for obstetricians and other caregivers (Table 16.7).

Fetal effects

Heroin crosses the placenta, and addiction is common among fetuses of heroin-addicted mothers. Fetal withdrawal with intrauterine convulsions has been postulated.^{66,67} The issue of low birthweight is confounded by elements of maternal lifestyle also known to affect fetal growth. Heroin-addicted mothers are more likely to deliver infants of low birthweight.⁶⁸ The relative risk of delivering low birthweight babies in heroin users is 4.61 (95% CI, 2.78–7.65) in pregnant heroin users, 1.36 (95% CI, 0.83–2.22) in methadone users, and 3.28 (95% CI, 2.47–4.39) in women who used both. Respiratory

Sudden infant death syndrome

distress syndrome may actually occur with less frequency in such children.⁶⁹ It is uncertain whether the 28% prematurity rate associated with heroin use seen in some studies is due to the drug use itself or to the influence of other factors. There are few convincing data to indicate an increased incidence of preterm delivery among pregnant heroin users. Teratogenicity has not been conclusively demonstrated, but behavioral teratogenicity is likely, with neonates of heroin addicts demonstrating impaired interactive abilities and motor changes.⁷⁰ Sudden infant death syndrome (SIDS) occurs with greater frequency among offspring of heroin-addicted mothers, but the mechanism is unclear.^{71,72} Chasnoff⁷⁰ suggested that this high rate of SIDS may be associated with sleep apnea and has used theophylline treatment to prevent it.

Neonatal abstinence syndrome

The most striking finding with perinatal heroin addiction is neonatal withdrawal. It occurs in 50–80% of infants born to mothers addicted to heroin or treated with methadone.⁶⁰ This syndrome includes tremors, restlessness, hyperreflexia, high-pitched cry, sneezing, sleeplessness, tachypnea, yawning, sweating, fever, and, in severe cases, seizures.⁷³ The onset of symptoms occurs anywhere from birth to as long as 2 weeks of age and may persist for up to 4–6 months.⁷⁴ Treatment has ranged from supportive measures to the use of medications such as diazepam, barbiturates, and opioids such as paregoric and methadone.⁶⁹ There is some evidence that withdrawal is less severe in infants whose mothers' methadone dose was down to 20 mg/day or less before delivery.⁷⁵

Treatment in pregnancy

Heroin-addicted mothers are usually treated with methadone maintenance. Specific programs for management of drug dependency during pregnancy have met with success in lowering the various morbidities encountered in such extremely high-risk pregnancies. Well-designed studies have demonstrated a threefold decrease in heroin use as well as a threefold increase in maintenance of treatment among women treated with methadone or buprenorphine when compared with women not so treated.⁷⁶ In addition, enrollment in a methadone maintenance program with adequate prenatal care results in an incidence of low birthweight infants similar to that of nondrug-using women with good prenatal care.⁷⁷ Heroin withdrawal during pregnancy has been associated with stillbirth in humans.⁷⁸ As a result, detoxification should be attempted only in a highly motivated patient.

Infection

The comorbidities of heroin use are similar whether or not the woman is pregnant. The most significant of these are infectious. Twelve percent of heroin addicts tested positive for hepatitis B surface antigen in one study,⁷⁹ and another study

reported a 43.5% infection rate of infants within 6 months of delivery when born to asymptomatic carrier mothers.⁸⁰ When acute infection occurred in the first trimester, 76% of infants were infected.⁸¹ The most significant problem facing intravenous drug users and their offspring now is the danger of acquired immunodeficiency syndrome (AIDS). Intravenous drug use accounts for the majority of human immunodeficiency virus (HIV) positivity among women, with some areas at one time reporting a 50% seropositivity rate among intravenous drug users.⁸² Significantly increased rates of infection with syphilis are also present in heroin users.

Hallucinogens

Hallucinogenic drugs such as LSD were commonly taken recreationally in the 1960s and 1970s, but few credible studies were performed regarding the effects of such chemicals on pregnant women and their fetuses. Even retrospective studies were confounded by polydrug use, lifestyle differences, and reporting bias. Chromosome damage from *in vitro* exposure of leukocytes to LSD, increased prevalence of chromosome breaks *in vivo*, and a malformation rate of 10% have been reported in fetuses exposed to this agent,⁸³ but teratogenicity for LSD has not been confirmed. Little recent data are available because LSD use has declined in recent years.

Phencyclidine (PCP) use has continued to a greater extent than LSD. In a prospective epidemiologic study of 2327 pregnant women, women were assessed by questionnaire and urinary assays. Twelve (0.5%) admitted PCP use during the index pregnancy, and an additional seven (0.3%) tested positive for this drug in their urine.⁸⁴ Mouse studies demonstrated that PCP crosses the placenta and appears in breast milk in concentrations 10 times those in maternal plasma.⁸⁵ PCP appears in umbilical cord plasma and amniotic fluid from human pregnancies, and the human placenta is an active site for conversion of PCP to its metabolic products *in vitro*.^{86,87} One case measured both maternal and umbilical cord levels and found the concentration of PCP in the fetus was double that in the mother.⁸⁸ Case reports describe abnormal neonatal behavior, abnormal brain wave patterns, depressed interactive behaviors, and diminished organizational responses to stimuli in infants exposed to PCP *in utero*, but no epidemiologic studies have quantified the risk.^{89–92} Finally, one study demonstrated an increased rate of preterm delivery and meconium-stained amniotic fluid in children exposed to PCP *in utero*.⁹³

Tobacco

Maternal smoking is associated with a wide variety of increased obstetric morbidities (Table 16.8). The major effects of tobacco present in the first trimester of pregnancy as decreased fecundity and increased spontaneous pregnancy loss, and in the second and third trimester as increased growth

Table 16.8 Obstetric morbidities among pregnant smokers.

restriction and preterm labor and delivery.^{94,95} Maternal smoking during pregnancy decreases birthweight by 10–15 g per cigarette smoked daily. This may be due to direct effects of smoking on fetal growth, to decreased maternal caloric intake seen in pregnant smokers, or to the decreased intervillous volume and decreased number and surface area of fetal capillaries seen in the placentas of pregnant smokers.^{96–98} The increased incidence of low birthweight and premature delivery associated with maternal smoking results in a 33% increase in overall perinatal and neonatal mortality.⁹⁹ Overall, perinatal mortality for infants of nonsmokers was 23.3 per 1000 births in the Ontario Perinatal Mortality Study.¹⁰⁰ Among smokers of more than one pack per day, that figure increased to 33.4 per 1000 births, and half of that increase was due to smoking-related increases in placental abruption and placenta previa. There are conflicting data on the effects of maternal smoking on human uterine and umbilical blood flow. Morrow et al.¹⁰¹ found that smoking increased maternal heart rate and blood pressure and fetal heart rate without any changes in uterine artery systolic-to-diastolic ratios. They did note, however, smoking-dependent changes in the umbilical artery systolic-to-diastolic ratio. It remains unclear whether the effects seen were the result of the nicotine in the smoke or the carbon monoxide. Some animal literature suggests that maternal nicotine exposure is associated with decreased uterine blood flow,¹⁰² but the evidence for a similar effect in primates and humans is less compelling. Nicotine administered to the mother has been associated with decreased uterine blood flow in rhesus monkeys but, in the human fetus, it has been associated with increased umbilical blood flow.^{103,104} Both standard cigarette smoke and smoke from nicotine-free cigarettes were associated with decreased fetal PO_2 when inhaled by pregnant rhesus monkeys.¹⁰⁵ This effect may be attributed to carbon monoxide, because carboxyhemoglobin is preferentially trapped on the fetal side of the placenta. The relative hypoxia induced by increased carboxyhemoglobin levels in the fetus could induce a wide variety of adverse effects. Clinical studies have demonstrated variable effects on fetal breathing¹⁰⁶ and increased fetal heart rate with decreased beat-to-beat variability¹⁰⁷ during acute maternal exposure to cigarette smoke, but no effect was seen on nonstress test re-

activity.¹⁰⁸ Chronic cigarette exposure was associated with lower Apgar scores in some but not all studies.^{109,110} Intimal injury of the umbilical arteries of newborns from smoking mothers has been demonstrated, as have placental changes.^{111–113} Maternal smoking has also been associated with a failure in expansion of total body water and mean plasma volume during pregnancy.¹¹⁴ Maternal smoking has been associated with changes in hemostatic and platelet function,^{115,116} but it is difficult to determine whether these changes are due to the effects of nicotine, carbon monoxide, or some other substance(s). Studies in rats have demonstrated damage to the fetal brainstem¹¹⁷ and both a decrease in the number of neonatal type I pneumocytes and an increase in the number of type II pneumocytes in rats.¹¹⁸ The type II pneumocytes were morphologically abnormal, with no microvilli on their alveolar surface.

The teratogenic potential of maternal cigarette smoking is becoming manifest. One study found increased mutations in the gene for hypoxanthine–guanine phosphoribosyltransferase in the cord blood T-cell lymphocytes of neonates exposed to maternal smoking as fetuses.¹¹⁹ One epidemiologic study suggested that isolated oral clefts are increased in the offspring of cigarette smokers,¹²⁰ but an analysis of the Swedish Medical Birth Registry found that the association between smoking and facial clefts depended on the type of analysis done: an association between cleft palate and smoking was seen in all case designs, but the association between cleft lip with or without cleft palate and smoking was seen only in case–control analyses.¹²¹ Lammer et al.¹²² found that orofacial clefts are increased among smokers whose fetuses have polymorphic variants of NAT1, an enzyme involved in detoxification of smoke components, possibly explaining the discrepancy in study findings. Maternal smoking during pregnancy has been associated with a decreased risk of respiratory distress syndrome in the prematurely delivered offspring, an effect that has generally been attributed to enhanced pulmonary maturation secondary to intrauterine hypoxic stress.¹²³ Children exposed *in utero* to smoking consistently score lower on scores of expressive language and conceptual understanding and have a greater incidence of behavioral difficulties.^{99,124,125}

Although it is possible to detect the effects of household smoking exposure on infants, one study was unable to demonstrate maternal–fetal transmission of thiocyanate acquired passively by the mother exposed to a smoking environment, but not herself a smoker.¹²⁶ Another study was able to show such an effect,¹²⁷ and one report demonstrated a significant reduction in birthweight among the offspring of mothers exposed passively to cigarette smoke, as evidenced by increased maternal cotinine levels during the second trimester.¹²⁸ A case-controlled study of 91 children found a dose-dependent relationship between maternal exposure to second-hand smoke and risk of childhood brain tumors,¹²⁹ and an adverse effect on language skills, visual, and spatial abilities was seen in children exposed prenatally to second-hand smoke when compared with children not exposed.¹³⁰

Table 16.9 Fetal tobacco syndrome.

1. A mother who smoked five or more cigarettes a day throughout the pregnancy
2. No evidence of hypertension during the pregnancy
3. Symmetric growth retardation at term
4. No other obvious cause of growth retardation

Table 16.10 Intervention to promote smoking cessation during pregnancy.

Ask: ask the patient to choose a statement that best describes her smoking status:

- I've smoked < 100 cigarettes in my lifetime
- I quit smoking before I found out I was pregnant
- I quit smoking after I found out I was pregnant
- I still smoke, but I've cut down
- I still smoke and I haven't cut down

Advise: give clear, firm advice to quit smoking. Stress the benefits to her and the fetus.

Assess: investigate her willingness to quit.

Assist: offer and encourage coping mechanisms for quitting smoking (identify trigger situations):

- Provide support as part of the treatment
- Arrange for social support; involve family and friends
- Pregnancy-specific smoking cessation programs

Arrange: follow-up is essential. Reassess and re-encourage.

Attempts to modify smoking behavior during pregnancy have met with mixed success. Nieburg and colleagues¹³¹ suggested the term fetal tobacco syndrome to describe infants meeting four conditions (Table 16.9). In 2000, the American College of Obstetricians and Gynecologists published a Technical Bulletin recommending that pregnant women be encouraged to stop smoking.¹³² Identification of the smoker at the first prenatal visit should be coupled with intensive education about the risks of smoking during pregnancy. A brief 5- to 15-min intervention will increase smoking cessation by 30–70% in smoking gravidae. It is most effective in women who smoke < 20 cigarettes per day¹³³ and consists of Ask, Advise, Assess, Assist, and Arrange¹³⁴ (Table 16.10).

Although there have been great strides in American society in prohibiting smoking in public areas and in decreasing the number of cigarette-smoking citizens, smoking during pregnancy continues to be a problem. Statistics suggest that 15–29% of women continue to smoke during pregnancy.¹³⁵ Pregnant smoking women treated with a cessation program demonstrated a significant increase in birthweight and length of their offspring when compared with untreated smoking control subjects,¹³⁶ and quitting at any point in pregnancy is helpful.¹³⁴ We must find out if our patients are smoking, educate them about the risks, and refer them to smoking cessation programs in our communities. Behavioral therapies are the first line of intervention. If these therapies fail, then pharmacological treatment with either bupropion or nicotine

replacement treatments (NRTs) can be considered. Bupropion is Food and Drug Administration (FDA) class B, and all the NRTs are FDA class C. A careful assessment of risks and benefits is necessary before starting these therapies.

Caffeine

Caffeine is a xanthine. The xanthines exert their systemic effects by increasing intracellular cyclic adenosine monophosphate, altering ionized calcium levels, and potentiating the action of catecholamines. These systemic effects include central nervous system excitation, smooth muscle relaxation, increased heart rate, increased cardiac output, an increase in gastric acid secretion, and increased diuresis. Caffeine is contained in coffee and tea (100–150mg per average cup), cola drinks (35–55mg per 12-oz serving), and cocoa (200mg of theobromine per average cup). Pregnant women near term eliminate caffeine considerably more slowly than nonpregnant control subjects, and ingestion of two cups of coffee by these women was associated with a small but significant decrease in intervillous blood flow.^{137,138} Caffeine is fat soluble and crosses the placenta in sheep and humans. Chronic coffee drinkers have increased fetal breathing activity, but acute ingestion of 200mg of caffeine had no significant effect on fetal breathing.¹³⁹

Caffeine is teratogenic in rodents. Doses of 50–75mg/kg in mice, and greater than 80mg/kg in rats induce malformations of limbs and digits.¹⁴⁰ These are levels higher than those likely to be achieved in human pregnancies. Additionally, if caffeine doses are given in split doses instead of in bolus fashion, 330mg/kg/day is required to cause teratogenicity in rats. A report of three human pregnancies in which high maternal caffeine intake was associated with ectrodactyly in the offspring created a great deal of interest in the possibility of teratogenicity, but each mother had consumed between 1100 and 1777mg of caffeine on an average day during her pregnancy.¹⁴¹ Three large epidemiologic studies in humans detected no increase in congenital anomalies related to caffeine intake among pregnant women.^{142–144} A recent review of the effect of caffeine on spontaneous abortion concluded that, while many epidemiologic studies have observed a positive association between caffeine intake and spontaneous pregnancy loss rates, the evidence should be considered equivocal because of the many methodologic flaws.¹⁴⁵ The data on the effect of caffeine on birthweight are similarly conflicting. Fortier et al.¹⁴⁶ found a dose-dependent effect of increasing caffeine consumption on decreasing birthweight in a population-based study of over 7000 women, but Mills et al.,¹⁴⁷ in their study on moderate caffeine intake, were unable to confirm this finding.

There is no convincing evidence supporting a teratogenic or other adverse role of caffeine in pregnancy when taken in amounts equivalent to less than 10 cups of coffee per day. Pregnant women should be advised to use moderation in their caffeine intake, but it need not be avoided altogether.

Key points

- 1 Drug effects on fetal development depend on the dose, the route of administration, physiologic handling of the drug by both the pregnant woman and the fetus, genetic predisposition, and timing of the exposure in the pregnancy.
- 2 Fetal alcohol syndrome (FAS) occurs in 2.5–10% of offspring of heavy drinkers, and includes growth restriction (either prenatal or postnatal in onset), craniofacial anomalies (small eyes, epicanthal folds, long philtrum, or midface hypoplasia), and central nervous system abnormalities (microcephaly, developmental delay, mental retardation, learning disabilities).
- 3 The categories of alcohol-related birth defects include: (1) FAS with confirmed maternal alcohol use; (2) FAS without confirmed maternal alcohol use but with characteristic malformations; (3) partial FAS with confirmed maternal alcohol use and some components of FAS; (4) alcohol-related birth defects with the presence of congenital anomalies resulting from prenatal alcohol exposure; and (5) alcohol-related neurodevelopmental abnormalities.
- 4 Women at risk for problem drinking during pregnancy can be identified using the “CAGE”, “T-ACE,” or “TWEAK” questionnaires. Interventions in women so identified can decrease problem drinking by more than 50%.
- 5 Drinking cessation before the third trimester of pregnancy will benefit the fetus, so it is never “too late.”
- 6 All studies of the impact and effects of a particular illicit drug on developing fetuses are complicated by problems in accurately quantifying the exposure, and the fact that polysubstance abuse is the rule and not the exception.
- 7 Cocaine blocks presynaptic reuptake of norepinephrine and dopamine, resulting in vasoconstriction, hypertension, myocardial irritability, and euphoria.
- 8 Cocaine use during pregnancy is associated with an increased incidence of placental abruption (a side-effect of vasoconstriction and hypertension), and this effect persists even if the pregnant cocaine user stops using in the first trimester.
- 9 Maternal medical effects of cocaine use include acute myocardial infarction, cardiac arrhythmias, hypertension, aortic rupture, subarachnoid hemorrhage, and ischemic bowel damage.
- 10 Fetal/neonatal effects of cocaine use in pregnancy include placental abruption, intrauterine growth restriction, preterm labor and delivery, increased incidence of genitourinary birth defects, and withdrawal.
- 11 The features previously ascribed to the so-called “crack baby syndrome” (abnormalities in arousal, attention, and neurologic and neuropsychologic function) are short-lived and correlate with other factors including exposure to alcohol, tobacco, and marijuana.
- 12 Convincing a woman to use methadone instead of heroin decreases the relative risk of delivering a low birthweight baby from 4.61 to 1.36.
- 13 Structural teratogenicity has not been associated with heroin use during pregnancy, but behavioral teratogenicity is likely.
- 14 Neonatal abstinence occurs in 50–80% of infants born to mothers using heroin or methadone, and includes tremors, restlessness, hyperreflexia, high-pitched cry, sneezing, sleeplessness, tachypnea, yawning, sweating, fever, and sometimes seizures.
- 15 Neonatal abstinence and withdrawal is less severe if the maternal methadone dose is < 20 mg/day at delivery.
- 16 The major effects of tobacco present in the first trimester as decreased fecundity and increased pregnancy loss, and in the second and third trimester as increased growth restriction and preterm labor and delivery.
- 17 The increased incidence of low birthweight and preterm labor and delivery explains the 33% increase in overall perinatal and neonatal morbidity seen in pregnant smokers.
- 18 Cigarette smoking during pregnancy is associated with an increased incidence of orofacial clefts.
- 19 Smoking cessation interventions during pregnancy will increase smoking cessation by 30–70% in smoking gravidae.
- 20 Caffeine is teratogenic in rodents, but probably only in doses that are exceedingly difficult to achieve in humans (i.e., > 10 cups of coffee per day).

Teratogenic viruses

Antonio V. Sison

A teratogen is an agent that induces malformations in humans, from the Greek word “teras” meaning monster. Teratogenic viruses include the following: cytomegalovirus (CMV), herpes simplex virus (HSV), varicella zoster virus (VZV), rubella virus, and Venezuelan equine encephalitis (VEE) virus. The role of parvovirus B19 in congenital malformations has been questioned but is briefly included in this chapter. The chapter reviews each individual virus’s epidemiology, biology, pathogenesis, diagnosis and management in pregnancy, effects on the fetus and infant, and prevention of spread. Other viruses have been shown to cause fetal damage but are not considered to be teratogenic; these viruses and their specific fetal effects are summarized in Table 17.1. Epidemiological studies using clinical data, virus isolation techniques, and serology have provided estimates of the frequency of teratogenic viral infections in pregnant women and their children (Table 17.2). Factors that influence these data include the population sampled, the occurrence of epidemics, the methods of diagnoses used, the use of vaccines for rubella and varicella, delivery by Cesarean section when maternal herpes infection is present, and changing social behaviors.

The first major development in the control of viral infections was the introduction of the rubella virus vaccine in 1969. Over the following 25 years, other significant developments in the management and treatment of perinatal viral infections have included: (1) the introduction of vaccines against the hepatitis B virus and VZV; (2) the universal administration of hepatitis B vaccine to all newborns; (3) the dramatic reduction of perinatally acquired infection with human immunodeficiency virus (HIV) by administration of antiretroviral medication at the time of delivery; and (4) the application of modern molecular biological techniques, such as *in situ* hybridization and the polymerase chain reaction (PCR), in the prenatal diagnosis of viral infection. A vaccine against hepatitis B virus first became commercially available in 1981, whereas the VZV vaccine became available in Europe in 1984 and in the USA in 1995. Use of the rubella vaccine resulted in a 99% reduction in the incidence of congenital rubella syndrome (CRS) in the USA.¹ The vaccination of

children with the VZV vaccine resulted in a 93% reduction in the expected number of cases compared with a historical attack rate of 87% in a cohort of unvaccinated children. Investigational vaccines against CMV, HSV, VEE, and HIV have been used in humans, although results of their efficacy are discouraging at present.

Cytomegalovirus

Biology

CMV is a DNA virus belonging to the Herpesviridae family. It is the most common congenitally acquired infection (Table 17.2). The name of the virus is derived from the characteristic “owl’s eye” appearance of cells seen in histological sections of tissues which have been infected by the virus; this appearance is due to massive viral cytoplasmic replications, creating the distinct viral or cytomegalic inclusions. In 1956, Rowe and coauthors² were the first to successfully isolate the virus in tissue culture and describe its cytopathic effects. The following year, Weller and coauthors³ independently reported the isolation of the same agent from infected infants.

Epidemiology

Seroprevalence studies of pregnant and nonpregnant women worldwide have consistently shown wide variations in seropositivity to CMV antibodies. These rates range from 40% to 80%, with higher rates related to lower socioeconomic status and an increase in patient age, gravidity, parity, and number of sexual partners. In general, the seroprevalence rate in the USA is approximately 60%. Studies using PCR have shown a cervical excretion rate of CMV of 13–40% and a urinary excretion rate of 1–13% throughout pregnancy.⁴ Using nested PCR techniques, viral nucleic acid has been detected in other fluids such as nasopharyngeal secretions, urine, breast milk, and amniotic fluid.⁵

Congenital infection with CMV occurs at a frequency of approximately 0.5–2.5% of all newborns. In the USA,

Table 17.1 Viruses which are perinatally acquired and which can cause fetal/neonatal damage.

Virus	Perinatal/neonatal effects
<i>Known teratogenic viruses</i>	See text for perinatal effects
Cytomegalovirus	
Rubella virus	
Varicella zoster virus	
Herpes simplex virus (HSV1, HSV2)	
Parvovirus B19	
Venezuelan equine encephalitis virus	
<i>Viruses that have been shown to cause fetal damage after transmission</i>	
Coxsackieviruses (group B)	Myocarditis, meningoencephalitis, pleurodynia
Dengue virus	Fever, leucopenia, thrombocytopenia
Echovirus (14 and 19)	Apneic spells, hepatitis, thrombocytopenia
Hepatitis B virus	Hepatitis
Hepatitis C virus	Hepatitis
Human immunodeficiency virus	Growth restriction, leukopenia, failure to thrive, hypogammaglobulinemia, AIDS-related infections
Human papillomavirus	Laryngeal papilloma
Influenza virus	Endocardial fibroelastosis (?)
Mumps virus	Pneumonitis, endocardial fibroelastosis (?)
Parvovirus B19	Nonimmune fetal hydrops, anemia
Poliovirus	Paralysis
Rubeola (measles) virus	Premature delivery, measles, otitis media
Vaccinia virus	Spontaneous miscarriage, fetal death
Variola virus	Spontaneous miscarriage, fetal death
Western equine encephalitis virus	Meningitis
<i>Viruses that have not been shown to cause fetal damage after transmission or when data on fetal transmission are inconclusive</i>	
Coxsackieviruses (group A)	
Epstein-Barr virus	
Hepatitis A virus	
Non-A, non-B, non-C hepatitis viruses	
Rabies virus	
Smallpox virus	

Table 17.2 Frequency of teratogenic viral infections in pregnant women and their children.

Virus	Mother (per 10000)	Child (per 10000)
Cytomegalovirus	300–500	50–150
Rubella virus		
Epidemic	200–400	20–40
Nonepidemic	10–20	1–2
Currently in the USA	< 1	< 0.1
Herpes simplex virus	50–150	0.5–5.0
Parvovirus B19	25	5–10
Varicella zoster virus	1–2	< 0.01–1.0
Venezuelan equine encephalitis	With epidemics	With epidemics

approximately 40 000 infants are born annually with either clinical or laboratory evidence of CMV infection. Worldwide, it is estimated that 1% of all newborns are infected with CMV. Severe damage from congenital infection, such as the classic

cytomegalic inclusion disease (CID), occurs at a rate of approximately 1 in 5000 to 1 in 20 000 births.

Perinatal transmission of CMV has been demonstrated in cases where the pregnant woman develops either a primary or recurrent CMV infection. Transmission rates of CMV after primary infection range from 15% to 50%,⁶ whereas neonatal infection occurs in approximately 0.5–1.0% of cases where there is a recurrent infection in the mother. In general, the following principles apply to fetal infection with CMV: (1) severe damage, such as that seen in fully developed CID, results almost exclusively from primary maternal infection, and (2) clinically evident manifestations in the newborn are more common following primary infection in the mother.

Clinical manifestations

In general, maternal infection with CMV is asymptomatic. Symptomatic patients develop fever, pharyngitis, lymphadenopathy, and other generalized symptoms of viral illness. Primary CMV infection has been described as a

Table 17.3 Clinical manifestations of CMV in newborns and adults.*Birth defects*

Cytomegalic inclusion disease (CID), which includes any of the following findings:

Early: petechiae, hepatosplenomegaly, jaundice, microcephaly, hemolytic anemia, cerebral calcifications, seizures, cerebellar or cortical atrophy, microphthalmia, intrauterine growth retardation, interstitial pneumonia, pneumonitis, mononucleosis-like illness, cardiovascular disease (e.g., ventriculomegaly, cardiomegaly), gastrointestinal defects, thrombocytopenia, ascites

Late: mental retardation, sensorineural hearing loss, learning disability, neuromuscular defects, psychomotor retardation

Early or late: chorioretinitis, optic atrophy, dental defects, spasticity

Clinical findings

Mother: mostly asymptomatic; when symptoms are present, heterophile-negative mononucleosis-like syndrome; laboratory diagnoses include CMV-specific IgG and IgM, viral culture

Infant: mostly asymptomatic; when symptoms are present, see above; laboratory diagnoses include CMV-specific IgM, viral culture, viral antigen, detection of viral DNA using *in situ* hybridization or PCR

heterophile-negative, mononucleosis-like syndrome. Following initial primary infection, CMV becomes latent; reactivation of latent infection is often asymptomatic and the factors that control reactivation are poorly understood at present. Fetal and neonatal infections can be acquired from mothers with either primary or recurrent infection; in general, the risk of fetal transmission and severity of the infection from reactivated disease in the mother is lower than with primary maternal infection.⁷

The clinical and laboratory manifestations of congenital CMV infection, summarized in Table 17.3, are divided into early and late findings. Most infected neonates are asymptomatic at birth, although 10% of these infants present with clinical manifestations later in life. In the USA, fully developed CID occurs at a rate of 1 case per 10 000 births; it involves multiorgan damage and is almost always a result of primary infection in the mother. The most common findings in CID include petechial rash (79%), hepatosplenomegaly (74%), jaundice (63%), and microcephaly (50%).⁸

Diagnosis

CMV infections usually go unrecognized unless symptoms develop. The presence of CMV-specific IgG antibodies in the mother confirms a recent or past infection; however, because CMV becomes latent in the mother, previous infection in the mother does not confer immunity against infection in the infant. CMV-specific IgM is detectable in both maternal and neonatal primary infections in 80% of cases.

Viral culture is the most accurate method of diagnosing CMV infection, although culture positivity cannot distinguish

Table 17.4 Prenatal methods of CMV detection.

Site/compartiment	Method of detection
Amniotic fluid	CMV-specific IgM Viral culture Nucleic acid using PCR
Chorionic villus	Nucleic acid using PCR Nucleic acid using <i>in situ</i> hybridization
Fetal blood (from percutaneous umbilical blood sample)	CMV-specific IgM Viral culture Nucleic acid using PCR Viral antigen

between primary and recurrent infection. Culture sites in the mother include the nasopharynx, cervix, vagina, and urine; in the infant, they include the nasopharynx, conjunctiva, and urine. Modern techniques, such as detection of viral DNA using PCR or *in situ* hybridization, have also been used in the prenatal diagnosis of CMV. Table 17.4 summarizes methods for the prenatal diagnosis of *in utero* infection with CMV.

Treatment and prevention

The treatment of CMV infection in the mother and infant is directed toward the symptoms, when they are present. Agents that have been used in the treatment of CMV include adenosine arabinoside, cytosine arabinoside, acyclovir, ganciclovir, and foscarnet (phosphonoformic acid). Unfortunately, they have had limited success; the first two agents are very toxic and the remainder have only been used in a very small number of studies. For example, ganciclovir has been used in the treatment of chorioretinitis and been shown to reduce viral shedding among infected infants; however, the reduction is only present for the duration of the treatment. Immunoprophylaxis with a live attenuated CMV vaccine has been used in seronegative kidney transplant recipients with some success.⁹ Vaccine recipients were significantly less susceptible to acquiring primary CMV infection than those who received a placebo.

To date, the most effective method of reducing primary CMV infection in all pregnant women who are at high risk is to observe: (1) proper handwashing techniques, particularly when handling infants and young children, who are frequently infected and shed virus for extended periods of time, and (2) proper handling of infected body fluids and secretions in high-risk areas.

Rubella virus

In 1941, the Australian ophthalmologist, Gregg,¹⁰ was the first physician to report congenital defects in children whose mothers had suffered an acute rubella (German measles) infection while pregnant. In total, 68 of the 78 infants who were

studied developed cataracts and many also had congenital heart defects. Out of all the known teratogenic viruses, infection with rubella results in the most severe malformations.

Epidemiology

The most recent rubella pandemic was from 1962 to 1964, when 12.5 million cases of rubella and 20 000 cases of CRS were reported worldwide. In 1969, the introduction of the rubella vaccine in the USA reduced the annual incidence of rubella by 99% and, over the next two decades, the annual incidence of rubella decreased to 0.05 cases per 100 000 live births.

In the USA, up to 10% of women are susceptible to acute rubella infection in pregnancy despite routine and mandatory vaccination programs in children. At present, the single most important source of serosusceptible individuals in the USA are foreign-born immigrants who have not been vaccinated in their countries of origin, primarily Mexico and Central America.¹¹ Less than 5% of countries worldwide offer routine vaccination against rubella. In addition, specific groups in the USA, such as the Amish communities in Pennsylvania, do not commonly accept the vaccine and have a high serosusceptibility to rubella.

Biology and pathogenesis

Rubella is a member of the *Togaviridae* family, genus *Rubivirus*. The clinical manifestations of rubella infection in humans were first described in the mid-eighteenth century but the virus was only successfully isolated in tissue culture in 1962.¹² Humans acquire rubella infection primarily through infected respiratory droplets that are inoculated through the nasopharynx of the host. Infection is followed by the rapid spread of virus to regional lymph nodes and the bloodstream. Patients are viremic within 7 days of inoculation, although incubation periods are typically from 14 to 21 days, and viremia ceases 1–2 days before the onset of the rash. Viral shedding from the nasopharynx of infected individuals begins 7 days before, and up to 5 days after, onset of the rash.

When pregnant women develop acute rubella, congenital infection occurs through the transplacental route. Evidence of perinatal transmission through the birth canal has not been substantiated even though virus has been recovered from cervical secretions. Most fetal damage occurs in the first trimester and, in general, the earlier in gestation that the infection occurs, the more severe the fetal damage and malformation.

Clinical manifestations

Children and adults with primary rubella infection present with malaise, fever, lassitude, and headaches. A fine, macular, “rubelliform” rash develops within 1–5 days after these initial symptoms. The rash generally starts on the face and neck, extending to the trunk and extremities. Lymph node enlarge-

Table 17.5 Clinical manifestations of rubella infection in newborns and adults.

Birth defects

Congenital rubella syndrome (CRS), which includes any of the following findings:

Neurological: meningoencephalitis, microcephaly, intracranial calcifications, psychomotor retardation, behavioral disorders, autism, chronic progressive panencephalitis, hypotonia, speech defects
Otic: hearing loss
Ophthalmological: cataracts, retinopathy, glaucoma, cloudy cornea, microphthalmia, subretinal neovascularization
Cardiac: patent ductus arteriosus, pulmonary artery stenosis, pulmonary artery hyperplasia, coarctation of the aorta, ventricular septal defect, atrial septal defect, myocarditis, myocardial necrosis
Miscellaneous: thrombocytopenia purpura, chronic rubelliform rash, dermatoglyphic abnormalities, jaundice, hepatosplenomegaly, hepatitis, hemolytic anemia, interstitial pneumonia, bone defects, genitourinary abnormalities (cryptorchidism, polycystic kidneys)

Clinical findings

Mother: macular rubelliform rash, lymphadenopathy (posterior auricular, suboccipital), prodromal symptoms (malaise, fever, headaches), arthralgias, peripheral neuritis; laboratory diagnoses include rubella-specific IgG and IgM, virus isolation from nasopharynx, viral antigen

Infant: CRS (as above); laboratory diagnoses include rubella-specific IgG and IgM, virus isolation from nasopharynx

ment in the posterior auricular and suboccipital regions is common. Less common symptoms include arthralgias, tenosynovitis, myalgia, and peripheral neuritis.

Congenital manifestations of rubella are summarized in Table 17.5, with hearing loss the most common clinical finding in newborns. Late-onset clinical findings commonly present as endocrinological abnormalities, such as diabetes mellitus and thyroid disorders.

Diagnosis

The rubelliform rash on the face accompanied by posterior auricular lymphadenopathy and viral illness is virtually diagnostic of acute rubella infection in adults and children. Rubella-specific IgM can be detected a week after the onset of the rash, and typically persists for up to 2 months; it is detectable by culture of nasopharyngeal swabs, urine, blood, amniotic fluid, placenta, and synovial fluid.¹³ Diagnosis of acute rubella infection is also made by the observation of a rise in acute and convalescent titers of rubella-specific IgG over a period of 3–4 weeks.

Congenital infection is diagnosed by the range of symptoms noted in Table 17.5. The Centers for Disease Control recently published a classification of CRS based on both clinical and laboratory findings.¹¹ Rubella-specific IgM is detectable for up

to 6 months in infected newborns, and rubella IgG may remain elevated beyond this 6-month period. As in the mother, rubella is detectable by culture of infant blood, stools, cerebrospinal fluid, and urine. Daffos and coauthors¹⁴ used cordocentesis to test fetal blood from pregnancies complicated by acute rubella in the first 20 weeks; the study demonstrated rubella-specific IgM in virtually all of the infants who were later shown to be infected at birth. Rubella viral RNA has also been detected using nested PCR techniques in chorionic villus samples, amniotic fluid, and fetal blood obtained by cordocentesis.¹⁵

Treatment and prevention

The treatment of acute rubella in adults and children is based on the symptoms. Most adults have complete recovery from the rash and lymphadenopathy within a week, although one-third may develop late-onset arthralgias. At present, there is no standard method of treating acute congenital rubella infections with antiviral therapy.

Since it was first introduced in the USA in 1969, the use of the rubella vaccine has been the most important factor in the worldwide management of rubella. The current strain of the live attenuated vaccine is still the original Wistar RA27/3 strain grown in human diploid fibroblasts; immunization with this vaccine induces rubella hemagglutination-inhibiting antibodies in approximately 97% of susceptible individuals. Two other live rubella vaccine strains were licensed in 1969, the Cendehill and HPV77 (DE-5 and DK-12) strains; however, the RA27/3 strain elicits a broader antibody response after vaccination.

Immunity against rubella is considered to be lifelong and enzyme-linked immunosorbent assay (ELISA) antibody levels persist for at least 10 years after vaccination. The American College of Obstetricians and Gynecologists (ACOG) currently recommends the following vaccination schedules: (1) all children from 12 to 15 months of age or older should be vaccinated against rubella and their mothers given a record of the vaccination; (2) all adults should be vaccinated, especially women who are known to be susceptible to rubella or who have a negative history of being immunized against rubella but whose serology status is unknown; however, pregnant women should not be vaccinated; (3) all prenatal patients should be tested for rubella IgG; and (4) all pregnant women identified as being susceptible to rubella should be advised about the potential risk of congenital rubella infection and be vaccinated after delivery.¹⁶ In 2001, the interval between the administration of rubella vaccine and attempting pregnancy was reduced from 3 months to 1 month.¹⁷ These guidelines also recommend that breastfeeding is not a contraindication to vaccine administration.

Varicella zoster virus

Congenital varicella syndrome is a collection of fetal abnormalities, primarily of the skin, eyes, and limbs, which were first described by Laforet and Lynch¹⁸ in an infant born to a mother

who contracted chickenpox at 8 weeks' gestation. VZV infection in adults and children presents as two different clinical conditions: as a primary infection (chickenpox), or as herpes zoster (shingles) resulting from reactivation of a latent infection.

Epidemiology

Chickenpox is one of the most contagious and, therefore, common infectious diseases of childhood. From 1980 through 1994, approximately 3.5 million cases of chickenpox were reported in the USA every year.¹⁹ Chickenpox has an annual incidence of approximately 1500 cases per 100 000 of the population and around 85% of adults show serological evidence of immunity to chickenpox. However, despite the high number of serosusceptible individuals (15%), the incidence of primary VZV during pregnancy is only 0.013–0.07%.²⁰ In around 10–20% of adults, VZV infection may present later in life as shingles by reactivation of a latent viral infection; this is more frequent in older individuals.

In one study, the risk of fully developed congenital varicella syndrome following acute VZV infection in the first 20 weeks of pregnancy was shown to be approximately 2–5%.²¹ However, more recently, a study of 347 pregnant women with acute VZV infection showed the frequency of congenital varicella syndrome to be only 0.4%.²²

Biology

VZV is a member of the Herpesviridae family; its genetic structure is therefore similar to that of other herpesviruses. Horizontal transmission of VZV occurs via passage of infectious respiratory droplets from the nasopharynx of an infected host or from vesicular fluid expressed from the characteristic skin lesions. Following inoculation, the incubation period for VZV is approximately 1–3 weeks. The virus replicates at the site of entry, usually the nasopharynx; hence, patients are commonly viremic 1 week before, and up to 2 days after, the onset of clinical symptoms. This period of viremia is accompanied by prodromal symptoms.

Clinical manifestations

Most infections with VZV are symptomatic; acute VZV infections commonly present with painless, multiple, vesicular lesions starting on the head and face, then extending to the trunk and extremities. The vesicles, ranging from 250 to 500 lesions during the acute stage, eventually rupture and develop a scab within several days. New vesicles may form as others heal, therefore the acute phase may involve lesions in different stages of development. The virus is detectable from skin lesions until the scab forms. The attack rates in susceptible individuals after exposure is approximately 90%.

After the primary infection, VZV remains latent in dorsal root ganglia and may present later in life as reactivated disease in the form of shingles. In both adults and children, shingles

Figure 17.1 Vesiculopapular rash (A) and unilateral rash (B) of shingles (herpes zoster).

presents as very painful, vesicular lesions that typically follow the dermatomal pattern of the involved dorsal root ganglia (Fig. 17.1). The lesions are almost always unilateral. Peripheral neuropathia, which presents as hypesthesia on the skin around the lesions, precedes the lesions by several days. Virus is also recoverable from the lesions of shingles, although the viral load in the vesicular fluid is significantly lower than with primary infection. Shingles is a sequela in around 10% of acute VZV infections; this rate is higher among immunocompromised patients such as those with Hodgkin's disease or HIV infection.²³

Vertical transmission of VZV has been well documented. *In utero* infection is the predominant method of transmission; the presence of virus in cervicovaginal secretions and the ability to transmit the virus through the birth canal have not been described. Congenital infection with VZV presents as one of four distinct clinical conditions: (1) fully developed congenital varicella syndrome; (2) disseminated varicella; (3) neonatal varicella; and (4) neonatal zoster (Table 17.6). The timing of maternal infection determines which clinical syndrome the newborn develops. Congenital varicella syndrome occurs following perinatal infection in the first 20 weeks of gestation. Infants born to women who develop clinical infection between 20 and 5 days before delivery are at risk of developing neonatal varicella. In contrast, those born to women who develop clinical infection from 5 days before and up to 2 days after delivery are at a 30% risk of developing disseminated varicella.

The most common findings in congenital varicella syndrome include skin, eye, and limb malformations, such as cicatricial scarring, chorioretinitis, anisocoria, cortical atrophy, limb

paresis, and limb hypoplasia ipsilateral to the scarred limb. Intracranial calcifications have also been demonstrated in congenital VZV infections. Disseminated varicella presents with generalized vesicular skin lesions, pneumonia, and hepatitis; one-third of these infants die from this severe infection. Neonatal varicella is generally a mild course of chickenpox. Finally, Paryani and Arvin have reported a case of neonatal zoster in a 7-month-old infant without a prior history of chickenpox whose mother developed an acute infection while pregnant.²⁴

Diagnosis

In adults and children, the characteristic rash (lesion) of VZV, which presents in multiple stages, is virtually diagnostic of primary infection. Virus is recoverable by culture of, and antigen detection in, scrapings of skin lesions. VZV-specific IgM becomes positive within several days of the onset of the rash. VZV-specific IgG confirms previous immunity to VZV and is present in 85–95% of adults. Approximately 70–90% of patients whose serology status to VZV is uncertain, or whose history of chickenpox in childhood is unknown, demonstrate previous seroimmunity.²⁵

Congenital infections present with clinical findings as shown in Table 17.6. VZV-specific IgM in cord blood or infant blood confirms the diagnosis of fetal infection. Virus can also be isolated by culture of lesion scrapings from newborns. PCR has been used to detect viral DNA in the amniotic fluid from pregnancies complicated by VZV infection. Interestingly, infected newborns, even when asymptomatic, show evidence of

Table 17.6 Clinical manifestations of VZV infection in newborns and adults.*Birth defects*

General: spontaneous abortion, fetal demise, premature delivery, low birthweight
 Congenital varicella syndrome, which includes any of the following findings:
 Neurological: cerebral cortical atrophy, microcephaly, encephalitis, seizures, mental retardation, intracranial calcifications, bulbar palsy, cerebellar hypoplasia, ventriculomegaly, neurodevelopmental delay, nystagmus
 Ophthalmological: microphthalmia, optic atrophy, cataracts, chorioretinitis, anisocoria, corneal opacification, hydrocephalus, meningocele
 Dermatological: cicatricial scarring of limb, vesicular lesions over dermatomal pattern
 Limb disorder: limb hypoplasia ipsilateral to skin scarring, limb paresis, hypotonia, areflexia, flexion contracture deformities
 Gastrointestinal: duodenal stenosis, colon atresia
 Miscellaneous: Horner syndrome, hydroureter

Clinical findings

Mother: chickenpox, pneumonia, encephalitis, Reye syndrome, aseptic meningitis, Guillain–Barré syndrome, ophthalmological complications (conjunctivitis, uveitis), hepatitis, shingles (zoster), pneumonitis, esophagitis, myocarditis, herpes gangrenosum; laboratory diagnoses include VZV-specific IgG and IgM, virus culture, viral antigen, detection of viral DNA using PCR
 Infant: four distinct clinical presentations:

- (1) Congenital varicella syndrome
- (2) Disseminated varicella; generalized lesions, pneumonia, hepatitis, viremia
- (3) Neonatal varicella
- (4) Neonatal zoster (shingles)

Laboratory diagnoses include VZV-specific IgG and IgM, virus culture, detection of viral DNA using PCR

lymphocyte transformation after stimulation with different VZV antigens.²⁴

Treatment and prevention

In adults and children, acute infection with VZV is self-limited and treatment is generally directed at the symptoms. Table 17.7 summarizes the management of pregnant women who have been exposed to, or who develop, acute chickenpox. Pregnant women exposed to chickenpox should have their immune status identified; within 96 h of exposure, those found to be susceptible should receive varicella zoster immunoglobulin (VZIG) at a dose of 0.125 mg/kg of body weight. Of pregnant women exposed to VZV who were administered VZIG, only 20% developed primary varicella compared with 89% of patients who did not receive VZIG.¹⁸ When administered more than 96 h after exposure, the efficacy of VZIG is questionable. Infants born to women who develop chickenpox from 5 days before and up to 2 days after delivery should be given VZIG.

Table 17.7 Management of pregnant women with VZV exposure and infection.*Pregnant women with VZV exposure, within 96 h of exposure*

Test for VZV IgG

If IgG positive, confirms previous immunity, discontinue evaluation

If IgG negative, administer VZIG, 0.125 mg/kg i.m.

Observe for symptoms of chickenpox

Pregnant women with VZV exposure, more than 96 h after exposure

Test for VZV IgG

If IgG negative, efficacy of VZIG questionable, weigh risks and benefits of vaccine administration

Observe for symptoms of chickenpox

Pregnant women with primary chickenpox

Isolate from susceptible persons

Test for VZV IgG

Treat symptoms

Infection within the first 20 weeks of gestation:

Counsel approximately 2–5% risk of congenital varicella syndrome, miscarriage, prematurity, low birthweight

Observe for complications (e.g., varicella pneumonia)

Consider acyclovir for pneumonia

VZIG not necessary

Infection from 20 to 5 days before delivery:

Counsel about risk for neonatal chickenpox

Observe infant for chickenpox

VZIG not necessary

Infection from 5 days before and up to 2 days after delivery

Counsel approximately 30% risk of disseminated varicella

Observe infant for disseminated varicella

Administer VZIG to infant at birth, 1.25–2 mL i.m.

Consider acyclovir for symptomatic infant

Consider delaying birth until mother recovers from acute infection

Pregnant women with herpes zoster (shingles)

Counsel theoretical risk of neonatal infection

Isolate from susceptible persons (vesicular fluid is infectious)

Treat symptoms

Administer famciclovir for postherpetic neuralgia

Both pregnant and nonpregnant patients with herpes zoster benefit from a short course of antiviral therapy to shorten the duration of postherpetic neuralgia. These antiviral agents include acyclovir, valaciclovir, and famciclovir.

The VZV vaccine is the Oka strain of a live attenuated virus obtained from a child in Japan with a natural chickenpox infection, which was introduced into human embryonic lung cell cultures, and propagated in human diploid cell cultures. The vaccine was first introduced to high-risk children in Europe in 1984, in Japan in 1986, and in Korea in 1988; it was subsequently licensed in the USA in 1995. Seroimmunity is conferred 4–6 weeks after vaccination in 97% of susceptible children. The reported annual attack rate of chickenpox among vaccinated children is 0.2–1.0%, compared with 8–9%

in unvaccinated children. This represents a 93% reduction in acute VZV cases.

The Centers for Disease Control has the following recommendations regarding the VZV vaccine: (1) all children from 12 to 18 months of age should be routinely vaccinated regardless of VZV infection; (2) VZV vaccine is recommended for all susceptible children by 13 years of age; and (3) susceptible persons older than 13 years of age who are at high risk of acquiring VZV should receive the vaccine. The vaccine is contraindicated in pregnancy as it is a live virus; the teratogenic potential of the vaccine given inadvertently to pregnant women is not known. Women who receive the vaccine should be advised not to become pregnant for 1 month after administration. Early studies show no evidence of active VZV in breast milk in postpartum mothers who received the vaccine,²⁶ therefore there is no clear evidence that breastfeeding should be discontinued after administration of the vaccine.

Herpes simplex virus

Epidemiology

The first neonatal cases of HSV infection were reported independently by Batignani in 1934²⁷ and Hass in 1935.²⁸ In adults, HSV is one of the most widely disseminated and prevalent infections worldwide. In the USA, an estimated 45 million adults and adolescents are infected with HSV,²⁹ and approximately one in four women of reproductive age has antibodies to HSV2.³⁰ Large-scale epidemiological studies have consistently shown that an increased incidence of HSV infection correlates with increased sexual activity, early age of first sexual contact, and increased number of sexual contacts. Asymptomatic shedding of virus in cervicovaginal secretions occurs at a rate of 0.02–4% in nonpregnant women.

In the USA, the incidence of neonatal HSV infection is approximately 1 case per 7500 live births. Congenital infections with HSV have increased in the last three decades; the annual incidence of neonatal HSV increased from 2.6 per 100 000 live births in 1966 to 11.9 per 100 000 live births in 1981.³¹

Biology

Herpes simplex is a member of the Herpesviridae family of viruses. There are two subtypes of herpes simplex, HSV1 and HSV2. These subtypes are difficult to distinguish serologically as they share very close genomic homology and produce similar glycoproteins. At present, detection methods for HSV are based on the antibody response to glycoprotein G-2 for HSV2 and glycoprotein G-1 for HSV1; most other immune responses are similar for both HSV subtypes.³⁰

Like other herpesviruses, HSV is neurotropic; after primary infection, HSV becomes latent in the infected host and virus is stored in the dorsal root ganglia. HSV is reactivated later in life and presents with recurrent episodes. Both HSV subtypes

present with clinical symptoms in the genitals although most genital infections are due to HSV2. Infections with HSV2 are also associated with higher recurrence rates than infections with HSV1, in both the first and subsequent years following primary infection.

Clinical manifestations

Adults and children with HSV2 infection present with three distinct clinical syndromes: (1) first-episode primary infection; (2) first-episode nonprimary infection; and (3) recurrent infection. Following transmission from an actively shedding individual to a susceptible host, first-episode primary infections occur after an incubation of 3–7 days. These infections classically present with multiple, exquisitely painful, vesicular lesions at the site of inoculation. The vesicles rupture within 48–72 h, become ulcerated, indurated, and then resolve completely within 3–4 weeks. Virus is easily recoverable from the primary lesions. Viral shedding from both male and female asymptomatic patients has been well documented.³² Lesions may be accompanied by fever, inguinal lymphadenopathy, malaise, and neuralgia. The majority of patients who show serological evidence of previous infection to HSV2 are asymptomatic, and up to 75% of patients with primary infection go unrecognized. Atypical clinical manifestations of genital HSV infection include genital fissures, furuncles and excoriations in the genitalia, aseptic meningitis, sacral autonomic nervous system dysfunction, and extragenital lesions. In rare instances, primary infection may progress into a more fulminant course, characterized by fever, anicteric hepatitis, and ulcerative pharyngitis.

After primary infection, HSV becomes latent. Reactivation of virus presents clinically as a first-episode, nonprimary infection or as a recurrent infection after a primary symptomatic outbreak. These reactivations are characterized by multiple, vesicular lesions of the genitals that are less painful, often without accompanying lymphadenopathy and generalized symptoms. Patients with first-episode, nonprimary infections and those with reactivation produce HSV2-specific IgG antibodies. Immunocompromised patients (e.g., those with HIV infection) may experience a more severe or protracted course of recurrent disease.

Nearly all HSV infection of neonates and infants occurs at delivery, through exposure to virus present in the birth canal. *In utero* transmission through transplacental passage of virus accounts for approximately 5% or less of all cases of congenital HSV.³³ For infants, the risks of acquiring HSV from the mother are summarized in Table 17.8.

Congenital infection with HSV manifests as one of three distinct clinical syndromes: (1) infection involving the skin, eyes, and mouth (SEM disease); (2) infection of the central nervous system (CNS), with or without SEM findings; and (3) disseminated HSV, when multiple organ damage is involved (Tables 17.9 and 17.10). Clinical disease is further classified as either early or late, depending on the timing of infection and onset

of clinical manifestations. Infants infected transplacentally present with symptoms within the first 24–48 h of life. In contrast, infants who acquire HSV at the time of birth become clinically symptomatic within 1–2 weeks. One-half of the infants with CNS manifestations will also have SEM

characteristics. CNS complications in infants, such as herpes encephalitis, can be life-threatening and carry a mortality rate of approximately 50%. Disseminated HSV with encephalitis carries the worst prognosis for infants, with a mortality rate of approximately 80%.

Table 17.8 Risk factors for transmission of HSV from mother to infant.

Incidence of neonatal HSV	1/3000–1/20 000 live births
Primary methods of infection	
Transplacental (<i>in utero</i>)	5%
Intrapartum	85%
Postpartum	10%
Risk of perinatal transmission	
Primary infection	30–50%
Nonprimary first episode	33%
Recurrent	< 5%
Percentage of infants with clinical syndrome at birth	
SEM disease	30%
CNS disease only	30%
Disseminated HSV	30%

SEM, neonatal herpes involving skin, eyes, and mouth.

Diagnosis

In adults and adolescents, genital infections with HSV are usually diagnosed clinically. Up to one-fourth of patients who present with a first-episode infection show serological evidence of a previous infection; these patients are, in fact, experiencing a recurrent infection. Commercial assays for HSV2-specific antibodies are useful in confirming a previous infection; however, cross-reactivity with HSV1 antibodies is possible. HSV2-specific IgG is detectable 2–12 weeks after exposure, with a mean seroconversion time of 22 days.²⁹ Therefore, many patients with primary infections do not demonstrate serological evidence of infection at the time of symptomatic clinical presentation. Virus isolation from vesicle fluid obtained from fresh lesions or from the cervix is the most specific laboratory method for detection of HSV.

Diagnosis of neonatal herpes includes a maternal history of HSV infection (primary or recurrent), clinical symptoms in the

Table 17.9 Clinical manifestations HSV infection in infants.

Site	Early symptoms	Late symptoms
Skin	Vesicles Exanthem Skin scarring	Recurrent cutaneous lesions
Eye	Chorioretinitis Keratoconjunctivitis Microphthalmia Cataracts	Chorioretinitis Blindness Cataracts Retinal dysplasia
Mouth	Oral ulcerations	
CNS	Microcephaly Cerebral atrophy Hydrancephaly Intracranial calcifications Encephalitis (bulging fontanelles, pyramidal tract signs, poor feeding, temperature instability)	Microcephaly Psychomotor retardation Learning disability Spasticity Seizures Porencephalic cysts Hydrancephaly
Disseminated HSV	Shock Disseminated intravascular coagulopathy Jaundice Respiratory distress Seizures Irritability Thrombocytopenia	
Miscellaneous	Hepatosplenomegaly Pneumonitis Purpura/petechiae	Hearing loss Dental anomalies Pneumonitis

infant (Table 17.9), and laboratory evidence of infection in both mother and infant. Because viral shedding may be asymptomatic in the cervix of pregnant women, symptomatic disease in the mother is not a requisite for the diagnosis of infection in the newborn. Detection of HSV1- and HSV2-specific IgM in the newborn may be helpful in the diagnosis of congenital infection. As in adults, virus isolation from skin vesicles, conjunctiva, nasopharynx, and cerebrospinal fluid remains the gold standard in the diagnosis of HSV in infants. Unfortunately, however, virus isolation carries a false-negative rate as high as 20% in primary infection and even higher in

recurrent disease. Recent data on the detection of viral DNA using PCR show that this technique has greater specificity and sensitivity than classical virus isolation techniques.³⁴

Treatment

HSV infections in adults and adolescents are treated symptomatically. Antiviral therapy with aciclovir has been shown to be effective in: (1) reducing both the severity and duration of symptoms in primary infection; (2) preventing the occurrence and reducing the frequency of recurrent outbreaks; and (3) treating fulminant, disseminated HSV in adults and infants.

Aciclovir is a synthetic thymidine analog that acts as a competitive inhibitor of HSV1 and HSV2 DNA polymerase. The drug has also been shown to have *in vitro* and *in vivo* antiviral activity against CMV, VZV, and Epstein-Barr virus. HSV thymidine kinase phosphorylates aciclovir and the resulting triphosphate derivative terminates the elongating chain, thus inhibiting further viral replication. Second-generation thymidine analogs (famciclovir and valaciclovir) are also approved treatments for HSV; *in vivo*, valaciclovir is converted to aciclovir, while the active antiviral agent in famciclovir is penciclovir. Table 17.11 summarizes treatment options using these three antiviral drugs. Topical treatments for both genital and oral lesions have not been shown to be effective.

Acyclovir has been shown to be effective in the treatment of neonatal HSV infections. Vidarabine, another nucleoside

Table 17.10 Clinical manifestations of HSV infection in mothers and infants.

Birth defects

General: miscarriage, preterm delivery

Early and late symptoms: see Table 17.9

Clinical findings

Mother: mostly asymptomatic; when symptoms are present, genital and extragenital lesions (painful, vesicular to ulcerative lesions), gingivostomatitis, pharyngitis, herpetic whitlow, keratitis, pneumonitis, hepatitis; disseminated HSV; laboratory diagnoses include HSV1- and HSV2-specific IgG and IgM, viral antigen, virus isolation, detection of viral DNA using PCR

Infant: see Table 17.9; laboratory diagnoses include HSV1- and HSV2-specific IgG and IgM, virus isolation, detection of viral DNA using PCR

Table 17.11 Antiviral treatment options for HSV infection in adults.²⁹

Type of infection	Drug	Dosage	Pregnancy category
<i>First episode (primary or nonprimary)</i>			
Treat for 7–10 days	Acyclovir	400mg p.o. t.i.d.	B
	Acyclovir	200mg p.o. 5 × /day	
	Valaciclovir	1 g p.o. b.i.d.	B
	Famciclovir	250mg p.o. t.i.d.	B
<i>Recurrent disease</i>			
Treat for 5 days	Acyclovir	400mg p.o. t.i.d.	
	Acyclovir	200mg p.o. 5 × /day	
	Valaciclovir	500mg p.o. b.i.d.	
	Valaciclovir	1 g po q.d.	
	Famciclovir	125mg p.o. b.i.d.	
<i>Suppressive therapy</i>			
May be given for several years	Acyclovir	400mg p.o. b.i.d.	
	Valaciclovir	0.5–1g p.o. b.i.d.	
	Famciclovir	250mg p.o. b.i.d.	
<i>Herpes zoster (recurrent VZV)</i>			
Treat for 7–10 days	Acyclovir	800mg p.o. 5 × /day	
	Valaciclovir	1 g p.o. t.i.d.	
	Famciclovir	500mg p.o. t.i.d.	

analog, has also been used successfully to reduce mortality in neonates with HSV encephalitis and disseminated HSV. A prospective, randomized trial comparing the efficacy of aciclovir and vidarabine in neonatal HSV showed no significant differences between the two treatments with regard to reduction of mortality and adverse sequelae.³⁵

Prevention

In 1999, ACOG established guidelines for the management of HSV infection in pregnancy to help prevent perinatal transmission.³⁶ Previous management protocols, which advocated weekly testing of the cervix for HSV using culture methods, are now obsolete; recent data have demonstrated a poor correlation between antepartum shedding of HSV and shedding at the time of delivery and, therefore, perinatal transmission. Approximately 1.4% of neonatal infection occurs in pregnancies where antepartum cultures were negative. The current ACOG guidelines for management of HSV in pregnant women in labor are summarized in Table 17.12. Cesarean delivery is recommended for patients in labor with active genital lesions resulting from HSV infection (primary or recurrent). Patients with lesions that may be due to HSV infection or those with prodromal symptoms (e.g., tingling in the vulva) are also recommended to undergo a Cesarean delivery. Asymptomatic patients and those with HSV lesions that are remote from the vagina (e.g., thigh or buttock) should be allowed to deliver vaginally.³⁶ Also, a Cesarean delivery would be considered beneficial for patients at term who have active lesions and whose membranes have ruptured for longer than 4 h.

There are no conclusive data on the management of patients with active lesions who experience preterm premature rupture of membranes. The current recommendation for these patients is to weigh up the benefits of delivery in order to prevent the perinatal transmission of HSV against the risks of delivering a premature infant. There are no contraindications to the use of antenatal corticosteroid therapy in this setting.

Table 17.12 Guidelines for the management of HSV infection in pregnancy.

Pregnant women with a previous known history of HSV infection

- Recommend prophylaxis against asymptomatic cervical shedding with antiviral therapy at 35 weeks
- Allow vaginal delivery if asymptomatic in labor
- Cesarean delivery for obstetric indications only
- Weekly cervical cultures for HSV are not indicated
- Perform culture in labor if symptomatic
- Observe infant for HSV

Pregnant women with herpetic genital lesions, clinically suspicious for HSV

- Culture lesions to confirm diagnosis
- Recommend Cesarean delivery
- Observe infant for HSV

A meta-analysis by Sheffield and coauthors,³⁷ using large multicenter studies, demonstrated that prophylaxis of asymptomatic pregnant women at term, who have a history of HSV and antiviral therapy, significantly reduced the incidence of HSV viral shedding at delivery. The use of acyclovir prophylaxis, starting at 36 weeks, effectively reduced the clinical recurrence and asymptomatic shedding of HSV at the time of delivery, and the need for Cesarean delivery for recurrent disease.

Parvovirus B19 infections

Erythema infectiosum, or fifth disease, is the major clinical presentation of parvovirus B19 infection in children and was first described in 1983.³⁸ The disease was named fifth disease as it is the fifth most common exanthema of childhood. The classic “slapped cheek” appearance of fifth disease typically presents in children; adults present with a generalized macular rash, anemia, and arthralgias. The teratogenic effects of parvovirus B19 infection have not been clearly defined although there have been several reports which identify parvovirus B19 as a teratogen.

The rash of erythema infectiosum is macular and reticulate; it typically starts on the face and extends to the trunk and extremities. Constitutional symptoms include fever, coryza, pharyngitis, and malaise; viremia occurs up to a week before the onset of the rash. Adult infections may be accompanied by a transient anemia; patients with hemoglobinopathies may precipitate a transient aplastic crisis. Fetal infection can lead to fetal death, miscarriage, and nonimmune hydrops fetalis; few reports have demonstrated fetal malformations following congenital infections, such as microphthalmia, bilateral cleft lip and palate, micrognathia, and hydrocephalus. The fetal hydrops is thought to result from the transient fetal anemia caused by the infection. A recent report by Enders and coauthors³⁹ has shown that the rate of development of fetal hydrops following acute infection in pregnancy is 3.9%. This study also revealed a high fetal death rate (6.3%), with the highest rates observed when hydrops developed before 20 weeks’ gestation.

Acute infections with parvovirus B19 are diagnosed by the clinical presentation (e.g., macular facial rash, arthralgias, anemia). Diagnosis is confirmed by the presence of parvovirus-specific IgM, which is detectable 7–10 days after the onset of constitutional symptoms. Parvovirus-specific IgG is produced shortly afterwards and persists for years; immunity to parvovirus is permanent. Because IgM does not cross the placenta, parvovirus IgM in cordocentesis samples, cord blood, or neonatal blood, should indicate congenital infection.

Parvovirus infections in children and adults are self-limited and treatment is therefore symptomatic. Following diagnosis of acute parvovirus in pregnancy, weekly ultrasonography to detect fetal hydrops should be performed for 15 weeks. Because fetal anemia is the physiological cause of the hydrops,

in utero transfusion has been shown to significantly improve fetal morbidity and mortality in severe cases. A study by Rodis and coauthors⁴⁰ of 5349 cases of fetal hydrops, secondary to acute parvovirus infection in the mother, showed a survival rate of 83%. Most cases of fetal hydrops revert back to normal within 4 weeks. There is clearly no risk of hydrops in mothers who have previous immunity to parvovirus B19. Following intrauterine fetal transfusion, Enders and coauthors³⁹ reported a survival rate of approximately 85% of hydrops cases.

Venezuelan equine encephalitis (VEE)

VEE is a member of the larger group *Alphavirus encephalitides*, which includes Western equine encephalitis, Eastern equine encephalitis, and chikungunya virus. VEE infections occur mostly in the Caribbean, southern USA, and South and Central America. Although VEE can result in an epidemic in horses, it usually causes only mild infections in humans. However, in October 1995, during a 6-week epidemic/

epizootic in the Guajira state of Colombia, a total of 12 403 patient visits for VEE were reported.⁴¹ The mosquito of the genus *Culex* is the most common vector, while humans and other wild mammals (monkeys, rats, opossums, and jackrabbits) are common hosts.

After an incubation period of 2–5 days, adults with VEE infection present with fever, headaches, malaise, and myalgia. Severe complications include seizures, mental confusion, coma, and tremors. Symptoms last for 3–8 days and virus is recoverable from the serum of symptomatic individuals by culture. VEE-specific antibody can be used to confirm previous infection. Congenital infection has been associated with pregnancy loss and fetal malformations including microphthalmia, absent cerebellum, and other CNS damage. Inoculation of pregnant rhesus monkeys with VEE has been shown to result in congenital microcephaly, hydrocephalus, cataracts, and porencephalic cysts.⁴²

VEE can be controlled by proper immunization and quarantine of animals, as well as by reducing the spread of mosquitoes in endemic areas. There is presently no effective vaccine against VEE in humans.

Key points

- 1 Cytomegalovirus (CMV) is currently the most common congenitally acquired infection in humans. In the USA, approximately 40 000 infants are born annually with evidence of perinatally acquired CMV infection.
- 2 Most infections with CMV in adults and newborns are asymptomatic; classic cytomegalovirus inclusion disease (CID) occurs in approximately 1 in 50 000 births.
- 3 Unlike other infections, congenital CMV can be acquired from mothers who develop either primary or recurrent infection; however, severe damage in the infant occurs principally from mothers who have primary infection.
- 4 Appropriate hand washing techniques are still the most effective method of preventing acute primary CMV infection among serosusceptible individuals, especially those who work in very high-risk areas.
- 5 The introduction of the rubella vaccine in the USA in 1969 has been the single most important factor in reducing the incidence of rubella infection in adults and children, and congenital rubella syndrome (CRS) in neonates. In 1999, the incidence of rubella was 0.1 case per 100 000 individuals.
- 6 The single most common source of individuals serosusceptible to rubella is foreign-born immigrants who have not been vaccinated in their country of origin.
- 7 Rubella is most commonly transmitted transplacentally; there is no definitive evidence that rubella is acquired perinatally through the birth canal.
- 8 Acute rubella most commonly presents in adults and children with a triad of symptoms: macular, rubelliform rash, lymphadenopathy of the head and neck, and generalized flu-like illness.
- 9 Characteristic congenital infections with varicella zoster virus (VZV) include malformations of the skin (cicatricial formation), eye (chorioretinitis, microphthalmia), and limb (limb hypoplasia and deformities).
- 10 Approximately 10–20% of individuals who acquire chickenpox will develop shingles (zoster) later on in life.
- 11 Clinical manifestations of congenitally acquired VZV infection correlate with the timing of infection in pregnancy. Infections in the first trimester result in birth defects while those in the third trimester result in chickenpox or disseminated varicella in the newborn.
- 12 There is no evidence that VZV infection is acquired perinatally through the birth canal. Horizontal transmission occurs through transfer of infectious respiratory droplets or from infectious fluid expressed from the skin lesions of chickenpox.
- 13 Varicella zoster immunoglobulin (VZIG) is indicated for serosusceptible pregnant women within 96 h of exposure to chickenpox. VZIG is also indicated for newborns whose mothers develop acute chickenpox from 5 days before and up to 2 days after delivery.
- 14 The highest risk of fetal infection with VZV occurs when the mother develops acute chickenpox from 5

days before and up to 2 days after delivery. In this case, the risk of neonatal disseminated varicella is approximately 30%.

- 15 The incidence of herpes simplex virus (HSV) infection correlates directly with increased sexual activity, early age of first sexual contact, and increased number of sexual contacts. Approximately one out of four women of reproductive age has serological evidence of HSV2 infection.
- 16 Transmission of HSV occurs primarily through exposure of the infant to the virus in the birth canal; *in utero* or transplacental infection rarely occurs.
- 17 The management of pregnant women with HSV includes the following: (1) Cesarean delivery for women with active or suspicious lesions; (2) in pregnant women with a history of HSV, consider

acyclovir prophylaxis at term, to reduce recurrent infections; and (3) antiviral therapy for patients with primary HSV.

- 18 Acyclovir is a synthetic thymidine analogue that competes with thymidine for binding sites in HSV DNA polymerase. Other agents which are active against HSV include famciclovir and penciclovir; penciclovir is metabolized to aciclovir *in vivo*.
- 19 Patients with suspicious lesions or prodromal symptoms at the time of delivery are also recommended to undergo a Cesarean delivery to prevent neonatal transmission of HSV.
- 20 Vaccines have dramatically reduced the incidence of perinatal infection with rubella and VZV. Although being developed, there are currently no effective vaccines available for CMV, HSV, and parvovirus B19.

Transplacentally acquired microbial infections in the fetus

Santosh Pandipati and Ronald S. Gibbs

Group B streptococcal infection

Group B streptococcus (GBS) is a bacterial member of a group of β -hemolytic streptococci that includes group A (*Streptococcus pyogenes*) and group D, which includes enterococci. Group B streptococci are facultative, Gram-positive diplococci with the vast majority causing complete (β) hemolysis on blood agar plates. Group B streptococci can be found as a colonizing organism in the gastrointestinal and genital tracts of humans. It can cause stillbirth, preterm labor, and chorioamnionitis. In the mother, GBS can cause urinary tract infection, endometritis, and septicemia; in the neonate, it is responsible for early- and late-onset sepsis, pneumonia, meningitis and, less frequently, osteomyelitis, septic arthritis, and cellulitis. There are several serotypes of GBS that cause human disease, and they can all be found in genital isolates; serotype III is the predominant cause of late-onset neonatal sepsis.

Epidemiology

Group B streptococci were first recognized as causing perinatal disease in the 1960s and, by the 1970s, they were recognized as a leading cause of neonatal and maternal infection. Neonatal fatality ranged from 20% to a staggering 50%. There were approximately 6100 early-onset and 1400 late-onset cases of neonatal disease in the pre-prevention era, with an incidence of early-onset disease in the 1980s and early 1990s of 1.5–2 cases per 1000 live births. Subsequent to the implementation of national prevention strategies in the mid-1990s, neonatal GBS disease incidence has declined to 0.4–0.5 cases per 1000 live births.

While it is possible that GBS colonizes all women at some point in their lifetimes, when cultured on their vaginas, rectums, or both, 20–30% of pregnant mothers are found to be rectovaginal GBS carriers. African-American women have higher colonization rates than Caucasians or Asians.¹ Colonization can be transient or intermittent, resulting in potentially different culture statuses between pregnancies.

Neonatal disease

Early-onset disease occurs within 1 week of life (with most cases being identified within 72 h of birth), while late-onset disease occurs after the first week of life. Owing to the dramatic decline in early-onset disease in the 1990s, early- and late-onset disease now have similar occurrence rates, with case fatality rates of 4.7% for the former and 2.8% for the latter.² Survival is largely dependent upon gestational age at birth, with 98% survival for greater than 37 weeks' gestation, 90% for 34–36 weeks, and 70% for infants less than 33 weeks old.²

Risk factors for early-onset disease include maternal GBS colonization, prolonged rupture of membranes, preterm delivery, GBS bacteriuria during pregnancy, birth of a previous infant with invasive GBS disease, maternal clinical chorioamnionitis, young maternal age, African-American race, Hispanic ethnicity, and low levels of antibody to type-specific, capsular polysaccharide antigens. Colonization with GBS, preterm delivery, maternal race, and young maternal age are also independent risk factors for late-onset disease. There is an increased risk of long-term neurologic sequelae in late-onset neonatal disease as up to one-third of these cases include neonatal meningitis.

Apart from neonatal disease, 9–15% of stillbirths have been attributed to infection, with GBS isolated in a large number of these cases. This is especially true of early stillbirths, i.e., those that occur at less than 28 weeks' gestation, as opposed to term stillbirths.

Maternal disease

In maternal infection, GBS is often found to be one of multiple miscreant organisms. In chorioamnionitis, group B streptococcal isolates can be found in as many as 15% of cases, often along with other organisms.³ Endometritis is similarly a polymicrobial infection, with similar culture rates to GBS.⁴ Group B streptococci can also be found in 2–15% of infected post-Cesarean section incisions. After *Escherichia coli*, GBS is the second most common bacteria found in maternal

bacteremia, including cases of pyelonephritis. Clinical presentation of GBS infection can include a maternal fever and elevated white blood cell count.

GBS has rarely been shown to cause fatal infections, necrotizing fasciitis, and maternal meningitis.^{5,6}

Diagnosis

The optimal culture site for lower genital tract colonization has been rectovaginal. Recently, GBS has been isolated from vaginoperianal, anorectal, and perianal specimens with equal rates of positivity. To optimize yield, swabs from the recto-genital tract should be inoculated in selective growth media (commercially available) to suppress competing bacteria. However, blood agar is adequate for GBS recovery from endometrial, amniotic fluid, urine, and blood specimens.

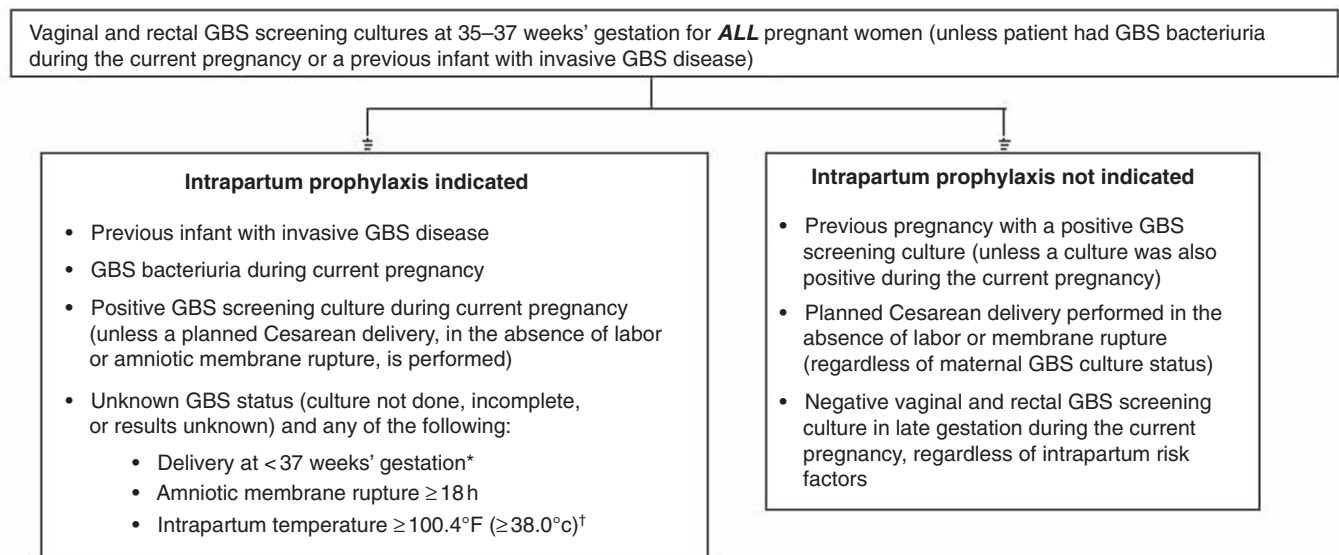

Rapid identification tests, including Gram stain, immunofluorescent antibody, colorimetric assay using starch serum media, and antigen detection (e.g., coagglutination, latex agglutination, enzyme immunoassay) all lack sufficient sensitivity or positive predictive value (PPV). Polymerase chain reaction (PCR) is a new technology that has not yet been widely implemented for rapid detection, but has been shown to be 97% sensitive and 100% specific, with a PPV of 100% and a negative predictive value (NPV) of 98.8%.⁷ Under ideal conditions, test results have been available in 40–100 min. There are several limitations of PCR technology, including the inability to test for GBS sensitivity to various antibiotics, which is something that would be necessary in patients who

have a history of anaphylaxis to penicillin. It is also unclear whether such rapid turnaround is adequate for routine use intrapartum, and whether all hospital laboratories can provide rapid results at night or at weekends. For now, screening should continue to rely upon genitoretal cultures as delineated in the 2002 Centers for Disease Control (CDC) guidelines (explained below).

Treatment

Fortunately, GBS continues to be susceptible to penicillin and ampicillin. However, as of 2003, 37% of invasive GBS isolates were noted to be resistant to erythromycin and 17% to clindamycin (Active Bacterial Core Surveillance/Emerging Infections Program Network, unpublished data). Resistance to cefoxitin, a second-generation cephalosporin, has also been detected.⁸

In 2002, the CDC, the American Academy of Pediatrics, and the American College of Obstetricians and Gynecologists produced new GBS chemoprophylaxis guidelines. These guidelines are predicated upon the GBS carrier status in the pregnant mother, which should have been obtained via a rectovaginal swab at approximately 36 weeks' gestation or within 5 weeks of delivery (see Fig. 18.1). In a circumstance in which one is testing a patient who has a history of penicillin allergy, especially anaphylaxis, upon obtaining a screening specimen, it is necessary to notify the laboratory to test for sensitivity to erythromycin and clindamycin if GBS is detected.⁹ Multistate data from 2003 showed a 34%

* If onset of labor or rupture of amniotic membranes occurs at <37 weeks' gestation and there is a significant risk for preterm delivery (as assessed by the clinician), a suggested algorithm for GBS prophylaxis management is provided.

† If amnionitis is suspected, broad-spectrum antibiotic therapy that includes an agent known to be active against GBS should replace GBS prophylaxis.

Figure 18.1 Guidelines for prophylaxis and treatment regimens (from ref. 9).

reduction in early-onset neonatal GBS disease incidence in the year following the issuing of these new guidelines.¹⁰

For maternal infection, penicillin G is the drug of choice; this is usually administered at 5 million units intravenously initially, followed by 2.5 million units intravenously every 4–6 h (see Fig. 18.2). For GBS prophylaxis intrapartum, the dosing interval should be 4 h. In cases of shortage, as has been seen recently in the United States, ampicillin is a suitable alternative at 2 g intravenously initially followed by 1 g intravenously every 4–6 h; again, note that intrapartum GBS prophylaxis necessitates dosing every 4 h until delivery.

In the case of chorioamnionitis, a polymicrobial condition, it is prudent to use broad-spectrum coverage that includes treatment for GBS and common Gram-negative organisms such as *E. coli*. Such an intrapartum regimen might be ampicillin (2 g i.v. every 6 h) along with gentamicin (1.5 mg/kg i.v. every 8 h). Treatment should be initiated as soon as the diagnosis is made, as intrapartum therapy will treat the fetus and reduce neonatal sepsis.¹¹

Postpartum endometritis is similarly a polymicrobial infection and deserves broad-spectrum treatment, preferably with i.v. antibiotics. Coverage should include anaerobic organisms and, hence, a triple antibiotic regimen of ampicillin, clindamycin, and gentamicin is commonly used.

For neonates suspected of having GBS sepsis, empiric treatment is initiated with i.v. ampicillin and i.v. aminoglycoside to provide coverage similar to that offered in the treatment of chorioamnionitis. If there is bacteremia without meningitis, the treatment is extended to 48–72 h. In the case of GBS as the sole isolate, then i.v. penicillin G is administered to complete a 10-day course of antibiotics. In the case of meningitis, i.v. ampicillin and gentamicin are administered until cerebrospinal fluid is sterile; i.v. penicillin G is continued to complete a 14-day course of antibiotic treatment.

Toxoplasmosis

The organism responsible for toxoplasmosis is *Toxoplasma gondii*, an obligate intracellular protozoan parasite that exhibits a complex life cycle. It exists in three forms: trophozoite (or tachyzoite), cyst, and oocyst. Trophozoites are the proliferative and invasive forms, whereas cysts are the latent forms, persisting in tissue for the lifetime of the host. Oocysts are found in cats that have ingested rodents infected with cysts. Humans become infected if they eat uncooked or undercooked fresh (never frozen) meat from infected animals. Human infection may also occur with hand-to-mouth contact with oocysts excreted in cat feces, most commonly due to poor handling of cat litter. Inhalation of aerosolized oocysts is another possible mechanism for infection. Parasitemia in a pregnant woman with acute toxoplasmosis may result in transplacental migration of the parasites, with subsequent fetal infection.

Recommended	Penicillin G, 5 million units i.v. initial dose, then 2.5 million units i.v. every 4 h until delivery
Alternative	Ampicillin, 2 g i.v. initial dose, then 1 g i.v. every 4 h until delivery
If penicillin allergic[†]	
Patients not at high risk for anaphylaxis	Cefazolin, 2 g i.v. initial dose, then 1 g i.v. every 8 h until delivery
Patients at high risk for anaphylaxis [§]	
GBS susceptible to clindamycin and erythromycin [‡]	Clindamycin, 900 mg i.v. every 8 h until delivery
OR	
	Erythromycin, 500 mg i.v. every 6 h until delivery
GBS resistant to clindamycin or erythromycin or susceptibility unknown	Vancomycin.** 1 g i.v. every 12 h until delivery

[†] History of penicillin allergy should be assessed to determine whether a high risk for anaphylaxis is present. Penicillin-allergic patients at high risk for anaphylaxis are those who have experienced immediate hypersensitivity to penicillin including a history of penicillin-related anaphylaxis; other high-risk patients are those with asthma or other diseases that would make anaphylaxis more dangerous or difficult to treat, such as persons being treated with beta-adrenergic-blocking agents.

[§] If laboratory facilities are adequate, clindamycin and erythromycin susceptibility testing should be performed on prenatal GBS isolates from penicillin-allergic women at high risk for anaphylaxis.

[‡] Resistance to erythromycin is often but not always associated with clindamycin resistance. If a strain is resistant to erythromycin but appears susceptible to clindamycin, it may still have inducible resistance to clindamycin.

** Cefazolin is preferred over vancomycin for women with a history of penicillin allergy other than immediate hypersensitivity reactions, and pharmacologic data suggest it achieves effective intra-amniotic concentrations. Vancomycin should be reserved for penicillin-allergic women at high risk for anaphylaxis.

Figure 18.2 Recommended regimens for intrapartum antimicrobial prophylaxis for perinatal group B streptococci disease prevention (from ref. 9). Broader-spectrum agents, including an agent active against GBS, may be necessary for treatment of chorioamnionitis.

Epidemiology

The prevalence of toxoplasmosis varies throughout the world, and is dependent upon the geographic location and age of the population under consideration. Hot, arid climates are associated with low prevalence; in the United States and Europe, the prevalence, based on serologic status, increases with age and exposure. Infection during pregnancy also varies by geography; acute antenatal infection occurs in 10 in 1000 pregnancies in France,¹² whereas it occurs in only 1.1 in 1000 pregnancies in the United States.¹³ The incidence of congenital infection is between 1 in 10 000 to 10 in 10 000 live births in the United States, or approximately 400–4000 births per year.¹⁴ It is believed that half of these congenital infections are due to the consumption of contaminated meat.¹⁴

Fetal infection only occurs with acute maternal toxoplasmosis. The likelihood of transmission and the severity of risk to the fetus vary with gestational age. Congenital toxoplasmosis is more frequent, but usually less apparent, when maternal infection occurs in later gestations. In France, Desmonts and Couvreur¹⁵ found that 17% of first-trimester pregnancies with acute maternal toxoplasmosis, 24% of the second-trimester pregnancies, and 62% of the third-trimester pregnancies resulted in infected infants at a time before treatment was available. However, severe infections or stillbirths occurred in 75% of the cases in the first trimester, 20% in the second trimester, and 0% in the third trimester.

Clinical manifestations

Maternal

An immunocompetent adult with acute toxoplasmosis is often only minimally symptomatic or completely asymptomatic. When the disease is clinically apparent, symptoms similar to infectious mononucleosis, including malaise, myalgias, sore throat, and fever, may be present. Painful, but nonsuppurative, lymph node enlargement, most commonly involving the posterior cervical lymph nodes, is a frequent finding in acute toxoplasmosis. Other associated findings include maculopapular rash, hepatosplenomegaly, and lymphocytosis. Ocular symptoms such as blurred vision, photophobia, and eye pain may be present with chronic disease. In the immunocompromised patient, severe disease with pulmonary and central nervous system involvement can be seen.

Fetal

Some investigators have reported an increased incidence of spontaneous abortion and preterm delivery in acute primary toxoplasmosis.^{16,17} Clinical manifestations that may prompt suspicion of infection include intrauterine growth restriction, nonimmune hydrops, hydrocephaly, microcephaly, anencephaly, and hydrancephaly.^{18,19} Ultrasound often fails to identify fetuses affected *in utero*. If ultrasonographic findings are present, they may include intracranial calcifications, ventricu-

lar dilation, hepatic enlargement, ascites, and increased placental thickness.²⁰

Neonatal

The most common finding is a normal infant. In fact, more than half of infants with congenital toxoplasmosis have no signs or symptoms in the newborn period. Chorioretinitis is the most common abnormal finding. The classic triad of periventricular calcifications, chorioretinitis, and hydrocephaly is actually uncommon. Other findings can include growth restriction, low birthweight, hydrocephalus, microcephaly, intracranial calcifications, jaundice, hepatosplenomegaly, cataracts, microphthalmia, strabismus, blindness, epilepsy, psychomotor or mental retardation, petechia secondary to thrombocytopenia, anemia, maculopapular rash, pneumonia, vomiting, and diarrhea.²⁰ Serious long-term complications include mental retardation, severe visual deficits, and seizures. Adverse sequelae have been detected in long-term follow-up of infants with subclinical infection at birth.¹⁹

Diagnosis

Detection can be achieved via direct and indirect methods. Indirect techniques should be used in immunocompetent patients, as these methods rely upon serologic analysis, specifically the detection of organism-specific IgG and IgM antibodies. Direct detection is with PCR, hybridization, isolation, and histology, and is largely reserved for diagnosis in immunocompromised individuals.

Detection of IgG and IgM antibodies should be performed in pregnant women who are suspected of having had toxoplasmosis exposure. IgM can appear as early as 1 week after an acute infection, increases rapidly, and then wanes, persisting for several weeks to months; in rare circumstances, IgM may even persist for years. IgG does not appear until several weeks after the IgM increase, but low titers usually persist for years. Traditionally, the Sabin–Feldman dye test, indirect fluorescent assays, indirect hemagglutination assays, and complement fixation tests have been used. More recently, enzyme-linked immunosorbent assay (ELISA), IgG avidity test, and agglutination and differential agglutination tests have been used for the detection of IgG antibodies.²⁰ Most laboratories no longer use the Sabin–Feldman dye test. Avidity, i.e., functional affinity, testing of IgG antibodies is now routinely performed to help to distinguish acute from chronic infection. High-avidity antibodies are not seen in cases of infections acquired in the most recent 3–4 months. The differential agglutination (AC/HS) test is useful in distinguishing between a probable acute or chronic infection in pregnant women.

The presence of *Toxoplasma*-specific IgG would indicate protection from further infection. The presence of a high *Toxoplasma* IgG titer with the presence of IgM is suggestive of a recent infection, especially if the IgM titer is high, but it must be remembered that IgM may persist for months or even years

in some instances following acute infection. A negative IgM test, if found within the first 24 weeks of gestation, especially if associated with low titers of IgG, essentially rules out an acute infection during gestation and points to a chronic infection antedating conception. However, a negative IgM titer in the third trimester does not negate the possibility of an acute infection in the first trimester with a subsequent decline. In this circumstance, additional testing, such as IgG avidity testing as explained above, can be helpful. Finally, women who test positive for IgM antibody in a nonreference laboratory should always undergo confirmatory testing in a reference laboratory, as 60% of these women are actually found to be chronically infected.²¹

Prenatal diagnosis of congenital toxoplasmosis is possible. Initially, ultrasound, cordocentesis, and amniocentesis were recommended. Serologic tests for specific IgM and IgG were performed on fetal blood, as were nonspecific tests, including white blood cell count and hepatic enzymes. Also, there was isolation of the organism by inoculation into mice.²² However, IgM-specific antibodies may not be detected even in culture-proven cases because antibody synthesis may be delayed in the fetus and neonate. Isolation of parasites may also be unsuccessful because parasitemia may be intermittent, and the samples of fetal blood or amniotic fluid may be limited in quantity.²³ More recently, prenatal diagnosis using PCR technology on amniotic fluid obtained by amniocentesis has essentially eliminated the need for periumbilical fetal blood sampling or serologic testing of amniotic or fetal specimens as this approach has greater sensitivity and is simpler. Sensitivity for PCR analysis of amniotic fluid depends on gestational age, but overall has a rate of 64% (and in some studies has been noted to be as high as 98.8%), with a specificity of 100%, a PPV of 100%, and a NPV of 87.8%.^{20, 21}

Treatment and prevention

In some European countries, large-scale seroscreening and specific therapy are used to prevent congenital toxoplasmosis. The efficacy of medication is approximately 50% in reducing congenital infection. If acute maternal toxoplasmosis is contracted between 2 and 10 weeks' gestation or if there are major lesions documented by ultrasound, the option of termination should be discussed. The combination of pyrimethamine (a folic acid antagonist) and sulfa drugs (sulfadiazine or triple sulfonamides) is the only effective medication generally available in the United States. Folinic acid should be used with pyrimethamine to minimize its potential side-effects of bone marrow suppression and pancytopenia. Spiramycin, a macrolide antibiotic, is used extensively in Europe, but is available for use in the United States only through the CDC. Spiramycin reduces the rate of fetal infection, but not the severity of infection. In Western Europe, spiramycin is used from diagnosis to delivery, and pyrimethamine plus sulfadiazine are used to protect against progressive fetopathy.

The primary method of prevention of congenital toxoplasmosis is the application of certain hygienic measures.²⁴ The pregnant woman should be advised to wash her hands thoroughly after contact with raw meat, cats, and materials potentially contaminated by cat feces. She should also eat meat only when it has been cooked to more than 66°C (about 151°F). The brown color of well-done meat is due to myoglobin turning to metmyoglobin at this temperature, which is also the temperature at which the cysts are rendered noninfectious. It is too early to tell whether a primary prevention program will significantly reduce the incidence of acquired toxoplasmosis. A prospectively evaluated prevention program reduced the rate of seroconversion by 34%, but this was not statistically significant.²⁵

Mandatory serologic screening for toxoplasmosis during pregnancy is required by law in France and Austria, and has been advocated as a means of improving treatment and prenatal diagnosis in the United States.²⁶ Because of the low prevalence of disease in the United States, the high cost of a systematic screening program, and concern about the reliability of serologic testing, routine toxoplasmosis testing is still not widely recommended in the US.

Another approach is simply to screen infants and treat them when there is serologic infection. In New England, this approach identified 52 infected infants among approximately 600 000 newborns. After 1 year of treatment, only one child in 46 had a neurologic deficit, and 4 of 39 had eye lesions. Thus, neonatal screening and early treatment may reduce serious infections.²⁷

Rubella

Rubella, or German measles, is caused by a single-stranded RNA virus that is a member of the togaviridae. There are two major genotypes, with European, North American, and Japanese isolates differing from some found in India and China. Given the stability of the viral genome, and the protective effect of IgG antibody, the humoral-mediated response confers immunity against future reinfection. The success of vaccination against rubella, and the subsequent decline of congenital rubella infection (CRI), stands as one of the major achievements of twentieth-century perinatal and neonatal medicine.

Epidemiology

The epidemiology of rubella infection was altered by the introduction of the vaccine in 1969. Before this, immunity to rubella through primary infection was acquired by 85% of the population by adolescence. The highest incidence was in the group aged 5–9 years, accounting for 38.5% of cases from 1966 to 1968. The incidence of rubella has declined by 99% from 57 686 cases in 1969 to 271 cases in 1999 (CDC, unpublished data, 2000, available at www.CDC.gov). The age distribution of rubella infection changed during the mid-1990s,

with those aged 15 years or older now accounting for the majority of cases, whereas this was the opposite in the early 1990s. By 1999, 86% of cases occurred in adults and, since 1992, outbreaks have occurred among young adults from specific groups such as Hispanics and Asians and Pacific Islanders as well as individuals who have immigrated from countries such as Mexico. Seventy-three percent of rubella cases in 1999 occurred in Hispanics, with the majority of patients having been foreign born.²⁸ Despite widespread immunization programs, 10–20% of the United States population is susceptible to rubella.²⁹ After the initial decrease in the incidence of congenital rubella syndrome (CRS), the incidence has plateaued at approximately 0.05 cases per 100 000 live births for the past 10 years because of continued rubella infection in women of childbearing age. Similar to the distribution of rubella infection in adults, during 1997–1999 in the United States, 81% of infants reported to have CRI were Hispanic, with 92% of their mothers having been foreign born (CDC, unpublished data, 2000).

Before the implementation of large-scale vaccination policies in the United States, epidemics of rubella occurred every 6–9 years. The last epidemic before the introduction of the vaccine was in 1964. It is estimated that more than 20 000 cases of CRS and 11 000 pregnancy losses occurred as a result of this epidemic. The vaccine was originally targeted at young children, but this had little effect on attack rates in the group aged over 15 years. Now efforts are also made to vaccinate susceptible adults,²⁹ but opportunities to do so are missed, including in the postpartum period. According to data from CRS surveillance, almost half of mothers of CRS infants have had a previous live birth. All these cases of CRS could presumably have been prevented by postpartum vaccination after the birth of the first child.²⁹

Transmission

Rubella virus is spread by respiratory droplets. This requires prolonged, close exposure. The virus is present in the nasopharynx and spreads via the lymphatics and then blood. It is less communicable than varicella, with an 80% attack rate. Fetal infection requires maternal viremia and placental transmission. Viremia has been thought to occur only with primary infection. Rare cases of reinfection leading to CRS have been reported.³⁰ Serologic evidence of fetal exposure to rubella has been documented after inadvertent vaccination in pregnancy. To date, no cases of congenital defects secondary to CRS have been reported due to vaccine.^{31,32} Nevertheless, vaccine administration is contraindicated in pregnancy because the theoretical risk of CRS after vaccination, although low, may not be zero.³³ Virus is shed in breast milk as well. Neonatal exposure to rubella during breastfeeding has not been associated with morbidity.³⁴ Prolonged viral shedding from the CRS infant may be a source of infection. Virus has been isolated in the urine, cerebrospinal fluid, and even the lens of CRS patients.

The variable risk of CRS at different gestational ages has long been recognized. Rubella infection before implantation has been implicated in spontaneous abortion, stillbirth, neonatal death, and CRS. Enders and co-workers³⁵ reported that rubella occurring from 12 days to 12 weeks after the last menstrual period (LMP) resulted in an 81–90% fetal infection rate. No infection was noted if the rash appeared before the LMP or up to 11 days after the LMP. Cradock-Watson and Ridehalgh³⁶ reviewed rates of rubella infection after the first trimester. The overall rate of CRI (seropositivity, with or without clinical disease) was 29% based on rubella-specific IgM and 49% based on persistence of rubella-specific IgG after 8 months of age. Gestational age-specific rates of CRI ranged from 12% when infection occurred at 24–28 weeks to 58% at 36–40 weeks.

Clinical manifestations

Maternal

Postnatally acquired rubella is a mild or asymptomatic infection. The incubation period is 14–21 days, with viral shedding beginning 1 week before the onset of rash. The rash is macular and lasts 3 days, hence the name 3-day measles. Malaise, fever, and postauricular and suboccipital adenopathy are also common. Arthralgias are common in adult women; arthritis, neuritis, encephalitis, and thrombocytopenia are rare in postnatal infection. Because these symptoms are nonspecific, diagnosis should be made on serologic rather than clinical grounds.³⁷

Fetal and neonatal

The pathogenesis of congenital defects includes impairment in organogenesis due to decreased mitosis and damage secondary to scarring and persistent infection.³⁸ Abnormalities resulting from impaired organogenesis occur with maternal infection in the first trimester. Other abnormalities, such as progressive hearing loss and pulmonic or aortic stenosis, are due to ongoing damage caused by persistent infection and immune response. In addition, first-trimester rubella infection is believed to cause abortion. This was difficult to confirm during the 1964 epidemic because of the small numbers of women who were both exposed in the first trimester and registered early in pregnancy. Current surveillance practices do not provide information on the incidence of pregnancy loss.²⁹

Congenital infection may be divided into three categories based on its manifestations: CRS, extended CRS, and delayed CRS. Newborn rubella, or CRS, and extended CRS are apparent at birth. Delayed manifestations of congenital infection may not be apparent for years or decades.

Four major defects in CRS, in order of decreasing frequency, are deafness, mental retardation, heart lesions, and ophthalmologic abnormalities. Types of malformation are gestational-age specific. Cataracts and cardiac lesions are present when infection occurs before 8 weeks. Deafness occurs with infection before 16 weeks, and retinopathy with infection before

130 days. Timing of fetal exposure is at best estimated because of difficulties in dating gestational age and lack of information regarding the incubation period of fetal rubella infection. Sever and associates,³⁸ in the Collaborative Perinatal Research Study (CPRS) of 1964, reported that deafness was the most common single defect and was present in 100% of infants with multiple defects resulting from first-trimester infection. Conversely, eye defects, with cataracts and glaucoma being most frequent, were present only with other abnormalities. Cardiac lesions include ventricular septal defect, patent ductus arteriosus, and peripheral pulmonic stenosis. Thrombocytopenic purpura (blueberry muffin rash), hepatosplenomegaly, osseous lesions, meningoencephalitis, and rubelliform rash may also be present in CRS. Contrary to the previously held perception that second- and third-trimester rubella infections are without clinical consequence in the fetus, abnormalities (including developmental delay, hearing loss, growth retardation, pulmonic stenosis, and thrombocytopenia) have been found in 15 out of 24 infants exposed to rubella at between 14 and 31 weeks' gestation.³⁹

The spectrum of extended CRS includes cerebral palsy, mental retardation, developmental and language delay, seizures, cirrhosis, growth retardation, and immunologic disorders (e.g., hypogammaglobulinemia). Delayed manifestations of CRI include endocrinopathies, late-onset deafness and ocular damage, renovascular hypertension, and encephalitis. Long-term follow-up of CRS patients revealed a 20% incidence of diabetes mellitus by the age of 35 years.³⁸ Other endocrinopathies include thyroid dysfunction and growth hormone deficiency. Deafness and ocular and vascular damage may be due to ongoing infection with scarring and inflammation.

Delayed manifestations of CRS are thought to be due to circulating immune complexes.^{40,41} Delayed manifestations occur in more than 20% of those with initially symptomatic CRS.³⁸ The incidence of delayed defects in those with asymptomatic CRI and their gestational age-related risk are not clear. Data from the CPRS showed delayed effects in almost two-thirds of those infected in the third trimester.⁴² Although major malformations due to infection in the first trimester may be devastating, the adverse effects from later infection are clearly not minor.

Progressive panencephalitis has been likened to subacute sclerosing panencephalitis due to rubeola infection and is a different entity from the encephalitis present at birth. Hypogammaglobulinemia may be a delayed result of CRI; altered cell-mediated immunity is necessary for continued latent viral infection. Because of altered cell-mediated immunity, the rubella virus persists in the congenitally infected person for up to a year, and perhaps longer.³⁷

Diagnosis

Clinical diagnosis of postnatal infection is unreliable and must be confirmed by serology. Before the availability of serologic

tests of rubella infection and immunity, virus isolation was attempted. The rubella virus is difficult to isolate. Serologic evidence of maternal primary infection includes the presence of rubella-specific IgM, which can persist for 8–12 weeks following acute infection. In the past, the presence of a fourfold increase in hemagglutination inhibition titer on acute and convalescent sera also provided evidence of a primary infection; commercially available enzyme immunoassays for rubella IgM and IgG are now routinely performed by most laboratories.⁴³ Indirect antibody assays are more prone to false-positive IgM results, due in part to crossreactivity with other IgM antibodies or with rheumatoid factor; hence, a second confirmatory test for rubella IgM by a different modality should be performed, especially before 20 weeks' gestation.

Prenatal diagnosis of CRI is possible. The presence of rubella-specific IgM in fetal blood confirms infection. Fetal immunocompetence is attained in the mid-second trimester; therefore, to avoid a false-negative result, fetal blood sampling to detect IgM must be delayed until 20–22 weeks' gestation.^{42,44,45} First-trimester confirmation of fetal infection was described by Terry and colleagues⁴⁶ by detecting virus-specific antigen and RNA in a chorionic villus sample. This method is superior to virus isolation in the products of conception.⁴⁷ Nevertheless, the presence of rubella virus in the placenta may not correlate with fetal infection. More recently, the development of PCR technology has the potential of rendering fetal blood sampling virtually unnecessary. With reverse transcriptase PCR (RT PCR), amniotic fluid obtained via amniocentesis (when performed at least 8 weeks after acute maternal infection or at 15 weeks of gestation) can be evaluated for virus-specific RNA; this has a sensitivity of 87–100%.⁴³ However, cases have been reported of finding rubella RNA and IgM in fetal blood following negative PCR analysis of amniotic fluid at 19 and 23 weeks.

Prevention and treatment

Prevention of *in utero* rubella infection requires the acquisition of immunity by all persons before the childbearing years. Programs to ensure vaccination of all schoolchildren, susceptible college students, and military personnel help, but do not eradicate CRI. Missed opportunities for vaccination of adults still occur and contribute to the continued existence of CRS.⁴⁸ Congenitally infected neonates are also a source of virus. The rubella vaccine is a live-attenuated virus that yields immune responses similar to native infection; the rate of seroconversion is as high as 95% in individuals older than 11 months of age.⁴³ Long-term efficacy exceeds 90%, but antibody titers can decline over time. As mentioned previously, administration of the vaccine is contraindicated in pregnancy as there is a theoretical risk of acquiring CRS, although there have never been such cases documented worldwide.

There is no specific antiviral therapy for rubella infection. If *in utero* exposure to rubella virus is documented, the woman should be counseled as to the risks and consequences of CRI.

Prenatal diagnosis, even in the first trimester, is possible. With the potentially devastating effects of first-trimester infection, a patient may choose to terminate the affected pregnancy if the diagnosis is made in a timely manner.

Herpes simplex virus

Herpes simplex virus (HSV) is a double-stranded DNA virus, primarily of two subtypes (1 and 2), that is responsible for a variety of infections involving mucocutaneous surfaces, the central nervous system (CNS), and visceral organs. Taking up residence in sensory neuronal ganglia, genital HSV infection is a recurrent, lifelong infection.

Systemic symptoms are more common in primary occurrences, and can include fever, malaise, myalgia, and headache. Local symptoms include pain, discharge, adenopathy, dysuria, and urinary retention secondary to pain or local nerve involvement. Painful vesicles, which may emerge 2–10 days following primary exposure, ulcerate and heal without scarring. Viral shedding persists until the lesions heal. Cervical shedding is present with primary infection in more than 80% of patients and in up to 30% of recurrences. Asymptomatic shedding occurs in 0.35–1.4% of pregnancies.⁴⁹

Genital HSV infection can lead to a number of complications that can profoundly affect the developing fetus and/or the neonate. Perinatal transmission has been linked with spontaneous abortion, preterm labor, and congenital malformations.⁵⁰ Anomalies linked to HSV are similar to those seen with congenital cytomegalovirus (CMV) infection: microcephaly, periventricular calcifications, chorioretinitis, intrauterine growth restriction, and vesicular eruptions.⁵¹ While evidence for the teratogenic potential of HSV is circumstantial, neonatal disease can be devastating. This can range from infection of the skin, eyes and mouth, which, though rarely fatal, can lead to neurologic impairment in 30% of affected children, to CNS infection (symptoms include seizures, poor feeding, and irritability; mortality is more than 50% if untreated), and disseminated infection, which is often complicated by encephalitis and can be fatal in over 80% of cases if left untreated, with neurologic impairment in nearly all survivors.⁴⁹

Epidemiology

HSV infection is ubiquitous. Among HSV infections, genital herpes is widely prevalent, affecting at least 50 million Americans. Seropositivity to type 1 HSV (HSV-1) is acquired by a majority of people by the age of 7 years. The incidence of seropositivity to HSV-2 varies with age, sexual habits, and economic status.⁵² HSV-1 is the serotype most often found in oral lesions, while HSV-2 causes most lesions below the waist. Eighty-five percent of adult genital HSV is due to HSV-2. From 1988 to 1994, overall adult prevalence of HSV-2 infection was 21.9%, and it was slightly higher at 25.6% among females.⁵³ The prevalence of HSV-2 infections in the US is rising, with

approximately 1.6 million new infections acquired annually.⁵⁴ Among adults, 5–10% have a history of symptomatic genital HSV-2 infection. However, another 20–30% who have never had symptomatic genital infection demonstrate type-specific antibodies against glycoprotein G (gG) of the HSV-2 virion. Thus, because HSV-2 infections rarely cause ulcerative lesions, most HSV-2-seropositive individuals are unaware of their exposure. Clearly then, much must be done toward prevention.

There are three primary types of genital herpes syndromes. Primary infection occurs with initial infection with either HSV-1 or -2 and without prior exposure to either. Recurrent infection is due to reactivation of latent virus, and is therefore not a reinfection. Finally, nonprimary first-episode genital herpes occurs when a patient has had a prior exposure to the other viral serotype.

Transmission

Transmission of genital HSV requires intimate contact of infectious secretions with susceptible mucous membranes or skin. Mechanical friction provides for more efficient transfer.⁵⁵ Unfortunately, clinical history does not provide reliable information regarding the likelihood of sexual transmission.⁵⁶ Although analysis of the survival characteristics of the herpes simplex virion in water and on plastic surfaces supports the possibility of fomite transfer, there are no documented cases of such transmission.⁵⁵ Essentially all cases of genital herpes are spread via sexual contact; genital HSV-1 is usually due to oral–genital contact.⁵⁷

Transmission to the fetus or neonate can occur antenatally, intrapartum, or postnatally. In the US, neonatal transmission occurs in 1 in 3200 to 1 in 15000 live births. The highest risk is at the time of delivery, responsible for 85% of all neonatal herpes cases.⁴⁹ Intrauterine infection, resulting mainly from transplacental passage or ascension via the cervix, accounts for 5–8% of cases. Intrapartum transmission is not necessarily dependent upon maternal symptoms, but rather upon maternal viral shedding, especially when that shedding occurs in the context of first-episode genital herpes as opposed to reactivation disease. The risk of intrapartum transmission with a vaginal delivery in HSV-2-seropositive, asymptomatic women is 0.02%, with symptomatic recurrence it is 1–3%, and with asymptomatic seroconversion, i.e., with primary infection, or with nonprimary first episode near the time of delivery it is 40%.

Diagnosis

Diagnosis can be made by viral culture, Pap smear, monoclonal antibody testing, ELISA, or PCR. Cultures are widely used in persons with ulcers, but sensitivity declines within a few days of ulcer occurrence. PCR testing is highly sensitive. Pap smear findings indicating disease are usually incidental, and should not serve as a primary diagnostic modality.

Monoclonal antibody and ELISA testing have limited sensitivity in the absence of lesions and do not allow for the distinguishing of HSV type. Serologic diagnosis with Western blotting of gG can identify types 1 and 2. Food and Drug Administration (FDA)-approved commercially available gG-based type-specific assays for HSV have sensitivities ranging from 80% to 98%, with specificity $\geq 96\%$.

Prevention

While adult genital HSV is problematic, transmission to the fetus or neonate can be far more tragic. Prevention of transmission to the fetus, and especially the neonate, is an important goal. Efforts toward this goal include recognition of lesions, elective Cesarean delivery, suppression of viral shedding during the peripartum period, and maintenance of neonatal skin integrity.

In the largest prospective study of its kind, Brown et al.⁵⁸ looked at over 58 000 women in the state of Washington who underwent collection of genital secretions for HSV culture at the time of their presentation in labor. None of these women received or were receiving suppressive viral therapy. Of these women, 202 had HSV-positive cultures. Fifty-eight percent of these women were delivered vaginally, and 42% were delivered via Cesarean section, with 71% of the latter having recognized genital lesions as the indication for surgical delivery. Although not quite reaching statistical significance, the odds ratio (OR) for neonatal HSV infection was 0.14 (95% CI, 0.02–1.08), tending towards favoring Cesarean delivery. Based on previous studies, and the lack of a randomized, prospective, controlled trial to evaluate Cesarean delivery versus vaginal delivery even in the case of active genital lesions, the American College of Obstetricians and Gynecologists, in a 1999 Practice Bulletin, recommended Cesarean delivery in women “with active genital lesions or symptoms of vulvar pain or burning, which may indicate an impending outbreak,” but did not recommend such a delivery modality in cases of recurrent disease with lesions distant from the perineum (such as the buttocks or the thigh).

Brown et al.⁵⁸ also found a statistically significant increase of nearly sevenfold for the development of neonatal HSV with the use of invasive fetal monitoring intrapartum. It is recommended that these monitors be avoided if possible, as should rupture of the membranes more than 4–6 h prior to delivery. Based on this finding, forceps and vacuum-assisted delivery should also be minimized. All these recommendations should of course be mitigated by concerns for fetal safety, and thus decisions should be made that are appropriate for the clinical situation at hand.

Oral suppressive therapy with the antiviral agent acyclovir in primary infection has been shown to decrease duration of shedding, pain, new lesion formation, and time to complete healing.⁵⁹ Duration of shedding may be decreased by 80%. Oral acyclovir is also effective in suppressing recurrences with

long-term use.⁶⁰ Furthermore, among 601 acyclovir-exposed pregnancies (425 in the first trimester), there was no notable increase in the rate of birth defects compared with background, and there was no notable pattern of anomalies.⁶¹ In a systematic review of acyclovir prophylaxis administered in five different trials that included women with first-episode disease, recurrent disease, and all HSV disease, Sheffield et al.⁶² were able to demonstrate that prophylactic use of acyclovir starting at 36 weeks' gestation reduced the rate of clinical recurrence at delivery (OR 0.25; 95% CI 0.15–0.40), the rate of Cesarean delivery for HSV (OR 0.3; 95% CI 0.13–0.67), the overall Cesarean delivery rate (OR 0.61; 95% CI 0.43–0.86), and the rate of asymptomatic HSV shedding (OR 0.09; 95% CI 0.02–0.39). Thus, acyclovir (or, alternatively, famcyclovir or valacyclovir) suppressive therapy starting at 36 weeks' gestation should be considered in genital HSV patients, especially those with first-episode disease occurring during pregnancy, as there may not be adequate time for the generation of homologous maternal IgG antibodies that seem to protect the neonate from congenital acquisition of disease.

Cytomegalovirus

Human cytomegalovirus (CMV), otherwise known as human herpes virus 5 (HHV-5), is an enveloped double-stranded DNA virus and a member of the Herpesviridae family. CMV-specific IgG and IgM antibodies may be detectable several weeks after infection. Many different strains of CMV have been identified by restriction endonuclease analysis. Owing to its ubiquity, CMV is the most common viral cause of intrauterine and congenital infection as well as of sensorineural deafness.⁴⁵ Unfortunately, CMV can be spread to the fetus with either primary infection or reactivation disease and, in most instances, with the mother remaining asymptomatic.

Epidemiology

An estimated 0.2–2.2% of all neonates are infected *in utero*, with only 5–10% of these infants symptomatic at birth.⁶³ Affecting approximately 1 in 40 000 liveborn infants in the United States annually, CMV causes 30 000–40 000 cases of congenital infection every year.^{64,65} Primary CMV infection occurs in 1–2% of pregnant women;⁶⁶ it is estimated that about 50% of reproductive-age women are susceptible to CMV infection. The rate of seropositivity, the risk of congenital infection, and the incidence of recurrent infection are greater in women of lower socioeconomic status. CMV infection is spread through infected secretions or body fluids such as endocervical mucus, semen, blood, urine, saliva, breast milk, and tears. High-risk environments for exposure to CMV include childcare centers, newborn nurseries, renal dialysis units, and areas of hospitals providing care for immunocompromised individuals.

Transmission

Fetal infection can occur with both primary and recurrent maternal infection; however, the likelihood and severity of congenital disease is greater with a primary infection.^{67,68} Transmission to the fetus occurs in approximately 20–50% of pregnancies with primary maternal CMV infection.^{65,69} Congenital infection can occur as a result of recurrent maternal infection, but the risk is less (approximately 1% detected in the newborn period and up to 8% if followed for 5 years) and the manifestations milder (mainly hearing loss). Transmission can occur at any time during pregnancy, with the lowest risk of transmission associated with primary CMV acquired periconceptionally, and an equal risk of transmission in the first and second trimesters; the third trimester poses the greatest risk of vertical transmission. However, there is evidence to indicate that fetuses that acquire infection earlier in gestation are at higher risk for worse outcomes compared with infection acquired later in gestation.⁶⁸ Studies indicate that recurrent infections and transmission to the fetus in immune women are more frequently due to reactivation than to reinfection.⁷⁰

Clinical manifestations

Maternal

CMV infection in the immunocompetent mother is usually asymptomatic. In some patients, a heterophile-negative mononucleosis-like syndrome may be present. Fever, malaise, myalgias, mild pharyngitis, minimal lymphadenopathy, lymphocytosis, and abnormal liver function test results may be present in such cases.

Fetal

Major target organ systems include the hematopoietic and central nervous systems and general development. Characteristics of fetal infection that may aid in prenatal diagnosis include intrauterine growth retardation, cerebral ventriculomegaly, ascites, microcephaly, hydrocephaly, periventricular calcifications, hepatosplenomegaly, cardiomegaly, hyperechogenic bowel, and oligo- or polyhydramnios. CMV may cause nonimmune hydrops. CMV has also been implicated in myocarditis; there have been reports of fetal heart block and of fetal supraventricular tachycardia.^{71–73} Ultrasound visualization of periventricular calcifications due to CMV has been reported, even in the second trimester.⁷⁴

Neonatal

Approximately 10% of infants with congenital infection are symptomatic at birth. From the CDC registry, the most common clinical findings of congenital infection are hematologic (petechiae/purpura, 54%; hepatosplenomegaly, 40%; jaundice, 38%; hemolytic anemia, 11%), neurologic (intracranial calcifications, 37%; microcephaly, 36%; hearing impairment, 25%; chorioretinitis, 11%; seizures, 11%; one or

more neurologic findings, 68%), small for gestational age (47%), pneumonia (8%), and death (9%).⁷⁵ Approximately 5–15% of the initially asymptomatic infants develop evidence of disease by 2 years of age, with sensorineural hearing deficits (5–10% of cases) and subsequent learning disabilities being the most important long-term sequelae.⁶⁴

Diagnosis

The most definitive method of diagnosis of CMV infection is by isolation of the virus from the blood, urine, or cervix. Several years ago, virus was often not detectable in culture for 2–6 weeks, but with newer techniques the virus is now detectable usually within days. A number of serologic studies are available for the detection of antibody to CMV, including indirect hemagglutination assay, ELISA, immunofluorescent assay, neutralization tests, and complement fixation (CF). CF assays are often inaccurate because of a high false-positive rate due to crossreactivity with other herpesviruses. CMV-specific IgM antibody tests are helpful but of limited value because 30% of women with primary infections are initially seronegative, and the test result is positive in 10% of women with recurrent infections.⁶⁶ Acute and convalescent paired specimens demonstrating a significant increase in titer are suggestive of a primary infection.

When maternal primary infection is suspected, or there are findings on ultrasonography that are suspicious of congenital CMV infection, prenatal diagnosis can be carried out by amniocentesis or fetal blood sampling. Ideally, prenatal diagnosis should occur beyond 21 weeks' gestation, as this optimizes the sensitivity of diagnostic tests. PCR and/or viral culture of amniotic fluid can be performed to detect CMV. PCR, including nested PCR, has been shown to have a sensitivity of 77–100%, specificity of 67–99%, PPV of 100% and NPV of 93%.^{76–78} Viral isolation has a sensitivity ranging from 50% to 72%, and a specificity of 97–100%.⁷⁹ PCR of amniotic fluid, when combined with viral isolation, has been shown to have a sensitivity of 84% and a specificity of 100%.⁷⁶

Fetal blood can be tested for the presence of fetal IgM after 20 weeks' gestation, and has a sensitivity of 51–58% and a specificity of 100%.⁷⁷ The presence of cord blood CMV-specific IgM, which is detectable in 60% of infants with congenital infection, establishes the diagnosis.⁶⁷ It is possible to obtain false-negative IgM titers when cordocentesis is performed early in the course of fetal infection; IgM levels correlate positively with abnormal fetal ultrasound findings and hematologic test results. PCR analysis of fetal blood for the presence of CMV DNA has a sensitivity of 41%, whereas viral culture is only 7% sensitive. Additional tests include searching for the presence of viremia (i.e., infectious CMV in leukocytes; sensitivity of 0–55%), antigenemia (i.e., pp65-positive leukocytes; sensitivity 16–64%), and messenger RNA (sensitivity 82%).⁶⁸ On the whole, fetal blood sampling and amniotic fluid analysis has sensitivity, specificity, PPV and NPV of

80%, 99%, 98%, and 93% respectively.⁷⁸ As fetal blood sampling adds little additional value to amniotic fluid sampling, it should now be considered only for possible confirmatory testing of the fetus.

Treatment and prevention

No treatment other than symptomatic therapy is necessary for the immunocompetent adult with CMV infection. A variety of therapeutic agents – ganciclovir, adenosine arabinoside, acyclovir, idoxuridine, cytosine arabinoside, 5-fluoro-2'-deoxyuridine, leukocyte interferon, and transfer factor – have been administered for the treatment of congenital CMV infection, but none has been found to be satisfactory because of toxicity or recurrence of infection after drug administration is terminated. Currently, there is no role for antenatal treatment of fetal CMV infection.⁷⁷

Vaccines have been investigated.⁸⁰ As the vast majority of congenital CMV infections occur in instances of maternal primary infection, a reasonable strategy is to vaccinate seronegative women prior to conception. Vaccine development has included investigations into live-attenuated vaccines, recombinant virus vaccines, subunit vaccines, DNA vaccines, and peptide vaccines.⁷⁷ None has been established as a superior method, and none has been adopted for routine use in humans.

Routine antepartum serologic screening for CMV is not recommended at this time. The detection of maternal CMV antibody before conception indicates prior infection, but the degree of protection that this immunity provides against congenital infection in subsequent pregnancies is unclear. The implications of a single antibody titer obtained during pregnancy are difficult to interpret. Even in a high-risk environment, the extent of risk for a seronegative pregnant woman by exposure is uncertain. One effective prevention strategy is the use of good handwashing, especially in high-risk settings such as daycare facilities or neonatal intensive care units.⁸¹

Parvovirus

Parvovirus B19, discovered in 1974, is the only member of the virus family Parvoviridae known to cause human pathology. B19, a ubiquitous single-stranded DNA virus with a predilection to infect erythroid precursor cells, causes variable disease dependent upon the immunologic and hematologic status of its host. In immunocompetent children, it is known to cause erythema infectiosum (Fifth disease or “slapped cheek syndrome”); in some individuals, especially adults, an acute symmetric polyarthropathy may develop.^{82,83} Underlying hemolytic disorders predispose to the development of a transient aplastic crisis. Red cell aplasia and chronic anemia can result from persistent infection in the immunocompromised host. In the fetus, B19 infection can result in *in utero* demise, hydrops fetalis, and congenital anemia.

Clinical features

Erythema infectiosum is characterized by a facial rash commonly referred to as “slapped cheek” in appearance.⁸² There is also a lace-like rash on the trunk and extremities. The rash may also reappear several weeks later, after exposure to temperature, sunlight, or emotional stress. Otherwise, the patient is well at the onset of the rash, but may have a history of mild systemic symptoms a few days before the rash's onset. Pruritus may be a common feature in some outbreaks. Erythema infectiosum is more common in the winter and spring and usually lasts approximately 5–9 days in children. Headache, fever, anorexia, sore throat, and gastrointestinal symptoms occur in a minority of children. Complications such as lymphadenopathy, arthralgia, or arthropathy rarely occur in children. As with other viral infections (such as rubella), erythema infectiosum tends to be more severe in adults. In adults, fatigue, fever, adenopathy, and arthritis are common. There have also been reports of more serious complications, such as encephalitis, pneumonia, and hemolytic anemia.

In investigations of outbreaks, asymptomatic infection has been reported in up to 20% of adults and children. B19 infection is also associated with a condition known as transient aplastic crisis with asymmetrical peripheral polyarthropathy and with severe chronic anemia in patients who are immunodeficient.

Epidemiology

The major concern for the obstetrician is infection with B19 in pregnant women.^{84–94} The incidence of primary B19 infection during pregnancy is approximately 1–5%, with transmission to the fetus occurring in 24–33% of cases. Thus, in most of the reported B19 infections during pregnancy, there has been no adverse outcome. The risk of developing hydrops fetalis in the case of congenital infection is approximately 1–1.6%, and B19 is estimated to cause 15–20% of all non-immune hydrops fetalis cases. The hepatic period of fetal hematopoiesis, 11–23 weeks of gestation, seems to be the most critical period of gestation that is prone to adverse fetal outcome; the fetus appears to be especially vulnerable to B19 infection because fetuses have a short blood cell survival time and the fetal red cell volume expands rapidly.⁸³

Studies in both the United States and the United Kingdom have suggested that the risk of fetal death in a pregnant woman with documented B19 infection and an infected fetus is less than 10%.⁹⁵ The CDC estimates that the risk of fetal death after exposure of a pregnant woman to a household member with a documented infection is less than 2.5%, while the upper limit of the risk of fetal death would be less than 1.5% in a pregnant woman who has prolonged exposure to B19 infection in the workplace. Further, it is estimated that the upper limit of risk of fetal death occurring in pregnant women with other types of exposure (e.g., limited exposure to students with erythema infectiosum) would be substantially

less. The mechanism of fetal death is undetermined, but it is likely that either severe anemia or direct myocarditis may precipitate congestive heart failure and hydrops. Once hydrops sets in, case fatality rates may be as high as 50% if untreated, but can improve to as low as 18% with fetal transfusions via cordocentesis.⁸³

Transmission

DNA specific for B19 has been identified in the respiratory secretions of viremic patients, suggesting this as a major mode of spread. At the time that erythema infectiosum develops, however, patients are probably past the point of greatest infectiousness. After close contact exposure, the virus appears to be transmitted effectively; during school outbreaks, 10–60% of students develop erythema infectiosum. In the setting of outbreaks, it is not clear whether the major mode of transmission involves direct contact, person-to-person contact, or large particle droplets, small particle droplets, or fomites. It is also known that the virus can be transmitted parenterally through transfusion and vertically from mother to fetus.

Diagnosis

Diagnostic testing is available through commercial and reference laboratories such as the CDC.⁸⁵ B19 antibody assays are available, with the most sensitive test to detect recent infection being the IgM antibody assay. This can be performed by a captured antibody radioimmunoassay or by enzyme immunoassay. There is also an IgG B19 antibody assay that is usually positive by the seventh day of illness. IgG persists for years. The IgM antibody, on the other hand, begins to decline after 30–60 days. Prior to the advent of PCR technology, the most sensitive test for detecting the virus was B19 DNA nucleic acid hybridization.⁸³ Because DNA can persist for some time in serum, synovial membranes, and basement membranes, detection of low levels of B19 DNA is not sufficient to make the diagnosis of acute infection.

Treatment and prevention

Currently, no specific treatment is available to individuals with presumed B19 infection. They are treated with supportive measures. In otherwise healthy individuals, B19 infection usually produces a mild self-limited infection. Further, there is no vaccine to prevent B19 infection, and no studies have been conducted to assess the value of commercially available immunoglobulin. At this point, the CDC does not recommend routine prophylaxis with immunoglobulin. In healthcare settings where exposures to B19 may be possible through contact with patients with B19 infection (such as transient aplastic crisis), the CDC has recommended infection control measures such as admission to private rooms of patients with transient aplastic crisis due to chronic B19 infection. It is noteworthy that most patients with erythema infectiosum are past the

period of infectiousness by the time that clinical symptoms develop, and these individuals do not present a risk for further transmission. Thus, isolation precautions are not necessary.⁸²

Hospital personnel who may be pregnant should know about the potential risks to their fetus from exposure to B19 infection. In homes, school, and the workplace, the greatest risk of transmitting B19 occurs before the symptoms of erythema infectiosum develop. Therefore, transmission cannot truly be prevented by excluding contact with persons who have erythema infectiosum. The only measure that is currently recommended is handwashing.

In the past several years, the advancement of Doppler ultrasound technology has led to the development of monitoring of fetal middle cerebral artery peak systolic velocities (MCA PSV). Presumably, in the setting of fetal infection and subsequent anemia, the reduced blood viscosity leads to a greater cardiac output, and hence increased MCA PSV values. In a recent multicenter, prospective study evaluating weekly MCA PSV for the prediction of anemia in patients referred for acute maternal B19 infection based upon the presence of IgM antibody, sensitivity, specificity, PPV, and NPV, utilizing a cutoff of greater than 1.50 multiples of the median (MoM), were 94.1%, 93.3%, 94.1%, and 93.3% respectively.⁹⁵ In this study, no fetuses that had MCA PSV values less than 1.50 MoM had anemia at the time of birth, and none of these fetuses died; all cases of moderate to severe anemia were detected by the 1.50 MoM cutoff. The two fetal deaths were in the setting of hydrops.

This method of detecting clinically significant anemia has led to a drastic reduction in the number of diagnostic cordocenteses and is rapidly becoming the standard of care. Weekly ultrasound evaluation for up to 12 weeks following exposure is necessary to insure that the potentially affected fetus does not develop hydrops or elevated MCA PSV values that would indicate moderate to severe anemia. Surveillance frequency should be increased for MCA PSV > 1.50 MoM or for hydrops fetalis. Once there is clinically significant anemia, or overt fetal hydrops, intrauterine blood transfusions, sometimes weekly, are necessary for improving the chances of fetal survival. It has been estimated that, in the setting of hydrops, fetal transfusions increase survival rates from 15% to 30% when no intervention is attempted to 60–80%.

Varicella

Varicella zoster virus (VZV) is a member of the human herpesvirus group. VZV is a DNA virus that exhibits viral latency. Primary infection usually occurs in childhood, presenting clinically as chickenpox. As a highly contagious disorder, VZV infection is acquired by most children in the United States before reproductive age and is generally a self-limited disease characterized by typical skin lesions.⁹⁶ It is recognized that, when adults contract the disease, both constitutional and pulmonary symptoms may be severe. Reactivation of latent zoster infection presents clinically as shingles, generally occurring in

the older population or in immunocompromised individuals. Zoster presents as painful crops of vesicular lesions occurring along the distribution of a segmental dermatome.

The remainder of this discussion is limited to the effects of VZV infection in pregnancy. There are two major concerns for the perinatologist. The first is the risk that the infection imposes upon the mother; the second is the risk of either teratogenesis in or perinatal acquisition by the fetus or neonate.

Epidemiology

More than 50 000 cases of chickenpox occur annually in the United States.⁹⁷ Yet, because of widespread under-reporting, it is estimated that the actual number of cases is 2–3 million.^{98,99} More than 90% of the population has been infected during childhood. The incidence of VZV infection in pregnancy is estimated at approximately 5 in 10 000 pregnancies.

Diagnosis

Because the clinical presentation is usually characteristic, serology is not usually indicated to confirm the clinical diagnosis. In adults with a positive history of varicella, 97–99% are seropositive.¹⁰⁰ However, 71–93% of adults with negative or uncertain histories are also seropositive. Serologic testing is indicated in a pregnant woman with exposure but with a negative or uncertain history of varicella. Many methods are used including CF, indirect fluorescent antibody, fluorescent antibody to membrane antigen, radioimmunoassay, latex agglutination, and ELISA. These tests vary in sensitivity. CF is widely used, but is the least sensitive. Fluorescent antibody to membrane antigen is sensitive, but cumbersome. Commercial ELISA tests range in sensitivity from 86% to 97%.¹⁰⁰

Clinical presentation

After an incubation period from 10 to 20 days (usually 13–17 days), fever and rash commonly occur simultaneously in children. In adults, fever and generalized malaise usually precede the rash by several days. The rash usually begins on the face and scalp and then spreads to the trunk. There is usually minimal involvement of the extremities. The skin lesions begin as macules and proceed to a vesicular and then a pustular stage. Healing is heralded by the presentation of crusts and scabs. The prominent feature of the disease is itching. Over a period of 2–5 days, new crops of lesions occur, and lesions in various stages of progression are usually present at the same time.

Bacterial infection of the skin is the common secondary complication of chickenpox.⁹⁶ Encephalitis, meningitis, myocarditis, glomerulonephritis, and arthritis are all rare complications in childhood. The most serious complication of varicella infection is pneumonia. It occurs more commonly in adults, but pneumonia does not appear to have an increased prevalence in pregnant women as opposed to other

adults.^{98,99,101} Currently, it is estimated that approximately 5–10% of adults with chickenpox develop pneumonia. In a review of the literature on varicella pneumonia in pregnancy, Young and Gershon⁹⁶ noted that, of 77 cases of chickenpox in pregnancy, 29% developed pneumonia. Because of selectivity, we estimate that this incidence of varicella pneumonia in pregnancy is high. Ten deaths occurred, all in women who had pneumonia. The mortality of varicella pneumonia in this series was 45%. There were no severe complications in women who did not develop pneumonia.⁹⁶

For the clinician, the main objective is to maintain a high index of suspicion for pneumonia in women who have varicella infection in pregnancy. Pulmonary symptoms usually begin on the second to sixth day after the appearance of the rash, and usually present with mild nonproductive cough. If the disease is more severe, there may be additional symptoms, including hemoptysis, dyspnea, pleuritic chest pain, or progression to frank cyanosis. Physical examination in women who develop pneumonia would include looking for signs of fever, rales, and wheezes. Chest radiography characteristically shows a miliary pattern or a diffuse nodular pattern. On chest radiography, the perihilar regions are more likely to be involved. Women who have varicella infection without complications in pregnancy do not need to be hospitalized. However, women with this infection must be warned to contact their physician immediately in the event of any pulmonary symptoms, including a mild cough. At this point, hospitalization with full respiratory support, if necessary, should be indicated.

In a series of 43 pregnancies complicated by maternal varicella, Paryani and Arvin¹⁰² noted that nine women had developed associated morbidity. Varicella pneumonia developed in four of these women (9%), one of whom died. Premature labor developed in 4 out of 42 (10%), with premature delivery occurring in two (5%). Another woman developed herpes zoster infection.

If a pregnant woman is exposed to varicella, it is likely that she is immune but, if she is not immune, it is most probable that she will be infected. McGregor and colleagues¹⁰³ pointed out that most pregnant women have detectable antibodies even if they have a negative history of chickenpox. In their series, 12 out of 17 (71%) such women were already antibody positive. Of those women with indeterminate histories, approximately 90% were immune. On the basis of these data, it appears appropriate and cost-effective to test for maternal antibody by any of the following tests: fluorescent antibody to membrane antigen, ELISA, enhanced neutralization test, and immune adherence hemagglutination. A reliable history of varicella is a valid measure of immunity, according to the CDC.¹⁰⁰

If it is found that a woman has been exposed and is susceptible, varicella zoster immune globulin (VZIG) should be strongly considered. When administered intramuscularly within 96 h of exposure, it is likely that VZIG ameliorates the course of the maternal disease as it does in children.¹⁰⁴ However, it is not at all certain that passive immunity with

VZIG prevents fetal infection. Currently, there is no reason to believe that VZIG in pregnancy is harmful. Thus, the only disadvantage of providing VZIG to nonimmune pregnant women with exposure to varicella is the cost, currently US\$400 for the adult dose.¹⁰⁰

Acyclovir is a synthetic nucleoside analog that was introduced into clinical practice in the early 1980s. Its activity against VZV is considerably less than its activity against HSV. The safety of acyclovir therapy in pregnancy has not been established, but considerable experience to date (mainly in women with genital herpes infection) has been reassuring. Accordingly, in instances of serious complications of varicella infection such as pneumonia, use of intravenous acyclovir should be strongly considered. Use of acyclovir orally for the treatment of milder manifestations of varicella infection is controversial. Clinical trials among adolescents and adults have shown that acyclovir is effective in reducing the duration of severity of illness if the drug is initiated within 24 h of the onset of the varicella rash. Although the CDC does not recommend oral acyclovir for pregnant women, consideration should be given to its use early in the course of infection, provided the limited benefits and hypothetical risks are considered.¹⁰⁰

In 1995, a live-attenuated varicella vaccine virus (Varivax) was introduced by Merck and Company. It is recommended that vaccination should be considered for susceptible women of childbearing age who are not pregnant. Varicella immunity may be ascertained at any routine healthcare visit, and women should be asked if they are pregnant and advised to avoid pregnancy for 1 month after each dose of the vaccine. The effects of the varicella vaccine on the fetus are unknown. It is recommended that pregnant women should not be vaccinated. Wild-type varicella poses only a small risk to the fetus and, because the virulence of the attenuated virus is less than that of the wild-type virus, the risk to the fetus, if any, is estimated to be even lower. In most circumstances, the decision to terminate a pregnancy should not simply be based on vaccine administration during pregnancy.¹⁰⁰

Varicella in the newborn

Acquisition by the fetus of maternal antibody is usually protective. However, an infant born after maternal viremia, but before maternal development of antibodies, is at high risk of potentially life-threatening neonatal varicella infection. Infants at risk are those whose mothers develop clinical varicella within 5 days prior to birth or within the first 5 days after delivery. Congenital varicella infection has been reported in approximately 20% of term infants born to mothers with varicella within this time-frame, and the case fatality has been reported at approximately 30%. Infants born five or more days after maternal development of clinical illness develop either a mild varicella infection or none whatsoever. Both zoster immunoglobulin and VZIG have been shown to modify or prevent varicella infection in children, leading Brunell¹⁰⁴ to recommend their use in preventing severe neonatal infections.

Accordingly, infants at risk, as outlined earlier, should receive VZIG as passive immunization at a dose of 125 units. Weibel and colleagues¹⁰⁵ have reported excellent results using a live-attenuated varicella vaccine. The seroconversion rate was 94%, and the vaccine was 100% effective in preventing varicella. In a placebo-controlled group, approximately 10% of children developed varicella.

Effect of varicella zoster infection in early pregnancy

Congenital birth defects due to varicella in early pregnancy were not recognized until 1947.¹⁰⁶ The syndrome of congenital varicella infection consists of limb hypoplasia, cicatricial skin lesions, atrophic digits, psychomotor retardation, and even bilateral cortical atrophy.¹⁰⁶ Ultrasound findings can include dermatomal skin scarring, limb hypoplasia, ventriculomegaly, microcephaly, gastrointestinal and genitourinary abnormalities, and cortical atrophy.⁴⁵ We now recognize that maternal varicella infection in the first trimester of pregnancy may be responsible for such a syndrome, but the risk of the fetus developing these anomalies with first-trimester chickenpox has only recently been recognized. The highest risk of transmission is between 13 and 20 weeks' gestation and occurs through viremic seeding of the placenta and subsequent fetal infection.¹⁰⁷ Of 11 infants of women with first-trimester varicella, one (9%) developed findings consistent with congenital varicella syndrome.¹⁰² More recent estimates have downgraded the risk to anywhere from 0.4% to approximately 1–2%.^{45,108,109} Fetal infection can be determined by either culture of or PCR detection in amniotic fluid, with PCR being the more sensitive method.⁴⁵

Effect of zoster in pregnancy

Herpes zoster infection, as noted, is caused by the same virus that causes clinical chickenpox. Zoster occurs rarely in pregnancy and, because it is a reactivation, maternal antibodies are already present. In healthy women, zoster poses no special threat to the fetus or newborn.

Influenza

Influenza viruses belong to the myxovirus group and cause the clinical entity of influenza that occurs in epidemics. Type A influenza is responsible for most epidemics and is associated with more severe disease, whereas types B and C occur less frequently.¹¹⁰

Epidemiology

The frequency and severity of influenza outbreaks have been related to changes in the viral antigens.¹¹⁰ The major antigenic changes occur at 10- to 30-year intervals and are associated

with severe infection because of the absence of protective antibodies. Two major pandemics occurred in 1918 and in 1957–1958. More than 20 million deaths occurred worldwide during the pandemic of 1918.¹¹¹

Clinical presentation

With a short incubation period of 1–4 days, influenza presents with abrupt onset of an upper respiratory infection, fever, malaise, myalgia, and headache. With wide clinical variability, the major portion of the disease lasts approximately 3 days in most cases.

Definitive diagnosis can be made by isolation of the virus from throat washings during acute illness or by serologic confirmation of a fourfold rise in antibody. Although these antibodies are of the CF or hemagglutination inhibition types, they are rarely indicated clinically.

Effects on the mother

For the obstetrician, the major concern of influenza infection in pregnancy is the increased likelihood of potentially life-threatening pneumonia. From reports from the epidemics of 1918 and 1957, it appears that pregnant women were disproportionately represented in individuals dying of influenza. In addition, reported estimates of overall maternal mortality were approximately 27%, with a mortality of up to 61% in cases complicated by pneumonia prior to the era of treatment.¹¹² It is not certain, however, whether pregnant women are more likely to develop influenza or whether they are more likely to develop influenza pneumonia. Yet, if influenza pneumonia develops in pregnancy, it is more severe. Deaths among pregnant women with influenza may result from secondary bacterial infection and from primary influenza pneumonia without secondary superinfection.

Effects on the fetus

Contradictory data exist on the effects of influenza on abortion, prematurity, and congenital anomalies.¹¹³ These studies may be summarized as noting that the vast majority of women who have influenza in pregnancy have normal outcomes and that there seems to be little influence on congenital abnormalities, intrauterine growth, prematurity, or stillbirth.

Hepatitis

Viral hepatitis is a common infection that predominantly affects the liver. Of all cases of hepatitis in pregnancy, approximately 50% are caused by hepatitis B. Hepatitis A is responsible for approximately 25% of cases, and hepatitis C (most of which was formerly nonA, nonB hepatitis) is responsible for most of the remainder. Laboratory diagnosis can now confirm the presence of hepatitis A, B, or C infection. Hepati-

tis A is also referred to as infectious hepatitis or short-incubation hepatitis, and hepatitis B has been referred to as serum hepatitis, long-incubation hepatitis, and hepatitis B surface antigen-positive hepatitis. Other infections that may cause a secondary hepatitis include Epstein–Barr virus (EBV) infection, coxsackie B infection, CMV infection, and others. In this chapter, the main emphasis is on the consequences of hepatitis B infection in pregnancy.

Epidemiology

Hepatitis B is a worldwide problem with an estimated 5% prevalence. Thus, it is estimated that there are more than 200 million carriers throughout the world. In the United States, which is a low-prevalence area, it is estimated that the prevalence is from 0.01% to 0.5% of the population [an estimated 1 million hepatitis B virus (HBV) carriers].¹¹⁰ Women in the United States most at risk for hepatitis B surface antigenemia (HBsAg) are characterized as follows:

- Asian Pacific Basin or Native Alaskan women, whether immigrants or born in the United States, 15%;
- Haitian, subSaharan African, Eastern European, Middle Eastern, Caribbean, Central or South American women, 15%;
- Women with occupational exposure (e.g., medical or dental), 0.5–1.0%;
- Women working or residing in custodial institutions, 3%;
- Women with acute or chronic liver disease, illicit drug users, or women with multiple blood transfusions, 7–10%;
- Women living in a household with an HBV-infected person, 6–13%.

The impact of HBV infection is immense. Its consequences include chronic hepatitis, cirrhosis, and primary hepatocellular carcinoma. Of an estimated 300 000 new cases yearly in the United States, 75 000 of these patients become clinically ill, including 15 000 requiring hospitalization. A small number, estimated at 375, die of fulminant disease. Some 6–10% become chronic carriers, and as many as 25% of these HBV carriers eventually die of cirrhosis or hepatocellular carcinoma. Despite the availability of an effective vaccine, the incidence of HBV reported to the CDC has remained high. The incidence of hepatitis B infection in pregnant women is the same as that in the general population, and the course of the disease in pregnancy is probably not altered.

HBV infection is spread by sexual transmission, blood transfusion, intravenous drug abuse, and intrauterine or perinatal transmission from the mother to the fetus or newborn. The major concern in pregnancy is transmission to the infant. In the Far East, approximately 40% of HBV cases in mothers result in vertical transmission to the fetus or newborn.¹¹⁴ In the United States, the reported overall risk of perinatal HBV transmission from HBV surface antigen-positive mothers ranges from 20% to 50%, with the rate of transmission depending on population characteristics. These influencing characteristics include ethnic background, lifestyle, and

persistence of the HBe antigen (HBeAg). Nonfulminant hepatitis probably does not increase fetal wastage, but may be associated with an increased risk of prematurity. Finally, there is no apparent increase in congenital anomalies associated with maternal hepatitis B infection in pregnancy.

For hepatitis C, the principal risk factors include intravenous drug use and multiple blood transfusions. Approximately 90% of cases of post-transfusion hepatitis now result from hepatitis C infection. Other risk factors include heterosexual contact, organ donation, needlestick injury, and vertical transmission from mother to fetus. The overall prevalence of hepatitis C infection has been reported to be approximately 2–7%, but these are data from at-risk populations, including those from sexually transmitted disease clinics and intravenous drug users.

Determining the rate of perinatal transmission of hepatitis C virus (HCV) has been problematic, as initial reports were highly variable. Two groups appear to be at high risk for perinatal transmission: women who are coinfectd with human immunodeficiency virus (HIV)¹¹⁵ and women who have a large viral inoculum.¹¹⁶ When the viral inoculum is low and when the mother is not coinfectd with HIV, the likelihood of perinatal transmission is approximately 4.5%, whereas it is about 18% in the presence of HIV co-infection. In mothers with circulating levels of HCV RNA of 10 million copies or greater, the risk of perinatal transmission seems to be as high as 36%, but perinatal transmission virtually does not occur when levels are below this viral load.¹¹⁷

Virology and serology

HBV is a DNA virus that is 42nm in diameter. The outer protein coat is the so-called surface, the HBsAg. This antigen is produced in excess by the virus and appears in the serum of individuals with active infection. The central core contains DNA, a DNA polymerase, and the core antigen, HBcAg. The core antigen is found only in infected liver cells, not in the serum. The third antigen, HBeAg, is found in the serum and is a marker of high rates of perinatal transmission.

Each of these three antigens has a corresponding antibody: anti-HBs, anti-HBc, and anti-HBe. The serologic pattern that is followed in 90% of cases of HBV infection is that, within 6 months of infection, all antigens are cleared from the serum. This individual becomes noninfectious. The antibodies to HBs and to HBc are lifelong markers of prior infection. [For further details, see the two figures in the hepatitis B section (diagnosis) in the following viral hepatitis website: <http://web.uct.ac.za/depts/mmi/jmoodie/diheb.html>.]

In the remaining 10% of individuals with HBV infection, there is persistence of HBsAg beyond 6 months. Approximately 60% of these women with persistence of infection develop chronic persistent hepatitis. Approximately 10% have asymptomatic HBsAg antigenemia, and approximately 30% have chronic active hepatitis. All these groups are potentially infective to others including, in pregnant women, transmission to the offspring. This is a group that is the target for prenatal

screening. Transmission rates from mother to fetus or neonate are as follows:^{118,119}

- Acute HBV in third trimester or within 1 month of delivery: 80–90% infection rate in infant;
- Asymptomatic, HBeAg positive: 90% infection rate in infant;
- Asymptomatic, HBeAg negative: 10–30% infection rate in infant;
- Asymptomatic, HBsAg positive: 0–10% infection rate in infant.

HCV is a single-stranded RNA virus that is 30–38nm in diameter. The antigen is the hepatitis C antigen (HcAg), and the antibody is the anti-hepatitis C antibody (anti-HC). Anti-HC antibody is identified by third-generation tests, including the enzyme immunoassay for screening and the recombinant immunoblot assay as the confirmatory test. The antibody may not be present until 6–16 weeks after the onset of clinical illness. PCR methodology is now used to detect hepatitis C RNA, with high levels denoting a high likelihood of infectivity.

Clinical manifestations

After an incubation period of 45–160 days, hepatitis B may become clinically evident. Initial symptoms often include fever, headache, and abdominal pain, followed in several days by spontaneous resolution. At this point, the urine may become dark, and jaundice may be evident. The liver is usually somewhat enlarged and tender. As the jaundice resolves, the patient spontaneously feels better and usually recovers rapidly. As noted, in approximately 10% of patients with hepatitis B, a form of chronic disease continues. Hepatitis B may present as an acute fulminated form that may become fatal, although this is quite rare in well-nourished Western populations. Fulminant hepatitis is heralded by a rapidly shrinking liver, rapidly rising bilirubin level, and abnormalities in prothrombin time, with development of encephalopathy and ascites. The mortality rate in such cases of fulminant hepatitis is greater than 80%.

In neonates, the most frequent presentation of hepatitis infection is an asymptomatic child with chronic infection. Clinical illness is relatively infrequent with congenital hepatitis, but approximately 10% of neonates with asymptomatic disease become jaundiced within the first 3–4 months of life.

Treatment

Most women with hepatitis B infection during pregnancy can be managed on an outpatient basis. There is no specific treatment, but supportive measures include increased bedrest and a high-protein, low-fat diet. Specific indications for hospitalization of women with viral hepatitis include severe anemia, diabetes, protracted nausea and vomiting, abnormalities in prothrombin time, a rapidly falling or low serum albumin level, and a high serum bilirubin greater than approximately 15mg/dL.

Table 18.1 Other microbial infections.

Organism	Congenital infection?	Maternal effects	Fetal and neonatal effects	Diagnosis	Treatment
Epstein-Barr virus (EBV) ^{107,127-132}	Rare to have primary infection in pregnancy, even among serosusceptible women; no reported cases of antenatal diagnosis of EBV congenital infection and only rare case reports of possible association with fetal anomalies	Asymptomatic (>50% of patients) to sore throat, fever, malaise, lymphadenopathy (rare: splenic rupture, meningitis, Guillain-Barré syndrome, death)	Possible association with cardiovascular defects and cataracts, as well as thrombocytopenia, hepatosplenomegaly, seizures, microcephaly, cerebral calcifications in rare case reports only	Maternal: in symptomatic patient detection of heterophil antibodies or EBV-specific serology Fetal: identification of umbilical cord blood lymphocyte transformation or EBV detection in oropharyngeal secretions	Supportive care in symptomatic patients; in cases with severe complications, corticosteroids and acyclovir have been used
Measles ^{110,133}	Rarely causes congenital measles (disease becomes clinically apparent within 10 days of neonatal life)	Fever, cough, coryza, conjunctivitis, maculopapular rash, malaise, Koplik's spots (complications: bacterial pneumonia, otitis media, encephalitis; rare: thrombocytopenic purpura, myocarditis, subacute sclerosing panencephalitis)	Increased risk of prematurity, especially with third-trimester disease; no constellation of anomalies	Based on clinical history and clinical presentation	Uncomplicated measles is treated symptomatically; antibiotics for secondary otitis media or pneumonia; susceptible exposed pregnant women, neonates (including those born to women who have measles in the last week of pregnancy), and contacts should receive passive immunization with immune serum globulin
Mumps ¹³⁴⁻¹³⁷	No	Prodrome of fever, malaise, myalgia, anorexia, (bilateral) parotitis (rare: oophoritis, aseptic meningitis, pancreatitis, mastitis, thyroiditis, myocarditis, arthritis, nephritis)	Twofold increase in spontaneous abortion when occurring in the first trimester; possible association with congenital endocardial fibroelastosis	Based on clinical presentation	Symptomatic, supportive treatment; avoid vaccination with MMR vaccine during pregnancy
Listeriosis ¹³⁸⁻¹⁴²	Yes	Illness usually in third trimester. May be asymptomatic. Fever, flu-like syndrome, abdominal/back pain, vomiting, diarrhea, headache, myalgia, sore throat. Preterm labor	Fetal and neonatal infection as evidenced by electronic fetal monitoring abnormalities (tachycardia, decreased variability, absence of accelerations), stillbirth; in neonates: respiratory distress, fever, meningismus, seizures, rash, jaundice	Culture and Gram stain of maternal blood, vagina, amniotic fluid (with finding of brown-stained fluid), and neonatal throat, skin, conjunctiva, cerebrospinal fluid	Intravenous antibiotics, usually ampicillin plus/minus gentamicin
Tuberculosis ¹⁴³⁻¹⁴⁸	Yes, most commonly following maternal miliary disease; maternal active pulmonary disease is more likely to lead to postnatal infection	May be asymptomatic. Cough, weight loss, fever, malaise, fatigue, hemoptysis. Increased rate of preclampsia, placental abruption/vaginal bleeding	Spontaneous abortion, stillbirth; no increase in anomalies. In neonate: low birthweight, hepatosplenomegaly, respiratory distress, fever, lymphadenopathy	Mother and neonate: purified protein derivative (PPD) testing, chest X-ray, possible lumbar puncture, and culture of appropriate sites. Placental examination and culture including acid-fast staining	In pregnant mother: antibiotic therapy for 9 months with rifampin, isoniazid, ethambutol, pyridoxine; pyrazinamide controversial

Prevention

Women with a definite exposure to HBV should be given hepatitis B immune globulin (HBIG) as soon as possible within a 7-day period of exposure, with a second dose 30 days after the first. Such passive immunization would be indicated for hospital exposures and inoculation with contaminated needles. Until June 1988, the CDC had recommended screening of pregnant women for asymptomatic hepatitis B infection on a selective basis. However, in mid-1988, the CDC¹²⁰ overhauled these recommendations based on several studies demonstrating that selective screening only identified 50% of women who were HBsAg positive.^{120–123} The study populations were medically indigent women in Cleveland, New Orleans, and Miami, for example. In middle-class populations, the sensitivity of selective screening has not been well studied. Yet, a cost-analysis study carried out at the CDC concluded that, even in extremely low-prevalence populations (with a prevalence of less than 0.1%), the universal screening program would be cost-effective.¹²⁴

The purpose of universal screening is to allow treatment of newborns of HBsAg-positive women with HBIG and hepatitis B vaccine, a regimen that is 90% effective in preventing the development of an HBV chronic carrier state in the newborn. The specifics of the recommendation are that women should be tested for HBsAg during an early prenatal visit. Testing for additional markers is considered unnecessary. Even though women who have HBeAg are at a much higher risk of perinatal transmission, there is still a risk of about 10–15% of perinatal transmission in women who do not have HBeAg but who have HBsAg. If a woman is identified as being HBsAg positive, she should be evaluated for active liver disease. Infants born to HBsAg-positive women should receive HBIG (0.5 mL intramuscularly) once they are stable, preferably within 12 h of birth. In addition, these infants should receive the recombinant HBV (Recombivax HB) vaccine (5 µg per dose), or they may receive the plasma-derived (Engerix-B) vaccine (10 µg per dose).¹²⁵ Either of these vaccines should be given intramuscularly in the following sequence of three doses: the first at birth and the second and third at 1 and

6 months of age respectively. It is estimated that the direct cost to prevent one newborn from becoming a chronic HBV carrier would be approximately US\$12 700 if the prevalence of HBsAg in a given population is approximately 5 in 1000.¹² In infants born to seronegative mothers, HBIG is not indicated, but active vaccination is now recommended for all neonates.

Household members and sexual partners of women identified as being HBsAg positive should be tested to determine susceptibility to HBV infection. Susceptible individuals should receive the HBV vaccine.¹²⁶

Women who deliver without prenatal care should be tested as early as possible on delivery admission so that infants at risk can begin to receive their prophylaxis within 48 h after birth. It is further recommended that hospitals that cannot rapidly test for HBsAg either develop this capability or offer testing to another laboratory.¹²⁶

As a further preventive measure, it is recommended that universal precautions be applied, including the use of gloves, masks, and glasses or goggles by delivery room personnel to keep infectious fluids away from the mouth, nose, eyes, and breaks in the skin. These precautions are equally important in guarding against HBV infection and in preventing the transmission of HIV. Thus, to prevent both these serious infections, as well as hepatitis C infection, universal blood and body fluid precautions are the best measures for preventing nosocomial transmission.¹²⁶ Finally, all healthcare personnel are required to undergo hepatitis B vaccination in most healthcare facilities.

With hepatitis C, there does not appear to be any prophylaxis against perinatal transmission, and there does not appear to be a protective benefit from Cesarean delivery over vaginal delivery. As a result, even routine screening of otherwise asymptomatic pregnant women for hepatitis C is not recommended.¹¹⁷

Other microbial infections

Details of these can be found in Table 18.1.

Key points

- 1 Group B streptococcus (GBS) is a significant contributor to neonatal morbidity and mortality. GBS prophylaxis is highly effective in reducing perinatal infection and is the standard of care in women known to be GBS carriers or who are considered to be high risk.
- 2 GBS prophylaxis should be with penicillin. In penicillin-allergic patients without anaphylaxis, intravenous cephazolin is the preferred treatment. In patients who have a history of anaphylaxis with penicillin exposure, sensitivities should be obtained for the GBS isolate with regard to erythromycin and clindamycin. If the isolate is resistant to either antibiotic or both, then intravenous vancomycin is the preferred antibiotic for prophylaxis.
- 3 Diagnosis of intrauterine (fetal) toxoplasmosis is clinically available in the form of PCR analysis of amniotic fluid obtained via amniocentesis.

- 4 Many maternal "Toxoplasma-specific" IgM antibodies reported from commercial laboratories are false-positives.
- 5 Congenital rubella infection is possible in women who are not appropriately vaccinated against the virus, and fetal diagnosis can be performed by the detection of rubella-specific IgM in fetal blood beyond 20–22 weeks' gestation, or by PCR analysis of amniotic fluid.
- 6 In patients with a history of genital HSV infection, prophylactic oral acyclovir administration beginning at 36 weeks' gestation reduces the rates of clinical recurrence at delivery as well as the rates of Cesarean delivery.
- 7 The correct classification of the type of HSV infection (primary, nonprimary, recurrence) cannot be made clinically, but requires type-specific antibodies and HSV viral type.
- 8 For the prevention of perinatal transmission of HSV, Cesarean delivery is still indicated in women who present with signs and symptoms of a genital outbreak of HSV.
- 9 Congenital CMV infection can occur with primary and recurrent maternal infection with attributable fetal effects including growth retardation, cerebral ventriculomegaly, microcephaly, hepatosplenomegaly, and periventricular calcifications.
- 10 Primary CMV infection occurs in 1–2% of all pregnant women. Diagnosis can be made by PCR or viral culture of amniotic fluid.
- 11 Parvovirus can cause a fetal hemolytic anemia and nonimmune hydrops fetalis. Treatment in such circumstances depends upon intrauterine blood transfusions.
- 12 Congenital varicella infection can lead to fetal limb hypoplasia, psychomotor retardation, cerebral ventriculomegaly, and microcephaly, as well as quite severe maternal disease including pneumonia.
- 13 Acute varicella exposure or infection in pregnancy can be treated with VZIG and/or acyclovir.
- 14 Influenza is not known to cause congenital infection.
- 15 Hepatitis B and C can be transmitted perinatally. Hepatitis B vaccination outside of pregnancy is the mainstay of prevention.
- 16 In neonates born to mothers who are HBsAg positive and are known to have chronic disease, treatment with HBIG and hepatitis B vaccination is the standard for prevention of neonatal transmission.
- 17 There are only rare case reports of congenital EBV infection.
- 18 Measles rarely causes congenital disease, which is apparent within 10 days of neonatal life and is associated with an increased risk of prematurity.
- 19 Listeriosis can cause congenital infection and can lead to preterm labor and stillbirth. Intravenous ampicillin with or without gentamicin is the treatment of choice.
- 20 Tuberculosis can be a cause of congenital infection, most commonly following maternal miliary disease, and can lead to preeclampsia, placental abruption, spontaneous abortion, and stillbirth.

Antibiotics and other antimicrobial agents in pregnancy and during lactation

Janet I. Andrews and Jennifer R. Niebyl

Antibiotics are widely used during pregnancy. Because of the potential for maternal and fetal side-effects, they should be used only when the indication is clear and the risk–benefit ratio justifies their use. Pregnant patients should be warned that they are particularly susceptible to yeast infections and may need therapy later with antifungal agents. Free samples of the newest drugs should not be given to women who might become pregnant, as there is often no human pregnancy information on recently marketed drugs.

Penicillins

The penicillins have a wide margin of safety and lack toxicity in both the pregnant woman and the fetus.¹ There is no evidence that penicillin or its derivatives are teratogenic. In the Collaborative Perinatal Project, 3546 mothers took penicillin derivatives during the first trimester of pregnancy, with no increased risk of anomalies.¹ In a separate study, there was no increase in birth defects in 86 women exposed to dicloxacillin during the first trimester.²

Several studies have revealed that, in patients receiving equivalent dosages, the serum level of penicillins is lower and renal clearance higher throughout pregnancy than in the non-pregnant state.³ Because of an increase in both renal blood flow and glomerular filtration rate, the increase in maternal renal function results in a higher renal excretion of drugs. The expansion of the maternal intravascular volume during the late stages of pregnancy is another factor that affects antibiotic blood levels.

The transplacental passage of penicillin occurs by simple diffusion. Maternal administration of penicillins with a high protein-binding capacity (e.g., oxacillin, cloxacillin, dicloxacillin, and nafcillin) results in lower fetal tissue and amniotic fluid levels than the administration of penicillins with a low protein-binding capacity (e.g., penicillin G, ampicillin, and methicillin).⁴ The antibiotic is ultimately excreted in the fetal urine and thus into the amniotic fluid. At term, maternal

serum and amniotic fluid concentrations of penicillin G, ampicillin, and methicillin are equal at 60 min after intravenous administration, representing rapid passage into the fetal circulation and amniotic fluid.

Most penicillins are primarily excreted in the urine unchanged, with only small amounts being inactivated in the liver. This requires a reduction in dosage in patients with impaired renal function, and an increase in dosage during pregnancy.

Clavulanate is added to penicillin derivatives to broaden their antibacterial spectrum. In a study of 556 infants exposed to clavulanate during the first trimester, no increased risk of birth defects was observed.⁵ Amoxicillin/clavulanate was studied in randomized controlled trials as potential therapy for chorioamnionitis in women with preterm premature rupture of membranes.⁶ During this trial, amoxicillin/clavulanate was compared with both placebo and erythromycin. An increased incidence of necrotizing enterocolitis was found in the amoxicillin/clavulanate group compared with both the placebo and erythromycin groups.⁶ It has been suggested that amoxicillin/clavulanate selects for specific pathogens, which leads to abnormal microbial colonization of the gastrointestinal tract and ultimately initiation of necrotizing enterocolitis. Therefore, amoxicillin/clavulanate should be avoided in women at risk of preterm delivery.⁷

Penicillin G, ampicillin, and amoxicillin are excreted into breast milk in low concentrations.^{4,8} Oxacillin and dicloxacillin⁹ are highly protein bound and are excreted into breast milk in particularly small amounts. Although no adverse effects are attributable to penicillin in breast milk, three theoretical problems might be seen in the nursing infant: modification of bowel flora (possible diarrhea, candidiasis), allergic response, or interference with the interpretation of culture results. The benefits of continued breastfeeding usually outweigh these potential risks; when these drugs are used to treat mastitis or other infections in breastfeeding mothers, continued nursing is recommended.

Cephalosporins

In a study of 5000 Michigan Medicaid recipients, it was suggested that there was a teratogenic risk (25% increase in birth defects) following exposure to cefaclor, cephalexin, and cephadrine but not other cephalosporins.¹⁰ A separate study of 308 pregnant women exposed to cephalosporins during the first trimester showed no increased risk of malformations.¹¹ However, because other antibiotics (e.g., penicillin, ampicillin, amoxicillin, erythromycin) that have been used extensively have not been associated with an increased risk of congenital defects, they should be first-line therapy when antibiotic treatment is required during the first trimester.

Maternal serum levels of cephalosporins during pregnancy are lower than those in nonpregnant patients receiving equivalent dosages owing to a shorter half-life in pregnancy and an increased volume of distribution. Renal elimination is also increased in pregnancy.¹² These drugs readily cross the placenta into the fetal bloodstream and, ultimately, the amniotic fluid.

The cephalosporins are excreted into breast milk in sufficiently low concentrations that the infant receives an insignificant dose. Although the same theoretical concerns exist as with penicillins, the advantages of continued breastfeeding during treatment usually outweigh any potential risks.

Sulfonamides

Studies of several thousand human infants to investigate the potential risk of exposure to sulfonamides during the first trimester of pregnancy have found no evidence of teratogenic effects.^{1,13}

Sulfonamides cause no known damage to the fetus *in utero* because the fetus can clear free bilirubin through the placenta. However, these drugs might theoretically have deleterious effects if present in the blood of the neonate after birth. The sulfonamides compete with bilirubin for binding sites on albumin, thus raising the levels of free bilirubin in the serum and increasing the risk of hyperbilirubinemia or kernicterus in the neonate.¹⁴ For that reason, it is recommended that an alternative antibiotic is used during the third trimester if possible. However, kernicterus in the neonate has been reported only with neonatal administration, not following *in utero* exposure.

The sulfonamides are easily absorbed orally and readily cross the placenta, achieving fetal plasma levels that are 50–90% of those attained in the maternal plasma. The maternal serum levels of the drug are similar to those in nonpregnant individuals.¹⁵

Trimethoprim, a folate antagonist in bacterial systems, is often given with a sulfa drug for the treatment of urinary tract infections. Two small trials including 131 women failed to show any increased risk of birth defects after first-trimester

exposure.^{16,17} However, in 2296 Michigan Medicaid recipients, first-trimester trimethoprim exposure was associated with an increased risk of birth defects, particularly cardiovascular,¹⁸ and in retrospective studies the risk of cardiovascular defects and oral clefts was increased two- to threefold.^{19,20}

Sulfonamides are excreted into breast milk in low concentrations.¹³ The amount of sulfonamide ingested by an infant is sufficiently low not to have any toxicity (less than 2% of the maternal dose) and so breastfeeding is usually continued during administration of these drugs. However, the administration of sulfa drugs to infants who are ill, stressed, or jaundiced, or who have glucose-6-phosphate dehydrogenase (G6PD) deficiency, is best avoided.¹³ With these precautions, the American Academy of Pediatrics considers sulfonamides compatible with breastfeeding.²¹ Trimethoprim is also excreted in breast milk in small amounts, and is compatible with breast feeding.

Nitrofurantoin

A link between the use of nitrofurantoin and congenital defects has not been reported. In the Collaborative Perinatal Project,¹ no significantly increased risk of anomalies or other adverse effects were seen in 590 infants exposed to nitrofurantoin during pregnancy (83 during the first trimester). In the Michigan Medicaid data,²² 1292 infants were exposed during the first trimester with no increased risk of birth defects.

Nitrofurantoin absorption from the gastrointestinal tract varies depending on the form of drug administered. The macrocrystalline form is absorbed more slowly than the crystalline form and is associated with less gastrointestinal intolerance. Therapeutic serum levels are not achieved; therefore, this drug is not indicated when there is a possibility of bacteremia, such as with pyelonephritis.

Nitrofurantoin is excreted into breast milk in very low concentrations; the drug could not be detected in 20 samples taken from mothers receiving a dose of 100mg, four times a day.^{23,24}

Tetracyclines

The tetracyclines readily cross the placenta and are firmly bound by chelating to calcium in developing bone and tooth structures.²⁵ This causes brown discoloration of the teeth, hypoplasia of the enamel, inhibition of bone growth,²⁶ and other skeletal abnormalities. The yellowish-brown staining of the teeth usually occurs after 24 weeks' gestation, during the second or third trimester, whereas bone incorporation can occur earlier. Depression of skeletal growth is particularly common among premature infants treated with tetracycline. At present, alternative antibiotics are recommended during pregnancy.

Hepatotoxicity has been reported in pregnant women treated with large doses (2.4–4 g daily) of intravenous tetracyclines. This is dose related and has not been reported with brief courses of therapy.

First-trimester exposure to tetracycline was not found to have any teratogenic risk in 341 pregnant women in the Collaborative Perinatal Project,¹ or in 174 women in a second study.² A third study looking at the effect of exposure to doxycycline in 63 women also found no teratogenic risk.²⁷

Tetracycline is excreted into breast milk in low concentrations. It is not detectable in the serum of breastfeeding infants, and delayed bone growth from tetracycline has not been reported in breastfed infants. This may be the result of the high binding capacity of the drug for calcium and protein, limiting absorption from the milk. The American Academy of Pediatrics considers tetracycline to be compatible with breastfeeding.²¹

Aminoglycosides

Gentamicin is preferred to tobramycin and amikacin, as it has been more extensively studied in pregnancy. Streptomycin and kanamycin have been associated with congenital deafness in the offspring of mothers who took these drugs during pregnancy. In one study,²⁸ the administration of 1 g of streptomycin twice weekly for 8 weeks during the first trimester resulted in ototoxicity. A second study²⁹ found that, out of the children born to 391 mothers who had received 50 mg/kg of kanamycin for prolonged periods during pregnancy, nine had hearing loss (2.3%).

Nephrotoxicity may be increased when aminoglycosides are given in combination with cephalosporins, and this should be avoided. Neuromuscular blockade may be potentiated by the combined use of these drugs and curariform drugs; therefore, the dosages should be reduced appropriately. Potentiation of magnesium sulfate-induced neuromuscular weakness has been reported in a neonate exposed to magnesium sulfate and gentamicin.³⁰

Ototoxicity is the only known teratogenic effect associated with the use of these drugs during the first trimester of pregnancy.³¹ No teratogenic effects were observed in 135 infants exposed to streptomycin in the Collaborative Perinatal Project.¹ In addition, in a group of 1619 newborns whose mothers were treated with multiple drugs, including streptomycin, for tuberculosis during pregnancy, the incidence of congenital defects was the same as that of the healthy control group.³²

The aminoglycosides are poorly absorbed after oral administration and are rapidly excreted by the normal kidney. Because the rate of clearance is related to the glomerular filtration rate, dosage must be reduced in cases of abnormal renal function and increased during pregnancy.

The serum aminoglycoside levels are usually lower in pregnant than in nonpregnant patients receiving equivalent doses

because of more rapid elimination. Thus, it is important to monitor levels to prevent subtherapeutic dosing,^{33,34} as wide interpatient variation in gentamicin levels has been observed in obstetric patients. At full term, the concentrations of gentamicin in fetal blood are lower than those in maternal blood.³⁵

Once-a-day dosing (7 mg/kg ideal body weight every 24 h) is recommended for gentamicin because this increases efficacy³⁶ while decreasing toxicity and cost.³⁷ This dosing schedule has been studied in patients with chorioamnionitis and endometritis and has been shown to be safe and effective.³⁸

Small amounts of gentamicin are excreted into breast milk;³⁹ because oral absorption of these drugs by the infant is poor, side-effects are not expected.

Macrolides

There have been no reports of a link between the use of erythromycin and teratogenicity. Furthermore, there was no increased risk of birth defects noted in 79 patients in the Collaborative Perinatal Project¹ nor in 6972 patients in the Michigan Medicaid data.^{40,41} There was no increased risk of birth defects in a study of 122 infants exposed during the first trimester to clarithromycin.⁴²

Erythromycin and its salts are not consistently absorbed from the gastrointestinal tract of pregnant women, and transplacental passage is unpredictable. Both maternal and fetal serum levels achieved after the administration of the drug in pregnancy vary considerably and may be low.⁴³ For the treatment of syphilis in pregnancy, desensitization and administration of penicillin is still the method of choice because erythromycin therapy often fails.⁴⁴ Fetal plasma concentrations are 5–20% of those in maternal plasma. The usual oral dose is 250–500 mg every 6 h, although the higher dose may not be tolerated well in pregnant women, who are susceptible to nausea and gastrointestinal symptoms.

Erythromycin is excreted into breast milk in small amounts; however, no reports of adverse effects have been noted in infants exposed to erythromycin in breast milk.⁴⁰

Lincosamides

Of 647 infants exposed to clindamycin during the first trimester, no increased risk of birth defects was noted.⁴⁵ Clindamycin crosses the placenta, achieving maximum cord serum levels of approximately 50% of the maternal serum.⁴³ When assessed at various stages of pregnancy, maternal serum levels after dosing were found to be similar to those of nonpregnant patients.³³

Clindamycin is excreted into breast milk in low levels, and nursing is usually continued during administration of this drug.⁴⁵ The American Academy of Pediatrics considers the use of clindamycin to be compatible with breastfeeding.²¹

Fluoroquinolones

The fluoroquinolones (e.g., ciprofloxacin, levofloxacin, norfloxacin) have a high affinity for bone tissue and cartilage and may cause arthropathies in children. However, no malformations or musculoskeletal problems were noted in 38 infants exposed *in utero* during the first trimester in one study,⁴⁶ or in 134 cases in a second study.⁴⁷ An international multicenter study⁴⁸ prospectively followed 200 pregnant women exposed to quinolones and compared them with a control group of pregnant women exposed to nonteratogenic antimicrobials. The rates of teratogenicity and achievement of developmental milestones were reported. There were no differences in the major malformations or musculoskeletal dysfunctions between the two groups; however, the manufacturer recommends that fluoroquinolones are not used during pregnancy or in children. Gatifloxacin and moxifloxacin have not been studied in pregnant women.

Ciprofloxacin is excreted in breast milk in small amounts, and the use of quinolones during breastfeeding has not been recommended because of the theoretical potential for arthropathy in the infant. The manufacturer recommends that, before breastfeeding is resumed, 48 h elapse after administration of the last dose;⁴⁹ however, the American Academy of Pediatrics considers the use of ciprofloxacin to be compatible with breastfeeding.²¹

Metronidazole

Controversy regarding the use of metronidazole during pregnancy began when the drug was shown to be positive in the Ames test, which correlates with carcinogenicity in animals. However, the doses used were much higher than the doses used clinically, and carcinogenicity in humans has not been confirmed.⁵⁰

Studies have failed to show any increase in the incidence of congenital defects among the newborns of mothers treated with metronidazole during early or late gestation. In a study of 1387 prescriptions filled, the risk of birth defects could not be determined;⁵¹ a subsequent meta-analysis confirmed no teratogenic risk.⁵²

Metronidazole is excreted into breast milk in small amounts. The American Academy of Pediatrics recommends interrupting breastfeeding for 12–24 h after a single oral dose of 2 g to allow clearance of the drug.²¹

Acyclovir and valaciclovir

The Acyclovir in Pregnancy Registry recorded 1695 exposures during pregnancy from 1984 to 1998 (including 756 during the first trimester), with no increased risk of abnormalities in the infants.⁵³ In addition, maternal systemic acyclovir treat-

ment has been used near term to prevent recurrent genital herpes, with no adverse effects on the infants.^{54,55} The Centers for Disease Control and Prevention (CDC) recommends that pregnant women with disseminated infection, e.g., herpetic encephalitis or hepatitis or varicella pneumonia, be treated with acyclovir.⁵⁶

Valaciclovir is rapidly converted to acyclovir, and the level in breast milk is 2% of that of the maternal serum level, which is far less than the therapeutic dose for neonates.⁵⁷

Antiretrovirals

In general, pregnancy should not preclude using the optimal regimen of antiviral therapy. Combination antiretroviral therapy, usually consisting of two nucleoside analog reverse transcriptase inhibitors and a protease inhibitor, is the recommended therapy for HIV-infected nonpregnant adults. However, it is important to take account of the circumstances before selecting the appropriate antiretroviral regimen during pregnancy.

Zidovudine (ZDV) should be included in the regimen whenever possible because of its excellent safety record and efficacy. In a prospective cohort study,⁵⁸ children exposed to ZDV during the perinatal period as a result of the Pediatric AIDS Clinical Trials Group Protocol 076 were studied up to a median age of 4.2 years, with no adverse effects observed in these children. The International Antiretroviral Registry was established in 1989 to detect any major teratogenic effects of antiretroviral drugs. Up to January 2004, over 1000 pregnancies had first-trimester exposures to ZDV and lamivudine with no reported increase in teratogenicity.⁵⁹

Concerns have been raised regarding the use of some antiretroviral therapies in pregnancy. Efavirenz is not recommended during pregnancy because of reports of significant fetal malformations in monkeys who received efavirenz during the first trimester of pregnancy, and also three case reports of fetal neural tube defects in women who received the drug.⁶⁰ In 2001, Bristol-Myers Squibb issued a warning advising against the use of didanosine and stavudine in pregnant women because of case reports of lactic acidosis, including fatalities.⁶¹ These two drugs should be used only if no alternatives are available.

Breastfeeding is not recommended in women with HIV infection, as the virus is transmitted in milk. However, one study has shown that women who received ZDV during pregnancy, labor, and for a week postpartum had a 38% reduction in the vertical transmission of HIV, despite breastfeeding, compared with control subjects.⁶²

Anti-influenza drugs

Four drugs are currently recommended for the prevention or treatment of influenza in the USA: amantadine, rimantadine,

Table 19.1 Teratogenic effects of antibiotics and anti-infective agents.

Drug	First-trimester teratogen	Perinatal effects	Compatible with lactation
Penicillins	No	No	Yes
Amoxicillin/clavulanate	No	Necrotizing enterocolitis in premature infants	Yes
Cephalosporins	Unclear: may be specific to cephalosporin	No	Yes
Sulfamethoxazole	No	Competes with bilirubin for albumin binding sites; increased risk of jaundice	Yes, except in ill or premature infants
Trimethoprim	Possible	No	Yes
Nitrofurantoin	No	No	Yes
Tetracyclines	No	Tooth discoloration, decreased bone growth	Yes
Aminoglycosides	No	Ototoxicity (deafness)	Yes
Erythromycin	No	No	Yes
Clindamycin	No	No	Yes
Fluoroquinolones	No	Arthropathies in exposed children?	Yes
Metronidazole	No	No	Unknown
Acyclovir	No	No	Yes
Zidovudine	No	No	Yes
Amantidine	Possible	Unknown	Unknown
Isoniazid	No	Maternal hepatitis	Yes

zanamivir, and oseltamivir. In a surveillance study of Medicaid recipients, 64 pregnant women were exposed to amantadine during the first trimester.⁶³ Five of their infants were diagnosed with congenital anomalies, which was higher than the expected number of three. The CDC states that, because of the unknown effects of influenza antiviral drugs on pregnant women and their fetuses, they should be used during pregnancy only if the potential benefit justifies the potential risk to the embryo or fetus.⁶⁴

Amantadine is excreted into breast milk in low concentrations. The manufacturer recommends that it is not used in nursing mothers; it has not been evaluated by the American Academy of Pediatrics.⁶⁵

Isoniazid

There is no evidence of any teratogenic effect of isoniazid (INH).⁶⁶ The American Thoracic Society and the American College of Obstetricians and Gynecologists state that treatment with INH for patients with a positive purified

protein derivative (PPD) test with a negative chest radiograph should be delayed until after delivery because of a small risk of maternal liver toxicity.⁶⁷ A recent decision analysis recommends starting treatment at 20 weeks antepartum.⁶⁸ However, if the probability of active tuberculosis is moderate to high, the American Thoracic Society and CDC recommend initiating therapy with INH, rifampin, and ethambutol during pregnancy.⁶⁹

Isoniazid is concentrated in breast milk; however, the American Academy of Pediatrics considers it to be compatible with breastfeeding.²¹ The infant should be periodically examined for signs of peripheral neuritis or hepatitis.⁷⁰

Conclusions

Most antibiotics are safe to use during pregnancy but, as there is the potential for fetal effects that are still unrecognized, they should be used only when clearly indicated. A summary of drug effects in pregnancy and lactation is presented in Table 19.1.

Key points

- 1 Penicillin and its derivatives are safe for use in pregnancy.
- 2 Amoxicillin/clavulanic acid should be avoided in women at risk for preterm delivery as it increases the risk of necrotizing enterocolitis in the premature infant.
- 3 Sulfonamides cause no harm to the fetus *in utero* as the fetus can clear free bilirubin through the placenta. In the neonate, they increase the risk of hyperbilirubinemia.
- 4 Trimethoprim should not be given during the first trimester of pregnancy as it is a weak folic acid antagonist and has been associated with a threefold increased risk of cardiovascular defects and oral clefts.
- 5 Nitrofurantoin does not achieve therapeutic serum levels and is inadequate therapy for pyelonephritis.
- 6 The tetracyclines bind to and inhibit developing bones and teeth during the second and third trimesters of pregnancy and are contraindicated at that time.
- 7 Once-a-day dosing is recommended for gentamicin as it increases efficacy and decreases toxicity and cost.
- 8 Erythromycin is inadequate therapy for syphilis. For penicillin-allergic patients, desensitization and treatment with penicillin is recommended.
- 9 Fluoroquinolones have a high affinity for bone and cartilage and the manufacturer recommends against their use in pregnancy.
- 10 Studies have failed to show any risks of metronidazole in pregnancy.
- 11 In patients with recurrent herpetic infections of the vulva, prophylactic acyclovir in the last month of pregnancy can prevent recurrences and the need for Cesarean sections.
- 12 Pregnant women with varicella pneumonia should receive acyclovir.
- 13 Pregnant women with HIV should receive combination antiretroviral therapy that includes zidovudine (ZDV).
- 14 Breastfeeding is not recommended in women with HIV as the virus is transmitted through breast milk.
- 15 A combination antiretroviral regimen that includes both didanosine and stavudine should be avoided because of the risks of lactic acidosis.
- 16 Pregnant women with a positive purified protein derivative (PPD) and a negative chest radiograph should have therapy with isoniazid (INH) postponed until after delivery because of a small risk of maternal liver toxicity.
- 17 Treatment of active tuberculosis during pregnancy should be initiated with INH, rifampin and ethambutol.
- 18 Efavirenz is not recommended during pregnancy because of reports of malformations in monkeys and fetal neural tube defects in women who received the drug.
- 19 All antibiotics are compatible with breastfeeding except for sulfonamides when the infant is ill or premature, and possibly metronidazole and amantadine, whose effects are unknown.
- 20 Gentamicin is poorly absorbed orally by the infant and is safe during lactation.

**Part
VI**

Fetal Diseases

Principles of human genetics: chromosomal and single- gene disorders

Joe Leigh Simpson and Maurice J. Mahoney

Genetic disorders can result from any one of several mechanisms: numerical or structural alterations in chromosomal constitution, mutation involving a single genetic locus (mendelian), or the cumulative effect of several genes (polygenic), possibly interacting with environmental factors (multifactorial). In this chapter, the major principles underlying these genetic mechanisms are reviewed. Perturbations of these mechanisms are responsible for most of the disorders whose diagnosis is considered elsewhere in Part VI.

Chromosomal analysis

Chromosomal analyses are usually performed on peripheral blood (lymphocytes) or fibroblasts cultured from skin, gonads, chorionic villi (mesenchyme), or amniotic fluid cells. Very rapidly dividing cells (e.g., bone marrow, chorionic villus trophoblasts, fetal cord blood, newborn cord blood, or cancer cells) may sometimes be analyzed without culturing. Rapid techniques have been developed for the analysis of cord blood or percutaneous umbilical cord blood. Fluorescence *in situ* hybridization (FISH) analysis using chromosome-specific probes can produce results within hours (see below), but it provides information only on the chromosomes or chromosome regions tested. This may suffice if a specific disorder (e.g., trisomy 21 or 18) must be excluded; however, the information obtained is obviously more limited than that resulting from a complete chromosomal analysis.

If cultures are necessary, cells are grown in nutrient media to which various growth factors are usually added. A specified period of growth is typical for a given tissue: overnight for bone marrow, cord blood, and chorionic villus trophoblasts; 48–72 h for peripheral blood; and 7–14 days for chorionic villus mesenchyme or amniotic fluid cells. The preparation of cells for chromosomal analysis usually requires the sequential addition of: (1) colchicine or desoxymethylcolchicine to accumulate metaphases; (2) a hypotonic solution that causes cells to swell; (3) an acetic acid–methanol solution to fix cells permanently; and (4) a dye to enhance chromosome

visibility. Traditionally, metaphases were photographed, prints developed, and individual chromosomes aligned (Fig. 20.1) Automated systems can now produce karyotypes directly from metaphases. Published karyotypes usually portray realigned chromosomes rather than the original metaphase. Analysis generally requires counting 15–20 cells and karyotyping 2–5 of them. Not all cells are intact; some will have been damaged (“broken”) in preparation and have hypodiploid counts. This technical point is clinically relevant because approximately 2% of chorionic villi or amniotic fluid specimens contain one or more spurious cells. A single hypodiploid cell is unlikely to have clinical significance.

Sometimes, two or more cell lines exist in a single individual, a phenomenon called *mosaicism*. Because mosaicism arises during embryogenesis, not all tissues show the same complements. Of additional relevance to the obstetrician is that the complements in chorionic villus trophoblasts may differ not only from the complements of cultured chorionic villus mesenchyme but also from those of the embryo.¹

Routine cytogenetic analysis usually reveals approximately 450–500 bands per haploid set of chromosomes. Using high-resolution chromosomal analysis, it is often possible to obtain a resolution of about 1000 bands. At this level, each band consists of approximately 3000–4000 kilobases (kb) of DNA, which are capable of translating about 30–40 genes. Therefore, deletions, duplications, and rearrangements involving considerable stretches of DNA can pass undetected, even with high-resolution chromosomal analysis.

Molecular cytogenetic analysis and fluorescence *in situ* hybridization

Exciting and useful advances have resulted from merging molecular techniques with traditional cytogenetics. The basic principle involves identifying a DNA sequence specific for a given chromosome and then making the sequence fluorescent for the purpose of cytological identification. In FISH analysis, a single-stranded DNA probe hybridizes to its complementary

Figure 20.1 Karyotype of normal male (46,XY) G bands. (From ref. 26, with permission.)

DNA sequence when that specific sequence is present (Fig. 20.2). The DNA probe may be labeled directly with a fluorochrome or indirectly by adding another compound (e.g., biotin) that is then conjugated secondarily with a fluorochrome. If the probe is labeled directly, the fluor intercalates into the host (unknown) DNA. FISH can be used to derive information from interphase cells (e.g., uncultured amniotic fluid cells).

Using composite probes coupled with suppressive hybridization, whole chromosomes or chromosome segments can be “painted” and uniquely visualized.

Definitions and cytological origin of numerical chromosomal abnormalities

Aneuploidy is the lack of expected number of chromosomes (n or $2n$) in a haploid gamete or diploid cell. If an additional chromosome is present ($2n + 1$), *trisomy* exists. The term

polysomy is sometimes applied if the additional chromosome is a sex chromosome (e.g., 47,XXY).

There are several cytological mechanisms that can result in trisomy, but in humans it usually arises *de novo* after meiotic or mitotic nondisjunction. Nondisjunction may originate after the failure of homologous chromosomes to disjoin in meiosis I or the failure of sister chromatids to disjoin in either meiosis II or mitosis. In humans, maternal meiosis I is by far the most common cytological origin of autosomal trisomy.² Nondisjunction in maternal meiosis I is usually associated with a maternal age effect (Table 20.1), whereas paternal nondisjunction is minimally associated with paternal age.

Irrespective of cytological origin, nondisjunction during meiosis produces aneuploid gametes and the resulting zygote has the identical chromosomal constitution in all cells. By contrast, nondisjunction during mitosis produces two or more cell lines (mosaicism).

Monosomy ($2n - 1$) arises by mechanisms that are similar to those which result in trisomy. Indeed, meiotic nondisjunction

Figure 20.2 Fluorescence *in situ* hybridization (FISH) on a human blastomere biopsied from an eight-cell stage embryo. Fluorescent signals corresponding to specific chromosomes 13, 18, 21, and X are shown, demonstrating detection of a normal female (XX) embryo. Courtesy of Farideh Z. Bischoff, Department of Obstetrics and Gynecology, Baylor College of Medicine, Houston, TX, USA.

tion leading to a disomic gamete also produces a complementary gamete lacking that chromosome. In addition, monosomy may result from a chromosome merely lagging behind and failing to pass to daughter cells (*anaphase lag*).

In *polyploidy*, more than two haploid sets of chromosomes exist. The most common form of polyploidy is triploidy ($3n = 69$), which may be characterized by either two maternal or two paternal haploid complements. In humans, dispermy is the most common mechanism resulting in polyploidy. Polyploidy is frequently detected among human abortuses but rarely among neonates. Triploidy accounts for 25% of chromosomally abnormal abortuses, or around 10–15% of all first-trimester abortuses.

Definitions and cytological origin of structural chromosomal abnormalities

Minor structural variation (polymorphism) exists among human chromosomes without any apparent phenotypic consequences. Examples include prominent satellites on acrocentric chromosomes (nos. 13, 14, 15, 21, and 22) and variation in the length of the Y long arm. Such “variants” are transmitted in a dominant fashion.

On the other hand, major structural alterations clearly cause phenotypic abnormalities. It can be assumed that many genes are duplicated or deficient; phenotypic abnormalities might also result if the position of a gene is altered with respect to its neighbors (*position effect*). Several types of chromosomal abnormalities are of clinical relevance.

Chromosomal deletion involves the loss of a portion of a chromosome, either terminal or interstitial. Deficiencies

Table 20.1 Chromosomal abnormalities in liveborns.

Maternal age	Risk of Down syndrome	Total risk of chromosomal abnormalities
20	1/1667	1/526*

47	1/18	1/12
48	1/14	1/10
49	1/11	1/7

From ref. 25. Because sample size for some intervals is relatively small, confidence limits are sometimes relatively large. Nonetheless, these figures are suitable for genetic counseling.

*47,XXX excluded for ages 20–32 (data not available).

usually result from breakage and loss of an acentric fragment, but may also arise after crossing over within a pericentric inversion loop (see below). Autosomal deficiency usually leads to embryonic death or malformation, but deficiency in a sex chromosome is not necessarily as damaging.

A *translocation* occurs when, after chromosome breakage, material is exchanged between two or more chromosomes (Fig. 20.3). Rearrangement of genes need not necessarily be deleterious, provided that genes are neither lost nor gained. If the individual is phenotypically normal, it is assumed that no genetic material is lost; such a translocation is said to be balanced. If a translocation has led to a deficiency or excess of genetic material, the rearrangement is said to be unbalanced. Even if it is not evident on a karyotype, an unbalanced rearrangement can be assumed if the individual is phenotypically abnormal. If a fetus or offspring shows the same

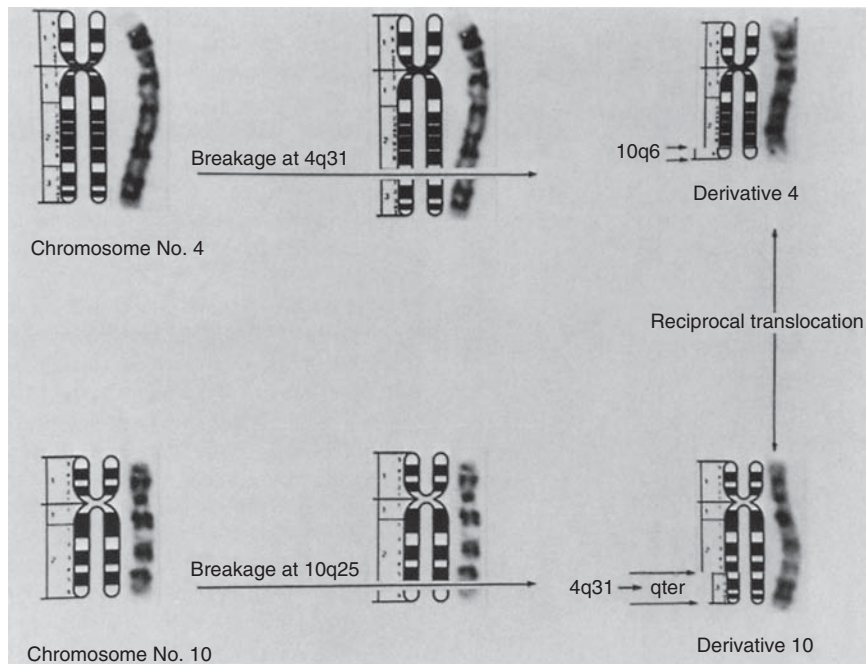

Figure 20.3 A reciprocal translocation between chromosomes 4 and 10. Origin of derivative chromosomes is shown. (From ref. 26, with permission.)

translocation as a normal parent, it can be assumed that the translocation is balanced and the fetus is normal. When a *de novo* translocation is detected in villi or amniotic fluid cells, it is hazardous to assume normalcy even if the translocation seems balanced. A subtle rearrangement may not be recognized, and this accounts for the 10–15% risk of phenotypic abnormality.

Translocations may be either reciprocal or robertsonian. In *reciprocal* translocations, breaks and rearrangements occur in two or more chromosomes but do not involve centromeres (see Fig. 20.3). Thus, translocation heterozygotes still have 46 chromosomes, although two pairs of homologous chromosomes differ in morphology and composition. In *robertsonian* translocations, two of the acrocentric chromosomes (nos. 13, 14, 15, 21, and 22) fuse at their centromere. Because no single acrocentric short arm is essential, heterozygotes are phenotypically normal. These individuals have only 45 chromosomes (centromeres) as a result of the fusion.

Robertsonian translocations

Robertsonian translocations involve the acrocentric chromosomes 13, 14, 15, 21, and 22. The most common single translocation involves chromosomes 14 and 21 (Fig. 20.4); 2–3% of Down syndrome cases result from this translocation. Theoretically, one-third of the viable offspring of translocation heterozygotes should have Down syndrome; however, of the viable offspring of female and male heterozygotes, empirical data reveal that only 10–15% and 2–4%, respectively, have Down syndrome.^{3,4} Liveborn normal offspring have an

equal likelihood of showing either translocation heterozygosity ($2n = 45$) like their parents or normal chromosomal complements ($2n = 46$).

In translocations involving chromosomes 21 and 22 [t(21;22)], female and male heterozygotes appear to be at a relatively high risk for Down syndrome offspring (10–15%).^{3,4} Abnormal liveborn infants are uncommon in most other robertsonian translocations involving two different chromosomes, e.g., in t(13;14) less than 1% of offspring have trisomy 13. These findings are not surprising, given that trisomies 13 and 14 are lethal and rarely result in liveborns. Nonetheless, individuals with any robertsonian translocation should be counseled about antenatal chromosomal studies.

Robertsonian translocations involving homologous chromosomes have a bleak prognosis. Translocations involving chromosome 13 [t(13;13)] or chromosome 21 [t(21;21)] yield only abnormal liveborns or abortions (trisomy 13 or trisomy 21). Homologous translocations involving chromosomes 14, 15, and 22 almost always result in abortions; liveborns with these trisomies have been reported but are very rare. Thus, females with homologous translocations should be counseled about sterilization or donor oocytes, whereas donor sperm can be offered for male heterozygotes.

Reciprocal translocations

Many different reciprocal translocations exist, involving every chromosome, including the acrocentrics. Ideally, empirical data should be available for each translocation; however, at present, only data for general categories exist. Counseling requires attention to the mode of ascertainment.

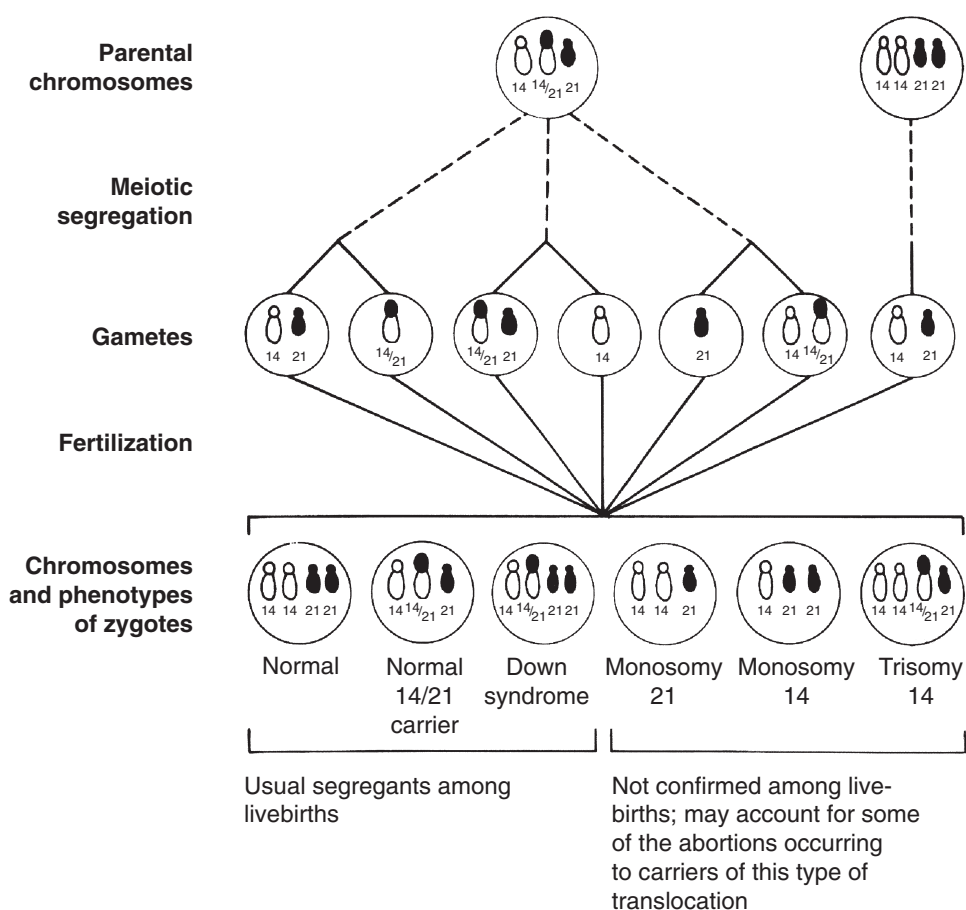

Figure 20.4 Diagram of possible gametes and progeny of a phenotypically normal individual heterozygous for a translocation between chromosomes 14 and 21. Three of the six possible gametes are incompatible with life. The likelihood that an individual with such a translocation would have a child with Down syndrome is thus 33%. However, the empirical risk is considerably less. (From ref. 27.)

A reciprocal translocation may be ascertained in one of several ways: through a balanced (clinically normal) proband that is coincidentally detected (e.g., in a survey), through phenotypically normal couples having repeated abortions, or through an abnormal fetus or infant having an unbalanced karyotype. The risk of a parent having a liveborn child with a chromosomal duplication or deficiency is higher in the last situation than in the first two.^{4,5} The lower risk in the first situation presumably reflects selection against unbalanced segregants at the level of the gametes or, more likely, of the embryo. Overall, prenatal diagnosis and surveillance of couples where either the male or female shows a reciprocal translocation indicates that the risk of an unbalanced fetus is approximately 10%.^{3,4} Although substantial, these risks are still less than the theoretical risks, which are as high as 50–60% (proportion of unbalanced gametes), assuming random segregation and no crossing over. Daniel and coauthors⁶ found that, if ascertained through a full-term unbalanced neonate, the risks in unbalanced amniotic fluid specimens are 19% and 24% for female and male carriers respectively. If ascertained through a couple with repeated abortions, the risks are 3.5% and 1.5%. If ascertained coincidentally, the risks are 5% and 4%. Liveborn offspring who are phenotypically normal are equally likely to have either normal chromosomes (46,XY or 46,XX) or the

same two balanced translocation chromosomes that are present in the carrier parent. Although most reciprocal translocations carry an empirical risk of only approximately 10%, the risk is higher for complex rearrangements involving more than two chromosomes⁶ and for situations in which 3:1 segregation occurs.

An unresolved question is whether a translocation ascertained through repeated abortions carries a risk for abnormal liveborns that is as high as the risk ascertained through an abnormal liveborn. In the study by Daniel and coauthors,⁶ the risks appear to be lower. The question frequently arises because approximately 2–3% of couples who experience repeated abortions show a translocation.⁷ The clinician should assume that the risks are similar, irrespective of ascertainment, although this is probably conservative advice.

Sometimes it is not clear whether a *de novo* translocation is balanced or not. An infant with an abnormal phenotype is assumed to have an unbalanced rearrangement. With a normal phenotype, the converse can be assumed. However, such reasoning is hazardous if a *de novo* translocation (or supernumerary marker chromosome) is detected at prenatal diagnosis, even with a normal ultrasound. Warburton^{8,9} has provided empirical data showing that the risks for *de novo* reciprocal or robertsonian translocations are 6.7% and 3.7%

respectively. For *de novo* nonsatellited or satellited marker chromosomes, the risks are 14.7% and 10.9% respectively.

Single gene abnormalities (mendelian inheritance)

In mendelian inheritance, a gene mutation usually involves only a single genetic locus. A chromosome carrying a single mutant gene with no other abnormality appears structurally normal because the change involves only a minute deletion or a change in a single nucleotide sequence. Analysis of a mutant gene is therefore not ordinarily facilitated by cytogenetic studies. Instead, the geneticist studies pedigrees, measures a gene product or its metabolite, or examines the DNA coding for the gene.

Definitions

Chromosomes exist in pairs, with one maternally derived and one paternally derived. Chromosomes contain genes; thus, genes, or more properly alleles (different states of a single gene), exist in pairs. Alleles occupy identical places on homologous chromosomes and can become interchanged during meiotic recombination.

The state of possessing a pair of identical alleles at a given position is termed *homozygosity*; if alleles are dissimilar, *heterozygosity* exists. An allele capable of expression in its heterozygous state is dominant, whereas an allele capable of expression only in homozygous form is recessive. These definitions apply only to autosomal loci; different circumstances exist for X-linked loci. A recessive trait whose allele is located on the X chromosome is expressed by all males (46,XY) carrying the recessive allele. Affected males are said to be *hemizygous*.

An important concept of particular relevance to autosomal recessive inheritance is *compound heterozygosity*, in which the two alleles are dissimilar but both abnormal (dysfunctional). Compound heterozygosity is often clinically indistinguishable from homozygosity for a single mutant allele. In autosomal recessive disorders, analysis using molecular techniques has shown that compound heterozygosity is the rule rather than the exception (the exception arises in consanguineous matings). In cystic fibrosis, some affected individuals are homozygous for deletion of three nucleotides at position 508 ($\Delta F508$), but others have one such mutant allele and one other dysfunctional allele at the same locus (e.g., the missense mutation producing the premature stop (X) codon W1282X).

Transmission of mutant genes in families

The familial patterns followed by mendelian traits depend not only on whether the mutant gene is dominant or recessive but also on whether the gene is located on an autosome or a sex chromosome. There are five potential patterns of transmission: autosomal dominant, autosomal recessive, X-linked dominant, X-linked recessive, and Y-linked. The concept of mitochondrial inheritance, which for some genes yields maternal transmission exclusively, is not discussed here. Y-linked inheritance is of relevance here with respect to transmission of male gender and transmission of certain genes necessary for spermatogenesis.

Autosomal dominant inheritance

An autosomal dominant allele is recognized by its ability to be expressed in more than one generation (Fig. 20.5). In autosomal dominant traits, equal numbers of males and females are usually affected; the likelihood is 50% that an individual

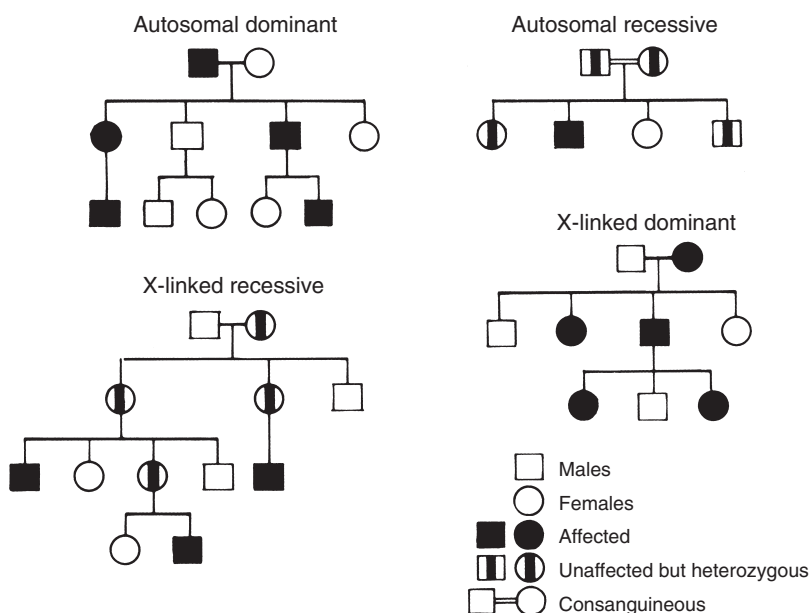

Figure 20.5 Idealized pedigree of common modes of mendelian inheritance. From ref. 28.

carrying a mutant autosomal dominant gene (allele) will transmit that allele to any given offspring, male or female. If penetrance (see below for definition) is complete, an unaffected individual will not have an affected offspring.

However, autosomal dominant patterns are not always associated with these idealized characteristics. Some individuals may be more severely affected than others, a phenomenon known as *variable expression*. This characteristic has been known clinically for decades, but the molecular basis has only recently been elucidated. In a given gene, the exact mutation may vary, e.g., a deletion or single-nucleotide substitution; this is called *molecular heterogeneity*. Some molecular changes are more deleterious than others; a mutation resulting in loss of a gene product (protein) is likely to be more serious than a mutation in which a single amino acid substitution has occurred. Variable expression occurs not only between families but also among affected members of a single family (intrafamilial *variability*). A single mutant gene may also be responsible for several ostensibly distinct phenotypic effects (*pleiotropy*). Occasionally, an autosomal dominant allele may exert its effect only on individuals of one sex (*sex limitation*). Another characteristic of autosomal dominant inheritance is that some individuals may be phenotypically normal yet carry a mutant autosomal dominant allele. Such a mutant allele is said to show *lack of penetrance* in the phenotypically normal individual. Lack of penetrance probably reflects our inability to study gene products or DNA directly; if molecular analysis was possible in all disorders, “nonpenetrant” individuals would probably show an abnormality in their DNA.

In the absence of an ability to measure DNA or its gene products, an autosomal dominant allele in humans must be recognized clinically. Usually, one of the following clinical characteristics must exist for dominant inheritance to be recognized:

- 1 a lack of interference with reproductive ability (e.g., polydactyly);
- 2 manifestation only after reproduction is completed (e.g., Huntington’s disease);
- 3 a lack of penetrance or variable expressivity (i.e., a minimally affected parent might have severely affected progeny).

Dominant disorders need not always have been transmitted from an affected parent. The disorder may have arisen *de novo*, as result of a new mutation in a sperm or oocyte. The more severe the trait, the more likely it is that an affected individual has a new mutation. Approximately 90% of achondroplasia cases occur as a result of new mutations, whereas this occurs in relatively few cases of polydactyly. All individuals with a dominant trait conferring sterility must represent a new mutation.

Autosomal recessive inheritance

An autosomal recessive trait is expressed when an individual is homozygous for the mutant allele, i.e., at a given genetic locus both alleles show an identical mutation. As noted above,

different but equally dysfunctional alleles can also exist (compound heterozygosity) and, for most disorders, this is usually the case. An individual with a recessive trait is usually the product of parents who are both heterozygous (carriers) for a mutation at the same locus. If two heterozygotes mate, the likelihood is 25% that a given offspring will be affected (see Fig. 20.5). If multiple siblings of both sexes are affected, autosomal recessive inheritance should definitely be considered. Consanguineous parents are more likely to carry an identical allele (mutant or normal) than nonconsanguineous parents. Thus, an individual with a recessive trait is relatively more likely to arise from a consanguineous than from a nonconsanguineous union. The rarer a trait, the higher the proportion of affected individuals who arise from consanguineous unions. For common traits (e.g., cystic fibrosis, sickle cell anemia), parents of affected offspring are usually not consanguineous.

Autosomal recessive inheritance can also occur if a homozygous individual mates with a heterozygous individual, in which case 50% of the offspring will be affected (pseudodominant inheritance). This phenomenon is becoming more frequent as survival to reproduction becomes less unusual for serious autosomal recessive traits (e.g., cystic fibrosis, sickle cell anemia).

The mathematical relationship between the frequencies of homozygotes and heterozygotes is clinically important and is expressed by the Hardy–Weinberg equilibrium. To illustrate, suppose that the normal allele is A and the mutant allele is a ; A is said to have the frequency p , and a has the frequency q . Because the frequencies of alleles at a given locus add up to 1, $p + q = 1$. Squaring both sides of the equation gives $p^2 + 2pq + q^2 = 1$. In this binomial expansion, p^2 becomes the frequency of individuals homozygous for allele A (AA); q^2 is the frequency of individuals homozygous for allele a (aa); and $2pq$ is the frequency of the heterozygote (Aa). The frequency of a mutant allele (q) is usually much less than the frequency of a normal allele (p). If q is much less than 0.5, q^2 will be much less than $2pq$ because p will be nearly equal to 1.

The relative magnitudes of $2pq$ and q^2 make it clear that the “load” for deleterious recessive traits is carried mostly by heterozygotes; relatively few homozygotes exist. To illustrate, suppose the incidence of a trait (q^2) is 1 in 10000. Thus, $q = 1$ in 100; $p = 99$ out of 100, or almost 1; and $2pq = 2 \times 1 \times 1$ in 100 = 1 in 50, which is much more frequent than 1 in 10000 (q^2). This mathematical exercise becomes clinically relevant when addressing proposals for eliminating mutant alleles from the population by selecting against homozygous fetuses. Theoretically, eliminating heterozygous individuals might also be unwise because they may possess an advantage over those normal homozygous individuals who may have been responsible for maintaining the mutant allele in the population. In fact, “normal” individuals may be heterozygous for at least five or six deleterious recessive genes.

Clinically unaffected individuals who have a sibling with an autosomal recessive disorder often inquire about the risk that

their own offspring will have the disorder. Assuming that they and their mate are not related, the risk of having affected offspring can usually be shown to be low. If heterozygote detection tests are not available (less often the case, fortunately, with the use of molecular techniques), the a priori likelihood that the unaffected individual is a heterozygote can be calculated if the incidence of the trait is known. The unaffected sibling will have one of three equally likely genotypes: two will be heterozygous and one homozygous for the normal allele; the fourth genotype (homozygous mutant) is excluded on clinical grounds. Thus, the likelihood of the sibling being heterozygous is two in three. The likelihood of the sibling's mate being heterozygous for the same mutant gene reflects gene frequency in the general population, as determined by the Hardy-Weinberg equilibrium. If the trait were to have an incidence of 1 in 8100 births, the heterozygote frequency is 1 in 45 ($q^2 = 1/8100$; $q = 1/90$; $2pq = 1/45$). Thus, the likelihood that any given offspring will be affected is $2/3 \times 1/45 \times 1/4 = 2/540 = 1/270$. Rarer traits naturally confer a correspondingly lower likelihood. Most patients are surprised to find the risks so low. Risks for other family members can be calculated, assuming that a heterozygous individual has an equal likelihood of either transmitting or not transmitting a mutant gene. Thus, for example, a normal individual whose uncle is affected will have only a 1 in 3 chance of being heterozygous (i.e., $2/3 \times 1/2 = 2/6 = 1/3$).

X-linked recessive inheritance

A mutant recessive gene located on the X chromosome is expressed by all males (46,XY) who carry it. Such individuals are said to be hemizygous. X-linked recessive alleles are usually transmitted through phenotypically normal females who are heterozygous (see Fig. 20.5). In a family in which an X-linked recessive mutant allele is segregating, affected individuals might include male siblings, maternal uncles, nephews, male first cousins, and certain other maternal male relatives.

For a heterozygous female to transmit an X-linked recessive allele to any given offspring, the probability is 0.5. Males inheriting the allele will be affected, whereas females inheriting the allele will be heterozygous, like their mothers. An affected man will transmit the allele to all of his daughters but none of his sons; male-to-male transmission thus excludes X-linked inheritance. All offspring of an affected man will be phenotypically normal, unless the mother is heterozygous for the same mutant gene. In such a case, four genotypes are possible and females may be affected. This is unlikely for severe traits (e.g., Duchenne muscular dystrophy) but quite possible for mild traits (e.g., color blindness) or successfully treatable traits (e.g., hemophilia).

Women may occasionally manifest X-linked recessive traits: 46,XX individuals can be affected if they are homozygous, a circumstance that could result if their mother were heterozygous and their father hemizygous. Vicissitudes of X inactivation

(preferential inactivation of normal X) can be so extreme that phenotypic effects exist which approximate those present in hemizygous men. Mutant genes also exist that skew X-inactivation away from randomization between the maternal X and paternal X in a given cell. Finally, women with only one X chromosome (45,X) may be affected if the X chromosome has a mutant allele.

The possibility of new mutations must be considered. It should not be assumed that the mother of a child with an X-linked recessive mutation is heterozygous because the child may represent a new mutation arising in the ovum. If the trait is lethal with respect to fertility, and if no other relatives are affected, the likelihood that a mutation is new can be shown to be one in three.

In counseling individuals at risk for X-linked recessive traits, it is frequently helpful to utilize Bayesian calculations. Conceptually simple, but sometimes complex in application, Bayesian calculations take into account all available data, not just a priori calculations. For example, common sense dictates that a woman at theoretical risk of having offspring with an X-linked recessive trait is actually less likely to be heterozygous if four consecutive sons prove unaffected. The following example illustrates this point. A prospective mother (proband) has two brothers who have an X-linked disorder for which neither metabolic nor DNA analysis is possible. It can be deduced that her own mother is an obligate heterozygote; thus, the likelihood of the prospective mother being heterozygous is 50%. This is known as the proband's a priori risk or prior probability. Suppose that the woman has three unaffected sons: if she is heterozygous, the probability of her having three consecutive unaffected sons is one in eight. However, it is more likely that she is, in fact, not heterozygous. Table 20.2 illustrates how to account for the three unaffected sons. The newly calculated likelihood of the woman being heterozygous is only one in nine, considerably lower than the likelihood calculated from a priori expectations alone.

X-linked dominant inheritance

In X-linked dominant traits, women are twice as likely to be affected as men; however, women are usually less severely affected and, in fact, some X-linked dominant traits are lethal in men. A man carrying an X-linked dominant allele transmits the mutant to all of his daughters but none of his sons (Table 20.3). There is a probability of 0.5 that a woman with an X-linked dominant allele will pass that allele to any offspring, male or female. Relatively few X-linked dominant traits are known.

Causes of gene mutation

Although specific gene mutations are rare, at least 1% of all infants have a disorder resulting from a single mutant gene. Some affected individuals inherit a mutant gene, whereas

Table 20.2 Bayesian analysis.

	Proband heterozygous	Proband not heterozygous
Prior probability	$\frac{1}{2}$	$\frac{1}{2}$
Conditional probability	$\left(\frac{1}{2}\right)^3 = \frac{1}{8}$	1
Joint probability (prior and conditional)	$\frac{1}{16}$	$\frac{1}{2}$
Posterior probability (joint and prior)	$\frac{\frac{1}{16}}{\frac{1}{16} + \frac{1}{2} \left(\text{or } \frac{9}{16} \right)}$	$\frac{\frac{1}{2} \text{ or } \frac{8}{16}}{\frac{1}{16} + \frac{1}{2} \left(\text{or } \frac{9}{16} \right)}$
	$= \frac{\frac{1}{16}}{\frac{9}{16}}$	$= \frac{\frac{8}{16}}{\frac{9}{16}}$
	$= \frac{1}{9}$	$= \frac{8}{9}$

This analysis calculates the likelihood of heterozygosity for a woman whose two brothers have an X-linked recessive disorder. The a priori risk (prior probability) of heterozygosity is 1/2, in as much as the woman's mother is an obligate heterozygote. Supposing the woman has three unaffected sons, what is the likelihood that she is nevertheless heterozygous? Multiplying prior by conditional probability yields joint probability. The posterior probability (1/9) is the newly derived heterozygosity risk, taking into account the three unaffected sons. (From ref. 30.)

Table 20.3 X-linked dominant inheritance.

Parents	Offspring
Affected male (Xy) and normal female (xx)	Xx, Xx, xy, xy
Normal male (xy) and affected female (Xx)	Xx, xx, Xy, xy

X carries an X-linked dominant allele; x does not carry the allele. For offspring of affected males, all females are affected, but no males. For offspring of affected females, 50% of females and 50% of males are affected. (From ref. 30.)

others are the first in their family to have the disorder. Spontaneous mutation rates average from 10^{-5} to 10^{-6} per locus per gamete per generation. Overall, each gamete is estimated to contain 20–30 mutations. Most mutations are neutral or lethal; otherwise, many more than 2–3% of liveborns would be abnormal.

Mutation rates increase with increasing paternal age, with fathers in their fifth or sixth decade having an increased likelihood of certain gene mutations arising in their germ cells. This applies to some but not all X-linked recessive and auto-

somal dominant disorders. This increase is believed to reflect the continuous germ cell replication (spermatogenesis) that occurs throughout a man's fertile lifetime, although the exact manner by which repeated replication leads to mutation remains obscure. Unlike the situation for chromosomal abnormalities, advanced maternal age is not associated with an increase in gene mutations.

Ionizing irradiation is a well-established mutagen. X-rays are the major source of ionizing irradiation, although ultraviolet light also causes mutations. An X-ray exposure of 50–100 rads (50–100 cGg) only doubles the mutation rate; therefore, the absolute risk is relatively low unless an individual is subjected to a massive exposure. Ultrasound and microwaves are not ionizing and probably not mutagenic.

Numerous chemicals cause mutations in animals and in *in vitro* testing systems, and many of these can be mutagenic in humans. Well-known examples include alkylating agents, DNA base analogs (e.g., 5-bromouracil), antimetabolites, nitrous acid, and acridine dyes. Inorganic salts, caffeine, nitrites, and other ubiquitous agents are also mutagenic under certain circumstances. It is difficult to determine the likelihood of particular compounds being mutagenic in humans in a given circumstance; retrospective clinical data cannot provide satisfactory information. However, even substantive exposure to alkylating agents or antimetabolites leads to little if any increase in abnormal liveborns. Individuals treated with chemotherapeutic agents before pregnancy show no increased abnormalities in subsequent progeny. This suggests that most induced mutations are lethal.

Linkage

Genes are located on chromosomes at given locations and in a definite linear relationship to one another. Genes on the same chromosome are said to be linked or to exhibit linkage. Specifically, genes show linkage if during meiosis, with its opportunity for recombination, they are more likely to remain on the same chromosome in parental combination than to behave as if they were on different chromosomes.

If the frequency of recombination between two linked genes is 1%, those genes are defined to be one map unit or one centimorgan apart (percentage recombination = centimorgans). Genes that are 50 centimorgans apart on the same chromosome fail, by definition, to show linkage because such genes segregate indistinguishably from genes on nonhomologous chromosomes. Linkage analysis is increasingly useful in antenatal diagnosis as a more complete map of the human genome becomes available. Linkage analysis in prenatal diagnosis usually relies on a polymorphic locus. Polymorphism exists when two or more alleles are present at a given locus, such that the less frequent allele is still present in 1% of the population. The polymorphism may be some aspect of a gene product, such as electrophoretic mobility. However, the type of polymorphism increasingly used diagnostically is that of DNA variants.

Nonmendelian inheritance: imprinting and uniparental disomy

Autosomal loci usually display biallelic gene expression, with both alleles of a pair (one paternally and one maternally derived) being active. Sometimes, however, only one of a pair of alleles is active (monoallelic expression), and the active allele must be derived from a particular parent (mother or father). An abnormal phenotype develops if the allele is not inherited from the appropriate parent, even if the other parent transmits a gene with a typically normal allele. In monoallelic expression, the allele not required must be inactivated; this process is well known in the case of inactivation of X chromosomes in excess of one, and is called imprinting. An imprinted gene is not expressed as a result of hypermethylation.

The prototypic disorders that led to the elucidation of autosomal imprinting in humans were Prader–Willi syndrome (PWS) and Angelman syndrome (AS). These two recognizable malformation syndromes are controlled by contiguous regions on the long arm of chromosome 15. A paternally derived critical region prevents the expression of PWS; a maternally derived region does not suffice because it is inactive. Conversely, in AS, a maternally derived critical region must be expressed because the paternal region is inactive. PWS and AS may manifest themselves under a variety of circumstances. In PWS, the paternally derived critical region may be deleted or two copies of the maternal region (both inactive) may be present, as a result of both copies of chromosome 15 being maternal in origin. The latter circumstance can result if a paternal chromosome 15 is expelled from a trisomic zygote consisting of two maternal and one paternal chromosome 15. Uniparental disomy (UPD) is then said to exist. If, in contrast, one of the two maternal chromosomes is expelled, a normal situation arises (zygotic correction).

UPD is a clinically relevant phenomenon. In total, 1–2% of chorionic villi contain trisomic cells, usually as a very low percentage. If the zygote had been trisomic and correction occurred by expulsion of one of the three chromosomes present in triplicate, the likelihood of UPD occurring is one in three. Whether UPD exerts a phenotypic effect depends on whether a given chromosome displays monoallelic expression for any of its genes. A special concern in prenatal diagnosis is that UPD can follow asymmetric segregation in a parent having a balanced robertsonian translocation.¹⁰ Both maternal and paternal UPD exists for chromosome 14;¹⁰ however, UPD does not seem to have a deleterious effect for all chromosomes, including chromosomes 13, 21, and 22.^{11–14}

Imprinting is also relevant to entire haploid sets of chromosomes. If both haploid sets in a diploid zygote are maternal in origin, an ovarian teratoma (dermoid) results, whereas if both haploid sets are paternal a hydatidiform mole results. The general principle is that paternal chromosomes govern placental growth, whereas maternal chromosomes control embryonic growth. In triploidy, if two of the three haploid sets

of chromosomes are paternal, a hydatidiform mole results; if two of the three sets are maternal, the placenta is small.

The relevance of imprinting to human pathology is only now being unraveled. The extent of its importance could be enormous not only for pregnancy loss and malformations, but also for somatic processes such as cancer.

Molecular basis of the gene

DNA exists in the form of a double helix, which may be envisioned as a twisted ladder. Each vertical column consists of alternating phosphate and deoxyribose carbohydrate residues. The carbohydrate and phosphate residues on opposite sides are connected by nitrogenous bases called nucleotides. The DNA nucleotides consist of the purines, adenine (A) and guanine (G), and the pyrimidines, thymine (T) and cytosine (C). Adenine is always connected to thymine by forming two hydrogen bonds (base pairing). Similarly, guanine is always connected to cytosine by three hydrogen bonds. As a result, the two DNA strands are complementary. If the sequence of bases on one strand is ATTGC (adenine–thymine–thymine–guanine–cytosine), the sequence on the opposite strand must be TAACG. The ratio of adenine to thymine is always 1:1, as is the ratio of guanine to cytosine. However, the ratio of adenine–thymine (AT) pairs to guanine–cytosine (GC) pairs varies not only in different parts of a single chromosome but also between different chromosomes. This variation is one basis for chromosomal banding.

Genetic information, specifically the amino acid sequence, is determined by the sequence of nucleotides on one of the two DNA strands. A sequence of three adjacent bases forms a codon; most codons specifically code for one of the 20 amino acids but a few code for a stop signal (i.e., cessation of transcription). Specifically, the message is said to be read from the *sense* strand of DNA, with the *antisense* strand being the complementary strand. The complementary strand corresponds to the messenger RNA (mRNA) sequence, although uracil is incorporated in mRNA rather than thymine.

Structural organization of the gene

Along the chromosome, genes are made up of *unique* sequences of DNA, which are able to code for protein, interspersed with *repetitive* or noncoding sequences. Other sequences are also present which are essential for DNA transcription and RNA translation, or which code for only part of a protein (e.g., *pseudogenes*); these types of DNA are less immediately relevant to this discussion.

Fig. 20.6 shows the sequence of events in which DNA is first transcribed into mRNA and then translated into protein. Upstream from the nucleotide sequence which codes for amino acids are sequences assumed to be involved in transcription regulation. Knowledge about gene regulation in humans is incomplete, but some intriguing observations have been made. The

Figure 20.6 Transcription and translation. Intervening sequences (introns) must be excised, leaving exons to be translated to proteins. (From ref. 30.)

nucleotide sequence TATA (“TATA box”) is consistently found 30 base pairs (bp) before (5′ to) the site at which transcription begins. The TATA box may be involved in positioning RNA polymerase II, the enzyme essential for transcribing mRNA from DNA. Another pivotal sequence is CAAT, located 50–75 bp upstream from the transcription site. The CAAT box may be the site at which RNA polymerase II actually binds. Transcription proceeds in the 5′ to 3′ direction, extending beyond the region of unique-sequence DNA. The signal terminating transcription is unknown, but the sequence AATAAA is consistently observed 15–30 bases 5′ to the site at which the polyadenylated [poly(A)] tail will be added.

Post-transcriptional events

The entire sequence (5′ region, unique-sequence region with its intervening repetitive sequences, 3′ region) is transcribed into mRNA in a 5′ to 3′ direction. Several post-transcriptional processes are necessary before the protein can be translated because the nucleotide sequence is discontinuous with respect to sequences coding for amino acids. A precise splicing mechanism exists to excise the noncoding intervening sequences (introns); the nucleotides GT on the 5′ side of the intervening sequence are removed (intron) along with nucleotides AG on the 3′ side (see Fig. 20.6). The remaining sequences are thus the coding sequences (exons).

Translation

Once the introns are excised, the transcribed mRNA can direct polypeptide synthesis (translation). The first step in translation is that mRNA moves into the cytoplasm to associate with ribosomes, which are structures consisting of both protein and a special high-molecular-weight RNA (ribosomal RNA, or rRNA). Adenosine triphosphate next reacts with the carboxyl end of specific amino acids to form an amino acid-specific transfer RNA that lines up on the ribosome complex at the point signified by its appropriate codon. The amino acids that make up the polypeptide chain are thus brought into correct sequence.

Molecular analysis of the gene and its clinical applicability

Analytical techniques

Understanding how molecular genetics can be used for pre-natal diagnosis requires a knowledge of analytical techniques. Here, several pivotal techniques are briefly described.

Southern blotting

DNA fragments of differing size can be distinguished using a technique called *Southern blotting*. DNA is digested by

restriction endonucleases (see Restriction endonucleases), which are enzymes present in bacteria that are capable of cutting specific nucleotide sequences to yield fragments of reproducible (and manageable) lengths. The fragments are allowed to migrate through an agarose gel; heavier DNA fragments are less mobile and remain near the origin of the gel, whereas lighter fragments migrate faster and thus are further from the origin (Fig. 20.7). The gel is laid on a piece of nitrocellulose filter paper, and buffer is allowed to flow through the gel into the nitrocellulose filter. DNA fragments concomitantly migrate out of the gel and bind to the filter, creating a replica of the DNA fragment pattern. The nitrocellulose replicate is exposed to a specific gene probe (see Gene probes), which hybridizes only to the portion of the filter containing its complementary DNA. To identify the bound fragment and its length, the probe is made radioactive or, more commonly, is biotinylated. Thus, a gene (or, more specifically, a DNA sequence that is part of a gene) can be identified among thousands of fragments that have been categorized according to length.

Gene probes

For a specific gene (or, more precisely, a specific DNA sequence) to be located among thousands of DNA fragments, DNA probes are created from cloned DNA. Probes of unknown sequence (anonymous) can be generated, but, in the present context, we are concerned with diagnostically useful probes. If purified mRNA is available, single-stranded DNA probes can be generated using an enzyme called *reverse transcriptase*. This enzyme, present in viruses whose hereditary information is RNA not DNA, directs the synthesis of DNA from RNA (the reverse of the situation in humans). Exposing human mRNA to viral reverse transcriptase produces *complementary* single-stranded human DNA called *cDNA*. This cDNA is injected into a vector that is able to replicate the foreign DNA as well as its own. Bacteriophages, various synthetic systems (plasmids and cosmids), and yeast artificial chromosomes can all be used as vectors. The presence of a disorder that is characterized by the absence of DNA can be detected by determining whether or not a DNA probe for the normal gene hybridizes to an individual's DNA. If it does not, the DNA sequence must be missing (gene deletion) and the individual must be affected. It is also possible to construct short oligonucleotide- or allele-specific DNA probes of usually 15–20 nucleotides in length. These sensitive probes hybridize only to sequences that are complementary for every single nucleotide. If only a single nucleotide is absent (or altered), the oligonucleotide probe will fail to hybridize.

Polymerase chain reaction

The polymerase chain reaction (PCR) has revolutionized molecular biology. In PCR, a target sequence of up to 1 kb can be quickly amplified by 10^5 to 10^6 times. The prerequisite

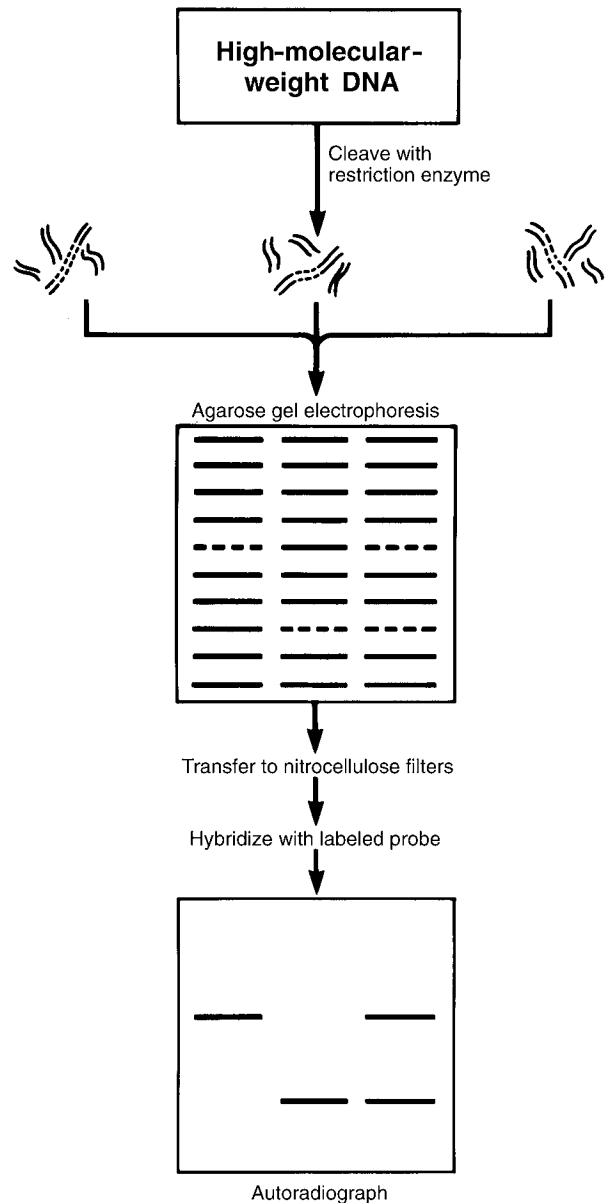

Figure 20.7 Southern blotting. DNA is cleaved with restriction enzymes, and the DNA fragments are separated by size, using agarose gel electrophoresis. The gel is then laid on a piece of nitrocellulose, and buffer allowed to flow through the gel onto the nitrocellulose. DNA fragments migrate out of the gel and bind to the filter. A replica of the DNA fragment pattern of the gel is thus created on the filter. The filter can then be hybridized to a suitably labeled probe, with DNA fragments that hybridize to the probe signaled by autoradiography or other techniques. (From ref. 29.)

for this amplification is the identification of unique DNA primers that flank and are specific for the DNA region to be amplified. This region may consist of a part of a gene (e.g., that containing a mutation), a polymorphic DNA sequence closely linked to a given locus, or a repetitive DNA sequence characteristic of a chromosomal region (e.g., the Y long arm).

A heat-stable DNA polymerase extracted from *Thermus aquaticus* is traditionally used in PCR (thus, the term *Taq* polymerase), but other enzymes can also be used. The target DNA, unique primers, and *Taq* polymerase are added together. When the temperature is raised, denaturation into single-stranded DNA occurs. On cooling, amplification occurs. Repetition of this cycle results in the DNA between primers increasing in logarithmic fashion. Other sequences are amplified but only increase linearly; thus, they are soon inundated by the exponential increase in the sequence flanked by the primers.

Restriction endonucleases and restriction fragment length polymorphisms

Restriction endonucleases are bacterial enzymes that recognize and cut specific nucleotide sequences in double-stranded DNA molecules. The sites at which DNA is cut are called *restriction sites*. Over 200 restriction enzymes have been identified, each recognizing a unique sequence of bases. DNA fragments resulting from digestion with restriction enzymes differ in length according to the distance between recognition sites; the greater the distance between sites, the longer the length of intervening DNA. *Restriction fragments* are specified according to the numbers of bases (e.g., 8000 bases or 8 kb). Usually, there is more than one restriction site per gene, but occasionally the sites are situated in such a way that an entire gene lies between two sites. If a gene contains more than one restriction site, its DNA will be digested into fragments of different lengths.

DNA from ostensibly normal individuals does not always show the same spectrum of DNA fragments after exposure to a particular restriction enzyme. Among individuals in the general population, differences in DNA sequence exist which confer no advantage or disadvantage. Thus, polymorphism exists with respect to the presence or absence of restriction sites (these polymorphisms contrast with differences in DNA sequence that cause disorders such as sickle cell anemia). This phenomenon is termed *restriction fragment length polymorphism* (RFLP). RFLPs provide markers for linkage analysis. If a given RFLP is closely linked to a locus that confers a disease, linkage analysis to detect the presence or absence of a disorder may be possible. Because RFLPs exist every few centimorgans, linkage analysis allows prenatal diagnosis for all loci in which the family is informative and the gene has been localized. RFLP linkage analysis forms the basis for prenatal diagnosis for many disorders in which the molecular basis is either not known or cannot practically be sought.

The types of DNA polymorphism now most commonly used for linkage analysis are dinucleotide repeats. For example, does a given locus on a particular chromosome have 5, 7, 10, 12, or more repeat sequences of cytosine–adenine (CA)? The number of repeats is inherited in a mendelian fashion.

RFLPs can be used in prenatal diagnosis to detect mutations if a mutation alters a specific restriction enzyme site, or results

in a new site. For example, in sickle cell anemia, codon 6 (the triplet signifying the sixth amino acid) has undergone a mutation from adenine to thymine. The restriction enzyme *MstII* recognizes the normal nucleotide sequence but not the mutant sequence. After digestion with *MstII*, hybridization of the digested DNA to a β -globin DNA probe can differentiate DNA containing the mutant gene from DNA containing the normal gene. The probe highlights a longer fragment in the mutant DNA as a result of the missing restriction site.

If the nucleotide sequence responsible for a given disorder is not known, a combination of linkage analysis and molecular techniques is used. If the mutant gene has been localized to a chromosome but not isolated, a nearby RFLP can serve as a marker. It is also possible to use polymorphic markers, such as the number of tandem repeats of nucleotides. To apply linkage analysis, one must determine whether an informative situation exists in the family. Figure 20.8 illustrates the approach used when an informative RFLP polymorphism does exist. The normal allele is signified by the presence of a 5700-bp fragment, whereas the mutant is signified by the presence of 3300- and 2400-bp fragments. Recall that the RFLP pattern that connotes an affected fetus in this family may show just the opposite in another family. The RFLP merely serves as a marker; its presence or absence is functionally independent from the disease. The same principles would apply if the polymorphic locus being used for linkage were a varying number of tandem repeats.

Polygenic–multifactorial inheritance

Genetic tendencies, rather than shared environmental factors, are very often responsible for physiological and anatomical variation, as well as for common anomalies affecting a single organ system (e.g., cleft palate); most of the latter show recurrence risks of 1–5% for first-degree relatives (siblings, offspring, parents). This can also be deduced from twin studies; monozygotic twins are much more likely to be concordant for any given anomaly than dizygotic twins. Both monozygotic and dizygotic twins are exposed to the same intrauterine environment; thus, genetic factors must be invoked to explain the differences.

Basis of polygenic inheritance

The logical explanation for either anatomical or physiological variation in a trait whose recurrence risk is 1–5% is the involvement of several genes. To illustrate, let us consider how the number of genotypic classes changes as the number of genes influencing a single characteristic increases. Suppose that only one gene controls a trait and that this gene has only two alleles, A and a. In the simplest case, the frequency of allele A equals the frequency of allele a. Thus, 25% of the population is AA ($p = q = 0.5$; $p^2 = q^2 = 0.25$), 25% is aa, and 50% is Aa ($2pq = 0.5$). If two genes influence the trait, alleles B and b

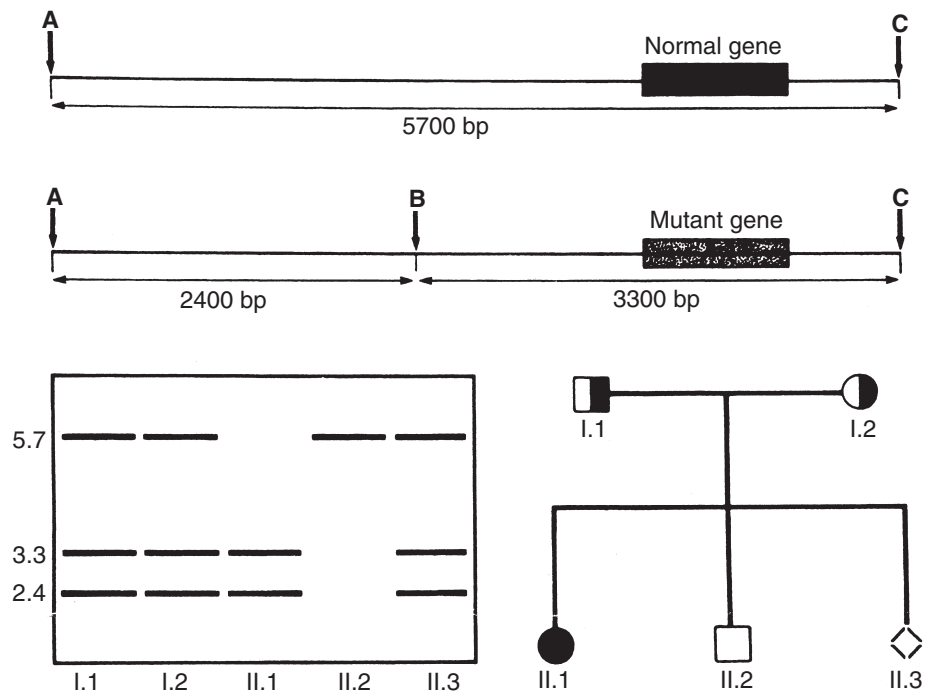

Figure 20.8 Prenatal diagnosis is achieved by use of a restriction fragment length polymorphism linked to the locus causing a disease. Suppose a restriction site (B) is closely linked to a gene. This restriction site is present in some individuals but not in others (polymorphism). A probe that hybridizes to DNA containing the polymorphic site identifies 2400-bp and 3300-bp fragments in individuals with the restriction site but identifies only a single 5700-bp fragment in those without the restriction site. On agarose gel electrophoresis, individuals homozygous for the restriction site display two bands (II.1). Homozygous individuals lacking the

restriction site display only one band (II.2). In this family, parents (I.1, I.2) are doubly heterozygous. They are each heterozygous both for the restriction site and for an autosomal recessive mutant (pedigrees). DNA analysis of the affected child (II.1) shows only two bands (3300 and 2400 kb). We can conclude that, in both parents, the mutant gene is located on the chromosome characterized by the presence of restriction site B. DNA analysis reveals that their unaffected son (II.2) is not heterozygous but homozygous normal. DNA analysis from amniotic fluid cells or chorionic villi reveals that the fetus (II.3) is normal but heterozygous. (From ref. 29.)

will be present at the second locus. Nine genotypes are now possible: AABB, AABb, AAbb, AaBB, AaBb, Aabb, aaBB, aaBb, and aabb. The population will contain nine distinct classes of individuals if A, B, a, and b all exert dissimilar influences (Table 20.4). Therefore, as the number of genes controlling a trait increases, the number of genotypic classes increases rapidly. If one gene has two alleles, there are three classes. If two genes exist, each with two alleles, there will be nine classes and thus nine histographic bars. If one continues to represent histographically the proportion of individuals in each genotypic class, normal distribution will be approximated as more and more genotypes become possible (Fig. 20.9). Thus, continuous variation is approximated in the population. A trait controlled by more than one gene is said to be inherited in polygenic fashion (Table 20.5). With the availability of molecular techniques, the scientific validity of these assumptions has been substantiated. Infrequently, one gene exists which has a major effect, with several other genes having lesser effects.

Although the term *polygenic inheritance* is often used synonymously with continuous variation, the latter may also result from other mechanisms, namely a single multiple-allele

Table 20.4 Relationship between the number of genes controlling a trait and the number of classes of individuals in a population.

Number of genes	Classes of individuals	Number of classes
1 (A, a)	AA, Aa, aa	3
2 (A, a; B, b)	AABB, AABb, AAbb, AaBB, AaBb, Aabb, aaBB, aaBb, aabb	9
n		3^n

From ref. 28.

locus influenced by environmental factors. If environmental as well as genetic factors influence a trait, the term *multifactorial* is more appropriate. Polygenic and multifactorial inheritance cannot usually be distinguished in humans, although comparisons between monozygotic and dizygotic twins theoretically permits such a distinction.

Polygenic-multifactorial inheritance is invoked to explain the inheritance of normal anatomical and physiological variables that display *continuous variation*, such as height, skin color, hair color, blood pressure, age at menarche, and ability

Figure 20.9 Histograms showing relative proportions in the population of individuals having the different genotypes that would be produced if two genes influence a trait and if each gene has two alleles. Further, each gene is comparable in effect, that is, $A = B$ and $a = b$. However, A and B exert a different effect than a and b . The graph approximates normal distribution. (From ref. 28.)

Table 20.5 Common polygenic–multifactorial traits.

Neural tube defects (most cases)
Hydrocephaly (most cases)
Cleft lip, with or without cleft palate
Cleft lip (alone)
Cardiac defects (most types)

Ureteral anomalies
Hypospadias
Posterior urethral valves
Uterine (müllerian fusion) defects (probably)
Hip dislocation
Limb reduction defects
Talipes equinovarus (clubfoot)

to metabolize a given drug or toxin. However, polygenic inheritance alone does not explain discontinuous variation in which the population consists of two discrete groups, one affected (e.g., cleft palate) and one unaffected. There exists no continuum in the population for such traits. To explain such dichotomy (discontinuity), one must postulate a threshold beyond which the accrued genetic liability for developing a specific trait becomes so great that a malformation is manifested (Fig. 20.10). Phenotypically normal parents delivered of a child with a polygenic–multifactorial trait (anomaly) are assumed to have genetic liabilities nearer the threshold than most other individuals in the general population. This model is biologically reasonable if “liability” reflects the rate of embryonic growth. A slow rate of growth may preclude a key embryonic step from occurring by a crucial time, thus leading to anomalous development.

Figure 20.10 Schematic presentation of one model for polygenic or multifactorial inheritance, assuming a threshold beyond which liability is so great that an abnormality is manifested. Parents of affected individuals presumably have a greater liability (i.e., are closer to the threshold) than most other individuals in the population.²⁸

Diagnosis of single-gene disorders

The previous sections of this chapter have reviewed the major mechanisms that result in genetic disorders and general approaches to their diagnosis. The following sections will examine specific approaches to the diagnosis of single-gene or mendelian disorders.

Single-gene disorders represent a large group of conditions that number in the hundreds and that are individually infrequent and often rare. Diagnosis depends mostly on gene analysis (i.e., DNA analysis) or analysis of a gene product, and occasionally on effects secondary to deficient gene function.

Multifactorial or polygenic disorders have complex etiologies, often depicted as combining small effects of several hypothetical factors. Neural tube defects, facial clefts, and dysplastic kidneys are examples of disorders in this category. At present, successful prenatal diagnosis of a multifactorial disorder is usually accomplished by sonographic imaging of altered anatomy. It may be that, eventually, a small number of genetic or nongenetic factors, perhaps as few as one or two, may be recognized as having the major causative role in generating an anomaly; that factor or factors could then become the target for diagnostic efforts. Prenatal diagnosis of multifactorial disorders may come to resemble the laboratory-based diagnosis of chromosomal and single-gene disorders if progress is made in this direction.

The continuing and rapid progress in molecular and biochemical genetics means that it is futile to make any attempt to compile a complete list of either possible diagnoses or the appropriate methodology to make a specific diagnosis. The list changes continually, especially as new genes are discovered. When an obstetrician or genetic counselor is faced with questions in this area, it is necessary to consult with specialists or refer to a prenatal diagnosis center.

Screening for recessive disorders

Most recessive disorders are rare, especially those associated with severe morbidities. Except in inbred communities, they often appear in a family as a first occurrence without other members being affected. When they recur, they do so in siblings. For several disorders, screening programs have been developed for potential parents; this will allow them to be prewarned about first occurrences and enable decisions to be made about prenatal diagnosis. Different paradigms have evolved for these programs in different locales. Some programs address both members of a couple simultaneously; other programs address one member initially, and the second only when the first person is shown to be a carrier. Although carrier screening and the counseling that must accompany it are ideally accomplished before conception, very often they occur in the early months of an ongoing pregnancy.

The frequency of recessive mutations among population groups depends on the disorder. These differences may result in targeting certain population groups that have a high carrier frequency for an autosomal recessive disease. The first carrier screening programs addressed Tay–Sachs disease in people of Ashkenazi Jewish heritage, and hemoglobinopathies (sickle cell disorders and thalassemias) in people of African, Mediterranean, and South Asian heritages. In the case of X-linked disorders, a screening program would test only women because hemizygous men would show obvious morbidities.

Methods of diagnosis

This section will describe the major methods used in diagnosis and the groups of disorders that are diagnosable today, with specific examples from each. For further details, the reader is referred to textbooks on prenatal diagnosis,^{15,16} online resources for single-gene disorders,^{17,18} and a catalog that lists prenatally diagnosed conditions.¹⁹

The primary abnormality in a single-gene disorder lies in the structure of the gene or, less often, in a controlling element of that gene. The simplest method of diagnosis is usually analysis of the gene, and this has become possible for over 200 genes. For many disorders, however, the gene is either not known or has not yet been isolated and studied, so other diagnostic strategies are necessary. These parallel the methods of postnatal genetic diagnosis that have been established for many decades. Even when a gene has been isolated and studied, at times a more efficient diagnosis of a disease state will be made by analysis of the gene product or some other effect secondary to the primary gene defect. This is the case, for example, when a disease state arises from a large number of different mutations in a specific gene (allelic variation or allelic heterogeneity) or when the disease state arises from mutations in more than one gene, each affecting a final common pathway that leads to disease expression (genetic

heterogeneity). Thus, a number of strategies that are one or more steps away from the primary gene defect have been used.

At present, most prenatal diagnoses of single-gene disorders require tissue or cells that contain the fetal genome and fetal gene products, usually cells external to the fetus itself but within the womb. These are recovered by amniocentesis or chorionic villus sampling. Occasionally, cells obtained directly from the fetus via fetal blood sampling (cordocentesis) or fetal organ biopsy (from skin, liver, or muscle) are required. Use of the least dangerous approach that will achieve accurate information is axiomatic to the discipline of prenatal diagnosis. Thus, fetal organ biopsy is rarely used, being reserved for situations in which a disease is expressed in that organ but not in amniotic fluid cells or chorionic villi. Diagnostic techniques that avoid entry into the uterus altogether are preferable. This has become possible with progress in the isolation of fetal cells and fetal nucleic acids (DNAs and RNAs), which cross into the maternal circulation and can be recovered from a small sample of the pregnant woman's blood.^{20,21}

The field of pre-implantation diagnosis, in conjunction with *in vitro* fertilization, is also being developed. In this technique, the diagnosis of a single-gene disorder is based on DNA analysis of either polar bodies or a single cell aspirated from an embryo before that embryo is transferred into the womb. Many aspects remain under active investigation, including the diagnostic accuracy, success of the methods, and safety of the procedures. A few errors have occurred, but over 1500 babies have now been born with correct pre-implantation diagnoses. Of mendelian disorders, cystic fibrosis has been the most frequently addressed.

In addition to the analysis of genes and gene products, several other approaches are used that depend on expression of the disease phenotype. Sometimes, they are not applicable at the early stages of pregnancy but must await expression of the disease as the fetus develops. These approaches include sonographic imaging and magnetic resonance imaging (MRI), embryo fetoscopic imaging, measurement of metabolite concentrations, histology of biopsies, and chromosomal analysis.

Sonographic imaging

Pedigree analysis has established single-gene mutations as the presumed or probable etiology of a large number of malformations and birth defect syndromes.²² Pathogenetic events take place during embryogenesis, leaving malformations as evidence of an earlier cell malfunction. Visualization of altered anatomy by sonographic imaging or MRI can be used to reach a diagnosis.

Certain genetic malformation syndromes will always manifest an anatomical abnormality. For example, type II osteogenesis imperfecta, which is most often a dominant disorder resulting from mutations in type I collagen genes, results in compacted, deformed limb bones by the second trimester. In other syndromes, one particular manifestation is much less constant than another. A cardinal feature of the recessive

disorder chondroectodermal dysplasia (Ellis–van Creveld syndrome) is the presence of six fingers, whereas heart defects occur in only approximately one-half of cases. The recessive disorder Meckel–Gruber syndrome usually shows the triad of encephalocele, polydactyly, and cystic kidneys, but any one of the three may be absent or rudimentary in a specific case. The variability in disease expression, and the time during gestation at which altered anatomy occurs and can be visualized, become crucial factors in diagnosis by ultrasound or MRI. Thorough knowledge of the disease and its expression are important. In many circumstances, positive findings can be accepted as establishing a diagnosis but negative findings will not exclude a diagnosis. When family history shows a high risk for an inherited malformation syndrome, that specific diagnosis can be inferred from an abnormal finding. Without the family history, the same finding can result in several considerations in a differential diagnosis.

Embryo fetoscopic imaging

Direct optical visualization of the fetus in the second trimester by fetoscopy was introduced in the 1970s. It had the capacity to visualize the surface of the fetus and allow diagnoses based on anatomical findings. The advantage of fetoscopy over sonographic imaging was in viewing small areas of anatomy such as the tips of the digits, details of the genitalia, or features of facial anatomy. Syndactyly, hypospadias, or preauricular sinuses could be visualized, enabling the diagnosis of a malformation syndrome that was beyond the capability of ultrasound. The embryo can now be visualized with an endoscope during the first trimester.²³ Today, these techniques are rarely used for prenatal diagnosis because of the risks associated with them and the increasing sophistication of sonographic imaging and MRI.

Metabolite analysis

Inborn errors of metabolism, in which there is typically a block in a metabolic pathway, can usually be characterized by an accumulation or deficiency of one or more metabolites. Measurements of metabolites in the blood or urine of the pregnant woman have not been useful, but analysis of fluids or tissues from the fetal compartment offer a much better opportunity for diagnosis. Here, metabolites can be obtained before they are acted on by maternal dilution or metabolism. Several disorders, including methylmalonic acidemias and propionic acidemia, have been accurately diagnosed solely through measurements of metabolites in amniotic fluid. Canavan disease, galactosemia, and adrenogenital syndrome resulting from 21-hydroxylase deficiency are also diagnosable in this way. However, extensive efforts are required to establish these diagnostic methods. The range of concentrations of metabolites from normal fetuses and fetuses with disease must be established although the number of pregnancies at risk for most inborn errors of metabolism is very small.

Histological examination

Tissue biopsies have played a limited role in prenatal diagnosis. The two tissues that are usually available with low risk to the fetus are cells from the amniotic fluid and chorionic villi (placenta), neither of which is part of the fetus *per se*. Unfortunately, uncultured amniotic fluid cells are a variable mixture of many cell types which, in the second trimester, are dominated by desquamated epithelial cells in varying stages of disintegration. Fetal blood sampling and skin, liver, and muscle biopsy increase the risks of miscarriage and fetal demise. Diagnoses based on histology have come from skin biopsies that can be used to assess the presence of inherited skin diseases, including ichthyoses, epidermolysis bullosa syndromes, and ectodermal dysplasias. Because these and other diseases with distinctive histopathology are often defined by abnormal genes, DNA tests are supplanting biopsies for many diagnoses.

Chromosomal analysis

A few single-gene disorders show chromosomal abnormalities when cells are examined by cytogenetic techniques, e.g., chromosome breakage syndromes, Fanconi pancytopenia syndrome, and Roberts–SC phocomelia syndrome, which is characterized by the premature separation of dividing chromosomes at centromeres.

Small chromosomal deletions have been described that are associated with defined clinical syndromes. The underlying defect is the absence of several contiguous genes. One of the absent genes may be largely responsible for the phenotype, or the disease expression may reflect the absence of two or more genes. Examples of contiguous gene deletion syndromes are Miller–Dieker syndrome, with a microdeletion on chromosome 17p, and DiGeorge velocardiofacial syndrome, with a microdeletion on chromosome 22q. If the disorder does not preclude reproduction, dominant transmission can be seen in a family. Increasingly, diagnosis utilizes DNA probes and hybridization with single probes or microarrays.

Another situation involving an unusual status of chromosomes is that of uniparental disomy (UPD), in which both members of a chromosome pair have originated from a single parent. Prader–Willi syndrome can be caused either by a microdeletion on the paternally inherited chromosome 15q when there is biparental disomy for chromosome 15 or by maternal uniparental disomy. In either case, the result is the absence of paternal genes in the Prader–Willi region of chromosome 15; these genes are imprinted and the absence of paternal copies leads to the syndrome. Diagnosis of UPD requires DNA analysis that compares the DNA of each parent with that of the fetus.

Gene products

Single-gene disorders are most often defined by a deficiency, alteration, or excess of a gene product. The analysis of gene

products continues to be important in both postnatal and prenatal diagnosis, even in this age of gene analysis and description of specific gene mutations. Gene product analysis has a major advantage when a disease shows important allelic or genetic heterogeneity.

Today, most gene products that are associated with a disease process are proteins or peptides. Abnormal RNAs as gene products have not yet become important in genetic diagnosis. In single-gene disorders, protein analysis usually involves the measurement of enzyme activity; occasionally, physical attributes of the protein, such as electrophoretic mobility or recognition of the protein by antibodies, are analysed. The large majority of prenatal diagnoses based on protein gene products use amniotic fluid cells and chorionic villi. Occasionally, another specialized tissue, such as liver or blood cells, is required because of limited expression of the gene, e.g., globins are expressed only in red blood cells.

Healthy, living tissue is usually necessary for accurate protein analysis. Amniotic fluid cells, obtained by amniocentesis, are almost always cultured to provide this healthy tissue. Biopsies of chorionic villi or blood cell aspirates, on the other hand, consist almost entirely of healthy cells and thus can be used without being cultured as well as being used as a source of cultured cells. Because the culture process takes many days, analyses on uncultured biopsies have the advantage of providing a more rapid diagnosis.

Gene analysis

To understand a genetic disease at the molecular level, the gene responsible for the disease must be isolated and molecular abnormalities demonstrated in that gene. This has been successful for many single-gene disorders; thus, DNA analysis has become the dominant method for prenatal diagnosis of these conditions. Examples of common disorders include cystic fibrosis, fragile X syndrome, Duchenne–Becker muscular dystrophy, and most hemoglobinopathies.

Gene analysis usually begins with an initial phase of gene mapping, in which the gene's approximate location on a chromosome or its relation to neighboring genetic material is determined, followed by the eventual isolation of the gene and documentation of its mutations. During the first phase, DNA analysis depends on linkage relationships to neighboring markers that can be followed from the parents to the fetus. These markers are known as RFLPs or tandem repeat polymorphisms. Because linked markers rather than the disease gene itself are being followed, the relationship of these markers to the mutant and normal alleles of the disease gene must be established individually for each family that requests prenatal diagnosis. Major limitations include the possibility that RFLPs may be unavailable in a given family to distinguish mutant and normal alleles (e.g., if all family members have the same polymorphic allele, the polymorphism is not informative in that family), a family member who is crucial to establishing linkage relationships is not available, and meiotic crossover events

occur between the linked marker and the gene of interest. The last limitation becomes minimized if informative markers are sought on both sides, thus flanking the gene of interest.

When the gene and its structure are known and mutations have been discovered, there is a possibility of direct DNA diagnosis based on the mutations present in the family. Family studies should be initiated well before prenatal diagnosis is necessary, although direct gene analysis can sometimes be accomplished during pregnancy for disorders in which there has been intensive study of the gene and its mutations. In most circumstances, fetal DNA is obtained from chorionic villi or amniotic fluid cells. Sometimes, uncultured amniotic fluid cells will not provide sufficient DNA of requisite quality, and diagnosis must await a period of cell culture. This delay is usually not necessary when chorionic villi are used. The polymerase chain reaction provides a method of amplifying tiny amounts of DNA and can help to minimize the time to diagnosis. In the future, fetal cells or fetal nucleic acids (DNA or RNA) recovered from the maternal circulation will probably become an alternative to chorionic villi and amniotic fluid cells.

Prenatal diagnosis of specific disorders

The following sections list specific disorders that can be diagnosed prenatally. The lists are not complete, and new information is constantly appearing. It is especially important to consult with specialists in prenatal diagnosis when dealing with single-gene disorders, because there are hundreds of disorders and sometimes several possible methods by which a diagnosis may be made. Texts relating to this specialty and on-line sources are also available.^{15–19} As more and more genes are isolated and previously unknown gene products discovered, it is becoming possible to diagnose disorders for the first time. In addition, different and improved methods may become available to improve the accuracy, safety, or timing of a diagnosis.

Another caveat for the diagnosis of single-gene disorders is the absolute requirement for an accurate diagnosis in a proband or gene carrier in the family, in order to apply many of the diagnostic tests. For example, if an enzyme assay or a mutation analysis is to be used, it must already be known from prior studies in the family that the proposed test is the appropriate one. Correct information about paternity is also required, sometimes for several matings in the family, if a DNA linkage method is being used.

Malformation syndromes

Sonographic imaging and MRI can detect malformations of many organ systems. When a specific diagnosis is being sought because of a previously affected child, a specific demonstrable malformation can be essentially diagnostic. The absence of a demonstrable malformation is often much less reassuring about the absence of the disorder. Examples of malformation syndromes are presented in Table 20.6.

Table 20.6 Malformation syndrome.

Syndrome	Inheritance pattern*
Aqueductal stenosis	XL (and others)
Walker–Warburg syndrome	AR
Craniofacial dysostosis and craniosynostosis syndrome	AD
Holoprosencephaly	AR (and others)
Achondrogenesis	AD, AR?
Ellis–van Creveld syndrome	AR
Asphyxiating thoracic dystrophy	AR
Thanatophoric dysplasia	AD
Short-rib polydactyly syndromes	AR
Thrombocytopenia–absent radius syndrome	AR
Adult polycystic kidney disease	AD
Arthrogryposis	AR, AD
Multiple pterygium syndrome	AR, XL
Meckel–Gruber syndrome	AR
Noonan syndrome	AD
Roberts syndrome	AR

AD, autosomal dominant; AR, autosomal recessive; XL, X-linked.

*Some malformation syndromes occur sufficiently often in families to warrant designation of an inheritance pattern; they may occur sporadically as well, raising possibilities of AD inheritance if reproduction is sharply limited, or have multifactorial etiologies.

Table 20.7 Skin disorders.

Disorders	Inheritance pattern
Epidemolysis bullosa syndrome	AR, AD
Ichthyosis syndromes	AR
Anhidrotic ectodermal dysplasia	XL, AR
Sjögern–Larsson syndrome	AR
Oculocutaneous albinism	AR

AD, autosomal dominant; AR, autosomal recessive; XL, X-linked.

Skin disorders

Severe skin disorders have previously been diagnosed using skin biopsies (Table 20.7). Specific proteins and the genes associated with these diseases are being discovered so that DNA or other biochemical assays now replace histological examination of biopsies in most circumstances.

Chromosome breakage syndromes and DNA repair defects

Fanconi pancytopenia syndrome has been successfully diagnosed many times; however, the diagnosis of Bloom syndrome and ataxia-telangiectasia, which also show increased chromosome breakage, has been limited. Xeroderma pigmentosum syndromes show faulty repair of induced DNA damage;

Table 20.8 Hematological disorders.

Disorder	Inheritance pattern
β -thalassemias	AR
α -thalassemias	AR
Sickle cell disorders	AR
Hemophilia A	XL
Hemophilia	XL
von Willebrand's disease	AD
Wiskott–Aldrich syndrome	XL
Chronic granulomatous disease	XL, AR
Severe combined immunodeficiency diseases	AR, XL
Hereditary elliptocytosis	AR

AD, autosomal dominant; AR, autosomal recessive; XL, X-linked.

prenatal diagnosis based on this phenomenon has had some success. For all of these conditions, it is likely that a gene-based diagnosis will be available in the near future.

Hematological disorders

Several different types of hematological disorder have been diagnosed prenatally (Table 20.8). These include globin abnormalities (especially the thalassemias and sickle cell disorders), hemophilias, and immune deficiency syndromes. Increasingly, DNA analysis has become available for this group of disorders. Before this, fetal blood, obtained by cordocentesis, was necessary for diagnosis and this is still used occasionally, e.g., to analyze a gene product or enumerate a class of cells. Some gene products, for example the globins, are present only in red blood cells. Because fetal red blood cells are significantly larger than maternal red blood cells, an automated cell size analyzer, such as the Coulter counter and Channelyser, is used to distinguish fetal and maternal blood cells in the aspirates obtained during fetal blood sampling (Fig. 20.11).

Fragile X syndrome

After Down syndrome, fragile X syndrome is the second most frequent genetic cause of significant mental retardation in most populations. The underlying gene defect is almost always an expansion of the number of trinucleotide repeats (strings of CGGs) in the *FMR-1* gene. Normal genes have fewer than 40–55 repeats, depending upon the authority. Men and boys with more than 200 repeats (defined as a full mutation) usually show moderate to severe retardation. One-half of women and girls with full mutations show few, if any, symptoms, whereas the other one-half have severe learning disabilities or mild retardation. Some asymptomatic women and men have a fragile X allele with an intermediate number of repeats, i.e., between 55 and 200. Such premutation alleles are unstable on transmission from mother to offspring; they have a tendency

Figure 20.11 Coulter Channelyser analysis of fetal and maternal red blood cells. (A) 100% maternal; (B) 30% fetal, 70% maternal; (C) 80% fetal, 20% maternal; and (D) 100% fetal. (From ref. 30.)

to enlarge, sometimes into the full mutation with associated symptoms. This tendency to expand is not observed when a premutation allele is transmitted by a man.

Limited population screening has begun to try and identify women who carry premutation or full mutation alleles and enable them the opportunity to undergo prenatal diagnosis. Diagnosis is accomplished using DNA from chorionic villi or amniotic fluid cells. Counseling is complex given the spectrum of disease expression and a varying probability of expansion, which is dependent on the size of the mother's allele; the larger the allele, the more likely it is to expand. A further complication has been the recognition that carriers of premutation alleles may face symptoms in adulthood. Approximately 20% of women show premature ovarian failure, and older men may develop a syndrome of tremor, ataxia, and possible dementia.

Cystic fibrosis

The gene and gene product for cystic fibrosis were discovered simultaneously. There is a common mutation in the cystic fibrosis gene that is present in 30–70% of people from different ethnic populations who carry cystic fibrosis mutations. The most common mutation in non-Ashkenazi Jewish Caucasians is a deletion of the three nucleotides coding for a phenylalanine (F) at position 508 of the cystic fibrosis protein ($\Delta F508$). In Ashkenazi Jews, the most common mutation is W1282X, the X denoting a stop codon that produces a trun-

cated protein. Today, over 1000 disease-causing mutations in the cystic fibrosis gene are known. For a person carrying two mutant alleles, disease is usually expressed as a severe lung, or lung and pancreatic malfunction. For some people, however, disease is expressed as a mild lung disorder or, sometimes, solely as atresia of the vas deferens. Population screening for carriers has begun in some countries. Most protocols test for a limited number of mutations although sequencing of the entire gene is becoming increasingly available. In the USA, it is recommended to test for a panel of 23 mutations; this panel identifies 94.04% of cystic fibrosis carriers in Ashkenazi Jews, 82.29% in other non-Hispanic Caucasians, 71.72% in Hispanic Americans, 64.46% in African Americans, and 48.93% in Asian Americans.²⁴ The absence of complete carrier detection and the recognition of a much wider spectrum of disease expression than previously realized has complicated prenatal diagnosis and counseling for cystic fibrosis.

Inborn errors of metabolism

Most inborn errors of metabolism that are diagnosable prenatally are detected by measuring enzyme activities. A few disorders are diagnosed by other types of protein analysis or by the measurement of secondary effects of the metabolic block. DNA analysis is beginning to play an important role as well. Tables 20.9–20.12 list many of the inborn errors that have been diagnosed.

Table 20.9 Inborn errors of lipid metabolism.

Disorder	Inheritance pattern
Fabry's disease	XL
Gaucher's disease	AR
Tay-Sachs disease	AR
Sandhoff's disease	AR
Metachromatic leukodystrophy	AR
Adrenoleukodystrophy	XL, AR
Zellweger syndrome	AR
Krabbe's disease	AR
Mucopolidoses	AR

AR, autosomal recessive; XL, X-linked. (From ref. 31.)

Cystinosis	AR
Homocystinuria	AR
Medium-chain acyl-CoA dehydrogenase deficiency and other fatty acid oxidation disorders	AR
Canavan disease	AR

AR, autosomal recessive; XL, X-linked. (From ref. 31.)

Muscle and nerve disorders

Mapping and cloning of genes have made possible the prenatal diagnosis of several muscle and nerve disorders for which little basic information had previously been known (Table 20.13). Most of the diagnostic activity has involved Duchenne-Becker muscular dystrophy, and its gene product (dystrophin) has proved useful in clarifying the presence or absence of disease in muscle obtained by biopsy or autopsy. Spinal muscular atrophy is usually caused by mutations in the survival motor neuron (SMN) gene. This is true for the severe infantile presentation (Werdnig-Hoffmann disease) as well as for the juvenile- and adult-onset forms. Several adult- (or juvenile-) onset neurological disorders, including myotonic dystrophy and Huntington's disease, result from the

expansion of trinucleotide repeats, as occurs in the fragile X syndrome.

Mitochondrial genes

In mitochondrial disorders, one or more of the functions of mitochondria are seriously impaired as a result of either abnormal nuclear genes inherited in the usual mendelian manner, or abnormal mitochondrial genes. Mitochondrial genes, which reside within the mitochondrion, are inherited solely from the mother via the cytoplasm of the oocyte.

Common mutations of these genes include point mutations, and small and large deletions. A pattern of maternal transmission of disease may be evident in a family pedigree. Satisfactory methods for the prenatal diagnosis of diseases caused by mutant mitochondrial genes are still being developed. The situation is complicated by the fact that cells contain many mitochondria and, hence, many copies of mitochondrial genes, and by the fact that there is a mixture of inherited mutant mitochondrial genes and normal mitochondrial genes. The distribution of mutant and normal genes in various tissues and organs gives rise to a wide range of symptoms, age of onset of disease, and organs primarily affected. This complexity presents a major challenge for prenatal diagnosis.

Conclusion

Single-gene disorders represent an extremely heterogeneous category of inherited problems. Many of the features that define a disorder in postnatal life can be sought in prenatal diagnosis, but extreme care must be taken to examine the variability of expression and onset of the disorder, possible genetic heterogeneity underlying the phenotype, and accuracy of diagnosis for the family that is requesting a prenatal diagnosis. Increasingly, these disorders are being defined by genes and their mutations, and prenatal diagnosis is relying on analysis of those genes.

Key points

- Genetic disorders can result from any one of several mechanisms: numerical or structural alterations in chromosomal constitution, a mutation involving a single genetic locus (mendelian), or the cumulative effect of several genes (polygenic–multifactorial).
- Routine cytogenetic analysis usually reveals 450–500 bands per haploid set of chromosomes. At this level, each band consists of approximately 1500–2000 kilobases (kb) of DNA (1 500 000–2 000 000 bases).
- Trisomy may arise by several cytological mechanisms, but in humans it usually arises *de novo* after maternal meiotic nondisjunction.
- In a couple in which one parent has a balanced robertsonian translocation involving chromosomes 14 and 21, Down syndrome will arise in 10–15% of viable offspring of female heterozygotes and 2–4% of viable offspring of male heterozygotes.
- In a couple in which one parent has an unbalanced translocation, the risk is 10–15% for offspring of either female or male carrier.
- When a nonfamilial (*de novo*) translocation that is apparently balanced is detected in amniotic fluid or chorionic villi, the risk of the fetus being abnormal is still increased over background: 7% for reciprocal translocations and less for robertsonian translocations.
- In autosomal dominant traits, equal numbers of males and females are usually affected. The likelihood that an individual carrying a mutant autosomal dominant gene (allele) will transmit that allele to any given offspring, male or female, is 50%.
- An individual with an autosomal recessive trait is usually the product of parents who are both heterozygous (carriers) for mutation at the same locus. The likelihood that a given offspring will be affected is 25%.
- In a family in which an X-linked recessive mutant allele is segregating, individuals at risk include male siblings, maternal uncles, maternal nephews, maternal male first cousins, and certain other maternal male relatives.
- Anomalies affecting a single organ system (e.g., cleft palate) show recurrence risks of 1–5% for first-degree relatives (siblings, offspring, parents).
- The multiple contributing causes of presumed multifactorial disorders are poorly understood. Prenatal diagnosis depends largely on some phenotypic feature, usually altered sonographic anatomy, and not on gene analysis.
- Screening potential parents to identify carriers of serious recessive disorders has evolved because most of these disorders are infrequent and the disease has yet to appear in the family.
- By 2006, recessive gene screening programs were commonly available for cystic fibrosis, hemoglobinopathies, and Tay–Sachs disease. Several other disorders characterized by an increased frequency in the Ashkenazi Jewish population along with a limited number of common mutations also had screening available.
- Fetal diagnosis using gene analysis (DNA analysis) can be carried out using cells from chorionic villi (placenta) or amniotic fluid. In the future, it may be possible to separate fetal DNA or RNA from maternal blood for fetal diagnosis.
- Many gene products (proteins) are present in chorionic villi or amniotic fluid cells and, therefore, fetal diagnosis can use these tissues for assays of enzyme activities and other protein characteristics.
- Most single-gene disorders that are expressed as anatomical abnormalities cause abnormalities that are also seen as isolated birth defects which are not part of a genetic syndrome (e.g., cleft lip, omphalocele, heart defect). If the *a priori* risk for a genetic syndrome is high based on family history, the diagnosis of a syndrome from the anatomical finding is very likely;

if the a priori risk is low, diagnosis is much less likely.

- 17 For mendelian disorders that are expressed by abnormal anatomy, there is usually considerable variability in the abnormalities in both structure and time of appearance during development; there is even variability in whether a given abnormality will be present or not.
- 18 Microdeletions or microduplications of small chromosomal segments that cause contiguous gene syndromes are diagnosable using DNA hybridization, often with microarray technology.

- 19 Uniparental disomy (UPD), when both members of a chromosome pair come from one parent (e.g., in Prader–Willi or Angelman syndromes), requires comparison of fetal DNA with parental DNA.
- 20 When gene mutations cannot be determined in a family at risk for a single-gene disorder, yet mapping of the causative gene has been accomplished, linkage analysis using restriction fragment length polymorphisms (RFLPs) or single nucleotide polymorphisms (SNPs) can often provide a very accurate diagnosis. A careful study of the family, often involving several members, is an absolute requirement in these circumstances.

Genetic counseling in prenatal and perinatal medicine

Jeff Milunsky and Aubrey Milunsky

There is no family, and hence no pregnancy, in which genetic factors can be ignored. Normal body structure and function are direct consequences of multiple gene action that is frequently conditioned by environmental interaction. Indeed the maternal milieu of the fetus is now increasingly recognized as not only influencing growth and development but also in some way seeding the origins of disease in adulthood.¹ Hypertension, type 2 diabetes, obesity, breast and prostate cancer, and coronary artery disease are but a few examples of disorders causally connected to fetal influences. Not unexpectedly, genetics has a role in virtually every illness: in causation, predisposition and susceptibility, immune response, modulation, or reaction to medical treatment. Determination of genetic susceptibilities reflects the widening scope of molecular diagnostics, which, in turn, has increased opportunities for predictive, preconception, preimplantation, and prenatal diagnosis. These advances are important as each of us carries some disadvantageous (and advantageous) genes. About one in 13 conceptions results in a conceptus with a chromosome abnormality and about 50% of first-trimester spontaneous abortions are associated with chromosome anomalies.² Live-born infants have a 0.4% rate of clinically significant chromosome defects and an additional 0.2% rate of balanced chromosomal rearrangements.^{3,4} Some 3–4% of all births are associated with a major congenital malformation, mental retardation, or genetic disorder, a rate that doubles by 7–8 years of age, given late-appearing and/or late-diagnosed genetic disorders.⁵ The burden of genetic disease is sufficiently significant in childhood to account for 71% of hospital admissions in a major North American Children's Hospital.⁶ Cataloged single-gene traits or disorders now approximate 10 000.⁷ The extent and importance of the role of genetics in disease causation becomes apparent immediately when one includes later-onset disease, such as heart disease, hypertension, diabetes, and the polygenic disorders in general. If chromosomal, monogenic, and polygenic disorders are combined, about 60% of all sick individuals have genetically influenced diseases.⁸ It is appropriate and important that parents are fully informed of the risks they normally undertake in having a

child⁹ and about any significant additional risks of 0.5–1.0% or more.

Preconception care and counseling

Major and continuing efforts must be made to educate the public at large about the importance of pregnancy planning and, in particular, of preconception care and counseling.⁹ Our knowledge of embryonic and fetal development and the sophisticated developments of the “new genetics” make the matter more compelling than ever. Physicians need to inculcate the wisdom not only of planning pregnancy, but also of initiating care in the preconception period. Many issues that influence fetal development and maternal welfare need to be addressed at the preconception visit.

Careful attention is necessary in eliciting the *medical history and examination*. Medical disorders may be detected that have a bearing on pregnancy, fetal development, delivery, and the newborn. For example, the significance of excessive joint laxity may be recognized for the first time at the preconception visit and point to diagnoses such as the Ehlers–Danlos syndrome, with its associated complications of premature delivery and tissue fragility.¹⁰ Excess bruisability may reflect a disorder of coagulation and a history of recurrent fetal loss may signal the presence of a factor V Leiden gene mutation.¹¹ A history of unexplained syncope or a family history of sudden death should alert the physician to the possibility of the long QT syndrome.¹² In these few examples, early detection affords the opportunity to avoid potential later complications and facilitates anticipatory obstetric and perinatal management.

The preconception visit is also the time to secure *control and treatment of specific disorders* that may affect an otherwise successful pregnancy. Prospective mothers with type 1 and type 2 diabetes need help and advice to achieve tight control of their hyperglycemia. They need to understand that the poorer the control of their diabetes, the higher the frequency of congenital malformations and the more severe they may be.¹³ Women with epilepsy, in particular,

require review by their own neurologists concerning anticonvulsant medication. When appropriate, anticonvulsants could be changed to those that might pose lesser risks of fetal anomalies without risking maternal health. Women with sickle cell disease¹⁴ or cystic fibrosis,^{15,16} who face serious personal and fetal risks, need special attention and treatment to secure the best chance for successful pregnancy and survival. Recognition of systemic lupus erythematosus allows appropriate careful medical surveillance and later monitoring of the fetal and neonatal heart for early detection and treatment of congenital heart block, which occurs much more frequently in this condition.¹⁷

The *obstetric and gynecologic* history, taken at the preconception visit, provides important opportunities again for intervention. Patients with prolonged infertility of unknown cause or recurrent spontaneous abortion, who may face a 3–8% risk of a parental chromosome abnormality,^{18,19} require chromosome analysis, as do their spouses. Failure to detect a parental chromosome translocation or other rearrangement may later be followed by the conception and birth of a child with an unbalanced karyotype.

History of a previous stillbirth should raise questions about the need for parental chromosome analysis. Between 6% and 11% of stillbirths have a chromosome abnormality,²⁰ and a small portion of such cases indeed may have a transmitting parent with a chromosome rearrangement or disorder. The preconception visit, in addition, facilitates determination of whether the prospective mother is susceptible to rubella, cytomegalovirus, or toxoplasmosis, or has herpes or AIDS. Timely vaccination for rubella, where indicated, should be provided well before conception.

Nutritional considerations that bear on fetal development have become more important. Our original data indicated that multivitamins containing folic acid taken during the preconception period and continuing at least through the first 6 weeks of pregnancy reduce the frequency of neural tube defects by 70%,²¹ a conclusion confirmed by definitive double-blind randomized control studies.^{22,23} Notwithstanding uncertainty about the precise mechanism by which folic acid exerts its protective effects, there are now clear indications that 0.4 mg daily provides the necessary supplementation dose. In pregnancies that follow the conception of offspring with a neural tube defect, a dose of 4 mg daily is recommended, taken while planning pregnancy and at least through the first 6 weeks post conception.^{22,24} For the 30% of cases of spina bifida that are resistant to folic acid supplementation, additional supplementation with the B-complex vitamin inositol may eventually be shown to add protective effects.²⁵

The *clinical genetic history* focuses first on analysis of the family pedigree. An obvious pattern of inheritance may emerge without a known named disorder. For example, a *maternal* history of nephews, brothers, or uncles with unexplained mental retardation may point to sex-linked mental retardation including the fragile X syndrome. A previous living child with a specified genetic defect might require

additional diagnostic studies, parental examination, or other appropriate investigations. Carrier detection tests using DNA analysis for conditions such as Duchenne or Becker muscular dystrophy, spinal muscular atrophy, chronic granulomatous disease, and ornithine transcarbamylase deficiency are among the many disorders now approachable through molecular analysis.⁴

Attention to the patient's *ethnicity* may be the only warning to the obstetrician of potential genetic risks. Virtually all ethnic groups carry some "genetic burden."⁹ For example, Caucasians have a risk of about 1 in 25 of carrying a cystic fibrosis gene mutation. Over 1300 cystic fibrosis mutations²⁶ have been reported and screening panels for the most common mutations detect between 85% and 90% of Caucasian carriers. Physicians are now expected to offer cystic fibrosis DNA carrier tests to all couples in their reproductive years.²⁷ Laboratory standards and guidelines now exist for population-based cystic fibrosis carrier screening.²⁸ The cystic fibrosis carrier screening panel has recently been revised to reflect more current data and exclude a polymorphism that was previously thought to be a mutation.²⁹ Prenatal diagnosis can be offered only if the parental mutations are known or if the pregnancy is suspected to be at risk for cystic fibrosis (i.e., presence of echogenic fetal bowel). About 1 in 12 individuals of Mediterranean extraction carry a gene mutation for β -thalassemia. Once again, a simple blood examination for mean corpuscular volume and for hemoglobins A₂ and F will assist in carrier detection. About 1 in 30 Ashkenazi Jews carry the gene for Tay-Sachs disease, and should be routinely offered the necessary carrier detection test for this lethal degenerative neurological disorder. DNA analysis for the three most common Tay-Sachs disease mutations in this ethnic group yields a detection rate of over 98%, without the problem of false-negatives or -positives and repeat sampling that hampers the hexosaminidase assay.³⁰ About 1 in 40 Ashkenazi Jews carries a gene mutation for Canavan disease and similarly should be routinely offered the necessary DNA carrier detection tests for this severe neurodegenerative condition.³¹ For all the autosomal recessive disorders just mentioned, only if both parents are carriers would there be a 25% risk of bearing an affected child. In all these instances, prenatal diagnosis would be available.⁴ This information becomes important for individuals who might select prenatal or preimplantation diagnosis as an option or for couples who could select other reproductive choices, such as artificial insemination or ovum donation, from donors who test negative for *detectable* gene mutations.

Dramatic and continuing advances in molecular genetics increasingly enable *predictive tests* for disorders not previously detectable by any method. Hence, even asymptomatic individuals may be able to determine whether they have a particular dominant gene for which there is a risk of 50% for transmission in each pregnancy, or whether they carry autosomal or X-linked genes, with their associated risks. Selected examples of such disorders for which presymptomatic and

Table 21.1 Examples of monogenic disorders for which DNA diagnostic tests facilitate presymptomatic and prenatal diagnosis as well as carrier detection.

<i>Autosomal dominant disorders</i>	
Adult polycystic kidney disease	Multiple endocrine neoplasia
Charcot–Marie–Tooth disease type 1A	Myotonic muscular dystrophy
Familial adenomatous polyposis	Spinocerebellar ataxia type 1
Huntington’s disease	Tuberous sclerosis
Long QT syndrome	Von Hippel–Lindau disease
Machado–Joseph disease (SCA III)	
<i>Autosomal recessive disorders</i>	
α -Thalassemia	Phenylketonuria
β -Thalassemia	Sickle cell anemia
Cystic fibrosis	Spinal muscular atrophy
Canavan disease	Tay–Sachs disease
Familial dysautonomia	Wilson’s disease
Friedreich’s ataxia	
<i>Sex-linked disorders</i>	
Adrenoleukodystrophy	
Charcot–Marie–Tooth disease	
Chronic granulomatous disease	
Duchenne/Becker muscular dystrophy	
Hemophilia A	
Lesch–Nyhan syndrome	
X-linked lymphoproliferative disease	
Menkes’ disease	
Myotubular myopathy	
Ornithine transcarbamylase deficiency	
Spinal and bulbar muscular atrophy	

prenatal diagnosis and carrier detection are feasible are listed in Table 21.1. Hence, for example, once a parent is shown to carry the dynamic gene mutation for myotonic muscular dystrophy, accurate prenatal diagnosis by direct DNA analysis can be accomplished. These tests allow detection of maternal myotonic dystrophy, facilitating prenatal diagnosis, anticipation,³² optimal surveillance, and possible early intervention or prevention of the frequently serious intrapregnancy, labor, delivery, and postpartum and neonatal complications (Table 21.2).

Discovery of disorders with mutations resulting from the unstable expansion of trinucleotide repeats has rapidly escalated. The first such reports in 1991 described unstable CGG triplet repeats in males with the fragile X syndrome.³⁶ Thus far, 17 such disorders with dynamic mutations have been described and are outlined in Table 21.3. Friedreich’s ataxia is the first autosomal recessive disorder that has been described with a triplet repeat expansion in about 96% of cases.³⁷ The remaining cases are due to other mutations within the gene. It is noteworthy that the typical carrier will have one normal allele and a second expanded allele.

The genetic mechanism of anticipation refers to progressively earlier manifestation and/or more severe expression of

Table 21.2 Myotonic muscular dystrophy: potential pregnancy, neonatal, and other complications.

a disorder with succeeding generations. Anticipation is seen in several of these disorders, and can be explained by the further expansion of the specific triplet repeat. In addition to expansions, triplet repeat reversions (decrease in number of repeats) have been documented in a small percentage of cases.³⁸ When interpreting test results, the number of such repeats may be used in genetic counseling to estimate the risk of recurrence and disease severity.

Advances in human genetics continue to escalate rapidly following the completion of the Human Genome Project. Obstetricians and all physicians who care for patients in their childbearing years should remain alert to these advances. In a growing number of centers, preimplantation diagnosis may require discussion during the preconception visit. Worldwide, over 5000 cases have been accomplished, and for some individuals this is an expensive, but possible, option.^{39,40} Finally, among the more important aspects of the preconception visit is the provision of *genetic counseling*, the details of which now follow.

Genetic counseling

Genetic counseling is a communication process concerning the occurrence and the risks of recurrence of genetic disorders within a family. The aim of such counseling is to provide the patient with a clear and comprehensive understanding of all the important implications of the disorder in question, as well as the possible options. The purpose is also to help families through their problems, necessary decision making, and emotional adjustments and adaptations, where indicated. Although the physician may wish to prevent or minimize the suffering of both patient and family and to decrease the incidence of serious genetic disease, the primary strategy must be to achieve clear understanding by prospective parents, facilitating rational decision making.^{8,9,41} All prospective parents

Table 21.3 Dynamic mutations with triplet repeat expansions.

Disease	Chromosome	Repeat sequence	Size in normal*	Size in carrier*	Size in affected*
Dentatorubral pallidoluysian atrophy	12p12-13	CAG	7-34	—	49-75
Fragile X syndrome†	Xq27.3	CGG	5-54	50-200	200 to 2000
Fragile XE	Xq27.3	GGC	6-25	116-133	200 to > 850
Friedreich's ataxia†	9q13	GAA	7-40	50-200	200 to > 1200
Huntington's disease	4p16.3	CAG	6-36	—	35-121
Kennedy's disease (spinal bulbar muscular atrophy)	Xq11-12	CAG	12-34	—	40-62
Machado-Joseph disease	14q32.1	CAG	13-36	—	68-79

†Mutation may not involve an expansion.

‡Expansion involves four nucleotides.

§Expansion involves five nucleotides.

have a right to know if they have an increased risk of having children with a genetic disorder, or other defect, and what their options are. The physician's duty is to communicate this information clearly and in simple language (with a translator if required), to offer specific tests (serially, if necessary), or to refer couples for second expert opinion and to document the consultation and recommendations.

The primary reasons couples seek genetic counseling in the context of risks and prenatal diagnosis are circumscribed:

- 1 Advanced maternal age. An arbitrary age of 35 years has long functioned as the standard of expected care, at which maternal age-related risks of chromosome defects should be discussed and prenatal genetic studies recommended.⁴ Increasingly, geneticists consider it appropriate to inform parents of their risks that the fetus has a chromosome disorder based on first- and second-trimester maternal serum multiple analyte screening. Indeed, the decision about amniocentesis reflects the balance of risks between fetal loss and fetal defects. Although decisions made for or against such studies should be primarily parental, based on appropriate consultation with their physician, third-party payers continue to influence many of these decisions through cost considerations.
- 2 Maternal serum screening using four analytes. These assays yield increased odds for Down syndrome, trisomy 18, and other chromosome defects⁴²⁻⁴⁵ or indicate increased risks for neural tube defects⁴⁶ necessitating ultrasound studies that may be followed by amniocentesis.
- 3 A previous fetus or child with a chromosomal, monogenic, or polygenic disorder.

- 4 A family history of a specific familial disorder.

- 5 One prospective parent with a suspected or known chromosomal, monogenic, or polygenic disorder.
- 6 A maternal disorder with or without specific drug treatment, associated with an increased risk of congenital defects.
- 7 A known or suspected carrier state for a certain genetic disorder on the basis of previous or required tests or ethnicity.
- 8 Exposure during, or prior to, pregnancy, to potentially hazardous medications, infectious organisms, X-rays, toxins, or occupational hazards.
- 9 Known or suspected consanguinity.
- 10 The background risk of congenital defects and genetic disorders.

In general, genetic counseling is best provided by a clinical geneticist or certified genetic counselor under supervision of a clinical geneticist. In both the USA and Canada, board-certified specialists in clinical genetics and medical genetics are available for referral. If an obstetrician is well informed, he or she should be able to provide the necessary counseling for advanced maternal age and, increasingly, for abnormal maternal serum screening results. Caution should guide the physician in avoiding areas outside expected expertise. Quotation of risk figures through intuitive judgments is strictly contraindicated. Clinical geneticists who provide counseling are expected to provide a letter to the referring physician, with a copy to the patient (or two separate letters, if preferred). Either way, documentation of the key elements transmitted during counseling would be regarded as mandatory, regardless of who provides such services.

The genetic basis for counseling

Genetic disorders that affect fetal development may be chromosomal, monogenic, or multifactorial in origin. Acquired disorders that complicate fetal development (e.g., infectious diseases, medications, toxins) will not be discussed here, even although their actions may be mediated through individual genetic susceptibility. Chromosomal disorders arise as a consequence of abnormal chromosome number or from structural rearrangements of one or more chromosomes. Single-gene disorders may be inherited or arise *de novo* as a consequence of mutation. The modes of inheritance for single-gene disorders are classified as autosomal dominant, autosomal recessive, X-linked, or mitochondrial. Multifactorial disorders result from an interaction between multiple genes and one or more environmental factors. The arbitrary distinction between chromosomal and single-gene inheritance should be understood, as many examples exist in which structural alteration of a chromosome results in deletion or interruption of one or more genes. Notwithstanding such arbitrary classifications, it is simpler, when trying to determine the origin of a specific phenotype, to think in terms of the preceding categorical classification.

Chromosomal disorders

Each of our somatic cells contains 46 chromosomes, with 23 derived from each parent. There are 44 nonsex chromosomes (called autosomes) and two sex chromosomes. Females have two X chromosomes (XX) and males have one X chromosome and one Y chromosome (XY). The chromosomes can be distinguished from each other on the basis of size, location of the centromere (which divides a chromosome into long and short arms), and the unique banding pattern. Not only can subtle details of chromosome structure now be delineated (e.g., deletions), but also the origin of an extra or abnormal chromosome can be determined frequently and precisely. For example, the extra chromosome 18 in trisomy 18 derives from a maternal source in 95% of cases, whereas the structurally abnormal chromosome (with a deletion) in Prader–Willi syndrome appears to be uniformly of paternal origin. High-resolution chromosome analysis of prophase chromosomes, rather than metaphase, allows easier recognition of structural defects.

It is now recognized that individuals can inherit two copies of part or all of a chromosome from one parent and no copy from the other parent. This process, called uniparental disomy (UPD), is uncommon, but contributes to the occurrence of some well-known clinical disorders. Uniparental heterodisomy refers to the inheritance of two homologous chromosomes that originate from one parent. Uniparental isodisomy indicates that the two chromosomes inherited from one parent are identical.⁴⁷ This derivation of a pair of homologs from one parent cannot be detected cytogenetically. Molecular cytogenetic techniques using fluorescence *in situ* hybridization

(FISH), painting probes, and DNA markers facilitate detection. UPD has been described most commonly in the Prader–Willi⁴⁸ and Angelman syndromes,⁴⁹ and in addition has been reported in cystic fibrosis,⁵⁰ spinal muscular atrophy,⁵¹ mosaic trisomy 15,⁵² and robertsonian translocations.⁵³ About two-thirds of Prader–Willi syndrome patients have a recognizable cytogenetic deletion in one chromosome 15q11–q13 region. Another approximately 30% of cases are due to maternal UPD.⁴⁸ A newly recognized concern is the increased likelihood of inheriting a severe or lethal form of recessive disease in cases of uniparental isodisomy. UPD has been identified for 12 autosomes (e.g., chromosome 7 and cystic fibrosis) and the X chromosome. The indication for UPD study in most instances has been either a genetic disorder such as Prader–Willi syndrome or Angelman syndrome or an abnormality found on prenatal diagnosis, especially involving chromosomes 11, 14, and 15.^{54,55} UPD is caused primarily by meiotic nondisjunction events, followed by trisomy or monosomy “rescue.”⁵⁶

Chromosomal disorders are classified as either numerical or due to structural rearrangements. Numerical disorders are characterized by extra or absent chromosomes. For example, the most common numerical chromosome disorder in newborns is characterized by an entire extra chromosome 21, resulting in trisomy 21 (Down syndrome). Among first-trimester abortuses, an absent sex chromosome, resulting in a 45,X fetus, is the most common numerical chromosome disorder. A single cell division, soon after fertilization, may go awry, resulting in a numerical chromosome abnormality in the daughter cells of that division and, consequently, in chromosomally abnormal cells from that original stem cell. These abnormal cells continue to divide and multiply alongside the subjacent chromosomally normal cells and eventually result in an individual who has two or more different cell lines – a chromosomal mosaic. Chromosomal mosaicism is found most frequently among the sex chromosome disorders.

Sex chromosome aneuploidy is the most common chromosome abnormality present at birth, with an overall incidence of 1 in 400.⁵⁷ Its incidence at amniocentesis is even greater and is estimated to be 1 in 250 in women over 35 years of age.⁵⁸ Genetic counseling after the prenatal diagnosis of sex chromosome aneuploidy often presents a challenge even for the experienced genetics professional. Knowledge of the phenotypic variability and the range of associated developmental and behavioral problems is essential to provide the most complete counseling. Linden et al.⁵⁹ reviewed the literature and summarized current knowledge on the intrauterine diagnosis of sex chromosome aneuploidy based on seven prospective studies. Sex chromosome mosaic karyotypes are most often 45,X/46,XX, 46,XX/47,XXX, or 46,XY/47,XXY, but many other combinations are possible. The presence of a normal 46,XX or 46,XY cell line tends to modify the effects of the aneuploid cells. On evaluations of intelligence, educational intervention, motor skills, and behavioral problems, those with mosaicism scored similarly to control subjects, and no

significant differences were determined.^{60,61} Fertility may vary, depending on the chromosomal constitution. Although 46,XX/47,XXX women usually are fertile, the prognosis for 45,X/46,XX and 46,XY/47,XXY mosaics is less definite.⁵⁹ When a prenatal diagnosis of sex chromosome mosaicism is made, a thorough discussion of the expected phenotype, developmental issues and probable learning disabilities should be tempered with the statement that a specific prognosis based on karyotype for any affected child is not possible. It should be explained that mental retardation is not typically associated with sex chromosome aneuploidy, but that the affected individual's IQ is often 10–15 points less than that of siblings. Owing to the information gleaned from these important prospective studies, genetic counselors can now better assist obstetricians in providing accurate and comprehensive information to parents of affected fetuses, thereby facilitating informed decision making about pregnancy management.

Chromosome mosaicism detected prenatally may also reflect confined placental mosaicism (CPM). CPM refers to the discrepancy between the chromosomal complement of the fetus and its placenta, due to postzygotic mitotic errors during embryonic development. CPM can be detected prenatally in about 2% of viable human pregnancies at 10–12 weeks of gestation.⁶² CPM may be caused by the trisomic zygote rescue, which may then result in either a liveborn trisomic fetus or a diploid fetus. A diploid cell line, the product of the random loss of a trisomic chromosome, is expected to have UPD for the chromosome pair involved in the original trisomy in one-third of these cases.^{63,64} The most common placental–fetal dichotomy involves placental trisomy for chromosome 16.⁶⁵ In pregnancies with CPM, a general effect of trisomy in the placenta may result in some degree of placental insufficiency, which may lead to intrauterine growth restriction, pregnancy associated hypertension, or intrauterine fetal death.⁶⁶ Ultrasound monitoring of fetal growth in such cases would be appropriate.

Structural chromosome defects may result from the breakage and loss of a variable-sized piece of a long or short arm (deletion) or the breakage of two chromosomes and transfer with fusion of parts of the broken fragments onto the residual chromosomes (translocation). About 1 in 500 liveborns has a balanced chromosomal translocation, whereas an unbalanced translocation occurs in about 1 in 1675 liveborn infants.

Translocations involving the acrocentric chromosomes in one parent are associated with risks of an unbalanced translocation, ranging mostly from 4% to 20%, with higher risks for maternal carriers (Table 21.4). Reciprocal translocations between autosomes are associated, almost invariably, with much lower risks for unbalanced karyotypes, mostly below 3% and frequently around 1%. An isochromosome is formed by abnormal splitting of a centromere during meiosis. This occurs infrequently but may cause the loss of an entire chromosome arm and duplication of the remaining arm, resulting in a single symmetric chromosome with two genetically identical arms.

Duplications of either an entire region (resulting in partial trisomy of the long or short arm of a specific chromosome) or a tiny segment of a chromosome arm may result in congenital malformations, with or without mental retardation.

Chromosome inversions, which occur following breakage at two sites along a chromosome length, followed by inversion and reattachment, are not uncommon. Such inversions, which involve the centromere (called pericentric inversions)⁶⁶ or do not involve the centromere (called paracentric inversions),⁶⁷ are generally thought to be associated with a risk of 5% for congenital defects, with or without mental retardation, when they occur *de novo* (see Table 21.4). The exception is the pericentric inversion involving the long arm of chromosome 9, which appears to have no clinical significance. This “normal” chromosomal variation is present in about 1% of individuals.⁷²

Subtle chromosome deletions pose serious diagnostic difficulties when they occur *de novo*.

High-resolution chromosome analysis (prometaphase chromosomes) and FISH have increased the recognition of these microdeletion syndromes. Virtually all microdeletion syndromes are associated with serious or fatal genetic disease (Table 21.5). The finding of a microdeletion in an infant should lead automatically to chromosome analysis of both parents seeking a translocation or other chromosomal rearrangement. Individuals with mental retardation of unknown etiology need to be assessed by a geneticist, who may test for one of these microdeletion syndromes. The most common microdeletion involving chromosome 22q11.2 has been associated with several distinct genetic disorders that are known to have overlapping clinical features. These disorders include DiGeorge syndrome, velocardiofacial syndrome, isolated conotruncal cardiac defects, Cayler syndrome, and Opitz syndrome. The expanding, variable phenotype of individuals with 22q11 deletions is now recognized. These advances pose additional diagnostic and counseling challenges.

Indications for chromosome analysis

- 1 For *both* prospective parents with infertility or three or more spontaneous abortions, or two or more stillbirths.
- 2 When one parent has a chromosome abnormality (most commonly a sex chromosome defect) or is a known carrier of a chromosomal translocation or other structural rearrangement.
- 3 For all of the offspring of one parent who carries a structural chromosome rearrangement.
- 4 For the prospective parent who has genital malformations or abnormalities of sexual development.
- 5 On all stillborns (with or without dysmorphic features or malformations) or babies following neonatal death without a specific diagnosis.
- 6 In newborns with dysmorphic features, or those who exhibit serious growth restriction, with or without a single major congenital malformation.

Table 21.4 Recurrence risks for the more common chromosome disorders.

Chromosome disorders	Risk of recurrence (%)	Notes
<i>Numerical abnormalities</i>		
A previous child born with trisomy 21	1–1.5	Includes risks for all aneuploidy and applies to all women < 30 years. Those > 30 have maternal age-associated risks of aneuploidy
A previous child born with trisomy 18	< 1	
A previous child born with trisomy 13	< 1	
A previous child with Turner syndrome (45X)	Population risk	As long as mother is not a Turner syndrome mosaic, risks of recurrence will approximate population risk (1 in 2500 females)
A previous child with XXX syndrome	Population risk	As long as neither parent has sex chromosome mosaicism and mother is < 35 years, risks of recurrence will approximate population risk (1 in 1000 females)
A previous child with Klinefelter syndrome (47,XXY)	Population risk	As long as neither parent has sex chromosome mosaicism and mother is < 35 years, risk of recurrence will approximate population risk (1 in 1000 males)
A previous child with 47,XYY	Population risk	Population risk approximates 1 in 1000 males
<i>Structural rearrangements</i>

7 In infants or children with developmental delay, with or without dysmorphic features or associated malformations.

FISH allows for the microscopic visualization of specific regions of the genome in metaphase chromosomes and interphase nuclei.⁷³ Examples of the many clinical applications of FISH are illustrated in Table 21.6. Diagnostic limitations exist when an additional molecular mechanism is responsible for the disorder (see details on uniparental disomy and Prader–Willi, above). FISH has been applied to neonatal and prenatal detection of aneuploidy and structural aberrations in chorionic villus cells and amniocytes. The use of multicolor FISH has enabled the identification of cryptic translocations

previously not elucidated by routine cytogenetic analysis. These translocations may be the etiology of multiple miscarriages, stillbirths, or prolonged infertility. Using this technology, the identification of microdeletions/duplications and marker chromosomes has become routine. Additional cryptic chromosome rearrangements either at the subtelomeric ends of chromosomes or along the length of the chromosome have now been identified in patients with mental retardation with or without additional congenital abnormalities. Subtelomeric FISH and comparative genomic hybridization have identified the etiology of previously idiopathic mental retardation in up to 10% of cases.^{74–76} Once a specific abnormality has been

Table 21.5. Examples of chromosome microdeletion syndromes.

Disorder	Clinical features	Deletion site
Angelman	Severe mental retardation, ataxia, jerky movements, inappropriate laughter, absent speech	15q11–q13
Langer–Giedion	Variable mental retardation, dysmorphic facies, multiple exostoses, sparse scalp hair, cone-shaped epiphyses	8q24.1
Miller–Dieker	Severe mental retardation, lissencephaly, dysmorphic facies, vertical furrowing in forehead when crying	17p13.3
Prader–Willi	Mild mental retardation, infantile hypotonia, obesity, hypopigmentation, hypogonadism	15q11–q13
Retinoblastoma	Retinal malignancy, typical facies, possible mental retardation	13q14
Rubinstein–Taybi	Variable mental retardation, dysmorphic facies, broad thumbs/toes	16p13.3
Smith–Magenis	Mental retardation, dysmorphic facies, self-destructive behavior, microcornea, renal abnormalities, hearing impairment	17p11.2
Steroid sulfatase deficiency	Frequent stillbirths, ichthyosis, low maternal estriol in urine and plasma	Xp22
Velocardiofacial/DiGeorge	Overlapping clinical features: mental retardation, cleft palate, cardiac defects, learning disabilities, hypocalcemia, hypoplastic lymphoid tissue, T-cell deficiency, dysmorphic facies	22q11.2
WAGR	Wilms tumor, aniridia, genitourinary abnormalities, mental retardation	11p13
Williams	Mental retardation, dysmorphic “elfin” facies, cardiac defect, renal anomalies, infantile hypercalcemia	7q11.23

determined, further testing of family members including parents may yield specific recurrence risks and prenatal diagnosis opportunities.

The frequency of chromosomal anomalies in liveborn infants is illustrated in Table 21.7. Careful consideration should be given to such anomalies in all cases of aberrant fetal development, including those detected in the third trimester (i.e., intrauterine growth restriction, IUGR). Advancing maternal age is associated with an increasing frequency of numerical chromosome disorders resulting from nondisjunction and includes not only trisomy 21, but also trisomies 13 and 18, triple-X, and the 47,XXY male (Klinefelter syndrome). The

risks of recurrence, following the birth of babies with different trisomies, are shown in Table 21.4. Certainly, one numerical chromosome abnormality, caused by nondisjunction, may be followed by a different one caused by the same basic mechanism. Hence, following conception of an offspring with trisomy 21, recurrence of a numerical abnormality has been different in some 50% of subsequent chromosomally abnormal offspring.⁴ Available data suggest no increased risk of chromosome abnormality in future pregnancies after spontaneous abortions of lethal trisomies or recurrent abortion with normal parental karyotypes.⁷⁷

Monogenic disorders

Single-gene disorders occur in approximately 10 per 1000 live births, with about 7 in 1000 being due to autosomal dominant genes, about 2.5 in 1000 being due to recessive genes, and 0.4 per 1000 being due to X-linked genes. Thus far, hundreds of genetic disorders with biochemical defects have been recognized.⁷⁸ Their single mutant genes have involved mainly abnormalities in enzymes and, increasingly, specific proteins. A reduced lifespan is associated with over half of all monogenic disorders, whereas reproductive capacity is reduced in about 69% of such disorders.⁷⁸

Clinically, dominant disorders are viewed as those in which symptomatic individuals are heterozygotes, whereas those with autosomal recessive disorders are symptomatic and are considered homozygotes. The distinction between dominant and recessive disorders is largely arbitrary, but useful clinically. It is known, for example, that for the autosomal recessive sickle cell disease, heterozygotes have subtle physiologic abnormalities, affecting renal concentrating ability as well as demonstrating a selective advantage for resistance to malaria. Heterozygotes for ataxia telangiectasia are known to be at an increased risk for developing malignancy. Hence, carriers of recessive genes may manifest disorders, just as do those individuals with dominant genes. Concerning the concept of dominant and recessive genes, other subtleties are recognized. For example, in retinoblastoma (typically transmitted as an autosomal dominant disorder with virtually full penetrance) the deletion, or point mutation, on one chromosome 13 has to be associated with another mutation in the homologous allele on the other chromosome 13 for retinoblastoma to develop. In other words, “two hits” are necessary, although for this classical, dominant disorder, a recessive gene mechanism is effective. Notwithstanding continued progress in understanding complex mechanisms resulting in genetic disorders due to dominant or recessive genes, it still remains useful to consider them clinically in their well-established categories.

Autosomal dominant disorders

As the genes for autosomal dominant disorders exist on one of the 22 autosomes, both males and females may be affected. An individual who is affected has a 50% risk of transmitting

the gene to each of his or her offspring. The phenomenon of pleiotropy is especially important in this category of disorders. A single gene that has several different effects is regarded as pleiotropic (e.g., either of the genes causing tuberous sclerosis may result in retardation, achromic spots, and subungual fibromas). In contrast, genetic heterogeneity means that several genes have the same effect. A good example is deafness, which can result from many different single-gene disorders. New mutations commonly cause autosomal dominant disorders. For example, about seven out of eight individuals with achondroplasia are due to a dominant *de novo* gene mutation. Moreover, the frequency of such mutations rises with advancing paternal age. Variability in clinical expression (called expressivity) is also especially important in dominantly inherited disorders. One excellent example is the multiple endocrine neoplasia syndrome, in which individual affected family members may have either hyperplasia or malignancy or both, in various endocrine organs. Also typical of autosomal dominant disorders is the variation seen in the age of onset, even for the same condition. Hence, Huntington’s disease may manifest in childhood or not until old age, even although the mutant gene has been present from the time of conception. Molecular analysis allows determination of the presence of the mutant gene, but does not usually provide any ability to predict onset time (except for several triplet repeat disorders). Some guidance on this point is likely to emerge from a study of disease onset ages within specific families. Predictive prenatal diagnostic testing for presymptomatic adult-onset disorders poses significant challenges. Disorders such as Huntington’s disease, familial breast/ovarian cancer syndromes, long QT syndrome, familial adenomatous polyposis, multiple endocrine neoplasia and Von Hippel–Lindau syndrome all are amenable to presymptomatic and prenatal diagnosis. Prenatal testing for these serious disorders that may only manifest years to decades after birth, may also reveal the presymptomatic affected status of an at-risk parent. Preconception/prenatal genetic counseling is critically important in such cases to consider the complex issues of diagnosis, penetrance, expressivity, anticipation, heterogeneity, risks, as well as available and future treatment.

Autosomal recessive disorders

The mutant genes that cause this group of disorders are located on one of the 22 autosomes, and therefore both males and females may be affected. Clinically obvious autosomal recessive disorders exist only in the homozygous state (each parent contributing one of the mutant genes). Hence, when both parents are carriers, they have a 25% risk of having affected offspring in each pregnancy. An autosomal recessive disorder can result in an offspring inheriting the same harmful gene from each parent, even although the site of the mutation within the gene may be different. These so-called compound heterozygotes still develop the disease, but the nature of its clinical manifestations and time of onset may be altered.

Important examples include cystic fibrosis, Tay–Sachs disease, and metachromatic leukodystrophy.

Typically, the rarer the mutant recessive gene, the greater the likelihood that those affected will result from consanguineous unions, or those where the couple has ethnicity in common. Although new mutations that result in recessive disorders may occur, they have not been easy to distinguish clinically. With increasing use of DNA analysis, the frequency and nature of recessive mutations are likely to be better understood. Meanwhile, for the more common autosomal recessive disorders, the physician needs to recognize the patient's ethnicity and provide the straightforward carrier detection tests for that specific group. Hence, couples who share Mediterranean, Ashkenazi Jewish, Black, or Asian extraction should be routinely offered indicated preconception carrier detection tests for at least β -thalassemia, Tay–Sachs and Canavan disease, sickle cell disease, and α -thalassemia, respectively.

X-linked disorders

The mutant genes that result in X-linked disorders are located on the X chromosome. Given that the male has only one X chromosome and the female has two, both the risk and severity of X-linked disease will vary between the sexes. Males will usually manifest the fullest expression of the disorder, whereas random X inactivation will largely influence expression in females. In contrast to females who carry autosomal recessive genes, those heterozygous for X-linked genes frequently manifest some sign(s) of the disease in question (Table 21.8). An important example is female carriers of Duchenne muscular dystrophy (DMD), who are at significant risk for developing either cardiomyopathy or cardiac conduction defects.⁷⁹ A careful surveillance protocol for these life-threatening conditions is warranted.

Male-to-male transmission does not occur in X-linked disease. This is because a male never contributes his X chromosome to a son. An affected male, by contributing his only X chromosome to all his daughters, will render them all carriers of the trait in question. In examining the pedigree of a family with possible X-linked disease, attention is usually given to whether the disease has occurred in maternal nephews, uncles, or first cousins and through the female line. Female heterozygotes have a 50% risk of having affected male offspring.

X-linked dominant traits are characterized by an affected male transmitting the condition to all his daughters and none of his sons, and by an affected female, with a 50% likelihood of transmitting the disorder to her sons or daughters. X-linked dominant disorders occur about twice as often in females as in males and may be less severe in affected females. Rarely, an X-linked dominant trait may be lethal in affected males, resulting in a disorder that appears to occur, clinically, only in females and in which an affected female has a 50% likelihood of transmitting the trait to her daughters. These affected women have an increased frequency of miscarriage, repre-

Table 21.8 Signs in females who are X-linked recessive disease carriers.

Achromatopsia	Decreased visual acuity and myopia
Adrenoleukodystrophy	Neurological and adrenal dysfunction
Alport syndrome	Hematuria and hearing impairment
Choroideremia	Chorioretinal dystrophy
Chronic granulomatous disease	Cutaneous and mucocutaneous lesions
Duchenne muscular dystrophy	Pseudohypertrophy, weakness, cardiomyopathy/conduction defects
Dyskeratosis congenita	Retinal pigmentation
Fabry's disease	Angiokeratomas, corneal dystrophy, "burning hands and feet"
Fragile X syndrome	Mild-moderate mental retardation; behavioral aberrations; schizoaffective disorders; premature ovarian failure, fragile X tremor ataxia syndrome
G6PD deficiency	Hemolytic crises, neonatal hyperbilirubinemia
Hypohidrotic ectodermal dysplasia	Sparse hair, decreased sweating
Omithine transcarbamylase deficiency	Hyperammonemia, psychiatric/neurological manifestations
Spondyloepiphyseal dysplasia, late onset	Arthritis

Modified from ref. 30.

senting affected male fetuses (e.g., incontinentia pigmenti). Mutations of X-linked genes are not uncommon and are most often associated with the occurrence of a sporadic affected male within a family. Because of advances in molecular genetics, we now know that even in some of these families, despite the presence of a normal gene in the mother of such an affected male, germline mosaicism may account for recurrence in a future pregnancy. The birth of a male with DMD, no family history, and no detectable mutation by DNA analysis of maternal peripheral leukocytes might lead to counseling based on spontaneous mutation rates. Once again, germline mosaicism is now well recognized in mothers of apparently sporadic DMD sons, and the risk of recurrence in such cases approximates 7–14% if the at-risk X-haplotype is determined.⁸⁰ Hence, genetic counseling following sporadic occurrence of a male with X-linked DMD should include the recommendation of prenatal genetic studies in all subsequent pregnancies notwithstanding negative DNA carrier testing of the mother.

Fragile X syndrome

Special attention must be given to the X-linked disorder known as fragile X syndrome, which represents the most common single cause of inherited mental retardation in males. Typical features include mental retardation of varying severity, macroorchidism, typical facial features (including a large head, prominent ears, forehead, and jaw), signs suggestive of a connective tissue disorder (including hyperextensibility, pectus excavatum, flat feet, possible mitral valve prolapse, and dilation of the aortic root) and behavioral disorders, seizures, stereotypies, speech disorders, autistic signs, and other neurological features. The fragile X syndrome occurs in 1 out of every 4500 males, and about 1 in 250 females carry the gene. About one-third of female heterozygotes may be variably mentally retarded. This disorder is named for the appearance of the chromosomal fragile site, located on the distal long arm of the X chromosome and demonstrated by using folic acid-depleted culture medium for blood chromosome study. Detection of the unstable CGG triplet repeat with concurrent ascertainment of the methylation status is the standard diagnostic test for fragile X syndrome. Where before two-thirds of fragile X carrier females were not detected cytogenetically, DNA analysis of triplet repeats will facilitate detection of 96% of carriers. In addition, females with the dynamic fragile X premutation may also develop premature ovarian failure.⁸¹ Normal transmitting males are those who carry a premutation, do not have fragile X syndrome, and transmit this premutation to their daughters. Although thought to be phenotypically normal, studies have now shown that a subgroup of older men with the fragile X premutation develop a progressive neurodegenerative syndrome that includes intention tremor, parkinsonism, ataxia, cognitive decline, and generalized brain atrophy.⁸² This disorder has been named the fragile X tremor ataxia syndrome and has also been shown to manifest in a subgroup of elderly women with the fragile X premutation.^{83,84}

A careful family history and pedigree analysis is important when considering testing for fragile X. Special awareness is needed for the manifesting carrier female, a family history of mental retardation or learning disabilities on the maternal side, and of the “unaffected” transmitting male. Prenatal diagnosis can now identify not only the affected male, but also the female with this X-linked disorder. Carrier females can mostly be distinguished from clinically manifesting females by the number of triplet repeats and the degree of methylation.

Interpretation of the methylation assay can be complicated, especially when chorionic villus samples are assayed.⁸⁵ Methylation is not well correlated with fragile X gene expression based on assays of chorionic villi.

Mitochondrial disorders

Mitochondrial disorders have protean manifestations, which include neurologic, multisystem, and tissue-specific conditions

that are primarily maternally inherited. One specific characteristic of mitochondrial disorders is called *heteroplasmy*, which is the coexistence of normal and mutant mitochondrial DNA molecules within each cell. Although possible, prenatal diagnosis for specific mitochondrial point mutations may be affected by heteroplasmy, resulting in many uncertainties including severity, type, and age of onset of symptoms, thus complicating prenatal counseling.

Multifactorial genetic disorders

Many disorders result from the interaction of multiple genes with one or more environmental factors. Typical birth defects in this category include cleft lip and palate, congenital heart disease, and neural tube defects. Generally, risks of recurrence tend mostly to range between 3% and 5%; important exceptions (such as pyloric stenosis) are well known. For example, if the mother had pyloric stenosis, the risk is 16–20% for having an affected son and 7% for having an affected daughter. If the father had pyloric stenosis, the risk is about 5% for having an affected son and about 2.5% for having an affected daughter.⁸⁶ Recurrence risks typically vary from family to family and are particularly influenced by the number of affected family members and the severity of the condition in the index case. In general, if there are more affected relatives with more severe disease, the risk to their other relatives will be higher.

Consideration of phenocopies is particularly important in determining the etiology of what might be considered a multifactorial disorder. For example, cleft lip and palate may also occur as a consequence of a monogenic disorder, a chromosome abnormality, or a specific teratogenic medication.

Evaluating the cause of stillbirth or perinatal death

The full spectrum of grief can be expected to attend all stillbirths and perinatal deaths. Therefore, the physician can, and should, anticipate feelings of denial, expressions of guilt, experience of depression, and expressed or contained anger from the parents. Although the intensity and duration of such *normal* responses by parents may vary, active steps to evaluate the cause(s) of their loss serves to assist in turning anguish into action and to possibly providing important information that would help alleviate the grieving process. A summary protocol for such evaluation is suggested in Table 21.9.

Genetic etiologies of stillbirth need to be considered as they may lead to increased risks for miscarriage, stillbirth, or abnormality in future offspring. Genetic causes include thrombophilias, chromosome abnormalities, or single-gene disorders, including X-linked dominant, lethal autosomal recessive, and lethal *de novo* autosomal dominant conditions. Following stillbirth or perinatal death, careful review of the family (genetic) history and of the medical and obstetric history is

Table 21.9 Protocol for evaluating the cause of stillbirth or perinatal death.

Review genetic, medical, and obstetric history
Determine possible consanguinity
Gently and persistently recommend that parents permit a complete autopsy
Obtain photographs, including full face and profile, whole body, and, where applicable, detailed pictures of any specific abnormality (e.g., of digits)
Obtain full-body skeletal radiographs
Consider full-body magnetic resonance imaging, ⁸⁷ if autopsy not permitted
Carefully document any dysmorphic features
Obtain heparinized cord or fetal blood sample for chromosomal or DNA analysis
Obtain fetal serum for infectious disease studies (e.g., parvovirus, cytomegalovirus, toxoplasmosis)
Obtain fetal tissue sample (sterile fascia best) for cell culture aimed at chromosome analysis, biochemical, or DNA studies
Obtain parental bloods for chromosome analysis, where indicated
Communicate final autopsy results and conclusions of special analyses
Provide follow-up counseling, including a summary letter

recommended. Assessment of consanguinity should include determination of possible common ancestral origins of the parents, as well as consideration of last names of grandparents or great-grandparents. Autopsy should automatically be recommended in all such cases, unless an absolute and definitive diagnosis is already known. During the overwhelming grief at such times, one or both parents frequently are not inclined to allow an autopsy. Experience has taught that many such parents later regret having lost the opportunity to determine specific answers to very definite questions. If the ward, medical, and nursing staffs have been unable to obtain permission for autopsy, judicious action would include requesting the senior attending physician to meet with the parents immediately, lending experience and authority to the recommendation, urging that information gained at autopsy may benefit their other or future children. Keeping the deceased child on the ward for a few hours pending this decision will sometimes prove helpful. Photographs of the face, including profile views, and whole-body pictures, including detailed photographs of any specific abnormality (e.g., of digits) would be helpful to a dysmorphologist later. Full-body skeletal X-rays may prove similarly important later. Any dysmorphic features should be carefully documented. Heparinized cord or fetal blood samples should be obtained for chromosome analysis in all cases. Between 6% and 11% of all such offspring will have a chromosome abnormality, whether or not an abnormal physical phenotype is present.¹⁹ A fetal serum sample should also be obtained for infectious disease studies, which might include, for example, parvovirus, cytomegalovirus, and toxoplasmosis.

Fetal tissue samples should be obtained for cell culture (internal fascia of the thigh) to determine the chromosome complement, to determine the biochemical phenotype, where applicable, or to analyze DNA (liver tissue frozen without preservative), where indicated. The obstetrician is expected to ensure that sterile culture medium is kept available for these often-unexpected circumstances, thereby avoiding submission to the laboratory of pieces of fetal tissue in dry gauze or in a container, without any culture medium whatsoever. Parental blood samples for chromosome analysis may be useful if fetal karyotyping fails or if a specific chromosomal anomaly is detected (e.g., translocation). Results of the autopsy, as well as those of any special tests performed, should be communicated directly to the parents. Many weeks may elapse before such communication can occur. Nevertheless, face-to-face consultation with *both* parents is recommended to reiterate any previous counseling, especially as anxiety block to the reception of information may have lessened somewhat by that time. This communication and counseling should be followed by a summary letter explaining their future risks and options and emphasizing any necessary recommendations.

Guidelines to genetic counseling

The principles guiding the delivery of genetic counseling have been discussed extensively elsewhere.^{4,41,88} The quintessential points will be summarized briefly here.

Accurate diagnosis

Current expectations demand that a careful and sharp focus be kept on fetal development throughout pregnancy. Discrepancy between gestational age and fetal growth, disparity in specific measurements (e.g., femur length, size of lateral ventricles), or questions of organ presence or normality (e.g., large or absent kidneys) will alert the perinatologist to the need for further study, including serial examinations, in order to seek accurate diagnosis. Reliable genetic counseling cannot begin if an accurate diagnosis has not been established. This same exhortation applies to the history obtained at the first obstetric visit (ideally the preconception visit), when pregnancy planning has been initiated. At this visit, expectations include careful review of the family pedigree and formal confirmation of specific congenital defects or genetic disorders that bear on the risk of the proband in the current or future pregnancies. Examination of previous autopsy reports, X-rays, and photographs – including those of previous stillborns – is often necessary for confirmation or for help in establishing a diagnosis not made earlier. Now more than ever, the advent of molecular genetic diagnosis makes it incumbent on the physician to determine precisely whether a history of “muscular dystrophy” was, in fact, Duchenne, myotonic, or some other type. Failure to check a history of “encephalocele” in a previous deceased newborn could result in counseling with an

approximate 3% risk estimate. The autopsy record, however, may have revealed polydactyly and polycystic kidneys, which, in combination with the encephalocele, constitute Meckel syndrome, an autosomal recessive disorder with a 25% risk of recurrence.

Nondirective counseling

Most therapeutic medicine involves paternalistic management, with directions to the patient to take a specific medication that will restore him or her to good health. The consensus among medical geneticists in the Western world is to provide nondirective genetic counseling, where the physician is expected to dispense the most complete information available while remaining impartial and objective. In contrast, a directive approach invites, consciously or subconsciously, the opportunity for the physician to insinuate his or her own religious, racial, eugenic, or other beliefs or dictates of conscience into the counseling process. Hence, whether they have antiabortion views or personal judgments of the estimated burden of a specific disease on a family, physicians are strongly encouraged to avoid directing patients' decisions. Efficacy in genetic counseling means helping the clients to rational decision making, which may not necessarily result in a reduction in the frequency of a genetic disease.

Concern for the individual

A physician's paramount concern is for the individual patient. The physician is *not* an advocate for society when in the midst of patient care and counseling. Hence, if a patient does not wish to terminate a pregnancy in the face of a serious fetal genetic disease, it is inappropriate for the physician to try to influence that decision, either on behalf of other family members or because of the "cost to society." This principle does not, however, preclude the requirement to inform the patient fully about all aspects, both advantageous and disadvantageous, of the decision he or she is making. An informative discussion, therefore, should range over issues that the patient may not be cognizant of to include future interrelationships of the couple, the effect on their other children, the suffering of the affected child, anticipated reactions by relatives and the public at large, and the many economic and other societal implications.

Truth in counseling

There are relatively few instances in genetic counseling when the abiding principle of telling the truth is threatened. Detection of unexpected nonpaternity perhaps ranks first in frequency and is likely to retain its favored status with increasing use of DNA diagnostic studies. Detection of nonpaternity during routine prenatal chromosome studies is not at all uncommon. Such discoveries are usually predicated on recognition or suspicion of a potential fetal chromosome

abnormality, necessitating blood samples from both "parents." Determination of what might appear to be a *de novo* translocation, rather than an inherited one, brings the issue into sharp relief. Because risk counseling for fetal normality will be decidedly different for the *de novo* versus inherited translocation and because the other male is invariably unaware of his possible translocation, every effort needs to be made to arrange a face-to-face consultation with the pregnant patient herself. These not-infrequent encounters raise tricky ethical and legal questions and require considerable finesse in management.

Discovery of nonpaternity during DNA diagnostic studies in members of the family distant to the proband (her own father, an uncle, a first cousin) represents the same thematic challenge. Once again, considerable judgment and insight is required by the physician in determining whether to transmit such information; ethical and legal issues exist and cannot be ignored. Nevertheless, where sufficient information (e.g., to set "phase" for genotype evaluation through DNA studies) is available, communication concerning nonpaternity might best be avoided. Only in situations in which life-threatening circumstances are clear is there an absolute need for communication and disclosure. Even then great sensitivity and finesse are required.

Confidentiality and trust

The traditional and expected confidentiality and trust relationship between physician and patient is no different in the genetics arena. This principle may be challenged, for example, when the need arises to inform the sisters of a proven X-linked disease carrier about their own risks and need for testing. Difficulty arises if the patient insists on not communicating with her family and specifically instructs the physician also to desist. Although statutes of conditional immunity cover physicians communicating private information concerning highly infectious diseases (e.g., meningococcemia), such immunity may not safeguard the physician transmitting genetic risk information. Notwithstanding this difference in informing about germs and genes, the advent of AIDS and the associated privacy issues further add to the dilemma in managing these kinds of genetic cases.

Information transmitted to the physician's or institution's employees about patients' serious genetic neurological genetic disorders (e.g., Huntington's disease) add a further dimension in which confidentiality and trust may be questioned. The physician's first and clearest duty is to the patient, and great caution must be exercised to safeguard this critical relationship and to secure all the elements of absolute privacy.

Timing of genetic counseling

The need for preconception counseling has been emphasized. Notwithstanding this frequently repeated recommendation,

huge numbers of couples emerge for genetic counseling *during* pregnancy. Professional and public education is needed to reverse this practice if couples are to benefit from available options (not to have children, adoption, *in vitro* fertilization, artificial insemination by donor, ovum donation, embryo transfer, surrogacy, vasectomy, tubal ligation, carrier detection tests, preimplantation diagnosis, prenatal diagnosis, treatment, and selection or avoidance of abortion).

The timing of genetic counseling following the birth of a child with a serious congenital defect is also important. Although communication and support are critical during these first unhappy days, formal genetic counseling should not be attempted. Anxiety block effectively prevents anguished parents from assimilating or comprehending the important information being communicated. Essential diagnostic information must be communicated, but not in a corridor, not to the patient alone without her partner, and not to the patient who is still under the effects of anesthesia. Sadly, examples of all of these practices are well known. Although a formal appointment should be scheduled with such a couple within 6 weeks of the birth, access by telephone should also be made available for response to urgent questions and concerns.

Parental counseling

Contribution of one-half of the genome by the father is not the only reason the physician should insist on the father accompanying his mate for genetic counseling. Not only may outright diagnostic information be obtained from such a face-to-face visit, but also a more reliable paternal family history may be obtainable. Moreover, issues to be discussed are frequently complex and invariably involve questions of guilt, family prejudices, religious obstacles, fear, and serious differences of opinion between mates. Physicians should systematically insist, at the time appointments are made, that a couple attend together for counseling. Even although a letter summarizing the essential points made during counseling should be routinely sent to the referring doctor and the parents being counseled, the male partner must be urged to attend.

Knowledge, jargon, and empathy

Enormous advances in human genetics over the past three decades have led to a huge and exponentially increasing body of specialized knowledge. As a consequence of these developments, a board-certified specialty in medical genetics was initiated in 1982 in the USA and, shortly thereafter, in Canada. Physicians who are not medical geneticists need to be especially careful about venturing into areas in which they lack expertise. Communication concerning risks, based on DNA studies for a rapidly increasing number of prenatally detectable disorders, serves as one example for which caution and referral would be appropriate. Understanding the full

expression of a disease not only in the fetus or newborn, but also in the child and adult, and its wider consequences for the family, requires special knowledge and experience.

Communications concerning genetic disorders are frequently based on complex information. An important principle is to avoid technical jargon in communication and to make no assumptions about a patient's basic knowledge or understanding. Some patients, especially professionals, are embarrassed to reveal their ignorance or lack of understanding even after an explanation has been provided. Great sensitivity is always necessary, and sufficient insight in these circumstances may encourage repetition of the communication then and there, or at a subsequent planned appointment.

The birth of a child with a fatal or serious genetic defect is invariably associated with complex responses and reactions from both parents. After the anticipated shock, self-incrimination or guilt, anger, and (one hopes) final adaptation will come the associated dashed expectations and dreams, fear of recurrence, anxiety about disability and/or death, economic woes, concern about social stigmatization, and stress between partners (often for not planning). The physician should be able to dispense empathy and sensitivity, not be judgmental, and to project warmth, understanding, and support. Together with knowledge, these prerequisites take time – the final ingredient for effective counseling. Genetic counseling cannot be brief and hurried.

Do no harm

The classical exhortation *primum non nocere* (“do no harm”) is no less pertinent to clinical genetics than to medicine generally. In this context, perinatologists may offer predictive diagnosis from chorion villi or amniotic fluid cells for disorders that will manifest decades after birth. Prime examples include Huntington's disease,⁸⁹ myotonic muscular dystrophy,³² and Friedreich's ataxia.⁹⁰ Recommendations and guidelines concerning predictive testing for the presymptomatic detection of Huntington's disease have been published by the International Huntington Association and the World Federation of Neurology Research Group on Huntington's disease.^{91,92} These recommendations propose rigorous pre- and post-test counseling and state that the test should not be available to individuals under the age of 18 years. The inherent danger in such presymptomatic testing (as opposed to prenatal predictive testing) is the potential depression and possible demoralization that a patient might experience. For a disorder without curative, let alone meaningful palliative, treatment the wisdom of providing presymptomatic diagnoses must be seriously considered. Although 50% of individuals at risk will receive good news, relieving them of anxiety, the other 50% face an effective death sentence. Given the high suicide rate in individuals at risk for Huntington's disease, it may reasonably be questioned whether one does more harm than good by providing this 50% with a death sentence years before manifestations appear.⁹³ Given the pace of advances in human

genetics, it might well be possible in the foreseeable future to develop a therapy that enhances the mechanism already in place and to delay the manifestations of Huntington's disease for decades after birth. It would be sad to find a life ruined by severe depression or suicide, only to be followed shortly thereafter by discoveries that delay the manifestations of Huntington's disease by decades or permanently. Difficult as these decisions may be for individual patients at risk, such undertakings can only be regarded as acceptable if performed with extreme care, concern, and professionalism. Although patients retain the right to make the choice for presymptomatic testing, there is reason to remain concerned about the wisdom of such choices for those who find themselves affected. On the other hand, an increasing number of examples already exist in which presymptomatic testing is possible and important to either the patient or the future offspring, or both. Use of DNA linkage analysis and mutation analysis⁹⁴ for autosomal dominant polycystic kidney disease may lead to unsuspected diagnosis of an associated intracranial aneurysm and pre-emptive surgery with avoidance of a life-threatening sudden cerebral hemorrhage. In a study of 141 affected individuals, 11% decided against bearing children on the basis of risk.⁹⁵ These authors noted that only 4% of at-risk individuals between 18 and 40 years of age would seek elective abortion for an affected fetus. The importance of accurate presymptomatic tests for potential at-risk donors has been emphasized.⁹⁶

Duty

The physician has a duty to inform the patient, impartially, fully, and in a nondirective way, providing a clear delineation of available risks and options. Where facts are uncertain or new advances possible, there is a clear duty for the physician to refer the patient to or consult with a medical geneticist. All communications with the patient must be documented and, preferably, summarized in a letter to the patient. Physicians have a duty to support patients and to remain nonjudgmental about their decisions. An additional duty is to remain aware of new advances and progress in human genetics so that patients may benefit from them in a timely manner. In 1991, Pelias⁹⁷ discussed the geneticist's duty to recontact patients when new relevant information concerning their diagnosis, or possible treatment, becomes available. This daunting task to recontact patients, perhaps years after their initial visit to the genetics clinic, can be tempered by initially informing the client of the expanding nature of genetic knowledge and the need to remain in at least annual contact with the clinical geneticist. This theme should be recorded in clinic notes and reiterated in follow-up letters to the patient and to referring and consulting physicians. Given the many millions who move each year and change their physicians, it would be judicious to vest the responsibility with both the primary care doctor and the patient to remain in contact with a clinical geneticist.

Key points

- 1 The preconception period is important for control and treatment of specific disorders that may affect an otherwise successful pregnancy.
- 2 Infertility may have a genetic basis for which genetic testing and counseling are indicated.
- 3 Stillbirths and/or multiple miscarriage may have a genetic etiology for which genetic counseling and testing are indicated.
- 4 Family history of a specific disorder may enable carrier testing and prenatal diagnosis and is an indication for genetic counseling.
- 5 Carrier testing for specific genetic disorders based on ethnicity is a recognized standard of care.
- 6 Identification of maternal myotonic muscular dystrophy will enable prenatal diagnosis, optimal surveillance, and possible early intervention or prevention of the frequently serious intrapregnancy, labor, delivery, postpartum, and neonatal complications.
- 7 Genetic counseling is a communication process concerning the occurrence and the risks of recurrence of genetic disorders within a family.
- 8 The physician should be aware of the multiple indications for a genetic counseling referral in the context of risks and prenatal diagnosis.
- 9 Uniparental disomy molecular testing may be indicated in the prenatal diagnosis of robertsonian translocations.
- 10 Sex chromosome aneuploidy is a frequent finding in prenatal diagnosis and may present genetic counseling challenges due to the phenotypic and developmental variability within each karyotype group.
- 11 The use of FISH has increased the identification of the etiology of previously idiopathic mental retardation allowing more accurate recurrence risk counseling and prenatal diagnosis opportunities.
- 12 Autosomal dominant disorders are characterized by pleiotropy, variable expressivity, variable age of onset, and often new mutations and heterogeneity.
- 13 Consanguinity increases the risk of autosomal recessive disorders.
- 14 Female carriers of X-linked genes often manifest sign(s) of the disorder due to random X inactivation.
- 15 Germline mosaicism complicates recurrence risk counseling in apparently sporadic cases of an increasing number of disorders.
- 16 Fragile X female carriers are at risk of developing premature ovarian failure, whereas both male and

female premutation carriers are at risk to develop the fragile-X tremor ataxia syndrome.

- 17 Heteroplasmy complicates the prenatal diagnostic interpretation of some mitochondrial disorders.
- 18 Reviewing the genetic, medical, and obstetric history as well as a complete autopsy are critical in evaluating the

cause of stillbirth and may be invaluable in future genetic counseling.

- 19 Reliable genetic counseling cannot occur if an accurate diagnosis has not been established.
- 20 Genetic counseling is best provided by a clinical geneticist or certified genetic counselor under supervision of a clinical geneticist.

Basic principles of ultrasound

Mladen Predanic, Frank A. Chervenak, and E. Albert Reece

Introduction

Ultrasound has had a profound influence on the practice of medicine, especially in obstetrics. Since its first introduction into medicine, almost half a century ago, ultrasound studies have shown a potential to provide information about the fetus in a noninvasive manner. Most importantly, it does not appear to be associated with any known adverse fetal bioeffects. Thus, diagnostic ultrasound gained wide clinical acceptance and become of considerable diagnostic value. The new powerful ultrasound machines, with superb resolution, three-dimensional capabilities, and various Doppler modalities, are convenient to use, comfortable for the patient, and not very expensive. It is an unquestionable fact that prenatal ultrasound provides information that allows diagnosis and treatment of fetal malformations that otherwise could be diagnosed only postnatally and often in an untimely fashion. However, a major question still remains unequivocally unanswered: Is prenatal diagnostic ultrasound safe? Although no known human epidemiologic data or unquestionable evidence exist to demonstrate any deleterious effect of diagnostic ultrasound in neonates over the last 40–50 years of clinical use, there are some tissue biological effects generated by ultrasound. Even more, the acoustic output of modern equipment constantly changes with the advancement of the technology, whereas investigations into the possibility of subtle or transient fetal adverse ultrasound bioeffects are still at an early stage. Therefore, diagnostic prenatal ultrasound should only be considered safe if used prudently.

Basic physics

Sound consists of waves and is described by frequency, wavelength, amplitude, intensity, and the propagation of speed. An *ultrasound* is a sound with a frequency higher than the human ear can detect. The frequency of ultrasound used in medicine for fetal imaging is in the range of 3–7.5 million cycles per

second (megahertz, MHz). Such high-frequency ultrasound is generated by high mechanical deformation of certain materials (e.g., crystals or ceramics), caused by electrical stimulation, which produces a generation of waves at ultrasound frequencies. This is described as the *piezoelectric* phenomenon, and it also works in reverse.¹ An ultrasound “receptor” will resonate at certain frequencies, creating electrical impulses when stimulated by reflected ultrasonic waves (echoes).

Materials amenable to the piezoelectric phenomenon make up the core of the ultrasound transducer. These “crystals” are arrayed at the tip of the ultrasound probe. An ultrasound wave is generated by the electric pulse, transmitted through the tissue, and at some tissue depth is reflected and returned to the transducer. Returned “echoes” are detected and converted by the same transducer into electric impulses of equivalent amplitude that corresponds to the depth of the returned ultrasonic wave. The array of the electric impulses is analyzed by the computer software and converted into the image. Depending on the mode of data analysis, we are able to demonstrate tissue structures by B-mode two-dimensional real-time sonography; M-mode (e.g., used for assessment of heart motion); a pulsed Doppler modality that pictures blood flow in the form of waveforms that correspond to the systolic and diastolic components of the cardiac cycle; color and power Doppler modes (superimposed blood flow in the form of colored dots/areas over the B-mode picture); and, more recently, three-dimensional sonography that renders analyzed structures in a static three-dimensional image, or four-dimensional ultrasound, which demonstrates a three-dimensional image in real time (Table 22.1). All of these advances were possible because of the tremendous advancements in computer technology and software systems that enable quick and accurate analysis of the received ultrasound data.¹

Ultrasound image and resolution

It is imperative to understand that ultrasound images are generated from an ultrasound beam that is three-dimensional in

Table 22.1 Basic ultrasound modes and images.

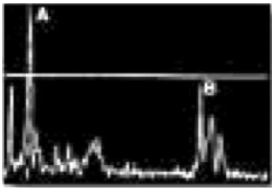

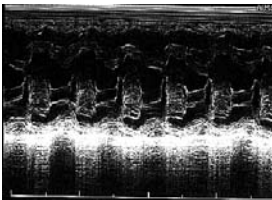

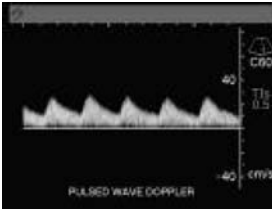

Ultrasound mode	Ultrasound image	Brief description	Comment
A-mode (one-dimensional)		Wave spikes occur when a <i>single</i> beam passes through objects of different consistency and hardness	Of historical value, now obsolete in medical imaging
B-mode (one-dimensional, 1-D)		Same as A-mode, but wave spikes (upper row) are replaced with <i>dots</i> (lower row) where “brightness” corresponds to amplitude of reflected sound	Of historical value, now obsolete in medical imaging
B-mode (two-dimensional) (in real time)		B-mode generated from multiple crystals (array) in real time (up to 100 images per second)	Today’s standard of ultrasound imaging, utilized by almost any ultrasound machine
M-mode		Combination of B-mode one-dimensional (vertical axis) and time (horizontal axis)	Fetal cardiac imaging
Pulsed Doppler		Based on Doppler principle* demonstrates blood flow in real time (wave spikes are systolic component of the blood flow)	Used to analyze blood flow characteristics (e.g., velocities and resistance to blood flow)
Color Doppler		Codes blood flow (or any motion) by Doppler principle, into two colored dots according to the direction and blood flow velocities; it is superimposed over B-mode image	Used to map blood flow spots within the investigated tissue or organ
Power (color) Doppler		Similar to color Doppler, but codes all blood flow into one color (no directional information) – more sensitive to slow blood flow than color Doppler	Used to enhance blood flow mapping in tissue with slow blood flow states

Table 22.1 Continued.

Ultrasound mode	Ultrasound image	Brief description	Comment
Three- and four-dimensional (four-dimensional is three-dimensional ultrasound in real time)		Two-dimensional B-mode with third dimension (depth) analyzed by powerful computer software to render three-dimensional image; three-dimensional image is static, whereas four-dimensional image is the three-dimensional image in real time	Diagnostic value of three- over two-dimensional B-mode real-time ultrasound is controversial, although may significantly reduce scanning time

*Doppler principle. Source moving toward the receiver has higher frequency than source moving away from receiver, which has lower frequency.

Figure 22.1 Comparison between conventional (A) and harmonic ultrasound imaging (B).

form. The three dimensions are thickness (*azimuthal* resolution), width, and depth (*lateral* and *axial* resolution). Any transducer that generates an ultrasound beam is capable of focusing that beam at certain depths via an “electromagnetic lens.” Generated ultrasound beams are unevenly thick, with the narrowest part at the level of their focus. If the beam is thick, the reflected echoes from the same plane at a certain depth will be unified in one two-dimensional image that may appear blurry. It is especially true for the images that are closest and farthest away from the probe where the ultrasound beam is the thickest. At the same time, the image is most clear at the focus level where the beam is narrowest. *Axial* resolution, or parallel to the direction of the sound waves leaving the transducer, is related to the length of the ultrasound pulse. Shorter ultrasound wavelengths or higher frequencies will produce better axial resolution. In contrast, *lateral* resolution is equal to the beam diameter in millimeters, is perpendicular to the axial, and inevitably poorer than axial resolution. Because it is related to the beam diameter, it is significantly affected in curved transducers where the beam diameter increases with depth and becomes equivalent in thickness to the azimuthal resolution. Thus, the image that is away from the probe appears not only blurry, but also distorted sometimes as well.

Although the image quality directly depends on the frequency of the ultrasound probe, resolution has been significantly

improved by an increase in the number of transducer crystals (or channels); improvements in transducer crystal technology (creating broadband and high-dynamic-range images); increased array aperture (more crystals firing in a single time-frame); faster computational capabilities (faster computer chipsets); improved technical algorithms for focusing on received ultrasound beam (increasing the number of focal zones along the beam); incorporating automatic time-gain controls, and progressively replacing analog portions of the signal path to digital. The signal path of the beam former (transducer), in the older analog processing data chain ultrasound machines, was analyzed based on the axial resolution formed by the use of the one or multifoci. With the employment of more powerful computers, the whole process became digitized. Super-fast digital beam formers allowed significantly increased numbers of focal points (microfine focuses) along the beam to the size of a screen pixel. This technology reduced signal–noise ratio in data processing by several hundred-fold and created a significantly clearer picture. The most recent advent in use is the so-called *harmonic* imaging (Fig. 22.1). Tissue harmonic imaging utilizes lower frequency echoes for the ultrasound penetration that receives and processes only the higher frequency echoes generated by the body’s inherent characteristics. The final product is dramatically cleaner contrast between adjacent tissue structures that is particularly useful in obese patients.

Ultrasound safety

The diagnostic ultrasound has widespread acceptance due to its clinical utility, convenience, and noninvasiveness. In the USA, approximately 65% of pregnant women have at least one ultrasound examination.² We usually reassure any prospective mother that ultrasound is safe and does not have any harmful effects on the baby; therefore, it is of paramount importance to be familiar with ultrasound safety.³ Some evidence exists that high-energy ultrasound may produce biological effects in exposed tissues. The most studied effects are the local increase in temperature (thermal changes), and oscillatory and potentially catastrophic motions of bubbles, if present, in the tissues (microcavitation).⁴

The nature of ultrasound is such that, during its propagation through the tissue, portions of its energy are absorbed and converted into heat. Although the heat is dissipated by the adjacent tissues and blood flow through the insonated area, tissue temperature may rise a fraction of a degree Celsius.⁵ Such temperature aberrations normally occur during the human diurnal cycle, and temperature may increase by 3–4°C in febrile states. Hyperthermia is a proven teratogenic agent in various animals (mouse, rat, hamster, monkey, sheep, and others) and is considered so in humans. In addition, certain stages of embryonic and fetal development may be more susceptible to thermal effects.⁶ Effects appear to be a threshold phenomenon when temperature increases of 1.5°C or higher are considered necessary for damage to occur. However, the energy output of the diagnostic ultrasound is of such low intensity that it is unlikely to induce temperature changes of such a degree to produce adverse pregnancy effects.⁷ In addition, no recently published study has demonstrated unequivocal adverse effects of diagnostic ultrasound. However, it is a theoretical possibility and should not be completely ignored.

The interaction of sound with microscopic gas bubbles that pre-exist in tissues may cause a bioeffect termed *microcavitation* or acoustic cavitation.⁴ Because of the succession of positive and negative pressures that can cause oscillatory motions of bubbles, several outcomes may result: (1) stable cavitation or (2) implosion of the bubbles described as transient cavitation. These can result in cell membrane disruption and even the release of free radicals that are cell toxic. Another potential effect is radiation stress, caused by acoustic streaming in liquid media secondary to the pressure gradient generated by the moving sound wave. These biological effects have been produced in plants, insects, and some mammalian tissues. Although there is no direct evidence to suggest that in humans, under clinical conditions, ultrasound-induced microcavitation produces biological effects, the Food and Drug Administration (FDA), together with the American Institute of Ultrasound in Medicine (AIUM), the American College of Obstetrics and Gynecologists (ACOG), and the National Electrical Manufacturers Association, introduced a method of displaying ultrasonic output that would control and minimize

possible bioeffects in insonated fetal tissues.^{5,7–10} If an ultrasound machine exceeds predetermined limits for output, either a thermal index or mechanical index must be displayed on the screen. If the thermal index, which is appropriate for Doppler applications, exceeds 1.0, there is a potential for the tissue temperature to rise. If the mechanical index, which is appropriate for scale imaging, exceeds 1.0, there is a potential for cavitation effects.^{5,8} It is important to note that although the more recent epidemiologic studies were published in 1998 through 2002, ultrasound examinations consisted exclusively of B-mode, and all machines used predated 1992, i.e., the “new” FDA regulations, allowing output to rise to more than 94 mW/cm², the then-accepted upper limit for fetal application. Those acoustic outputs can be considered “low” by today’s standards. Still, available published evidence showed no difference in the prevalence of delayed speech or motor development, impaired neurological development, growth, vision, or hearing, low birthweight, dyslexia, or childhood cancer among children exposed to ultrasound *in utero*.^{11–13} The only well-designed study showing some effect was a recent article that presented a small increase in the frequency of non-right-handedness (ambiguity) in male infants of mothers exposed to diagnostic ultrasound.¹⁴ Nevertheless, in general, it is safe to say that when sonography is performed for a valid medical indication by a well-trained individual who respects the basic rules of time and exposure, the information that can be obtained is of such great value that it clearly overshadows the remote risks that may exist.^{15–19} In contrast with medical indications, performing ultrasound for “keepsake” records of the fetus, especially in the first trimester of the pregnancy, should be discouraged. Embryonic tissue may not have the tensile strength of fetal or adult tissue secondary to underdevelopment of the intercellular matrix to withhold cellular damage due to biological effects caused by ultrasound, especially if the energy output is above recommendations, or if it is used for prolonged periods of time. The risk of thermal bioeffects is increased when imaging is advanced from simple grayscale B-mode (in which the risk may be nonexistent) to pulsed Doppler. Doppler examinations present the highest risk of thermal *bioeffects* owing to their high pulse repetition frequency and longer pulses.^{17,18} It also appears that the risks of appreciable harmful *bioeffects* may increase with increasing scanning time, ultrasound frequency (increases thermal risks but decreases cavitation risks), and output power (increasing the gain on the “output” knob, an “energy” trackball, or a “power” cursor) (Table 22.2). However, we believe that newer technologies, such as harmonic imaging and three-dimensional sonography, may be safer. Both modalities are based on data post processing; therefore, one might speculate that time used for ultrasound scanning may be significantly reduced and thereby decrease the potential for adverse ultrasound biological effects.

In conclusion, the duration of exposure and output levels should be kept at a minimum, which is the basis of the ALARA (*as low as reasonably achievable*) principle, endorsed, among

Table 22.2 A summary of the recommendations published by several national and international organizations, including the American Institute of Ultrasound in Medicine (AIUM), International Society for Ultrasound in Obstetrics and Gynecology, Australasian Society for Ultrasound in Medicine, British Society for Medical Ultrasound, and World Federation for Ultrasound in Medicine and Biology.

Ultrasound induces biological effects (bioeffects) in the tissues but is generally considered safe if properly used – no epidemiologic studies have shown, so far, harmful effects in humans

A clear medical indication should be present for performance of diagnostic sonography; when a clear medical indication exists, the benefits outweigh the risks potentially caused by performing sonography

Ultrasound services should be provided by people with adequate training, including knowledge of safety and bioeffects issues

An elevation of fetal body temperature above 41°C for 5 min or more is considered hazardous

Nonthermal bioeffects (microcavitation) may result in capillary bleeding, particularly in the lungs and bowels when gas bubbles are present; fetal lungs and bowels do not contain gas, therefore a mechanical risk is probably nonexistent

B- and M-mode sonography appears entirely safe in pregnancy

Pulsed Doppler and color Doppler sonography with a small region of interest have the greatest potential for bioeffects; these should be carried out with particular care in the first trimester

New technologies, such as harmonic imaging and three-dimensional sonography, do not present more risk than native B-mode imaging

Sonographic examination, particularly spectral Doppler sonography, in a pregnant patient with an elevated temperature might pose additional risks to the fetus

The duration of exposure and output energy levels should be kept at a minimum – ALARA (*as low as reasonably achievable*) principle

Continuous research and education in ultrasound safety and biological effects are strongly encouraged

Modified from Abramowicz JS. Ultrasound in obstetrics and gynecology: is this hot technology too hot? *J Ultrasound Med* 2002;21:1327–1333.

others, by the American Institute of Ultrasound in Medicine, the National Electrical Manufacturers Association, and the FDA.⁵ Nevertheless, continuous research and education on ultrasound safety are strongly encouraged.

Ultrasound examination

The current standpoint of ACOG is that ultrasound in pregnancy should be performed only when there is a valid medical indication (Table 22.3).²⁰ Therefore, physicians are not obligated to perform ultrasonography in patients who are at low risk and have no indications. However, if a patient requests ultrasonography, it is reasonable to honor the request – the

Table 22.3 Indications for ultrasonography during pregnancy.

Estimation of gestational age

Evaluation of fetal growth

Vaginal bleeding

Abdominal and pelvic pain

Incompetent cervix

Determination of fetal presentation

Suspected multiple gestation

Adjunct to amniocentesis

Significant uterine size and clinical dates discrepancy

Pelvic mass

Suspected hydatidiform mole

Adjunct to cervical cerclage placement

Suspected ectopic pregnancy

Suspected fetal death

Suspected uterine abnormality

Evaluation for fetal well-being

Suspected amniotic fluid abnormalities

Suspected placental abruption

Adjunct to external cephalic version

Premature rupture of membranes and/or premature labor

Abnormal biochemical markers

Follow-up evaluation of a fetal anomaly

Follow-up evaluation of placental location for suspected placenta previa

History of previous congenital anomaly

Evaluation of fetal condition in late registrants for prenatal care

Modified from American Institute of Ultrasound in Medicine (AIUM). Practice guideline for the performance of an antepartum obstetric ultrasound examination. *J Ultrasound Med* 2003;22:1116–1125.

final decision to have an ultrasound scan rests with the physician and patient jointly.^{15,20}

It is our belief that the benefits of routine ultrasound in pregnancy outweigh the risks associated with potential adverse ultrasound effects. The early recognition of fetal anomalies may introduce *in utero* treatment, or at least prepare parents for the emotional ordeal that follows delivery of the fetus with a major malformation. Although 90% of infants with congenital anomalies are born to women with no risk factors, a controversy about routine ultrasound use exists.²¹ A minimal and inconsistent impact on perinatal morbidity or mortality was observed with the use of routine ultrasound screening in the second trimester of pregnancy.^{22–24} However, there are data that support its cost-effectiveness when performed in tertiary centers.²⁵

The ACOG, in its most recent clinical management guidelines for obstetricians and gynecologists, has defined three types of ultrasound examinations performed during the second or third trimester of pregnancy.²⁰ The *standard* examination includes an evaluation of fetal presentation, amniotic fluid volume, cardiac activity, and placental position, fetal biometry, and an anatomic survey. Fetal anatomy may be assessed adequately at 16–20 weeks of gestation (Table 22.4).

Table 22.4 Essential elements of the fetal anatomic ultrasound survey.

<i>Head and neck</i>
Cerebellum
Choroid plexus
Cisterna magna
Lateral cerebral ventricles
Midline falx
Cavum septi pellucidi
<i>Chest</i>
The basic cardiac examination includes a four-chamber view of the fetal heart. If technically feasible, an extended basic cardiac examination can also be attempted to evaluate both outflow tracts
<i>Abdomen</i>
Stomach (presence, size, and situs)
Kidneys
Bladder
Umbilical cord insertion site into the fetal abdomen
Umbilical cord vessel number
<i>Spine</i>
Cervical, thoracic, lumbar, and sacral spine
<i>Extremities</i>
Legs and arms (presence or absence)
<i>Gender</i>
Medically indicated in low-risk pregnancies only for evaluation of multifetal gestations

Modified from American Institute of Ultrasound in Medicine (AIUM). Practice guidelines for the performance of an antepartum obstetric ultrasound examination. *J Ultrasound Med* 2003;22:1116–1125.

If technically feasible, the uterus and adnexae should also be examined. A *limited* examination is performed when a specific question requires investigation. For example, it may be employed to verify fetal presentation in a laboring patient, or to confirm heart activity in a patient with absent fetal movements. A *specialized* examination is a detailed or targeted anatomic examination that is performed when an anomaly is suspected on the basis of patient history, biochemical abnormalities, or clinical evaluation. Other specialized examinations include fetal Doppler studies, biophysical profile, fetal echocardiography, or additional biometric studies.

In addition to indications in the second and third trimester of pregnancy, Table 22.5 demonstrates indications for the use of ultrasound in the first trimester of pregnancy. The first trimester is a time of rapid embryonic–fetal development. Highly accurate first-trimester dating can be obtained by measuring the crown–rump length (CRL) of the fetus (Fig. 22.2). A number of studies have demonstrated that fetal CRL is the most accurate measurement for the sonographic dating of pregnancy. It has a high reproducibility and can be used reliably until approximately 12 weeks’ gestation. Beyond this period, a variety of sonographic parameters, such as bipari-

Table 22.5 Indications for ultrasound in the first trimester of pregnancy.

To confirm the presence of an intrauterine pregnancy
To evaluate a suspected ectopic pregnancy
To define the cause of vaginal bleeding
To evaluate pelvic pain
To estimate gestational age
To diagnose or evaluate multiple gestations
To confirm cardiac activity
As an adjunct to chorionic villus sampling, embryo transfer, or localization and removal of an intrauterine device
To evaluate maternal pelvic masses or uterine abnormalities
To evaluate suspected hydatidiform mole

Modified from American Institute of Ultrasound in Medicine (AIUM). Practice guideline for the performance of an antepartum obstetric ultrasound examination. *J Ultrasound Med* 2003;22:1116–1125.

etal diameter (BPD), abdominal circumference, and femoral diaphysis length can be used to estimate gestational age. However, the variability of gestational age estimations increases with advancing pregnancy. As early as the late first trimester, separate fetal body structures can be examined.

Head

The oval outline of the fetal head should be sought in all examinations. The intracranial anatomy should be examined to ascertain that major midline structures are present, such as thalami, intrahemispheric fissure, and cavum septi pellucidi (Fig. 22.3). Advanced head evaluation includes other head measurements, such as the extra- and intraorbital distances, ventricular diameters, as well as the occipital frontal

Figure 22.3 Transverse ultrasound image at the level of the biparietal diameter, demonstrating thalami (T) and septum cavum pellucidum (SCP).

Figure 22.5 Longitudinal image of the fetal spine.

Figure 22.4 Posterior fossa with cerebellar diameter, fourth ventricle, and cisterna magna.

distance and the cephalic index. The cephalic index is the ratio of BPD to occipital front distance, which is normally in the range of 0.75–0.85. The posterior fossa reveals information about the cerebellar diameter, which correlates with gestational age, presence of the cerebellar vermis, and the size of the cisterna magna (Fig. 22.4).

Fetal spine

The fetal spine ossifies as early as 10 weeks and is seen as parallel sets of echoes representing the articulating vertebral facets. It is usually examined in the longitudinal (coronal) plane, although in a targeted examination for neural tube defects, the transverse view of the total spine should be demonstrated (Fig. 22.5).

Figure 22.6 Four-chamber view of the fetal heart.

Fetal heart

A four-chamber heart view (Fig. 22.6) is a basic part of all examinations after 18 to 20 week's gestation. It is fast and easy to perform a screening test for congenital heart disease because the majority of heart structural anomalies may be detected using this single view. However, outflow tract anomalies (e.g. transposition of the great vessels) can be easily missed if “long” and “short” axis heart views are not performed (Fig. 22.7).

Abdomen

The fetal abdomen and stomach, as a single cystic area, can be visualized as early as 14 weeks' gestation. Ventral wall

Figure 22.7 Left and right ventricle outflow tracts of the fetal heart: (A) LVOT, left ventricle and aorta; (B) RVOT, right ventricle and pulmonary artery.

defects can be excluded by the demonstration of an intact abdominal umbilical cord insertion (Fig. 22.8). Fetal kidneys (Fig. 22.9) and other upper abdomen organs can be easily demonstrated, such as gallbladder and liver. Fetal bladder is usually visible as a fluid-filled structure in the midline of the pelvis.

Extremities

The four fetal limbs are identified routinely during ultrasound examination. Although it is not necessary to measure all six tubular bones in every fetus, measurements of at least one or two segments (femur and humerus) are performed. Both bones of the normal distal segments should be present. An image of the fetal hands and feet are also highly desirable, but are not required for a basic ultrasound examination (Fig. 22.10).

Fetal biometry

Fetal biometry is used to assess the size or estimated fetal weight that is usually plotted against a growth curve (generated from the large portion of general fetal population) to

Figure 22.8 Fetal abdominal umbilical cord insertion.

evaluate fetal growth characteristics. The estimated fetal weight is derived from various combinations of fetal measurements at certain gestational age, and mainly includes BPD, head circumference, abdominal circumference, and femoral diaphysis length, described elsewhere in this text. However, it

is important to ascertain caution with the results of the fetal biometry, because there is large inter- and intraobserver variation in measurements at extremes of the fetal age (e.g., less than 24 or beyond 36 weeks' gestation).

Key points

- 1 Sonography principles are based on the *piezoelectric phenomenon* and generated ultrasound waves. These ultrasound waves are reflected from tissue boundaries of different density, and processed by powerful computer software to generate real-time two- or three-dimensional images.
- 2 Recent advances in ultrasound data processing, such as “harmonic” imaging and super-fast digital beamers, permit significantly improved ultrasound resolution.
- 3 Although three- and four-dimensional (real-time three-dimensional) ultrasound produce excellent fetal images, their clinical superiority over conventional real-time two-dimensional ultrasound is controversial.
- 4 Ultrasound waves may produce certain biological tissue effects, e.g., thermal changes and mechanical effects (microcavitation), if used for prolonged periods of time with extremely high-energy outputs. However, these ultrasound energy output levels are *not* used with diagnostic ultrasound at present time.
- 5 To ensure ultrasound safety, it is the general consensus that the thermal and mechanical indexes are displayed on the screen if the ultrasound machine exceeds predetermined limits for energy output.
- 6 At the present time, diagnostic ultrasound is considered safe for the fetus when used appropriately and prudently. However, casual use of ultrasound, especially during the first trimester of pregnancy, should be avoided, especially implementation of pulsed Doppler ultrasound, which, theoretically, may produce a high thermal index.
- 7 Ultrasound examination in pregnancy is an accurate method of evaluating viability of the pregnancy, fetal number, and placental location, as well as gestational dating, which is most accurately determined in the first trimester of pregnancy.
- 8 Ultrasound is also able to accurately diagnose major fetal anomalies; however, the diagnosis of fetal growth abnormalities is less precise.
- 9 The optimal timing for a single ultrasound examination (if performed in the absence of specific indications) is at 18–20 weeks of gestation.
- 10 Appropriate patient counseling before the ultrasound examination regarding its limitations for diagnosis is of paramount importance and should be exercised routinely.

Prenatal diagnosis of central nervous system malformations

Gianluigi Pilu and Sandro Gabrielli

Only a small proportion of congenital anomalies of the central nervous system (CNS) are clinically recognizable and are therefore identified at birth. Long-term follow-up studies suggest that the prevalence of these conditions is much greater than expected for epidemiologic survey of neonates and is about 1 in 100 births.¹ Modern high-resolution ultrasound equipment has a unique potential for evaluating normal and abnormal anatomy of the fetal neural axis from the very early stages of development. Yet, identification of selected anomalies, such as ventriculomegaly and spina bifida, remains a challenge in many cases. In this chapter, the sonographic investigation of the fetal brain and the identification of CNS anomalies will be reviewed.

Normal sonographic anatomy of the fetal central nervous system

The fetal cerebrum undergoes major developmental changes throughout gestation. Fetal neurosonography demands a thorough knowledge of the ontogenesis of the brain. The interested reader is referred to specific publications on this subject.^{2,3} Starting from 7 weeks' gestation, the primary cerebral vesicles can be identified with transvaginal sonography as fluid-filled areas. From 11 weeks' gestation, the brightly echogenic choroid plexuses filling the large lateral ventricles are the most prominent intracranial structures. In the second trimester, a detailed sonographic examination of the already well-developed cerebral structures allowing the detection of most anomalies is feasible. However, the results of an obstetric sonogram depend greatly upon the level of expertise of the sonographer and the time dedicated to the scan. In evaluating the fetal brain, a distinction must be made between a standard scan (frequently referred to as a level 1 scan) and an expert (or level 2) scan. The standard scan is fundamentally a screening examination for low-risk patients, and there is a general consensus that it is conveniently carried out with two axial views of the head, demonstrating the lateral ventricles, basal ganglia, and posterior fossa.⁴ Measurement of the biparietal diameter, head circumference, internal diameter of the

atrium and cisterna magna depth, and choroid plexuses is recommended.

A level 2 scan is a diagnostic examination, usually performed in a patient at increased risk of fetal anomalies, and may include coronal and sagittal views of the head that are more difficult to obtain, but have the advantage of delineating more clearly subtle details of intracranial anatomy, particularly by using a vaginal probe in vertex fetuses.⁵ Three-dimensional ultrasound (Fig. 23.1) is a useful adjunct to the bidimensional examination in that it allows visualization of scanning planes that are difficult or impossible to obtain directly.⁶

Magnetic resonance of the fetal brain

Magnetic resonance imaging (MRI) has been used in obstetric patients for the diagnosis of fetal cerebral anomalies. The MRI procedure is not believed to be hazardous to the fetus, and the new equipment allows fast scanning at a reasonable level of resolution. In general, the anatomy is well depicted in fetuses older than 20 weeks' gestation. Compared with ultrasound, MRI allows a better discrimination between the cortex and the liquid spaces, and is particularly valuable in the assessment of migrational disorders, intracranial hemorrhage, and complex cerebral anomalies (Fig. 23.2). Furthermore, it is not influenced by fetal position, skull calcification, and oligohydramnios. There is a controversy in the current literature as to whether or not MRI provides valuable information to the sonographic examination when it is performed by an expert.⁷⁻⁹ Nevertheless, the use of MRI in obstetric patients is becoming widespread. It should be stressed that, with current technology, this technique gives the best results only after fetal viability, when in most countries termination of pregnancy is no longer possible.

Ventriculomegaly

Enlargement of the lateral cerebral ventricles can be regarded as a specific marker of abnormal brain development, and is

Figure 23.1 Multiplanar imaging of the fetal brain using three-dimensional sonography. The data volume has been obtained with the probe aligned along the axial plane (A). Two orthogonal sections have been reconstructed, simultaneously demonstrating the coronal (B) and midsagittal plane (C). The corpus callosum and cerebellar vermis are easily recognized. 3v, third ventricle.

Figure 23.2 Magnetic resonance imaging of fetal cerebral anomalies. (A) Large teratoma with an intracranial and an extracranial component (arrows); (B) grade 4 intraventricular hemorrhage with destruction of the surrounding cortex (arrow); (C) unilateral megalencephaly: this anomaly is the consequence of a migrational abnormality affecting one hemisphere (arrow) that is overgrown, has abnormal convolutions, and lacks a well-developed cortical plate. Note the normally developed cortical plate in the ipsilateral hemisphere.

encountered with many different cerebral anomalies. Evaluation of the integrity of the cerebral lateral ventricles is therefore of particular importance while screening for fetal cerebral anomalies. Although many different approaches to the evaluation of the integrity of lateral ventricles have been proposed, measurement of the internal width of the atrium of the lateral ventricle at the level of the glomus of the choroid plexus is currently favored (Fig. 23.3). Under normal conditions, the

measurement is less than 10 mm, while a value of more than 15 mm indicates severe ventriculomegaly, almost always associated with an intracranial malformation.^{4,10,11} The outcome of these fetuses is variable and depends largely upon the underlying etiology of the ventricular dilatation. The available studies suggest that fetuses with isolated severe ventriculomegaly have an increased risk of perinatal death and a probability of severe neurologic sequelae in the range of 50% of

Figure 23.3 (A) Normal transventricular scan demonstrating an atrium of lateral ventricle of normal size; (B) mild ventriculomegaly; (C) severe ventriculomegaly.

survivors.¹⁰ An intermediate value of the atrial width, 10–15 mm, is commonly referred to as mild ventriculomegaly and is associated with a much increased probability of cerebral and extracerebral malformations, aneuploidies, and infections, and therefore should be carefully evaluated in an expert center. Fetuses with isolated mild ventriculomegaly usually have a good outcome and, in most instances, the ventricles return to normal size during gestation. However, these infants run an increased risk of neurologic compromise and, in some cases, develop severe cerebral anomalies in the last part of gestation or after birth, including hydrocephalus, white matter injury, and cortical plate abnormalities. The risk is particularly increased when the atrial width is greater than 12 mm, when the dilation affects both lateral ventricles, and in females.¹¹

Congenital hydrocephalus has genetic implications. It should be stressed that the experience thus far indicates that antenatal ultrasound is unreliable for predicting the recurrence of isolated ventriculomegaly, particularly of the X-linked variety, because in many cases enlargement of the lateral ventricles only develops late in gestation or after birth.¹² DNA analysis for the X-linked variety is now available and should be considered, although the exact sensitivity remains uncertain.^{12–14}

When the diagnosis of severe ventriculomegaly is made prior to viability, many parents would probably request termination of pregnancy. In continuing pregnancies, no modifications of standard obstetric management are required. A Cesarean section is recommended only in those cases with associated macrocrania. Cephalocentesis to reduce cranial size is associated with significant morbidity, and is indicated only in cases with a presumption of a severe prognosis.

Neural tube defects

The average incidence of neural tube defects is 1–2 in 1000 births, with a peak of 7 in 1000 in South Wales. The multifactorial etiology of this anomaly is well established.

Anencephaly is characterized by the absence of the cranial vault and telencephalon. Necrotic remnants of the brain stem and rhombencephalic structures are covered by a vascular membrane. Associated malformations are common and include spina bifida, cleft lip palate, clubfoot, and omphalocele. Polyhydramnios is frequently found. The diagnosis is easy in the midtrimester, and relies upon the demonstration of the absence of the cranial vault. Although the fetal head can be positively identified by vaginal sonography as early as the 7th week of gestation, the diagnosis may be difficult in the first trimester.¹⁵ Anencephaly is considered to be the final stage of acrania, as a consequence of disruption of abnormal brain tissue unprotected by the calvarium.^{16,17} A cephalic pole, albeit overtly abnormal, is therefore usually present in early gestation, and may be difficult to identify prior to 11 weeks' gestation (Fig. 23.4).

Spina bifida is commonly subdivided into open and closed forms.¹⁸ Open spina bifida is predominant at birth and is a full-thickness defect of the skin, underlying soft tissues, and vertebral arches exposing the neural canal. The defect may be covered by a thin meningeal membrane (meningocele). In the presence of neural tissue inside the sac, the lesion is defined as a myelomeningocele, a term often used to indicate all cases of spina bifida aperta. The defect may vary considerably in size. The lumbar, thoracolumbar, or sacrolumbar areas are most frequently affected. Leakage of cerebrospinal fluid through the defect causes an increased concentration of alpha-fetoprotein (AFP) in the amniotic fluid and maternal serum.¹⁹ Closed spina bifida is characterized by a vertebral schisis covered by skin. The skin is usually pigmented, dimpled, or presents areas of hypertrichosis. A subcutaneous mass, a meningocele, or lipoma may be present. Maternal serum and amniotic fluid AFP are usually within normal limits.

The diagnosis of open spina bifida is possible from midgestation, but it is often difficult and requires meticulous scanning (Fig. 23.5). The accuracy depends heavily on the experience of the operator, the quality of the equipment, and the amount

Figure 23.4 Three-dimensional ultrasound of anencephaly at different gestational ages: on the left, a 12-week-old fetus with an abnormal cephalic pole; on the right, absence of the cephalic pole in the third trimester (courtesy of Dr R. Ximenez, Sao Paulo, Brazil).

Figure 23.6 The cranial signs associated with open spina bifida.

of time dedicated to the scan. The accuracy of referral centers is close to 100%.^{19–21} The accuracy of routine nontargeted examinations is uncertain. Examination of the fetal head can assist the sonologist, as open spina bifida is consistently associated with easily recognizable cranial lesions (Fig. 23.6). Leakage of cerebrospinal fluid leads to displacement of the cerebellar vermis, fourth ventricle, and medulla oblongata through the foramen magnum inside the upper cervical canal (Chiari type II or Arnold–Chiari malformation). Sonographically, this results in a small head measurement at mid-gestation, obliteration of the cisterna magna, small size and abnormal shape of the cerebellum that is impacted deep into the posterior fossa (banana sign), and frontal bossing (lemon sign).²² Hydrocephalus of variable degrees is present in virtually all cases of spina bifida aperta at birth, but in less than 70% of cases in the midtrimester.

Closed spina bifida is associated with normal intracranial anatomy and normal AFP levels and is therefore usually unpredictable, with the possible exception of cases associated with large subcutaneous lesions.

Anencephaly is invariably fatal. The outcome for infants with open spina bifida is dictated by the site and extension of the lesion.²³ The mortality rate is high, the 7-year survival rate being only 40% despite early treatment. Many of the survivors will suffer from significant disabilities such as lower limb paralysis or dysfunction and incontinence. The association of spina bifida and severe hydrocephalus was traditionally considered a poor prognostic factor for intellectual development. More recent studies indicate that, in many cases, control of intracranial hypertension by shunting results in normal intelligence.

Recently, attempts have been made at intrauterine repair of spina bifida, and it has been suggested that these operations may reduce the morbidity of the affected infants.²⁴

The outcome of closed spina bifida is difficult to predict *in utero*. These infants usually do not develop Arnold–Chiari malformation and hydrocephalus. However, particularly those with subcutaneous masses may suffer from neurologic sequelae of variable degrees.¹⁸

The term cephalocele indicates a protrusion of intracranial contents through a bony defect of the skull. In most cases, the lesion arises from the midline, in the occipital area, and less frequently from the parietal or frontal bones. Encephaloceles are characterized by the presence of brain tissue inside the lesion. When only meninges protrude, the term cranial meningocele should be used. Cephaloceles often cause impaired cerebrospinal fluid circulation and hydrocephalus. Massive encephaloceles may be associated with microcephaly.

Fetal cephaloceles should be suspected when a paracranial mass is seen on sonography. The diagnosis of encephaloceles is easy, as the presence of brain tissue inside the sac is striking on ultrasound. Differentiation of a cranial meningocele from soft tissue edema or a cystic hygroma of the neck may be difficult. Demonstration of the bony defect in the skull would allow a proper diagnosis, but cranial meningoceles are often associated with extremely small (a few millimeters) defects that are not amenable to antenatal sonographic recognition. Indirect clues can assist the diagnosis. Cranial cephaloceles are very often associated with ventriculomegaly. Cystic hygromas arise from the region of the neck, have multiple internal septations and a thick wall, and are often associated with generalized soft tissue edema and hydrops.

The pediatric literature suggests that the outcome of cephaloceles is mainly related to the presence or absence of brain tissue inside the lesion. However, the largest available antenatal series reports a dismal prognosis for both varieties.^{25,26}

Midline anomalies

Midline cerebral anomalies include a group of brain defects that encompass a wide spectrum of severity and are typically associated with craniofacial malformations (Fig. 23.7).

The holoprosencephalies are complex abnormalities of the forebrain that share in common an incomplete separation of the cerebral hemispheres and formation of diencephalic structures.²⁷ The most widely accepted classification of these

Figure 23.7 (A) Normal coronal scan at mid-gestation; (B) alobar holoprosencephaly; (C) complete agenesis of corpus callosum.

disorders recognizes three major varieties: the alobar, semilobar, and lobar types. In the alobar variety, the most pronounced one, the interhemispheric fissure and the falx cerebri are totally absent, there is a single primitive ventricle (holoventricle), the thalami are fused on the midline, and there is absence of the third ventricle, neurohypophysis, olfactory bulbs and tracts. In semilobar holoprosencephaly, the two cerebral hemispheres are partially separated posteriorly, but there is still a single ventricular cavity. In both alobar and semilobar forms, the roof of the ventricular cavity, the tela choroidea, normally enfolded within the brain, may balloon out between the cerebral convexity and the skull to form a cyst of variable size – the dorsal sac. Alobar and semilobar holoprosencephaly are often associated with microcephaly, and less frequently with macrocephaly, which is invariably due to internal obstructive hydrocephalus. In the lobar variety, the interhemispheric fissure is well developed posteriorly and anteriorly, but there is still a variable degree of fusion of the cuneate gyrus and of the lateral ventricles, and absence of the septum pellucidum. The facial anomalies are pleomorphic, but can be regarded as the consequence of hypoplasia of the mid-facial structures. They span between cyclopia and severe hypotelorism with median cleft lip–palate. The nose can be absent, replaced by a proboscis or extremely flattened.

The incidence of holoprosencephaly at birth is uncertain. This anomaly was, however, found in 1 of 250 voluntary terminations of pregnancy.²⁸ This observation suggests a high intrauterine fatality rate. The etiology is heterogeneous. In most cases, the anomaly is isolated and sporadic. In other cases, chromosomal abnormalities (trisomy 13 and polyploidy), and/or anatomic abnormalities are found.

Prenatal diagnosis of alobar holoprosencephaly depends upon the demonstration of a single rudimentary cerebral ventricle.²⁷ Additional findings include the presence of typical facial anomalies.^{29,30} Similar findings are expected with the semilobar type. Recognition of the lobar variety has also been reported. Diagnosis requires a midcoronal scan, demonstrating absence of the cavum septum pellucidum and central

fusion of the frontal horns, which have a flat squared roof and communicate amply with the inferior third ventricle.^{27,31} The presence of the fused fornices, which appear as a linear structure running within the third ventricle from the anterior to the posterior commissure, is a frequent and very specific finding with this condition.³² As in lobar holoprosencephaly, the interhemispheric fissure is shallow anteriorly as a result of the fusion of the frontal lobes; the branches of the anterior cerebral artery run along the surface of the brain giving rise on color Doppler to a typical sign that has been referred to as the serpent crawling under the skull.³³

The invariably poor prognosis for infants affected by alobar and semilobar holoprosencephaly is well established. Thus far, cases diagnosed *in utero* have had extremely poor neurologic development.³¹

Agenesis of the corpus callosum (ACC) is an anomaly of uncertain prevalence and clinical significance. Estimates of 0.3–0.7% in the general population and 2–3% in the developmentally disabled are usually quoted.³⁴ The etiology is heterogeneous. Genetic factors are probably predominant. The high frequency of associated malformations and chromosomal aberrations suggest that ACC is often part of a widespread developmental disturbance.

ACC may be either complete or partial. In the latter case, also referred to as dysgenesis of the corpus callosum, the caudad portion (splenium and body) is missing to varying degrees.

The diagnosis of ACC is possible from mid-gestation, but is a challenge even for expert sonologists.³⁴ In routine examinations, an increased atrial width with a “tear-drop configuration” of the lateral ventricles and/or failure to visualize the cavum septum pellucidum (which is always absent with complete ACC) should alert to the possibility of fetal ACC.

Once a suspicion has been formulated, a direct diagnosis is possible by demonstrating the absence of the corpus callosum by coronal and sagittal scans. These views are at times difficult to obtain, in particular in vertex fetuses. However, vaginal sonography is of great advantage in such cases. Abnormal

branching of the anterior cerebral artery can also be demonstrated with the use of color Doppler ultrasound.³⁴

Diagnosis of partial ACC has also been reported, but the sonographic findings are even more elusive than with the complete form.³⁴

The outcome of ACC is mainly dictated by the associated anomalies. Isolated ACC is associated with a normal to borderline intellectual development in most cases.³⁵ However, long-term studies indicate a progressive decrease in intellectual capacity over time, and most infants tend to have significant difficulties at school.³⁶ ACC has also been linked to psychosis.³⁷

The term Dandy–Walker syndrome was originally introduced to indicate the association of: (1) ventriculomegaly of variable degree; (2) a large cisterna magna; and (3) a defect in the cerebellar vermis through which the cyst communicates with the fourth ventricle. At present, the term Dandy–Walker complex (or continuum) is used to indicate a spectrum of anomalies of the posterior fossa that share in common a cystic posterior fossa and/or hypoplasia of the cerebellar vermis.³⁸

The classic type of Dandy–Walker malformation has an estimated incidence of about 1:30 000 births, and is found in 4–12% of all cases of infantile hydrocephalus. The frequency of minor variants of this condition is unknown.

Dandy–Walker malformation is frequently associated with other neural defects, mostly with other midline anomalies, such as ACC and holoprosencephaly. Other deformities include encephaloceles, polycystic kidneys, cardiovascular defects, and facial clefting. Postnatal studies indicate a frequency of associated malformations ranging between 50% and 70%.^{38,39}

The sonographic landmark of the Dandy–Walker complex is an enlarged cisterna magna (by common definition, a depth greater than 10 mm),^{40,41} usually associated with a midline cleft of the vermis (Fig. 23.8). The classic type of Dandy–Walker malformation is associated with a large cisterna magna and severe ventriculomegaly, and tends to have a poor prognosis. However, minor variations are encountered more fre-

quently.^{38,42,43} The clinical significance of these findings is uncertain, and no clear-cut prognostic data exist. Recent neuropediatric series suggest an association between the size of the cerebellar vermis and intellectual development.³⁹ Under normal conditions, it is usually possible with either sonography or MRI to obtain a midsagittal view of the fetal cerebellar vermis demonstrating the fastigium of the fourth ventricle and the two main fissures from about mid-gestation.³⁹ With hypoplasia of the vermis, these landmarks cannot be identified. Nomograms of the normal size of the vermis throughout gestation are also available⁴⁴ (Fig. 23.9).

Caution is warranted while making the diagnosis of a minor variety of the Dandy–Walker continuum. Development of the cerebellar vermis is incomplete prior to 20 weeks' gestation, and this frequently creates an artifact mimicking a vermian defect.⁴⁵

When the classic form of Dandy–Walker malformation is found prior to viability, pregnancy termination can be offered to the parents. In continuing pregnancies, no modification of standard obstetric management exists. Cesarean delivery is indicated only if macrocrania is present. A careful search for associated malformations is indicated when the cisterna magna is greater than 10 mm or there is the impression of a vermian defect after 20 weeks.^{40,43}

As the diagnosis of midline anomalies depends mostly upon scans of sagittal and coronal planes of the fetal head that are sometimes difficult to obtain, we have found that three-dimensional ultrasound is frequently of considerable help. Multiplanar slicing of a volume obtained from axial scans usually provides images of diagnostic quality (Fig. 23.10).

Destructive cerebral lesions

Many congenital anomalies of the brain are not the consequence of an embryogenetic malformative process, but are due to a destructive process. The pathophysiology is frequently

Figure 23.8 The normal transcerebellar scan (A) compared with variations of the Dandy–Walker continuum; (B) a cerebellar “cleft” (arrow) suggesting a vermian defect; (C) an enlarged cisterna magna (arrow) with a seemingly normal vermis.

Figure 23.9 The normal midsagittal view (A) demonstrating the main landmarks of the cerebellar vermis (fastigium of fourth ventricle and the two main scissures) (arrows) is compared with variations of the Dandy–Walker continuum: (B) upward rotation of a hypoplastic vermis; (C) upward rotation of a seemingly intact vermis; (D) enlargement of the cisterna magna with an intact vermis

(megacisterna magna). Although the outcome cannot be clearly predicted, a hypoplastic vermis (B) is a poor prognostic factor, while the upward rotation of a seemingly intact vermis and a megacisterna magna (C and D), when isolated, may be asymptomatic.

Figure 23.10 Multiplanar imaging of the fetal brain using three-dimensional ultrasound. (A) Complete agenesis of the corpus callosum; (B) upward rotation of a hypoplastic cerebellar vermis; (C) upward rotation of an intact vermis. The images are of

comparable quality to those obtained with direct bidimensional scanning (compare with Figs 23.7C, 23.9B, and 23.9D respectively). 3v, third ventricle.

unclear, and the conditions remain idiopathic. A link with obstetric complications of a different nature is however frequently found.^{46–48}

Intracranial hemorrhage (ICH) is usually found at the level of the lateral ventricles, although it can occur in other anatomical locations. It is a frequent complication in premature infants. Although rarely, it may occur antenatally, as a consequence of coagulopathy or trauma, or other as yet unexplained factors.⁴⁶ The sonographic appearance of an ICH is extremely variable depending upon the severity and the time since it occurred (Fig. 23.11). Blood accumulated into the ventricles appears as an echogenic collection. With time, the blood clot retracts, demonstrates an anechoic core, and is frequently associated with ventricular dilation (grade 3 hemorrhage). Large hemorrhagic collections may be complicated by infarct and destruction of the surrounding white matter (grade 4 hemorrhage).

The prognosis is severe. In a review of the literature,⁴⁶ perinatal death occurred in about 50% of cases, and 50% of survivors had neurologic compromise at long-term follow-up. There was a correlation between the outcome and the grade of the hemorrhage. The prognosis was more favorable with grade 1 and 2 hemorrhages (hemorrhage limited to the germinal matrix or lateral ventricles without ventriculomegaly), which at times may even resolve *in utero*, and was usually severe with grade 3 and 4 lesions (intraventricular hemorrhage associated with severe ventriculomegaly and white matter destruction respectively).

Congenital porencephaly is defined as the presence of cystic cavities within the brain matter (Fig. 23.12). The cavities usually communicate with the ventricular system, the subarachnoid space, or both. Loss of cerebral tissue may derive from a morphogenetic disorder (true porencephaly or schizencephaly). More frequently, it is the consequence of an

Figure 23.11 Types of intracranial hemorrhage. (A) Soon after the hemorrhage, the blood is intensely echogenic (arrow); this is a grade 2 hemorrhage. (B) An old hemorrhage (arrow); the coronal scan demonstrates a typical blood clot and ventricular enlargement (grade 3 hemorrhage). (C) Hemorrhage (arrow) associated with destruction of the cortex (grade 4 hemorrhage).

Figure 23.12 Destructive lesions of the fetal brain: (A) porencephalic cyst (arrow); (B) schizencephaly (arrows); (C) periventricular leukomalacia (arrows).

intrauterine disruption (pseudoporencephaly or encephaloclastic porencephaly). The developmental form is typically bilateral and symmetrical, and is frequently associated with microcephaly. In pseudoporencephaly, a unilateral lesion is usually found. In both cases, there is wide variability in the size of the lesion. Cerebrospinal fluid turnover is often impaired, and hydrocephalus is present. Hydranencephaly can be regarded as an extreme form of pseudoporencephaly. Most of the cerebral hemispheres are replaced by fluid. The brain stem and rhombencephalic structures are usually spared. The head may be small, of normal size, or extremely enlarged. The etiology is heterogeneous. Congenital infections, including toxoplasmosis and cytomegalovirus, and intrauterine strangulation or occlusion of the internal carotid arteries have been reported. Accurate antenatal diagnosis of both schizencephaly and porencephaly has been reported.⁴⁹ It should be stressed, however, that porencephaly is a disruption that usually occurs only in the third trimester.

The outcome of infants with congenital destructive process of the brain is dictated by the size and location of the lesion. Extensive porencephaly, particularly if associated with hydrocephalus or microcephaly, and hydranencephaly have a uniformly poor outcome.

Periventricular leukomalacia is a degenerative disorder of the white matter that is most frequently encountered in premature infants and is frequently associated with a severe prognosis. The cystic variety of this condition has been described recently in the fetus.⁴⁸ The diagnosis is made by demonstrating multiple small cysts close to the upper corner of the lateral ventricles (Fig. 23.12).

Disorders of nerve cell proliferation

The association between decreased head size and reduction in both brain mass and total cell number in microcephalic infants

is well established. However, the threshold of abnormality is uncertain. Some authors suggest employing a head circumference below -2 standard deviations from the mean as the diagnostic criterion. Others prefer to consider head circumference below -3 standard deviations as abnormal. The incidence of microcephaly obviously varies in different surveys, depending upon the definition used to identify the lesion.

Microcephaly should not be considered as a single clinical entity, but rather as a symptom of many etiologic disturbances, including both environmental and genetic factors. Microcephaly features a typical disproportion in size between the skull and the face. The forehead is sloping. The brain is small, with the cerebral hemispheres affected to a greater extent than the diencephalic and rhomboencephalic structures. Abnormal convolutional patterns, including macrogyria, microgyria, and agyria, are frequently found. The ventricles may be enlarged. Microcephaly is frequently found in cases of porencephaly, lissencephaly, and holoprosencephaly.

Many difficulties arise in attempting to identify fetal microcephaly.⁵⁰ The utility of head measurements alone may be hampered by incorrect dating or intrauterine growth retardation. Furthermore, the natural history of fetal microcephaly is largely unknown. A progressive development of the lesion interfering with early recognition has been described. A comparison of biometric parameters such as the head circumference:abdominal circumference ratio and the femur length:biparietal diameter ratio has been suggested. Nevertheless, both false-positive and false-negative diagnoses occur frequently. It is clear that the predictive value of ultrasound biometry has significant limitations. A qualitative evaluation of the intracranial structures is a very useful adjunct to biometry because many cases of microcephaly are associated with morphologic derangement, particularly with ventriculomegaly, schizencephaly, and disorders of ventral induction. Demonstration of a sloping forehead also increases the index of suspicion.⁵¹

The final outcome of microcephaly is uncertain. Infants with small heads have a much increased risk of neurologic compromise, and this correlates with head size. When the head circumference is extremely small, 4 standard deviations or more below the mean, and/or there are associated abnormalities, the prognosis tends to be severe.

Megalencephaly, that is, an abnormally large brain, is usually found in individuals of normal and even superior intelligence, but it may be associated with mental retardation and neurologic impairment.⁵² Megalencephaly is also part of congenital anomalies and syndromes such as Beckwith-Wiedemann syndrome, achondroplasia, neurofibromatosis, and tuberous sclerosis. Obstetric and pediatric sonographers are frequently challenged by the problem of megalencephaly, a condition that should be suspected in the presence of abnormally large head measurements without evidence of hydrocephalus or intracranial masses. In such cases, examination of the parents may be of help, as asymptomatic megalencephaly is frequently familial.

Anomalies of neuronal migration

The neuronal cells that form the gray matter originate internally to the brain, on the surface of the lateral ventricles, and only later migrate along radially aligned glial cells to the surface of the brain. The migration occurs in different waves that last for several weeks. Most of the process takes place between 8 weeks' and 16 weeks' gestation, but continues up to 25 weeks. Once the neuronal cells have reached their destination on the surface of the brain, they undergo a process of maturation and differentiation, grow axons and dendrites, and develop synapses with other neurons, giving rise to a well-ordered, six-layer cortex. Migrational abnormalities are characterized by the incomplete formation of the cortical layers, with abnormal locations of neurons that have failed to reach their final destination. In general, the cortex is thickened by a large, disorganized layer of neurons. Conversely, the white matter underneath the cortex is thinned by failure in production of axons by the disorganized neuronal cells. Macroscopically, the main finding is an alteration in the convolutional pattern of the brain, which may be associated with modifications in brain mass and the size of the ventricles.

Failure of neuronal migration includes a broad spectrum of anomalies: absence to severe reduction of convolutions (lissencephaly), increased number of small convolutions (polymicrogyria), unilateral megalencephaly, schizencephaly, and gray matter heterotopias. The migrational process may be arrested by environmental factors (ischemia, teratogens), but a genetic predisposition is clearly present at least for some anomalies.

Postnatally, the technique of choice for the diagnosis of this condition is MRI, which allows a clear discrimination between white and gray matter. Sonographic detection of typical macroscopic abnormalities of brain anatomy (clefts in the cortex, gyral anomalies, etc.) has led to the diagnosis of these conditions antenatally, although usually only in late gestation^{8,53,54} (Fig. 23.2).

Choroid plexus cysts

Choroid plexus cysts are sonolucent spaces within the choroid plexus, with well-defined walls. The cysts may be unilateral or bilateral and are occasionally multiple. They are typically found at the level of the atrium of lateral ventricles, and less frequently within the bodies. When examined with high-resolution ultrasound equipment, the choroid plexus of the lateral ventricle often appears slightly dishomogeneous. A choroid plexus cyst should measure at least 2 mm in diameter. Large cysts up to 14 mm may be seen, and usually contain internal sediments.

Fetal choroid plexus cysts are benign findings that are however associated with an increased likelihood of trisomy

18.^{55,56} The available data do not indicate an association with other chromosomal aberrations, including trisomy 21.^{57,58} In 80–90% of fetuses with trisomy 18, anatomic deformities will be detected by ultrasound.⁵⁹ On the basis of these data, a prudent approach is to perform a thorough sonographic examination of the fetus when a choroid plexus cyst is identified. This examination should include evaluation of the hands, feet, and heart. If an additional ultrasound abnormality is identified, chromosomal analysis should be offered to the patient. Otherwise, the patient may be counseled with the figures suggested by Snijders and co-workers,⁵⁸ that is, that the risk of trisomy 18 is increased 1.5 times over the baseline.

Isolated choroid plexus cysts do not modify standard obstetrical management. As no deleterious effect on the fetus has been reported with this finding thus far, there is no need in our opinion for follow-up scans. A handful of very large cysts of the choroid plexuses causing intracranial hypertension has been described in the neurosurgical literature, but these probably represent a separate clinical entity.⁶⁰

Conclusions

Modern ultrasound equipment yields a unique potential for the evaluation of the normal and abnormal fetal CNS. A large number of congenital anomalies can be consistently recognized. Transvaginal sonography is extending antenatal diag-

nosis to very early gestation.^{61–63} MRI can be used to improve the accuracy of the diagnosis in selected cases.

Nevertheless, it is important to stress that development of the brain continues throughout gestation and that a significant number of anomalies cannot be predicted even by an expert examiner at mid-gestation. In a recent study, 17% of fetal cerebral abnormalities could not be diagnosed prior to viability.⁶⁴ Furthermore, when an anomaly is identified, counseling the parents and deciding on a sensible obstetric management is frequently difficult. Some cerebral anomalies have outcomes that can be predicted with reasonable precision. This is certainly the case with catastrophic lesions such as anencephaly and severe holoprosencephaly, as well as with anomalies that are invariably detected at birth, such as spina bifida. There are, however, a large number of conditions that can be accurately identified *in utero* and yet have an unclear natural history. ACC, mild ventriculomegaly, and minor variations of the Dandy–Walker continuum are remarkable examples in this regard. It has to be appreciated that, at present, there is quite a dramatic discrepancy between the diagnostic capability of antenatal ultrasound (which is potentially very high) and our understanding of the prognostic implications of anatomic alterations (which is limited by many points of view).

Eventually, the diagnosis of acquired brain lesions owing to hemorrhagic or ischemic causes will be possible, and it is likely to become part of the management of selected high-risk pregnancies.^{46–48}

Key points

- 1 The incidence of central nervous system malformations is in the range of 1:100 births.
- 2 Ultrasound allows the diagnosis of many malformations from mid-gestation; the results of the examination depend partly upon the expertise of the sonologist and the time dedicated to the examination; a standard sonogram is performed in low-risk patients by the use of two scanning planes demonstrating the lateral ventricles and posterior fossa; an expert sonogram is performed by using other scanning planes oriented along the sutures and fontanelles of the fetal head that allow the identification of other details; the use of three-dimensional ultrasound facilitates the examination.
- 3 Some cerebral malformations may not be detected antenatally by ultrasound, particularly in early gestation.
- 4 Magnetic resonance is frequently used in fetuses at high risk of cerebral malformations, particularly to assess hemorrhage, abnormalities of cortical development, and complex cerebral anomalies.
- 5 Under normal conditions, the internal diameter of the atrium of the lateral ventricles is less than 10 mm; a value of 10 mm greatly increases the likelihood of a cerebral anomaly.
- 6 An atrial diameter of more than 15 mm is usually associated with an intracranial malformation.
- 7 An atrial diameter of 10–15 mm, a condition usually referred to as mild ventriculomegaly, may represent a normal variant, but greatly increases the likelihood of cerebral anomalies and extracerebral anomalies, chromosomal aberrations, and abnormal neurodevelopment.
- 8 Anencephaly is easily diagnosed sonographically at mid-gestation and may be identified as early as 12 weeks' gestation.
- 9 Spina bifida is one of the most frequent anomalies of the central nervous system; the most severe type, the open variety, can be identified sonographically by mid-gestation, although the diagnosis is at times difficult; obstetric patients usually undergo screening by assay of maternal serum alpha-fetoprotein; the

sonographic diagnosis is assisted by the demonstration of typical cranial alterations, the lemon and banana signs, that are usually easier to identify than the spinal defect.

- 10 Closed spina bifida is usually unpredictable sonographically.
- 11 The most severe varieties of holoprosencephaly, the alobar and semilobar forms, are usually recognized by mid-gestation by the demonstration of the absence of the midline echo and the presence of a single rudimentary ventricular cavity.
- 12 The less severe variety of holoprosencephaly is more difficult to identify and diagnose; the main clue is the absence of the cavum septi pellucidi and the central fusion of the frontal horns.
- 13 Agenesis of the corpus callosum may be one of the most frequent congenital anomalies; in a standard examination, it may be suspected by indirect findings, such as mild ventriculomegaly and/or the absence of the cavum septi pellucidi; a specific sonographic diagnosis is possible but requires an expert examination; agenesis of the corpus callosum is an important risk factor for mental retardation; infants with isolated agenesis of the corpus callosum may have a normal, albeit frequently low, intellect.
- 14 The term Dandy–Walker complex is used to define cases in which the cisterna magna is large (more than 10 mm) and/or there is hypoplasia of the cerebellar vermis; many variations exist, and the prognosis is difficult to predict.
- 15 Many congenital anomalies of the cerebrum are not the consequence of an embryogenetic malformative process but are due to a destructive antenatal event, usually hemorrhagic or ischemic; fetal intracranial hemorrhage may be recognized by sonography, but the findings vary depending upon the time the lesion has occurred and the severity of the hemorrhage; most intracranial bleeding occurs at the level of the ventricles; a recent hemorrhage appears as an echogenic collection that may be associated with ventricular enlargement; in the weeks following the hemorrhage, the blood clot retracts and develops a sonolucent core; severe forms of intraventricular hemorrhage (those associated with either hydrocephalus and/or destruction of the nearby cortex) are associated with an excess of perinatal deaths and neurologic compromise.
- 16 Destructive insults of the brain result in cystic cavities (porencephaly) of the cortex; cystic degeneration of the white matter (periventricular leukomalacia) has also been described in the fetus; in some cases, these lesions are the consequence of obstetric complications such as intrauterine hypoxia/ischemia, infections, or congenital coagulopathy.
- 17 Microcephaly is associated with an increased risk of neurologic compromise; the fetal head can be effectively measured with sonography, but the diagnosis of microcephaly is hampered by an overlap with normal variations (there is no clear quantitative threshold) and particularly by intrauterine progressive development, which occurs in many cases; when the head is small, a specific antenatal diagnosis may be difficult; as microcephaly is associated with intracranial abnormalities in many cases, a careful inspection of cerebral anatomy may be helpful.
- 18 Disorders of neuronal migration include a wide spectrum of disorders characterized by abnormal sulcation of the brain; they may be diagnosed sonographically and/or with magnetic resonance, but usually only in late gestation.
- 19 Choroid plexus cysts are small fluid collections within the choroid plexus of lateral ventricles; they are identified in 1% or more of fetuses at mid-gestation, and are transient and benign findings that however increase the risk of trisomy 18; as most cases of trisomy 18 are associated with anomalies that are readily identified with sonography, there is a general consensus that a careful inspection of fetal anatomy is indicated; amniocentesis may not be necessary.
- 20 Any time that a sonographic examination is performed in the second or third trimester, a survey of intracranial anatomy should be performed; the sensitivity of antenatal sonography remains uncertain; certainly, many even severe anomalies are associated with subtle antenatal findings or become manifest only in late gestation and therefore escape antenatal detection.

Prenatal diagnosis of thoracic and cardiac abnormalities

Gianluigi Pilu, Philippe Jeanty, and Juliana M.B. Leite

Cardiac anomalies

Abnormalities of the heart and great arteries are among the most common congenital abnormalities, with an estimated incidence of 5 per 1000 births and about 30 per 1000 stillbirths. In general, about one-half are either severe or require surgery early in life and are generally referred to as major cardiac abnormalities.

Fetal echocardiography is the primary diagnostic tool used to assess fetal cardiac structure and function.^{1,2} This is a specialized sonogram that is certainly indicated when there is an increased risk of fetal cardiac abnormalities, and is usually performed at 18–22 weeks' gestation. When the risk of a fetal cardiac anomaly is particularly high, an earlier evaluation, at around 13–15 weeks, by either transabdominal or vaginal sonography, may be considered, as many cardiac anomalies are already demonstrable at this stage. This early examination should, however, be corroborated by a repeat evaluation around mid-gestation.

A complete fetal echocardiographic examination should incorporate the following standard views: a demonstration of the visceral and cardiac situs, a four-chamber view, ventriculo-arterial connections, and course of the great arteries (Fig. 24.1). Real-time examination of cardiac structures is enhanced by the use of color Doppler. Different approaches are possible to visualize these anatomical details, and the interested reader is referred to specific works on this subject.^{3,4}

Fetal echocardiography allows the detection of many cardiac malformations, but the precise accuracy is difficult to establish. Antenatal studies have a tendency to detect the more severe anomalies and miss the more benign lesions.² Defects that have commonly been missed include ventricular septal defects, atrial septal defects, semilunar valve stenosis, and tetralogy of Fallot, among others. Lesions that affect the four-chamber view are more commonly detected than conotruncal lesions. Finally, the natural evolution of some anomalies may be such that they only appear in the third trimester. Examples of this include premature occlusion of the foramen ovale,

aortic and pulmonary stenosis with intact ventricular septum, and cardiac tumors, among others. Most studies in which a detailed fetal echocardiogram was performed report sensitivities in the range of 70–85%.⁵

The sensitivity of the four-chamber view, which should always be included in any standard sonographic examination performed from mid-gestation on, is controversial. Albeit in some studies it has been found to be as high as 80%, others have reported disappointing results, with sensitivities of 5–15%^{6,7} – most likely the experience of the sonologist performing the examination is critical from this point of view.

A new technique for the sonographic evaluation of the fetal heart, based upon the use of three-dimensional ultrasound, has been recently introduced, commonly referred to as STIC (*spatiotemporal image correlation technology*) (Fig. 24.2). The use of this technology has provided many potential advantages, both for diagnostic use (e.g., to reconstruct scanning planes that cannot be directly obtained)^{8–11} and for screening and teleconsultation,^{12,13} which have been only partially investigated thus far.

Septal defects

Defects of the atrial and ventricular septum represent about 10% and 30%, respectively, of all cardiac defects. Prenatal diagnosis is based upon demonstration of a gap of the septa (Fig. 24.3). In general, identification is difficult and is impossible in most cases. Most atrial defects involve the *septum secundum*, which is difficult to analyze owing to the physiologic presence of the foramen ovale. Most ventricular septal defects are small and equally difficult to demonstrate antenatally. As they are usually associated with blood shunting across the septum, color Doppler may aid in the diagnosis, which remains nevertheless difficult, and is very rarely made.¹⁴ When a ventricular septal defect is identified, STIC technology has been suggested to be useful in that it allows visualization of the septal gap in three orthogonal planes, allowing demonstration of both dimensions and position^{8,15} (see Fig. 24.2).

Atrial and ventricular septal defects are not a cause of

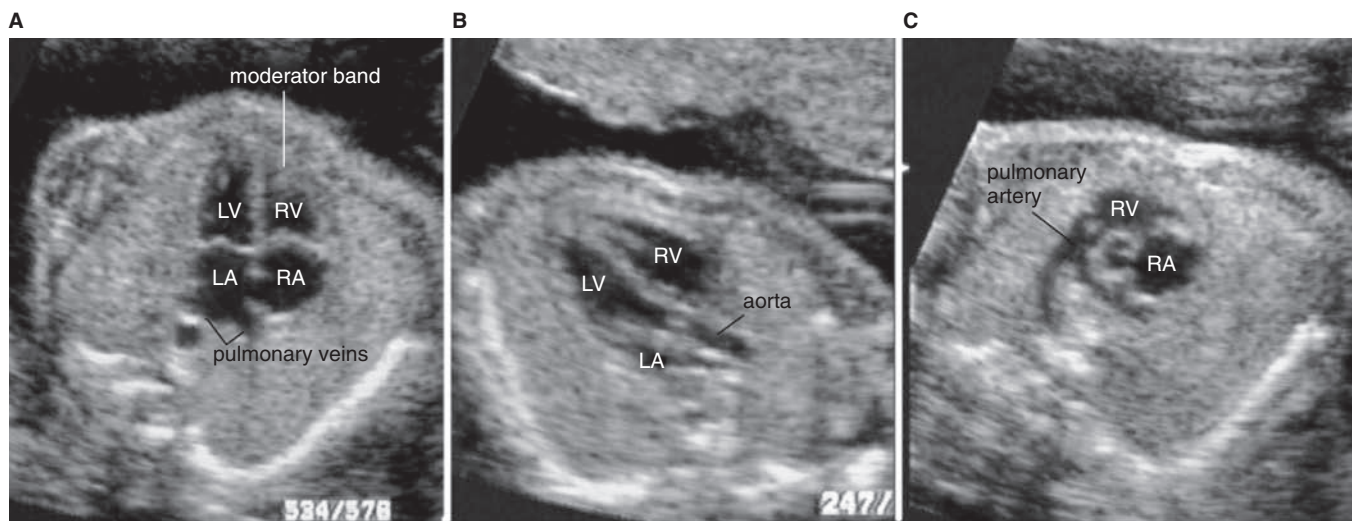

Figure 24.1 The essential views used for an echocardiographic examination in a normal fetus at 22 weeks' gestation. (A) Four-chamber view. (B) View of the left ventricle demonstrating the left ventriculoarterial connection. (C) Transverse section of great vessels demonstrating the right ventriculoarterial connection and the crossing of great arteries. (RA/LA, right/left atrium; RV/LV, right/left ventricle.)

Figure 24.2 Sonogram of fetal tetralogy of Fallot obtained with three-dimensional technology and STIC technology. Three orthogonal planes are simultaneously visualized and can be observed in motion during one reconstructed cardiac cycle. (A) Axial view of the chest demonstrating the aorta (Ao) overriding by about 50% the ventricular septum. (B) Coronal view demonstrating a short axis of both ventricle. (C) Reconstructed sagittal view of the chest demonstrating a lateral view of the entire ventricular septum and ascending aorta; this view demonstrates the subaortic location and extent of the ventricular septal defect.

Figure 24.3 Four-chamber views demonstrating abnormalities of cardiac septa: (A) muscular ventricular septal defect; (B) complete atrioventricular septal defect; (C) double-inlet single ventricle.

impaired cardiac function *in utero*, as a large intracardiac right-to-left shunt is a physiologic condition in the fetus. Most affected infants are asymptomatic even in the neonatal period. When they are not associated with other cardiac anomalies, the prognosis is excellent. Spontaneous closure is frequent. *Primum* atrial septal defect is the simplest of the atrioventricular septal defects and will be considered below.

The core of the heart, being the apical portion of the atrial septum, the basal portion of the interventricular septum and the medial portion of atrioventricular valves, develops from the mesenchymal masses, or endocardial cushions. Abnormal development of these structures, commonly referred to as endocardial cushion defects, atrioventricular canal, or atrioventricular septal defects, represents about 7% of all cardiac anomalies. In the complete form, *persistent common atrioventricular canal*, the tricuspid and mitral valve are fused in a large single atrioventricular valve that opens above and bridges the two ventricles (see Fig. 24.3). In the complete form of atrioventricular canal, the common atrioventricular valve may be incompetent and systolic blood regurgitation from the ventricles to the atria may give rise to congestive heart failure. In the partial form, there is a defect in the apical portion of the atrial septum (septum primum defect). There are two separate atrioventricular valves, but they are inserted at the same level on the ventricular septum.

Antenatal diagnosis of complete atrioventricular septal defects is not always easy. When the atrial and septal defects are large, the four-chamber view reveals an obvious deficiency of the central core structures of the heart.¹⁶ Color Doppler ultrasound can be useful in that it facilitates the visualization of the central opening of the single atrioventricular valve. The atria may be dilated as a consequence of atrioventricular insufficiency. In such cases, color and pulsed Doppler ultrasound allow the identification of the regurgitant jet. However, we have seen cases in which the defects of the septa were so small that they presented a real diagnostic challenge. False-negatives

have also been reported.¹⁷ The incomplete forms are even more difficult to recognize. A useful hint is the demonstration that the tricuspid and mitral valves attach at the same level at the crest of the septum. The low detection rate of fetal atrioventricular septal defects is attested by several large studies of low-risk patients.^{7,18} To improve the sensitivity of ultrasound, the ratio of the atria to the ventricular portion of the heart has been recently suggested.¹⁹

Atrioventricular septal defects do not impair the fetal circulation *per se*. However, the presence of atrioventricular valve insufficiency may lead to intrauterine heart failure. The prognosis of atrioventricular septal defects is poor when detected *in utero*, probably because of the high frequency of associated anomalies in antenatal series.^{16,20} Atrioventricular septal defects will usually be encountered either in fetuses with chromosomal aberrations (50% of cases are associated with aneuploidy, 60% being trisomy 21, 25% trisomy 18) or in fetuses with cardiosplenic syndromes. In the former cases, an atrioventricular septal defect is frequently found in association with extracardiac anomalies. In the latter cases, complex cardiac anomalies and abnormal disposition of the abdominal organs are almost the rule. Survival after surgical closure is more than 90%, but in about 10% of patients a second operation for atrioventricular valve repair or replacement is necessary. Long-term prognosis is good.^{16,20}

Univentricular heart

This term defines a group of anomalies characterized by the presence of an atrioventricular junction that is entirely connected to only one chamber in the ventricular mass. Therefore, univentricular heart includes both those cases in which two atrial chambers are connected, by either two distinct atrioventricular valves or a common one to a main ventricular chamber (*double-inlet single ventricle*) (see Fig. 24.3), and those in which, because of the absence of one atrioventricular

connection (tricuspid or mitral atresia), one of the ventricular chambers is either rudimentary or absent. Univentricular heart is rare; it represents about 1.5% of all congenital cardiac defects. Tricuspid atresia is by far the most frequent variety.

In double-outlet single ventricle, two separate atrioventricular valves are seen opening into a single ventricular cavity without evidence of the interventricular septum. In tricuspid atresia, there is only one atrioventricular valve connected to a main ventricular chamber. A small rudimentary ventricular chamber lacking an atrioventricular connection is a frequent but not constant finding.

Surgical treatment (the Fontan procedure) involves separation of the systemic circulations by anastomosing the superior and inferior vena cava directly to the pulmonary artery. The survivors from this procedure may develop several complications including arrhythmias, thrombus formation, and protein-losing enteropathy. The 5-year survival is about 70% and the long-term outcome is uncertain.²¹

Aortic stenosis

Aortic stenosis represents about 3% of all cardiac defects and is commonly divided into supravalar, valvar, and subaortic forms. Supravalar and subaortic are rare and usually cannot be detected antenatally. The valvar form of aortic stenosis can be due to dysplastic, thickened aortic cusps or fusion of the commissure between the cusps. With severe valvar aortic stenosis, the left ventricle may be either hypertrophic or dilated and hypocontractile. The ascending aorta is frequently enlarged. Hyperechogenicity of the aortic valve and pulsed Doppler demonstration of increased peak velocity (usually in excess of 1 m/s) support the diagnosis. At the color Doppler examination, high velocity and turbulence usually results in aliasing, with a mosaic of colors within the ascending aorta. Severe aortic stenosis may result in atrioventricular valve insufficiency and intrauterine heart failure. Most cases of mild to moderate aortic stenosis are probably not amenable to early prenatal diagnosis. Asymmetric septal hypertrophy and hypertrophic cardiomyopathy of fetuses of diabetic mothers resulting in subaortic stenosis has been diagnosed occasionally by demonstrating an unusual thickness of the ventricular septum.

Depending upon the severity of the aortic stenosis, the association of left ventricular pressure overload and subendocardial ischemia, due to decrease in coronary perfusion, may lead to intrauterine impairment of cardiac function. Subvalvar and subaortic forms are not generally manifested in the neonatal period. Conversely, the valvar type can be a cause of congestive heart failure in the newborn and fetus as well. The neonatal outcome depends on the severity of the obstruction. If the left ventricular function is adequate, balloon valvoplasty is carried out in the neonatal period, and in about 50% of cases surgery is necessary within the first 10 years of life because of aortic insufficiency or residual stenosis. If left ventricular function is inadequate, a Norwood type of repair is necessary (see Hypoplastic left heart syndrome, below).

Coarctation, tubular hypoplasia, and interruption of the aortic arch

Coarctation is a localized narrowing of the juxtaductal arch, most commonly between the left subclavian artery and the ductus. Cardiac anomalies are frequently present and include aortic stenosis and insufficiency, ventricular septal defect, atrial septal defect, transposition of the great arteries, and truncus and double-outlet right ventricle. Noncardiac anomalies include diaphragmatic hernia and Turner syndrome but not Noonan syndrome. Interrupted aortic arch is typically associated with chromosome 22 microdeletion.²²

Coarctation or interruption of the aortic arch should be suspected when the right ventricle is enlarged (right ventricle–left ventricle ratio of more than 1:3 (Fig. 24.4). Narrowing of the isthmus, or the presence of a shelf, is often difficult to demonstrate because in the fetus the aortic arch and ductal arch are close and are difficult to distinguish. In most cases, coarctation can only be suspected *in utero* and a definite diagnosis must be delayed until after birth.²¹ The characteristic finding of an ascending aorta that is more vertical than usual and the impossibility of demonstrating a connection with the descending aorta suggests the diagnosis of interrupted aortic arch. Coarctation/interrupted aortic arch should always be considered when intracardiac lesions diverting blood flow from the left to the right heart are encountered (aortic stenosis and atresia in particular).

Critical coarctation and interruption are fatal in the neonatal period after closure of the ductus and therefore prostaglandin therapy is necessary to maintain a patent ductus. Surgery (which involves excision of the coarcted segment and end-to-end anastomosis) is associated with a mortality of about 10% and the incidence of restenosis in survivors (requiring further surgical repair) is about 15%.

Interrupted aortic arch should always be considered when intracardiac lesions diverting blood flow from the left to the right heart are encountered (aortic stenosis and atresia in particular). Isolated interruption of the aortic arch is often encountered with enlargement of the right ventricle (right ventricle–left ventricle ratio of more than 1:3).

Interrupted aortic arch is one of the lesions most frequently associated with a microdeletion of chromosome 22, and represents an indication for prenatal diagnosis of this condition. In the most typical case, there is aortic arch interruption and a small or absent thymus.²² Recent reports suggest an overall late survival of more than 70% after surgery.

Hypoplastic left heart syndrome

Hypoplastic left heart syndrome accounts for 4% of all cardiac anomalies at birth, but it is one of the most frequent cardiac malformations diagnosed antenatally. It is a spectrum of anomalies characterized by a very small left ventricle with mitral and/or aortic atresia or hypoplasia. Blood flow to the

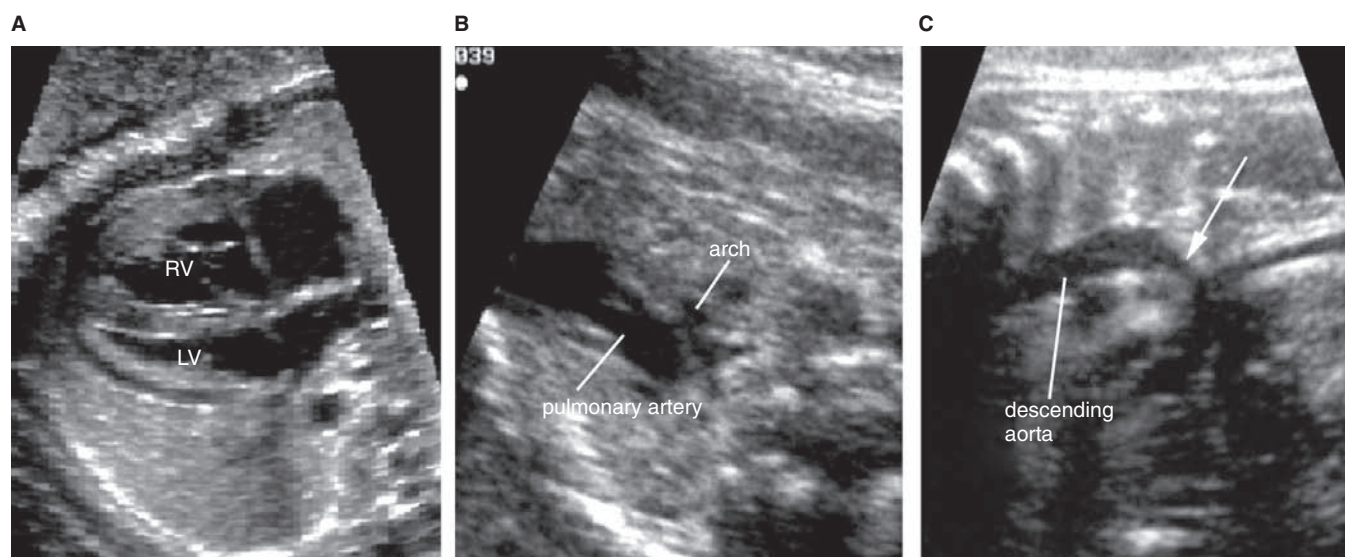

Figure 24.4 Aortic coarctation in a third-trimester fetus. (A) Four-chamber view demonstrating a disproportion in the size of the ventricles with predominance of the right cavities. (B) Transverse section of the upper thorax demonstrating a discrepancy in the size of the great vessels with a narrow transverse aortic arch. (C) Sagittal view of the chest demonstrating narrowing of the aortic arch.

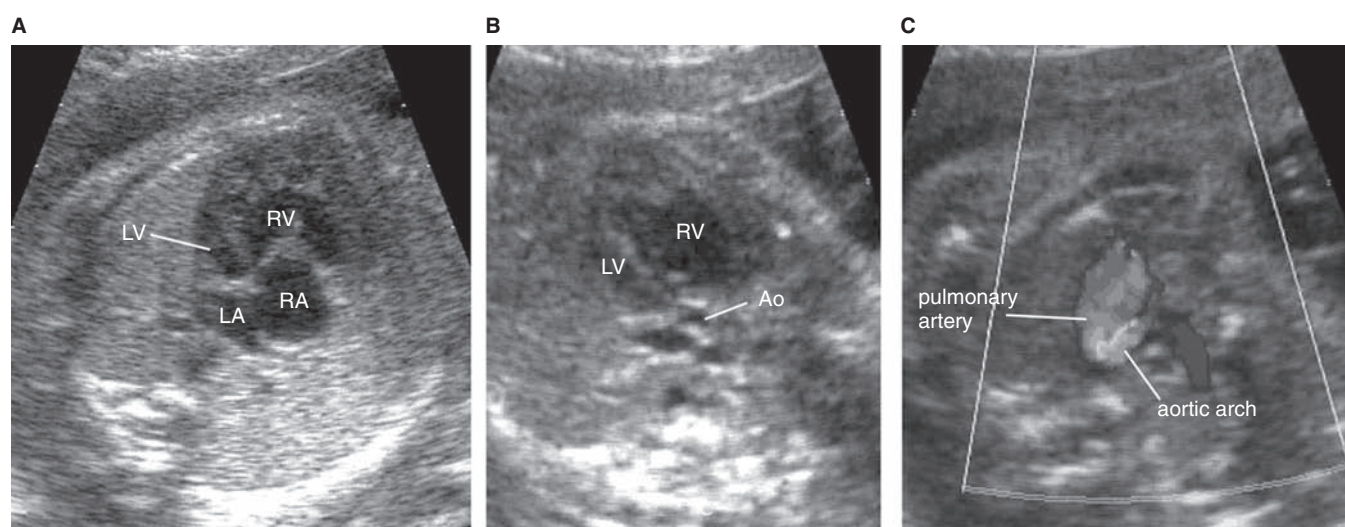

Figure 24.5 Hypoplastic left heart syndrome at mid-gestation. (A) Four-chamber view demonstrating a small left ventricle that does not reach the apex of the heart. (B) View of the left ventricle demonstrating a very small ascending aorta. (C) Color Doppler demonstrates reverse blood flow into the small aortic arch.

head and neck vessels and coronary artery is supplied in a retrograde manner via the ductus arteriosus.

Prenatal echocardiographic diagnosis of the syndrome depends on the demonstration of a diminutive left ventricle and ascending aorta (Fig. 24.5). In most cases, the ultrasound appearance is self-explanatory, and the diagnosis an easy one. There is, however, a broad spectrum of hypoplasia of the left ventricle and in some cases the ventricular cavity is almost normal in size. We anticipate that these cases will certainly be missed in most routine surveys of fetal anatomy. At closer scrutiny, however, the movement of the mitral valve appears severely impaired to nonexistent, ventricular contractility is decreased, and the ventricle often displays an internal

echogenic lining owing to endocardial fibroelastosis. The definitive diagnosis depends on the demonstration of hypoplasia of the ascending aorta and atresia of the aortic valve. Color flow mapping is an extremely useful adjunct to the real-time examination, in that it allows the demonstration of retrograde blood flow within the ascending aorta and aortic arch (see Fig. 24.5).

Hypoplastic left heart is well tolerated *in utero*. The patency of the ductus arteriosus allows adequate perfusion of the head and neck vessels. Intrauterine growth may be normal, and the onset of symptoms most frequently occurs after birth. The prognosis for infants with hypoplastic left heart syndrome, however, is extremely poor and this lesion is responsible for

25% of cardiac deaths in the first week of life. Almost all affected infants die within 6 weeks if they are not treated. In the neonatal period, prostaglandin therapy is given to maintain ductal patency but still congestive heart failure develops within 24 h of life. Options for surgery include cardiac transplantation in the neonatal period and the two-staged Norwood repair. *Stage 1* involves anastomosis of the pulmonary artery to the aortic arch for systemic outflow, placement of systemic–pulmonary arterial shunt to provide pulmonary blood flow, and arterial septectomy to ensure unobstructed pulmonary venous return; the survival rate of fetuses diagnosed *in utero* is in the range of 40%. *Stage 2* (usually carried out in the sixth month of life) involves anastomosis of the superior vena cava to the pulmonary arteries. Neurodevelopmental abnormalities have been reported in survivors of the Norwood operation. The survival rate for hypoplastic left heart diagnosed *in utero* at 3 years of life is in the range of 30%.^{21,23} Although there is controversy in the literature, some reports indicate that prenatal diagnosis increases the likelihood of survival, presumably by optimizing perinatal treatment.^{24,25}

Pulmonary stenosis and pulmonary atresia

Pulmonary stenosis and pulmonary atresia with intact ventricular septum (also known as *hypoplastic right ventricle*) represent 9% and about 2% of all cardiac anomalies, respectively.

The most common form of pulmonary stenosis is the valvar type, due to the fusion of the pulmonary leaflets. Hemodynamics are altered proportionally to the degree of the stenosis. The work of the right ventricle is increased, as well as the pressure, leading to hypertrophy of the ventricular walls. The same considerations formulated for the prenatal diagnosis of aortic stenosis are valid for pulmonary stenosis as well. A handful of cases recognized *in utero* have been reported in the literature thus far, mostly severe types with enlargement of the right ventricle and/or poststenotic enlargement or hypoplasia of the pulmonary artery.

Pulmonary atresia with intact ventricular septum in infants is usually associated with a hypoplastic right ventricle. However, cases with enlarged right ventricle and atrium have been described with unusual frequency in prenatal series.²⁶ Enlargement of the ventricle and atrium is probably the consequence of tricuspid insufficiency. Prenatal diagnosis of pulmonary atresia with intact ventricular septum relies on the demonstration of a small pulmonary artery with an atretic pulmonary valve. The considerations previously formulated for the diagnosis of hypoplastic left heart syndrome apply to this condition as well.

Patients with mild stenosis are asymptomatic and there is no need for intervention. Patients with severe stenosis and right ventricular overload may develop congestive heart failure and require balloon valvoplasty in the neonatal period with excellent survival and normal long-term prognosis. Fetuses

with pulmonary atresia, severe tricuspid insufficiency, and an enlarged right heart have a very high degree of perinatal mortality.

Ebstein's anomaly and tricuspid valve dysplasia

Ebstein's anomaly results from the faulty implantation of the tricuspid valve. The posterior and septal leaflets are elongated and tethered below their normal level of attachment on the annulus or displaced apically, away from the annulus, down to the junction between the inlet and trabecular portion of the right ventricle. The anterior leaflet is normally inserted but deformed. The resulting configuration is that of a considerably enlarged right atrium at the expense of the right ventricle. The portion of the right ventricle that is protruding into the right atrium is called the *atrialized* inlet of the right ventricle. It has a thin wall that may even be membranous and is commonly dilated. The tricuspid valve is usually both incompetent and stenotic. Associated anomalies include atrial septal defect, pulmonary atresia, ventricular septal defect, and supraventricular tachycardia. Ebstein's anomaly may be associated with trisomies 13 and 21, and Turner, Cornelia de Lange and Marfan syndromes. Maternal ingestion of lithium has also been incriminated as a causal factor.

The characteristic echocardiographic finding is that of a massively enlarged right atrium, a small right ventricle, and a small pulmonary artery. Doppler can be used to demonstrate regurgitation in the right atrium.²⁷ About 25% of the cases have supraventricular tachycardia (from re-entrant impulse), atrial fibrillation, or atrial flutter. Similar findings are encountered with dysplasia of a normally implanted tricuspid valve (Fig. 24.6).

Although the disease has a variable severity, with some cases discovered only late in life, Ebstein's anomalies and tricuspid dysplasia detected prenatally have a dismal prognosis, with a very high perinatal mortality rate.²⁷ This probably reflects that the prenatal variety is more severe than the forms detected in children or adults.

Conotruncal malformations

Conotruncal malformations are a heterogeneous group of defects that involve two different segments of the heart: the conotruncus and the ventricles. Conotruncal anomalies are relatively frequent. They account for 20–30% of all cardiac anomalies and are the leading cause of symptomatic cyanotic heart disease in the first year of life. Prenatal diagnosis is of interest for several reasons.²⁸ Given the parallel model of fetal circulation, conotruncal anomalies are well tolerated *in utero*. The clinical presentation occurs usually hours to days after delivery, and is often severe, representing a true emergency and leading to considerable morbidity and mortality. Yet, these malformations have a good prognosis when promptly treated. Two ventricles of adequate size and two great vessels are commonly present, giving the premise for biventricular surgical

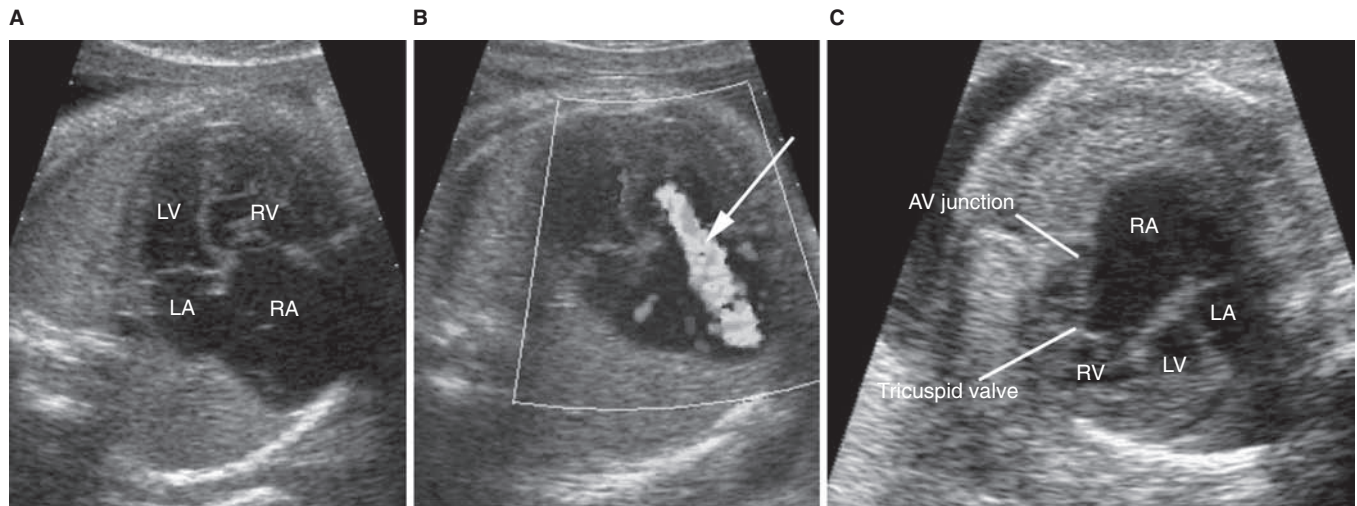

Figure 24.6 Tricuspid abnormalities associated with severe insufficiency and cardiomegaly: (A and B) tricuspid dysplasia with a very large right atrium and severe insufficiency at the color Doppler

examination; (C) Ebstein's anomaly of the tricuspid valve: note that the tricuspid valve inserts at a much lower level than the AV junction.

Figure 24.7 Conotruncal anomalies. (A) Tetralogy of Fallot: a large vessel (arrow) overrides the ventricular septum by about 50% and forms the aortic arch; similar findings are expected with truncus arteriosus and some types of double outlet right ventricle, and meticulous scanning is required for a differential diagnosis. (B) Complete transposition of the great vessels; the great arteries (arrows) arise from the base of the heart in parallel fashion without correction. The outcome is indeed much more favorable than with most of the other cardiac defects that are detected antenatally.²¹ Unfortunately, the recognition of these anomalies remains difficult. The four-chamber view is frequently unremarkable in these cases. A specific diagnosis requires meticulous scanning and at times may represent a challenge even for experienced sonologists (Fig. 24.7). Recently, an association has been demonstrated between conotruncal anomalies and microdeletion of chromosome 22. This association is particularly frequent with truncus arteriosus and tetralogy of Fallot, and, in particular, in those cases with absence of the pulmonary valve. A small or absent thymus in these cases greatly increases the likelihood of the association.²²

crossing. (C) Corrected transposition: the four-chamber view demonstrates that the posterior ventricle, which is connected to an atrial chamber, which, in turn, is connected to the pulmonary veins, has a moderator band (MB) that is a characteristic feature of the morphologic right ventricle; an increased deviation of the cardiac axis is also noted; compare this image with the normal four-chamber view demonstrated in Fig. 24.1.

Transposition of the great arteries (TGA) is an abnormality in which the aorta arises entirely or in large part from the right ventricle and the pulmonary artery arises from the left ventricle. Associated cardiac lesions are present in about 50% of cases, including ventricular septal defects (which can occur anywhere in the ventricular septum), pulmonary stenosis, unbalanced ventricular size ("complex transpositions"), and anomalies of the mitral valve, which can be straddling or overriding.

Complete transposition is probably one of the most difficult cardiac lesions to recognize *in utero*. In most cases the four-chamber view is normal, and the cardiac cavities and the vessels have normal dimensions. A clue to the diagnosis is the

demonstration that the two great vessels do not cross but arise parallel from the base of the heart (see Fig. 24.7). The most useful echocardiographic view, however, is the left-heart view, demonstrating that the vessel connected to the left ventricle has a posterior course and bifurcates into the two pulmonary arteries. Conversely, the vessel connected to the right ventricle has a long upward course and gives rise to the brachiocephalic vessels. *Corrected transposition* is characterized by a double discordance, at the atrioventricular and ventriculoarterial level. The left atrium is connected to the right ventricle, which is in turn connected to the ascending aorta. Conversely, the right atrium is connected with the right ventricle, which, in turn, is connected to the ascending aorta. The derangement of the conduction tissue secondary to malalignment of the atrial and ventricular septa may result in dysrhythmias, namely complete atrioventricular block. For diagnostic purposes, the identification of the peculiar difference of ventricular morphology (moderator band, papillary muscles, insertion of the atrioventricular valves) has a prominent role (see Fig. 24.7). Demonstration that the pulmonary veins are connected to an atrium, which, in turn, is connected with a ventricle that has the moderator band at the apex, is an important clue, which is furthermore potentially identifiable even in a simple four-chamber view. Diagnosis requires meticulous scanning to carefully assess all cardiac connections, using the same views described for the complete form. The presence of atrioventricular block increases the index of suspicion.

As anticipated from the parallel model of fetal circulation, complete transposition is uneventful *in utero*. After birth, survival depends on the amount and size of the mixing of the two otherwise independent circulations. Patients with transposition and an intact ventricular septum present shortly after birth with cyanosis and deteriorate rapidly. When a large ventricular septal defect is present, cyanosis can be mild. Clinical presentation may be delayed for 2–4 weeks, and usually occurs with signs of congestive heart failure. When severe stenosis of the pulmonary artery is associated with a ventricular septal defect, symptoms are similar to patients with tetralogy of Fallot. The time and mode of clinical presentation with corrected transposition depend upon the concomitant cardiac defects.

Surgery (which involves arterial switch to establish anatomic and physiologic correction) is usually carried out within the first 2 weeks of life. Operative mortality is about 10% and 10-year follow-up studies report normal function in the vast majority of cases. It has been suggested recently that prenatal diagnosis reduces perinatal mortality presumably by allowing early treatment avoiding heart failure and hypoxemia.²⁹ The outcome of corrected transposition depends largely upon the associated cardiac defects that are variable. As the systemic ventricle is the right ventricle, there is a high chance of cardiac failure in adulthood.

The essential features of *tetralogy of Fallot* are a subaortic ventricular septal defect, aorta overriding the ventricular

septal defect, and infundibular stenosis of the aorta (see Fig. 24.5). In about 20% of cases there is atresia of the pulmonary valve, a condition that is commonly referred to as *pulmonary atresia with ventricular septal defect*. Tetralogy of Fallot can be associated with other specific cardiac malformations, defining peculiar entities. These include atrioventricular septal defects (found in 4% of cases) and absence of the pulmonary valve (found in less than 2% of cases). Hypertrophy of the right ventricle, one of the classic elements of the tetrad, is always absent in the fetus and only develops after birth.

Echocardiographic diagnosis of tetralogy of Fallot relies on the demonstration of a ventricular septal defect in the outlet portion of the septum and an overriding aorta (see Figs 24.2 and 24.7). Color and pulsed Doppler can be used to identify the patency of the pulmonary valve and exclude pulmonary atresia. Diagnostic problems arise at the extremes of the spectrum of tetralogy of Fallot. In cases with minor forms of right outflow obstruction and aortic overriding differentiation from a simple ventricular septal defect can be difficult. In those cases in which the pulmonary artery is not imaged, a differential diagnosis between pulmonary atresia with ventricular septal defect and truncus arteriosus communis is similarly difficult. Abnormal enlargement of the right ventricle and main pulmonary trunk and artery suggests absence of pulmonary valve.

Tetralogy of Fallot does not result in cardiac failure in fetuses. Even in cases of tight pulmonary stenosis or atresia, the wide ventricular septal defect provides adequate combined ventricular output, while the pulmonary vascular bed is supplied in a retrograde manner by the ductus. The only exception to this rule is represented by cases with an absent pulmonary valve, which may result in massive regurgitation to the right ventricle and atrium. When severe pulmonic stenosis is present, cyanosis tends to develop immediately after birth. With lesser degrees of obstruction to pulmonary blood flow, the onset of cyanosis may not appear until later in the first year of life. When there is pulmonary atresia, rapid and severe deterioration follows ductal constriction. Survival after complete surgical repair (which is usually carried out in the third month of life) is more than 90%, and about 80% of survivors have normal exercise tolerance.

In *double outlet right ventricle* (DORV), most of the aorta and pulmonary valve arise completely, or almost completely, from the right ventricle. The relation between the two vessels may vary, ranging from a Fallot-like to a TGA-like situation (the Taussig–Bing anomaly). DORV is not a single malformation from a pathophysiologic point of view. The term refers only to the position of the great vessels that is found in association with ventricular septal defects, tetralogy of Fallot, transposition, and univentricular hearts. Pulmonary stenosis is very common in all types of DORV, but left-outflow obstructions, from subaortic stenosis to coarctation and interruption of the aortic arch, can also be seen.

Prenatal diagnosis of DORV can be reliably made in the fetus but differentiation from other conotruncal anomalies can

be very difficult, especially with tetralogy of Fallot and transposition of the great arteries with ventricular septal defect. The main echocardiographic features include (1) alignment of the two vessels totally or predominantly from the right ventricle and (2) presence in most cases of bilateral conus (subaortic and subpulmonary). The hemodynamics are dependent upon the anatomic type of DORV and the associated anomalies. As the fetal heart works as a common chamber where the blood is mixed and pumped, DORV is not associated with intrauterine heart failure. However, DORV, in contrast with other conotruncal malformations, is commonly associated with extracardiac anomalies and/or chromosomal defects. Usually, DORV does not interfere with hemodynamics in fetal life. The early operative mortality is about 10%.

A single arterial vessel that originates from the heart overrides the ventricular septum and supplies the systemic, pulmonary, and coronary circulations, characterizing truncus arteriosus. The single arterial trunk is larger than the normal aortic root and is predominantly connected with the right ventricle in about 40% of cases, with the left ventricle in 20%, and is equally shared in 40%. The truncal valve may have one, two, or three cusps and is rarely normal. It can be stenotic or, more frequently, insufficient. A misaligned ventricular septal defect, usually wide, is an essential part of the malformation. There are three types based on the morphology of the pulmonary artery. In *type 1*, the pulmonary arteries arise from the truncus within a short distance from the valve, as a main pulmonary trunk, which then bifurcates. In *type 2*, there is no main pulmonary trunk. In *type 3*, only one pulmonary artery (usually the right) originates from the truncus, whereas a systemic collateral vessel from the descending aorta supplies the other. Similar to tetralogy of Fallot, and unlike the other conotruncal malformations, truncus is frequently (about 30%) associated with extracardiac malformations.

Truncus arteriosus can be reliably detected with fetal echocardiography. The main diagnostic criteria are: (1) a single semilunar valve overrides the ventricular septal defect and (2) there is direct continuity between one or two pulmonary arteries and the single arterial trunk. The semilunar valve is often thickened and moves abnormally. Doppler ultrasound is of value to assess incompetence of the truncal valve. A peculiar problem found in prenatal echocardiography is the demonstration of the absence of pulmonary outflow tract and the concomitant failure to image the pulmonary arteries. In these situations a differentiation between truncus and pulmonary atresia with ventricular septal defect may be impossible.

Similar to the other conotruncal anomalies truncus arteriosus is not associated with alteration of fetal hemodynamics. Truncus arteriosus is frequently a neonatal emergency. These patients usually have unobstructed pulmonary blood flow and show signs of progressive congestive heart failure with the postnatal fall in pulmonary resistance. Many patients will present with cardiac failure in the first 1 or 2 weeks of life.

Surgical repair (usually before the sixth month of life) involves closure of the ventricular septal defect and creation of a conduit connection between the right ventricle and the pulmonary arteries. Survival after surgery is about 90%, but the patients require repeated surgery for replacement of the conduit.

Heterotaxy

In heterotaxy, also referred to as cardiosplenic syndromes, the fetus is made of either two left or two right sides. Other terms commonly used include left or right isomerism, asplenia, and polysplenia. Unpaired organs (liver, stomach, and spleen) may be absent, midline, or duplicated. Because of left atrial isomerism (thus absence of the right atrium, which is the normal location for the pacemaker) and abnormal atrioventricular junctions, atrioventricular blocks are very common. Heterotaxy represents about 2% of all congenital heart defects.

In polysplenia, the fetus has two left sides (one in the normal position and the other as a mirror image); this is called left isomerism. Multiple small spleens (usually too small to be detected by antenatal ultrasound) are found posterior to the stomach. The liver is midline and symmetric but the stomach and aorta can be on opposite sides. In asplenia, the fetus has two right sides (right isomerism). The liver is generally midline and the stomach right- or left-sided. The aorta and cava are on the same side (either left or right) of the spine.

Cardiac malformations are almost invariably present and are usually severe, with a tendency towards a single structure replacing normal paired structures: single atrium, single atrioventricular valve, single ventricle, and single great vessel.

The main clue for the diagnosis of fetal heterotaxy is the demonstration of complex cardiac anomalies associated with abnormal disposition of the thoracic and/or abdominal organs.^{30,31} In polysplenia, a typical finding is interruption of the inferior vena cava with azygous continuation (there is failure to visualize the inferior vena cava and a large venous vessel, the azygos vein, runs to the left and close to the spine and ascends into the upper thorax). Symmetry of the liver can be sonographically recognized *in utero* by the abnormal course of the portal circulation, which does not display a clearly defined portal sinus bending to the right.

The heterogeneous cardiac anomalies found in association with heterotaxy are usually easily seen, but a detailed diagnosis often poses a challenge; in particular, assessment of connection between the pulmonary veins and the atrium (an element that has a major prognostic influence) can be extremely difficult. Associated anomalies include absence of the gallbladder, malrotation of the guts, duodenal atresia, and hydrops.

The outcome depends on the number of cardiac anomalies, but it tends to be poor. Atrioventricular insufficiency and severe fetal bradycardia due to atrioventricular block may lead to intrauterine heart failure.^{30,31}

Fetal dysrhythmias

Irregular patterns of fetal heart rhythms are a frequent finding. Short periods of tachycardia, bradycardia, and ectopic beats as well as very commonly seen, and in the vast majority of cases have no clinical significance. A sustained bradycardia of less than 100 beats per minute (bpm), a sustained tachycardia of more than 200 bpm and irregular beats occurring more than one in 10 should be considered abnormal and require further investigation.³² The fetal electrocardiogram is of little value in the prenatal diagnosis of dysrhythmias, as a satisfactory transabdominal recording can be obtained in a minority of cases. At present, M-mode and pulsed Doppler ultrasound are the best available techniques for the assessment of irregular fetal heart rhythm.^{32,33} The study of the mechanical events of the sequence of contraction may be accomplished in different ways. Simultaneous visualization of atrioventricular valves and ventricular wall motion, aortic valve opening and atrial wall movement with M-mode, and sampling of the ventricular inlet or inferior vena cava with M-mode can be used from time to time. The sequence of excitation can be reasonably inferred by the sequence of contraction (Fig. 24.8).

Premature atrial and ventricular contractions are the most frequent fetal dysrhythmias. Repeated premature contractions can give rise to complex rhythm patterns. Premature atrial contractions may be either conducted to the ventricles or blocked, depending upon the time of the cardiac cycle in which they occur, thus resulting in either an increased or a decreased ventricular rate. Blocked premature atrial contractions should be differentiated from atrioventricular block. Premature atrial and ventricular contractions are considered a benign condition. They probably do not induce any hemodynamic perturbation, do not appear to be associated with an increased risk of structural abnormalities, and usually disappear *in utero* or soon after birth. However, as there is at least a theoretical possibility that in a few cases an ectopic beat triggers a re-entrant tachyarrhythmia, serial monitoring of the fetal heart during pregnancy is suggested.³³

Supraventricular tachyarrhythmias include supraventricular paroxysmal tachycardia (SVT), atrial flutter, and atrial fibrillation. SVT is characterized by an atrial frequency between 200 and 300 bpm and a 1:1 atrioventricular conduction rate. It can occur by one of two mechanisms: automaticity and re-entry. In the former case, an irritable ectopic focus discharges at high frequency. In the latter case, an electrical impulse re-enters the atria giving rise to repeated electrical activity. Re-entry may occur at the level of the sinoatrial node, inside the atrium, the atrioventricular node and the His-Purkinje system. Re-entry may also occur along an anomalous atrioventricular connection such as the Kent bundle in the Wolff-Parkinson-White (WPW) syndrome. In atrial flutter, the atrial rate ranges from 300 to 400 bpm. Owing to variable degrees of atrioventricular block, the ventricular rate ranges between 60 and 200 bpm. In atrial fibrillation, the

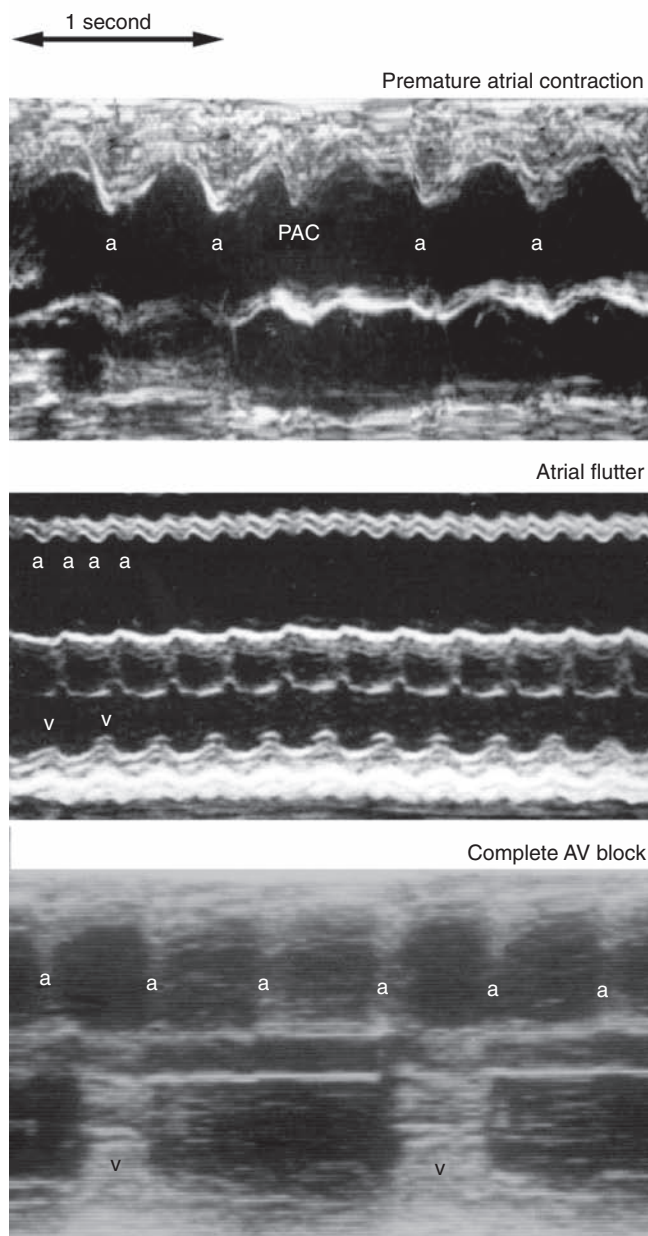

Figure 24.8 Diagnosis with M-mode of fetal dysrhythmias: *a* indicates atrial contractions, *v* ventricular contractions. In the upper panel, a premature atrial contraction (PAC) is seen. In the middle panel, the atria contract rapidly with a frequency of about 440/s and the ventricle respond with a frequency of 220/s. This is atrial flutter with 2:1 atrioventricular block. In the lower panel, the atria contract regularly with a frequency of about 120/s. The ventricle contract with a frequency of about 50/s, independently from atrial contractions. This is complete atrioventricular block.

atrial rate is more than 400 bpm and the ventricular rate ranges between 120 and 200 bpm. Atrial flutter and fibrillation often alternate, and are thought to arise from similar mechanisms, which include circus movement of the electrical impulse, ectopic formation, multiple re-entry, and multifocal

impulse formation. SVT is by far the most common tachyarrhythmia in children. The most frequent form is the one caused by atrioventricular nodal re-entry.

The association between fetal tachyarrhythmia and non-immune hydrops is well established. It has been postulated that a fast ventricular rate results in suboptimal filling of the ventricles. This would lead to decreased cardiac output, right atrial overload, and congestive heart failure. The frequency of nonimmune hydrops is variable. We have seen fetuses with SVT that did well *in utero* and were successfully treated after birth. It can be postulated that in those cases in which a re-entry mechanism is involved, the fetus alternates phases of tachycardia and phases of normal rhythm. Intrauterine pharmacologic cardioversion of fetal tachyarrhythmia by maternal administration of drugs has been attempted with success in many cases. Transplacental passage of antiarrhythmic drugs is limited when fetal hydrops is present, and under these conditions a direct administration by ultrasound-guided funipuncture has been proposed. The optimal approach to the treatment of this condition is still uncertain. Digoxin, verapamil, propranolol, quinidine, procainamide, flecainide, and amiodarone have all been used from time to time. The interested reader is referred to specific works in this subject. Independent of the therapeutic regimen employed, the largest available series suggests a survival rate in the range of 90%.³³⁻³⁶

Atrioventricular (AV) block can result from immaturity of the conduction system, absence of connection to the AV node or abnormal anatomic position of the AV node. AV block is commonly classified into three types. First-degree AV block corresponds to a simple conduction delay, which is associated with prolongation of the PR interval on the ECG. Second-degree AV block is subdivided into Mobitz types 1 and 2. Mobitz type 1 consists of a progressive prolongation of the PR interval that finally leads to the blocking of one atrial impulse (Luciani-Wenckebach phenomenon). In Mobitz type

2 the ventricular rate is a submultiple of the atrial rate (e.g., 2:1, 3:1). In third-degree or complete AV block, there is a complete dissociation of the atria and ventricles, usually with independent and slow activation of the ventricles. Third-degree AV block is associated in over one-half of the cases with cardiac structural anomalies, mostly atrioventricular discordance. In cases without structural cardiac disease, the etiology of AV block mostly depends upon the presence of maternal antibodies against SSA and SSB antigens (anti-Ro and anti-La). Transplacental passage of these antibodies would lead to inflammation of and damage to the conduction system. Anti-SSA antibodies have been reported in over 80% of mothers who delivered infants with AV block, although only 30% had clinical evidence of connective tissue disease, mostly lupus erythematosus.

First- and second-degree AV block are not usually associated with any significant hemodynamic perturbation. Third-degree AV block may lead to important bradycardia, determining a decreased cardiac output and congestive heart failure *in utero*. Outcome is poor when there are associated cardiac anomalies and/or hydrops. Conversely most fetuses with isolated block will survive.³⁷⁻³⁹

The use of maternal steroids to limit the inflammatory response in the fetal cardiac conducting system has been postulated to carry an advantage. The use of immunosuppressive agents has also been advocated.³⁷

Thoracic anomalies

Hyperechogenic and cystic lungs

The typical finding is that of enlarged brightly echogenic lungs displacing the mediastinum and causing an inversion of the diaphragm (Fig. 24.9).^{40,41} Most frequently, part of one lung, or one entire lung, is affected, causing lateral displacement of the heart and mediastinum. Rarely, both lungs are affected,

Figure 24.9 Thoracic anomalies. (A) Echogenic lung (arrow). (B) Bilateral pleural effusions (arrows) associated with hydrops and polyhydramnios. (C) Left diaphragmatic hernia: the heart is shifted to the right side of the chest and the left hemithorax is occupied by a complex area in which stomach and bowel loops can be recognized.

compressing both sides of the mediastinum. The pathophysiology is related to obstruction of the respiratory tree, which causes accumulation of fluid and secretions in the lungs. The effects of respiratory obstruction on the lungs are variable. Accumulation of fluid may lead to lung hyperplasia. Early and longstanding obstruction is probably responsible for the histological alterations that are commonly referred to as *cystic adenomatoid malformation* of the lungs. The etiology is variable. Obstruction may result from primary atresia or be the consequence of a mucus plug. A further possibility is pulmonary sequestration. With this condition, part of the lung develops separately from the bronchi and the pulmonary circulation, and is supplied through arteries that arise from the descending aorta. A differential diagnosis between these three conditions is often difficult. With lung sequestration, a specific diagnosis is possible by demonstrating the abnormal vessels connecting the aorta to the abnormal lung using color Doppler. Spontaneous regression or resolution of the increased echogenicity indicates that a mucus plug is the most likely hypothesis. When both lungs are affected, the most likely diagnosis is an obstruction of the upper airways, usually atresia of the trachea. Polyhydramnios and fetal hydrops may occur, particularly with bilateral echogenic lungs and large sequestration. Lung sequestration may also be associated with cardiac and diaphragmatic defects.

In some cases, macroscopic cysts may be associated with increased echogenicity. Occasionally, large and multiple cysts are the dominant finding. Cystic adenomatoid malformation is usually found at birth in these cases (macrocytic variety) and the pathophysiology probably overlaps that of echogenic lungs.

Unilateral echogenic and/or cystic lungs, without other anomalies or hydrops, have a very good outcome. The lesions usually decrease in size with gestation, and the infants are asymptomatic at birth. However, dysplastic lung tissue, is usually present and must be surgically removed.^{42,43} Conversely, bilateral lesions or those associated with hydrops usually have a poor outcome. In these cases, drainage, or shunting of the cysts may be attempted.

Pleural effusions

Fetal pleural effusions may be an isolated finding or they may occur in association with generalized edema and ascites (Fig. 24.9).⁴⁴ Irrespective of the underlying cause, infants affected by pleural effusions usually present in the neonatal period with severe, and often fatal, respiratory insufficiency. This is either a direct result of pulmonary compression caused by the effusions or due to pulmonary hypoplasia secondary to chronic intrathoracic compression. Isolated pleural effusions in the fetus may either resolve spontaneously or they can be treated effectively after birth. Nevertheless, in some cases severe and chronic compression of the fetal lungs can result in pulmonary hypoplasia and neonatal death. In others, mediastinal compression leads to the development of hydrops and

polyhydramnios, which are associated with a high risk of premature delivery and perinatal death. Attempts at prenatal therapy by repeated thoracenteses for drainage of pleural effusions have been generally unsuccessful in reversing the hydropic state, because the fluid reaccumulates within 24–48 h of drainage. A better approach is chronic drainage by the insertion of thoracoamniotic shunts. This is useful both for diagnosis and treatment. First, the diagnosis of an underlying cardiac abnormality or other intrathoracic lesion may become apparent only after effective decompression and return of the mediastinum to its normal position. Second, it can reverse fetal hydrops, resolve polyhydramnios and thereby reduce the risk of preterm delivery, and may prevent pulmonary hypoplasia. Third, it may be useful in the prenatal diagnosis of pulmonary hypoplasia because in such cases the lungs often fail to expand after shunting. Furthermore, it may help distinguish between hydrops due to primary accumulation of pleural effusions, in which case the ascites and skin edema may resolve after shunting, and other causes of hydrops such as infection, in which drainage of the effusions does not prevent worsening of the hydrops. Survival after thoracoamniotic shunting is in the range of 50% and is more likely with isolated pleural effusions than with generalized hydrops.⁴⁵

Diaphragmatic hernia

Diaphragmatic hernia is found in about 1 in 4000 births. Development of the diaphragm is usually completed by the ninth week of gestation. In the presence of a defective diaphragm there is herniation of the abdominal viscera into the thorax at about 10–12 weeks, when the intestines return to the abdominal cavity from the umbilical cord. However, at least in some cases intrathoracic herniation of viscera may be delayed until the second or third trimesters of pregnancy. Diaphragmatic hernia is usually a sporadic abnormality. However, in about 50% of affected fetuses there are associated chromosomal abnormalities (mainly trisomy 18, trisomy 13, and Pallister–Killian syndrome – mosaicism for tetrasomy 12p), other defects (mainly craniospinal defects, including spina bifida, hydrocephaly, and the otherwise rare iniencephaly, and cardiac abnormalities) and genetic syndromes (such as Fryns syndrome, de Lange syndrome, and Marfan syndrome).

Prenatally, the diaphragm is imaged by ultrasonography as an echo-free space between the thorax and abdomen. However, the integrity of the diaphragm is usually inferred from the normal disposition of the thoracic and abdominal organs. Diaphragmatic hernia is usually diagnosed by the ultrasonographic demonstration of stomach, intestines, or liver in the thorax and the associated mediastinal shift to the opposite side. Herniated abdominal contents, associated with a left-sided diaphragmatic hernia, are easy to demonstrate because the echo-free fluid-filled stomach and small bowel contrast dramatically with the more echogenic fetal lung (see Fig. 24.9). In contrast, a right-sided hernia is more difficult to

identify because the echogenicity of the fetal liver is similar to that of the lung.

Antenatal prediction of pulmonary hypoplasia remains one of the challenges of prenatal diagnosis because this would be vital both in counseling parents and also in selecting those cases that may benefit from prenatal surgery. Poor prognostic signs include herniation of the liver into the fetal chest and a lung-head ratio (area of the demonstrable lung divided by head circumference) < 1.00 .⁴⁶

In the human, the bronchial tree is fully developed by the 16th week of gestation, at which time the full adult number of airways is established. In diaphragmatic hernia the reduced thoracic space available to the developing lung leads to reduction in airways, alveoli, and arteries. Thus, although isolated diaphragmatic hernia is an anatomically simple defect that is easily correctable, the mortality rate is high in cases with severe hernia.

In a few cases of diaphragmatic hernia, hysterotomy and fetal surgery were carried out but these interventions have now been abandoned. Endoscopic occlusion of the fetal trachea has also been carried out in human fetuses with diaphragmatic hernia but the preliminary experience thus far has not been encouraging.⁴⁷

Conclusions

Sonography allows the detection of many congenital anomalies of the heart and thorax. Congenital heart defects are among the most common malformations and a major cause of perinatal death. Evaluation of the fetal heart allows a precise diagnosis of most major cardiac anomalies beginning early in gestation. However, a specific expertise is required. The outcome of some severe cardiac abnormalities may be ameliorated by prenatal diagnosis. Thoracic anomalies are rare. Echogenic lungs and diaphragmatic hernia are the most frequent entities. The former are usually benign, and although they may have a dramatic sonographic presentation, in general, they have a good prognosis. Diaphragmatic hernia continues to be associated with significant mortality and long-term morbidity. Despite many attempts, the value of antenatal treatment remains highly uncertain.

Key points

- 1 Congenital heart disease occurs in approximately 0.5% of births. In general, about one-half are either severe or require surgery early in life and are generally referred to as major cardiac abnormalities. Despite advances in pediatric cardiology and cardiac surgery heart defects remain a major cause of perinatal and infantile death.
- 2 Diagnosis of cardiac defects is possible; however, a specific examination is required (fetal echocardiogram) and this is usually performed in pregnancies with an increased risk. The sensitivity is in the range of 80%. Most of the severe cardiac anomalies can be recognized by at least mid-gestation.
- 3 While performing a standard sonogram from mid-gestation on, it is recommended to obtain a four-chamber view of the heart; the sensitivity of this approach varies in different studies, but the general consensus is that it is an acceptable approach.
- 4 Septal defects are the most common form of congenital heart disease. In most cases the lesions are small and prenatal diagnosis is not possible; these anomalies may have little clinical significance but at times require surgical correction.
- 5 Atrioventricular septal defects (or atrioventricular canal) are a more relevant entity mostly because of the very frequent association with other anomalies such as trisomy 21; diagnosis of this defect is simpler although false-negatives may occur.
- 6 The term univentricular heart applies to anomalies in which the atria are connected with one single ventricular chamber. These anomalies constitute the lion's share of the cardiac malformations diagnosed *in utero*. These conditions can be treated after birth with a likelihood of survival at 3 years in the range of 60%; only complex palliative procedures are possible, however, and the long-term outcome remains difficult to predict.
- 7 Hypoplastic left heart syndrome includes a continuum of malformations that share in common atresia or extreme hypoplasia of the aorta; it is one of the major causes of perinatal and infant death. The most important clue to the diagnosis is the presence of a very small left ventricle and ascending aorta, typically with inversion of blood flow into the aortic arch. Survival may be increased by prenatal diagnosis. Only 30% of infants diagnosed *in utero* are alive, however, at follow-up in 3 years.
- 8 A disproportion in the size of the ventricles with a predominance of the right side is very frequently a presenting sign of fetal coarctation or interrupted aortic arch; a definitive diagnosis may be difficult *in utero* and at times can only be made after birth.
- 9 Aortic and pulmonary stenosis are among the most frequent cardiac anomalies; however, mild and moderate cases go usually undetected *in utero*. Prenatal diagnosis is limited to the severe varieties that may

- progress *in utero* toward hypoplastic left heart or pulmonary atresia with intact septum.
- 10 Tricuspid dysplasia and Ebstein's malformation of the tricuspid valve may be complicated by severe tricuspid insufficiency, cardiomegaly, and hydrops; such combination is most frequently lethal, with very few infants surviving.
 - 11 Conotruncal anomalies include transposition of the great arteries, tetralogy of Fallot, double outlet right ventricle, and truncus arteriosus communis. They represent about 30% of congenital heart defects and usually have a good outcome if adequately treated after birth in that usually biventricular repair is possible. Diagnosis is difficult because assessing the connections between ventricles and great arteries requires meticulous scanning; however, prenatal diagnosis would be important because at times these conditions (complete transposition in particular) represent neonatal emergencies.
 - 12 Heterotaxy, or cardiosplenic syndromes, includes a group of anomalies characterized by the association between cardiac defects and anomalous disposition of abdominal organs; cardiovascular malformations are frequently complex and the prognosis tends to be poor.
 - 13 Irregular patterns of fetal heart rhythms are frequent. Short periods of tachycardia, bradycardia, and ectopic beats as well are very commonly seen, and in the vast majority of cases have no clinical significance. A sustained bradycardia of less than 100 bpm, a sustained tachycardia of more than 200 bpm and irregular beats occurring more than 1 in 10 should be considered abnormal and require further investigation. The techniques of choice for the diagnosis of fetal dysrhythmias are M-mode and/or spectral Doppler ultrasound.
 - 14 Premature atrial or ventricular beats are by far the most frequent fetal arrhythmias. They are benign, are not associated with an increased risk of cardiac malformations, and tend to disappear throughout gestation. Serial monitoring has been recommended because, although rare, they sometimes can evolve toward fetal tachycardia.
 - 15 Fetal tachycardias (frequency greater than 200 bpm) are potentially serious dysrhythmias that may cause fetal hydrops and perinatal death. Treatment is possible, however, usually by maternal administration of antiarrhythmic agents, and the survival rate exceeds 90%.
 - 16 Congenital complete heart block may occur either as a consequence of a cardiac malformation (heterotaxy or corrected transposition) or because of transplacental passage of maternal autoimmune (anti-Ro and anti-La) antibodies. In the former case, prognosis is poor; in the latter, most infants survive. Maternal administration of steroids has been proposed for the treatment of immune heart block.
 - 17 Echogenic lungs arise as a consequence of cystic adenomatoid malformation of the lungs, airway obstruction, or lung sequestration. There is clinical as well as pathophysiological overlapping among these entities, however, when they are not complicated by hydrops they have a good outcome generally.
 - 18 Pleural effusion may be isolated or a part of fetal hydrops. Primitive pleural effusions may evolve toward hydrops, probably because they compress the mediastinum and obstruct venous return to the heart; prenatal treatment is possible by implantation of a thoracoamniotic shunt; survival rate is in the range of 50%.
 - 19 Diaphragmatic hernia is a severe fetal anomaly that can be treated after birth but continues to be associated with significant mortality and morbidity as a consequence of lung hypoplasia. Diagnosis is possible and is based upon demonstration of abdominal organs into the fetal chest. The identification of cases with only bowel loops herniated in the second trimester and of the right diaphragmatic hernias remains difficult; some sonographic findings including the herniation of the liver into the chest and the ratio of the demonstrable lung to the head have prognostic implications.
 - 20 Prenatal treatment of diaphragmatic hernia has been attempted using different strategies. Open fetal surgery had been abandoned. More recently attempts have been made by tracheal occlusion using endoscopic techniques but the first series has not been encouraging.

Gastrointestinal and genitourinary anomalies

Sandro Gabrielli, Nicola Rizzo, and E. Albert Reece

Gastrointestinal anomalies

Structural anomalies of the gastrointestinal (GI) tract are relatively common. Fetuses with GI anomalies, which often allow a good quality of life after postnatal surgical correction, largely benefit from prenatal diagnosis.¹ Anomalies can be subdivided into two groups: intestinal obstructions and ventral wall defects.

Normal ultrasound anatomy of gastrointestinal and urinary tract

The liver occupies most of the upper abdomen, showing a homogeneous, echogenic ultrasound pattern. The portal circulation, the hepatic veins, the hepatic arteries, and the biliary ducts represent the ductal system crossing into the liver. The gallbladder is often distended *in utero*, appearing as a pear-shaped, fluid-filled structure arising from the hilum, and angles from the anteroposterior axis of the abdomen at 45°. The intra-abdominal umbilical vein can be confused with the gallbladder. The left umbilical vein (the right umbilical vein is reabsorbed before 6–7 weeks' gestation) penetrates into the abdomen through the umbilical ring; it runs centrally and cranially, entering the liver and receiving the venae advehentes, and then anastomoses with the left portal vein. From the junction with the left portal vein, the oxygenated blood may reach the heart through the ductus venosus or the hepatic veins. The stomach is almost constantly distended and, in a transverse scan, appears as a semilunar, fluid-filled, and neatly outlined area. Stomach dimensions can vary significantly at each gestational age, due to the filling and emptying state. An axial section, in which the intrahepatic umbilical vein, the stomach, and the liver are simultaneously visualized, is used to measure the abdominal circumference (Fig. 25.1).² The spleen appears as a triangular area posterior to the stomach, with a similar structure to the liver. The study of the visceral situs is of great importance as structural cardiac defects are frequently associ-

ated with abnormal location of abdominal viscera (polysplenic and asplenic syndromes). Normally, the stomach and spleen are located on the left side, while the portal sinus, which corresponds to the hepatic hilum, is on the right side; the descending aorta can be visualized close to the vertebrae and slightly on the left, the inferior vena cava more anteriorly and on the right. The fetal bowel is usually uniformly echogenic, and it may be difficult to distinguish bowel from liver, particularly in the second and early third trimester. Late in pregnancy, loops distended by the accumulating meconium are easily visualized. In the second trimester, a diffuse hyperechogenicity is quite often seen in the lower abdomen (Fig. 25.2). This finding is of no clinical significance when isolated. It has been reported, however, in association with trisomy 21, cystic fibrosis, and intrauterine growth retardation (IUGR).³ Hyperechogenicity seems to be a consequence of intra-amniotic bleeding.⁴ During the third trimester, as meconium accumulates in the lumen of the bowel, a suspicion of pathological obstructive dilation is sometimes raised. Loops of small and large bowel measuring less than 7 and 20 mm, respectively, seem to be perfectly normal. Therefore, ultrasound diagnosis of bowel obstruction is rather difficult. An increased fluid content in the lumen of the bowel, giving a clearly anechoic picture, is another useful criterion for diagnosis.

All components of the urinary system, except ureters, can be visualized *in utero* from the beginning of the early second trimester. Viewing a cross-section of the abdomen, as early as 14 weeks' and up to 20 weeks' gestation, the kidneys appear circular and slightly hypoechoic, compared with the liver and bowel loops, at both sides of the vertebral bodies.⁵

At 20 weeks, the kidneys show a hyperechoic capsule, the parenchyma is less hyperechoic, and calices sometimes surround a minimally physiologically dilated pelvis. This dilated pelvis has nothing to do with hydronephrosis, and is probably due to a more efficient diuresis than in later gestation. At this gestational age, the cortical area is slightly more echogenic than the medulla.⁶

With progressing gestation, fat tissue accumulates around the kidneys, enhancing the borders of the kidneys in contrast

Figure 25.1 Cross-section of the fetal trunk during the second trimester of pregnancy, showing the intrahepatic umbilical vein (uv). Ao, aorta; ivc, inferior vena cava; s, stomach; sp, spine.

Figure 25.3 Cross-section of the abdomen of a fetus during the second trimester, demonstrating normal kidneys (k) at both sides of the spine (Sp); p, pelvis.

Figure 25.2 Longitudinal scan of the fetal trunk at 22 weeks' gestation showing diffuse hyperechogenicity of the lower abdomen (arrow).

with the other splanchnic organs. Around 26–27 weeks' gestation, renal pyramids can be detected, and the arcuate arteries can be seen pulsating in their proximity in real-time ultrasonography.

During the midtrimester, kidneys should be differentiated from adrenals by looking for the renal pelvis.

Transverse and coronal sections of the abdomen can be used to study the kidneys. In a transverse scan, kidneys appear as roundish structures at both sides of the spine, while on coronal

scans, they appear as elliptical areas (Figs 25.3 and 25.4). On a cross-section of the abdomen, kidneys cover less than one-third of the surface of the entire abdomen. Biometry of the kidneys has been suggested by various authors to diagnose congenital anomalies.⁷ Moreover, on coronal scans, renal arteries are clearly seen with color power Doppler (Fig. 25.5).

The fetal bladder can be detected as a fluid-filled area in the anterior lower abdomen from early midtrimester, when urine formation begins. At both sides of the bladder, branches of the umbilical artery are visualized with color power Doppler

Figure 25.5 Renal arteries are visualized on coronal scans with color power Doppler.

Figure 25.6 Branches of the umbilical artery are clearly seen at both sides of the urinary bladder.

(Fig. 25.6). The contribution of the kidneys to the amniotic fluid dynamics is little before 16 weeks, but it increases steadily throughout gestation so that, in the second half of gestation, amniotic fluid is formed mostly by urine.⁸ Change in shape and volume depends on alternate emptying and filling. It has been demonstrated that micturition occurs approximately every 110 min.⁹ The fetal bladder, however, should always be visualized, because of incomplete emptying.

Obstructions

The echo-free areas resulting from fluid collection and progressive dilation of the bowel cephalad to the obstruction site are easily detected by ultrasound.¹⁰ Furthermore, a GI obstruction is often associated with hydramnios, allowing a better visualization. A proximal obstruction can be expected in approximately 1 in 15 pregnancies with polyhydramnios.¹¹ GI obstructions can involve the esophagus, duodenum, and small bowel; they can be intrinsic or extrinsic (e.g., intrathoracic cyst or annular pancreas). Conversely, distal obstructions are not usually associated with hydramnios, and their detection is rather more difficult.

Esophageal atresia

Esophageal atresia is a relatively frequent anomaly, occurring in 1 in 3000–3500 live births. It is caused by an impairment in the process of recanalization of the primitive esophagus. An abnormal connection between trachea and esophagus is

usually derived from an imperfect development of the respiratory diverticulum. In the most common type of fistula (90–95%), the upper portion of the esophagus ends blindly (esophageal atresia), and the lower portion develops from the trachea near the bifurcation. The two portions of the esophagus may be connected by a solid cord. Less common are: (1) the upper portion ending in the trachea, the lower portion being of variable length; (2) double fistula, in which upper and lower portions end in the trachea; (3) tracheo-esophageal fistula without esophageal atresia; (4) esophageal atresia without tracheo-esophageal fistula; and (5) tracheal aplasia (lethal).

Severe structural anomalies are associated in nearly 50% of cases, including heart, GI, and genitourinary (GU) tract anomalies, skeletal deformities, cleft defects of the face, and central nervous system (CNS) lesions such as meningoceles or hydrocephalus. Chromosomal anomalies, particularly trisomy 21,¹² are also commonly present. The VACTERL syndrome refers to a condition where vertebral, anorectal, and cardiac anomalies, tracheo-esophageal fistula, esophageal atresia, renal anomalies, and limb anomalies are associated.¹³

Prenatal diagnosis is suspected when, in the presence of polyhydramnios (usually after 25 weeks), serial ultrasound examinations fail to demonstrate the fetal stomach, or the stomach appears permanently small (< 15% of the abdominal circumference) (Fig. 25.7);¹⁴ gastric secretions, however, may be sufficient to distend the stomach and make it visible. Also, in the case of an associated fistula, the stomach may look normal. Occasionally, after 25 weeks, the dilated proximal esophageal pouch can be seen as an elongated upper mediastinal and retrocardiac anechoic structure (Fig. 25.8). The

Figure 25.7 Coronal section of the neck in a fetus with esophageal atresia, showing the blind end of the esophagus (arrow). N, neck.

differential diagnosis for the combination of absent stomach and polyhydramnios includes intrathoracic compression, from conditions such as diaphragmatic hernia, and musculoskeletal anomalies, causing inability of the fetus to swallow.

Factors such as associated anomalies, respiratory complications at birth, gestational age at delivery, and neonatal weight play the most important prognostic role. Thus, for babies with an isolated tracheo-esophageal fistula, born after 32 weeks, when an early diagnosis is made, avoiding reflux and aspiration pneumonitis, the postoperative survival rate is more than 95%. In the case of fetal weight < 2.5 kg and in the presence of respiratory complications or other anomalies, the survival rate decreases to 6%.¹⁵ Drainage of fluid can be performed in cases of severe polyhydramnios. Time and mode of delivery are not influenced by prenatal diagnosis. Delay in postnatal recognition, however, results in increased neonatal morbidity and mortality.¹⁶ Prenatal diagnosis alerts the pediatrician, facilitates prompt neonatal diagnostic confirmation, and enables the prevention of potentially severe complications, such as aspiration pneumonia.

Duodenal obstruction

Duodenal obstruction occurs in approximately 1 in 7500–10 000 live births. It is a sporadic abnormality, although in some cases there is an autosomal-recessive pattern of inheritance. The anomaly can be either extrinsic or intrinsic. Extrinsic lesions are mainly the consequence of a compression of the

Figure 25.8 Cross-section of the fetal abdomen in a fetus with esophageal atresia. Stomach is not visualized. sp, spine; uv, umbilical vein.

duodenum by the surrounding annular pancreas or by peritoneal fibrous bands. Duodenal atresia or stenosis (intrinsic lesions) derives from an incomplete developmental process during the second and third month of fetal life.¹⁷ As the intestine turns from a solid structure into an empty tubular one, the persistence of one or more septa, resulting in a diaphragm, is defined as stenosis. Complete atresia develops from the separation of solid intestine into two or more blind portions, which can be either totally isolated from each other or connected by fibrous bands.

Approximately half of the fetuses with duodenal atresia have associated abnormalities, including trisomy 21 in about 40% of the cases and skeletal defects (vertebral and rib anomalies, sacral agenesis, radial abnormalities, and talipes), gastrointestinal abnormalities (esophageal atresia/tracheo-esophageal fistula, intestinal malrotation, Meckel diverticulum, and anorectal atresia), and cardiac and renal defects.

Detection of two echo-free areas inside the abdomen (“double-bubble” sign), representing the dilated stomach and the first portion of the duodenum, is crucial for prenatal diagnosis¹⁸ (Fig. 25.9). Polyhydramnios is invariably associated. However, obstruction due to a central web may result in only a “single bubble,” representing the fluid-filled stomach. Sonographic demonstration of continuity of the duodenum with the stomach enables differentiation of a distended duodenum from other cystic masses, including choledocal or hepatic cysts (Fig. 25.10).¹⁹ Potential pitfalls derive from visualization of a double bubble on a longitudinal scan of the fetal trunk in cases of intense peristaltic activity. By performing axial scans of the trunk, one should avoid a misdiagnosis. Prenatal diagnosis is not usually made until after

Figure 25.9 Cross-section of the upper fetal abdomen in a case of duodenal atresia, showing the pathognomonic “double-bubble” sign. D, dilated duodenal bulb; sp, spine; st, stomach.

Figure 25.10 Oblique scan of the abdomen in a fetus with duodenal atresia. Notice the thin connection between stomach and duodenum (arrow). D, duodenum; st, stomach.

25 weeks, suggesting that the fetus is unable to swallow a sufficient volume of amniotic fluid for bowel dilation to occur before midtrimester. Diagnosis has occasionally been reported in the second trimester. Recently, a case of duodenal atresia has been recognized in the first trimester.²⁰

Postnatal prognosis of duodenal atresia depends mainly on the following: associated anomalies, birthweight, and prompt confirmation of prenatal diagnosis.

Survival after surgery in patients with an isolated anomaly is more than 95%. Obstetric management is not influenced by prenatal diagnosis; however, spontaneous premature labor is frequent due to polyhydramnios. Prenatal diagnosis allows prevention of neonatal vomiting or aspiration pneumonia through early aspiration of gastric contents.

Intestinal obstructions (below the level of the duodenum)

Intestinal obstructions occur in about 1 in 2000 births. In about half of the cases, there is small bowel obstruction and, in the other half, anorectal atresia. Small bowel obstruction may derive from primary atresia or stenosis of the bowel, meconium ileus, and extrinsic constriction from adhesions. The most frequent site of small bowel obstruction is the distal ileus, followed by the proximal jejunum. In about 5% of cases, obstructions occur in multiple sites. Although the condition is usually sporadic, in multiple intestinal atresias, familial cases have been described.

Associated abnormalities and chromosomal defects are rare. However, in the case of anorectal atresia, associated defects such as genitourinary, vertebral, cardiovascular, and gastrointestinal anomalies are found in about 80% of cases. Meconium ileus may be associated with cystic fibrosis.

The lumen of the small bowel and colon does not normally exceed 7 mm and 20 mm respectively. Diagnosis of obstruction is usually made late in pregnancy, after 25 weeks, because dilation of the intestinal lumen is slow and progressive. Jejunal and ileal obstructions are imaged as multiple fluid-filled loops of bowel in the abdomen (Fig. 25.11).²¹ The more distal the site of the obstruction, the greater the number of anechoic structures (Fig. 25.12). The abdomen is usually distended, and active peristalsis may be observed. If bowel perforation occurs, transient ascites, meconium peritonitis, and meconium pseudocysts may ensue. Polyhydramnios, usually after 25 weeks, is common, especially with proximal obstructions.²² Similar bowel appearances and polyhydramnios may be found in fetuses with Hirschsprung disease, the megacystis-microcolon-intestinal hypoperistalsis syndrome, and chloride diarrhea. The differential diagnosis of small bowel obstruction includes renal tract abnormalities and other intra-abdominal cysts such as mesenteric, ovarian, or duplication cysts. A specific clue for bowel obstruction is the presence of peristalsis. Prenatal diagnosis of anorectal atresia is rather difficult, because the proximal bowel may not demonstrate significant dilation, and the amniotic fluid volume is usually normal; occasionally, calcified intraluminal meconium may be seen in the fetal pelvis.

Figure 25.11 Cross-section of the abdomen in a fetus with small bowel atresia. Dilated bowel is visible.

The prognosis is related to gestational age at delivery, associated abnormalities, and the site of obstruction.²³ In those born after 32 weeks with isolated obstruction requiring resection of only short segments of bowel, the survival rate is more than 95%. Loss of large segments of bowel can lead to short gut syndrome, which is a lethal condition.

Fetuses with uncomplicated intestinal obstruction can be delivered vaginally at term. Induction should be considered when perforation with ascites occurs. In these cases, fetal paracentesis to decrease abdominal pressure on the diaphragm, thus allowing expansion of the lungs, may be indicated.²⁴ If perforation and bleeding into the abdominal cavity occur, delay in delivery may cause hydrops fetalis, owing to severe anemia, decreased oncotic pressure, and loss of plasma volume.²⁵

Meconium peritonitis

Meconium peritonitis is a chemically sterile peritonitis consequent to intestinal perforation *in utero*. Various conditions may be the cause: intestinal atresia, vulvulus, meconium ileus, etc. In 25–40% of cases, it is secondary to perforation of a meconium ileus such as in the case of cystic fibrosis. In a minority of cases, the cause remains unknown.

As meconium begins to accumulate in fetal bowel at 4 months, any perforation occurring after that time could bring the outflow of meconium into the peritoneal cavity.

Figure 25.12 Cross-section of the abdomen in a fetus with small bowel atresia. Multiple distended loops of bowel are visible.

As a result, an intense reaction occurs, leading to extensive adhesions. If it is localized at the site of perforation, a calcified mass develops (fibroadhesive type). In other cases (cystic type), the continuous outflow of intestinal content into a cavity (pseudocyst) determines the formation of a highly echogenic mass at the site of the perforation (Fig. 25.13). Polyhydramnios is a frequent finding; ascites may also be present.²⁶

A peritonitis can be suspected when a fetus affected by intestinal obstruction suddenly shows the presence of ascites or generalized hydrops. Differential diagnosis should be made with other abdominal masses, in particular with abdominal teratomas and gallbladder calcifications. However, teratomas are complex masses, and gallbladder calcifications are strictly connected with the gallbladder.

Prognosis is generally severe. Only a few cases have been described in the literature; therefore, the most suitable management of pregnancy is still questioned. Serial ultrasound examinations are indicated. In stable conditions, without ascites, obstetric management should not change. In case of a deteriorating condition, with developing ascites, preterm delivery could be considered to avoid damage to the bowel. Pregnancies that continue until term should be monitored intensively to assess fetal well-being. Cesarean section does not seem to ameliorate the prognosis; the risk of abdominal dystocia, however, should always be considered. Delivery in a tertiary-care facility allows immediate postnatal surgical intervention.²⁷

Figure 25.14 Oblique scan at the level of the right upper abdomen in a fetus with choledochal cyst (cy) close to the gallbladder (g). sp, spine; s, stomach.

Cystic anomalies of the gastrointestinal tract

Choledochal cysts

The etiology is unknown. The presence of a cyst in the upper side of the fetal abdomen suggests the diagnosis of choledochal cyst. They represent cystic dilation of the common biliary duct. Differential diagnosis includes intestinal duplication cysts, hepatic cysts, situs inversus, and duodenal atresia. The absence of the connection with the stomach, which does not appear dilated, enables the exclusion of duodenal atresia (Fig. 25.14). The absence of polyhydramnios or peristalsis suggests a nonintestinal disorder. A prompt diagnosis and surgical postnatal removal (although, carrying a 10% mortality rate) could avoid complications such as biliary cirrhosis, portal hypertension, calculus formation, and adenocarcinoma.

Mesenteric, omental, and retroperitoneal cysts

Cystic structures located in the small or large bowel mesentery, the omentum, or the retroperitoneal space are caused by obstruction of the lymphatic drainage system or may represent lymphatic hamartomas. Quite rare, these cystic lesions are usually anechoic, multi- or unilocular, median, and of variable size. The fluid contents may be serous, chylous, or hemorrhagic. Obstetric management is unchanged; surgical removal

is required in the case of bowel obstruction or acute abdominal pain following torsion or hemorrhage into a cyst.

Hepatic cysts

Hepatic cysts are typically located in the right lobe of the liver. They are quite rare and result from obstruction of the hepatic biliary system. They appear as unilocular, intrahepatic cysts, and they are usually asymptomatic, although they may rarely show complications such as infections or hemorrhages. In 30% of the cases of polycystic kidneys (adult type), asymptomatic hepatic cysts may be associated.²⁸

Intestinal duplication cysts

These are quite rare, and may be located along the entire GI tract. They appear sonographically as tubular or cystic structures of variable size. They may be isolated or associated with other GI malformations.²⁹ Thickness of the muscular wall of the cysts and the presence of peristalsis may facilitate the diagnosis. Complications in the first months of postnatal life are represented by bowel obstruction and respiratory complications.

Anomalies of the umbilical vein

These are very rare anomalies. They can be divided into three groups: persistence of the right umbilical vein with ductus

venous and presence or absence of left umbilical vein; absent ductus venosus with extrahepatic insertion of umbilical vein; dilated umbilical vein with normal insertion and decurrence.³⁰ Normally, the umbilical vein enters the abdomen almost centrally at the level of the liver and courses on the left of the gallbladder. Persistence of the right umbilical vein is demonstrated by the fact that it is localized on the right of the gallbladder, bending toward the stomach.³¹ Color Doppler may help to diagnose these anomalies and may allow the differential diagnosis with other cystic abdominal lesions. Associated anomalies are frequent in the first two groups, and this influences the prognosis. These anomalies include cardiac, skeletal, GI, and urinary anomalies. IUGR is also present, together with single umbilical artery. The anomalies of the third group are rarely associated with other defects, and prognosis depends upon the time of diagnosis and dimension of the varicosity.

Gallbladder anomalies

Agenesis of the gallbladder is associated with biliary atresia in 20% of cases. Prenatal diagnosis has not yet been described. Gallstones may be visualized as minute hyperechogenic intraluminal structures. Conservative management is indicated, as they may disappear postnatally.

Hepatosplenomegaly

Isolated hepatomegaly or splenomegaly is rare. Causes of hepatosplenomegaly are immune and nonimmune hydrops, hemolytic anemia, congenital infection, metabolic disorders, and hepatic tumors. Hepatic hemangioma, despite its benign nature, is associated with a high mortality rate (81%) secondary to congestive heart failure due to arterial-venous shunting. The sonographic finding is usually a hypoechogenic intrahepatic structure. The tumor may be pulsating and recognizable with Doppler ultrasound. The presence of hepatic calcifications and a hyperechogenic solid mass may suggest a diagnosis of hepatoblastoma, which represents the most frequent malignant tumor during fetal life. Hamartomas usually present as a multilocular cystic mass. Hepatic hyperechogenicity, unrelated to infections or tumors, seems to carry a favorable prognosis when other anomalies are absent and the karyotype is normal.³²

Abdominal wall defects

Defects of the abdominal wall including omphalocele and gastroschisis (defect of the upper abdominal wall) and bladder and cloacal exstrophy (defect of the lower abdominal wall) are recognizable owing to the protrusion of abdominal contents into the amniotic fluid cavity. Prognosis largely depends

on associated anomalies and complications such as fetal growth restriction.

Omphalocele

Omphalocele, or exomphalos, occurs in about 1 in 4000 births, and results from failure of normal embryonic regression of the midgut from the umbilical stalk into the abdominal coeloma. The abdominal contents, including intestines and liver or spleen covered by a sac of parietal peritoneum and amnion, are herniated into the base of the umbilical cord.³³ When omphalocele is small, the umbilical cord is inserted into its apex; in cases of large defects, the cord is attached inferiorly, and the umbilical vein and arteries are splayed out in the wall of the sac. If the sac ruptures *in utero*, its remnants, with the umbilical vessels, are still visible on the border of the lesion. The defect varies greatly in size, from a small opening through which only one or two loops of the small intestine or a Meckel's diverticulum protrude to an enormous defect containing most of the abdominal contents.

The majority of cases of omphalocele are sporadic, and the recurrence risk is usually less than 1%. However, in some cases, there may be an associated genetic syndrome.

Omphalocele is often associated with other abnormalities, as a result of general interference with embryonic development during early gestation.³⁴ Malrotation of the gut and duodenal obstruction are frequent. GU anomalies, including exstrophy of the bladder, penile anomalies, and undescended testes, are also very common. Congenital heart diseases are frequent and represent the most important cause of death for the affected child. Craniofacial anomalies are quite rare. Chromosomal abnormalities (mainly trisomy 18 or 13) are found in about 30% of cases at mid-gestation and in 15% of neonates.³⁵ If macrosomia is present, one should suspect Beckwith-Wiedemann syndrome (EMG syndrome), which includes multiple abnormalities such as omphalocele, macroglossia, occasionally requiring partial glossectomy to prevent mandibular prognathism, and macrosomia with hyperplastic fetal visceromegaly; a severe resistant neonatal hypoglycemia may be expected in 50% of cases. In some cases, Beckwith-Wiedemann syndrome is associated with mental handicap, which is thought to be secondary to inadequately treated hypoglycemia. About 5% of affected individuals develop tumors during childhood, most commonly nephroblastoma and hepatoblastoma. In Beckwith-Wiedemann syndrome, most cases are sporadic, although autosomal-dominant, recessive, X-linked, and polygenic patterns of inheritance have been described. Omphalocele is also present in pentalogy of Cantrell, which includes a large upper abdominal omphalocele, an anterior diaphragmatic hernia, a sternal cleft, ectopia cordis, and various cardiac anomalies such as ventricular septal defect or tetralogy of Fallot. A low omphalocele is frequently associated with bladder or cloacal exstrophy and other anomalies, including anal atresia or myelomeningocele, and lower limb anomalies.³⁶

Prenatal diagnosis of omphalocele is based on the demonstration of the midline anterior abdominal wall defect, the herniated sac with its visceral contents, and the umbilical cord insertion at the apex of the sac (Figs 25.15 and 25.16).^{37,38} As normal migration of the midgut back into the abdomen occurs between the 9th and the 12th gestational weeks, the diagnosis of ventral wall defects should not be made before 14 weeks.³⁹ Exceptionally, heart and bladder are contained in the herniated sac.⁴⁰ In small defects, umbilical cord insertion is on top of the mass, whereas in large lesions, the cord is attached to its lower border. A cystic structure associated with the umbilical cord, representing an allantoic cyst often associated with omphalocele, can be interpreted as protrusion of abdominal contents through a defect in the abdominal wall.⁴¹ Polyhydramnios is often present. The differential diagnosis includes mainly gastroschisis, in which the only herniated abdominal contents are bowel loops, not contained by an amnioperitoneal membrane.

Isolated lesions have a good prognosis with a survival rate after surgery of higher than 90%.^{42,43} The volume of the protruded viscera is crucial for determining fetal prognosis: giant defects associated with liver evisceration and ectopia cordis may have a much worse prognosis than small defects, in which only bowel loops are extruded.^{44,45} In cases of small defects or an isolated anomaly, if omphalocele is intact, there is no need to anticipate delivery.⁴⁶ When omphalocele has gone into a rupture, a preterm Cesarean section has been suggested to avoid the exposure of the bowel to the amniotic fluid, which may compromise the outcome of postnatal surgical correction.⁴⁷ However, risks of prematurity should be taken into

account. Large or ruptured omphalocele should probably be delivered by Cesarean section, in strictly sterile conditions, to avoid trauma and infection of the herniated viscera and to decrease the risk of dystocia. However, it has yet to be demonstrated whether this management improves fetal outcome. In 1983, in a large retrospective study of 112 cases of abdominal wall defects, Kirk and Wah⁴⁸ found no adverse effects related to vaginal delivery or to the success of surgical post-natal correction. However, because the mortality rate of newborns affected by abdominal wall defects largely depends on the clinical condition of the malformed baby on admission,⁴⁹ maternal transport to a tertiary center and an accurately planned Cesarean delivery would probably avoid the risks of a sudden, unexpected delivery leading to a delay in surgical care.

Gastroschisis

Gastroschisis is found in about 1 in 4000 births. In gastroschisis, the primary body folds and the umbilical ring develop normally, and evisceration of the intestine occurs through a small abdominal wall defect located just lateral and usually to the right of an intact umbilical cord.⁵⁰ Other pathogenetic theories suggest that gastroschisis results from an intrauterine rupture of an incarcerated hernia into the cord,⁵¹ or from a vascular accident involving the omphalomesenteric artery, leading to disruption of the umbilical ring and herniation of abdominal contents.⁵² The loops of intestine lie uncovered in the amniotic fluid. Occasionally, only a short tract of the intestine is herniated; in most cases, however, all the small and large intestines protrude. Stomach, gallbladder, urinary bladder, testes or uterus, and adnexae are also prolapsed. Chemical peritonitis is an ominous complication due to

Figure 25.15 Cross-section of a fetus with omphalocele. Note the herniated hyperechogenic mass (arrow) at the level of cord insertion. L, liver; P, placenta; uc, umbilical cord on top of the defect.

Figure 25.16 Cross-section of a 20-week fetus with a large omphalocele. The liver protrudes from the abdominal wall defect covered by an amnioperitoneal membrane.

amniotic fluid exposure of eviscerated abdominal contents. In such cases, the intestine shows marked dilation of the lumen and increased thickness of the walls, which appear edematous, of leathery consistency, and matted together and encased in a net of fibrinous material. In many cases, the intestine reveals an abnormal shortening. Single or multiple atretic sites of the protruded gut can be detected. Gastroschisis is a sporadic abnormality.

Associated anomalies are uncommon compared with omphalocele, and usually involve the intestinal tract (malrotation). Occasionally, intestinal obstruction due to angulation of gut, adhesions, or atresia secondary to vascular impairment of the wall can be seen as ancillary complications.

Prenatal diagnosis is based on the demonstration of the normally situated umbilicus and the herniated loops of intestine, which are free-floating and widely separated (Fig. 25.17).⁵³

Hypoechoic areas can sometimes be identified within the bubble-like structures, suggesting the presence of meconium. The extruded structures are not covered by amnioperitoneal membrane, and normal umbilical cord insertion is present (Fig. 25.18). Polyhydramnios is common, as well as increased amniotic fluid alpha-fetoprotein (AFP) levels. About 30% of fetuses are growth restricted, but the diagnosis can be difficult because gastroschisis as such is associated with a small abdominal circumference.⁵⁴ In these cases, the volume of amniotic fluid is often reduced and visualization suboptimal.

Prognosis has improved dramatically during the last three decades.⁵⁵ Decreased perinatal mortality from 82% in 1960 to less than 10% in 1984 is likely to be attributable to improved surgical technique and the use of parenteral nutrition. Mortality is usually the consequence of short gut syn-

drome. It is still debated whether sonographic findings such as dilation and thickening of the bowel wall can predict infant outcome.^{56–58} Dilation of the stomach seems to be associated with increased perinatal morbidity and mortality.⁵⁹

Gastroschisis is less frequently associated with other congenital anomalies than omphalocele. As with omphalocele, it can be part of amniotic band syndrome. Unlike omphalocele, gastroschisis is often associated with IUGR⁶⁰ and oligohydramnios; in these cases, risks related to prematurity should be balanced against benefits of the shortened exposure time to the action of amniotic fluid.

In cases with associated growth restriction, strict surveillance of fetal well-being is recommended between 34 and 36 weeks.⁶¹

As with omphalocele, the impact of route of delivery on outcome is still debated. Some authors show that babies born from elective Cesarean section had less sepsis and less short-term morbidity,⁶² while other groups do not demonstrate the benefit of Cesarean section versus vaginal delivery.^{63,64}

It seems crucial, however, that delivery takes place in tertiary-care centers where the neonate can receive intensive care and where neonatal surgical correction is promptly available. Delay in pediatric care, in fact, increases the risk of sepsis and may be the cause of severe dehydration and rapid heat loss, which may compromise the outcome of surgical correction. Long-term follow-up of survivors is excellent: children show normal growth and development in follow-up to 5 years of age.⁶⁵

Figure 25.17 A case of gastroschisis diagnosed at 22 weeks' gestation: free-floating loops of bowel (B) herniated through a lateral abdominal wall defect.

Figure 25.18 Loops of bowel protruding through a lateral defect of the abdominal wall. See the intact insertion of the cord (arrow). B, bowel; uv, umbilical vein.

Body stalk anomaly

Body stalk anomaly is a rare fatal disease with a birth incidence of 1 in 14 000.⁶⁶ It is characterized by a defect of the anterior abdominal wall with absence of the umbilicus and umbilical cord. The placenta appears to be fused with the herniated viscera, and consequent skeletal kyphosis is a common feature. This anomaly derives from failure of the cephalic, caudal, and lateral body folds to develop, together with the abnormal persistence of the coelomatic cavity, which usually obliterates by the fourth week of embryonic life. Prenatal diagnosis is based upon demonstration of a vast defect in the anterior abdominal wall, through which herniated viscera protrude and fuse with the placenta.⁶⁷ Major anomalies of any apparatus may be associated.

Bladder exstrophy and cloacal exstrophy

Bladder and cloacal exstrophy are rare sporadic anomalies, even if familial cases have been described. Incidence of bladder exstrophy is 1 in 30 000 live births, while incidence of cloacal exstrophy is 1 in 200 000 live births. Bladder exstrophy is a consequence of impaired development of the caudal fold of the anterior abdominal wall. The anterior wall is absent, and exposure of the posterior bladder wall is common. Omphalocele is frequently associated, as well as epispadias, incomplete descent of the testicles, and imperforate anus. In cloacal exstrophy, both GI and GU tracts are involved. Cloacal exstrophy (also referred to as OEIS complex) is the association of an omphalocele, exstrophy of the bladder, imperforated anus, and spinal defects such as meningomyelocele. The hemibladders are on either side of the intestines.

Bladder exstrophy should be suspected when the fetal bladder is not visualized in the presence of normal amniotic fluid (the filling cycle of the bladder is normally about 15 min) or when an echogenic mass is seen protruding from the lower abdominal wall in close association with umbilical arteries.⁶⁸ In cloacal exstrophy, the findings are similar to bladder exstrophy (large infraumbilical defect that extends to the pelvis), but a posterior anomalous component is present.⁶⁹ Other findings include single umbilical artery, ascites, vertebral anomalies, clubfoot, and ambiguous genitalia. In boys, the penis is divided and duplicated. With aggressive reconstructive bladder, bowel, and genital surgery, the survival rate is more than 80%.⁷⁰ Bladder exstrophy is compatible with complete repair, although permanent urinary tract diversion becomes necessary in some cases. Cloacal exstrophy is a much more severe disease involving the lower abdominal tract as well, and is associated with significant sequelae.

Genitourinary tract anomalies

Congenital malformations of the GU tract are relatively frequent, probably due to the complexity of embryologic

development, representing the major cause of neonatal abdominal masses. Prenatal diagnosis is crucial to choose the most appropriate prenatal and postnatal management, and has greatly improved the prognosis of affected children.⁷¹ The volume of amniotic fluid should be carefully evaluated. A significant decrease in amniotic fluid volume heralds the presence of many GU anomalies and, when detected after the second trimester, is an ominous prognostic factor because of the association with pulmonary hypoplasia.⁷² Owing to the paucity of amniotic fluid, the diagnosis of GU tract anomalies is sometimes a difficult task; recently, magnetic resonance imaging (MRI) has been proposed as a useful tool to provide adequate visualization of renal and bladder regions, despite a reduced volume of amniotic fluid.⁷³

Bilateral renal agenesis

Bilateral renal agenesis is found in 1 in 5000 births, while unilateral disease is found in 1 in 2000 births. Renal agenesis derives from failure of development of the ureteric bud or nephrogenic blastema, because both components occur at the formation of normal kidneys.

This abnormality is usually isolated and sporadic, although it may rarely be secondary to a chromosomal abnormality or part of a genetic syndrome such as Fraser syndrome, or a developmental defect such as VACTERL association. In non-syndromic cases, the risk of recurrence is approximately 3%. However, in about 15% of cases, one of the parents has unilateral renal agenesis and, in these families, the risk of recurrence is increased.⁷⁴

Renal agenesis can be part of Potter's syndrome, which includes pulmonary hypoplasia, skeletal deformities, and typical facies, characterized by low-set ears. Oligohydramnios is considered to be responsible for pulmonary hypoplasia and skeletal deformities, which are also present in some cases of prolonged rupture of membranes or IUGR.⁷⁵ Conversely, when oligohydramnios is not severe, the characteristic features of Potter's syndrome are uncommon.⁷⁶ Other structural anomalies, such as cardiac and GI tract anomalies, are associated with variable incidence.

Failed visualization of kidneys and bladder, associated with oligohydramnios, prompts the diagnosis of bilateral renal agenesis. Additionally, adrenals are usually hypertrophic and can be confused with normal kidneys (Fig. 25.19). Prenatal diagnosis can be rather difficult owing to the lack of amniotic fluid and the "crumpled" position adopted by these fetuses. Identification of the renal capsule and renal pelvis enables the two structures to be distinguished.⁷⁷

The differential diagnosis includes premature rupture of the membranes, severe uteroplacental insufficiency, and obstructive uropathy or bilateral multicystic or polycystic kidneys. Vaginal sonography with a high-resolution probe is useful in

these cases. Failure to visualize the renal arteries with color Doppler is sometimes crucial to the diagnosis (Fig. 25.20A and B). Prenatal diagnosis of unilateral renal agenesis is difficult as there are no major features, such as anhydramnios and empty bladder, to alert the sonographer.

Bilateral renal agenesis is a lethal condition. Amniotic fluid enables normal development of the lungs up to 22–24 weeks. Early severe oligohydramnios invariably leads to pulmonary hypoplasia, and infants die in the neonatal period owing to

respiratory insufficiency. Unilateral agenesis has a favourable prognosis.

Cystic kidneys

Four main categories of cystic dysplastic kidneys are recognized. Two different entities can be identified with certainty via antenatal ultrasonography: multicystic kidney and cystic dysplasia occurring as a consequence of early and longstanding obstructive uropathy.

Multicystic kidneys

Multicystic kidneys are usually unilateral, although bilateral renal involvement has been reported.⁷⁸ The dysplastic process is usually limited to the medulla, but can involve the cortex as well. The prevalence of the unilateral type is unknown; bilateral involvement is estimated to occur in 1 in 1000 live births.⁷⁹

In the majority of cases, this is a sporadic abnormality, but a few examples of familial cases have been described.⁷⁹ Pathogenesis of the anomaly is controversial; it is most likely secondary to atresia of the ureter, the pelvis, or both during the metanephric stage of development.⁸¹

Multicystic kidney is often associated with other congenital anomalies, including mainly congenital heart diseases and chromosomal aberrations (mainly trisomy 18), and it is often part of genetic syndromes. It may frequently be associated with contralateral renal agenesis and hydronephrosis.⁸² Misdiagnosis can occur when the contralateral kidney is ectopic.

Figure 25.19 No demonstrable kidneys and flattened adrenal gland in a 20-week fetus with bilateral renal agenesis.

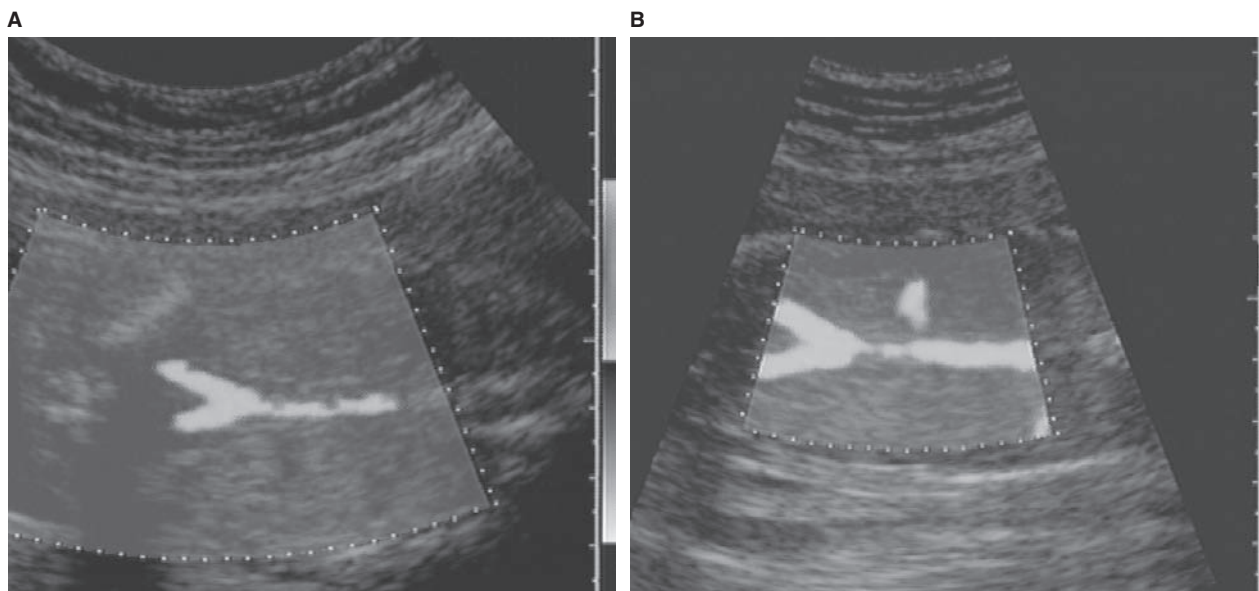

Figure 25.20 Color Doppler failed to demonstrate the renal arteries in the case of bilateral (A) and unilateral (B) renal agenesis.

In 10% of cases, the anomaly is associated with contralateral hydronephrosis, usually from obstruction at the ureteropelvic junction (UPJ). Because the obstructed kidney is the only functioning one, serial examination should be planned to monitor dilation of the pelvis and the amount of amniotic fluid.

Multicystic kidneys are usually unilateral and appear as a cluster of multiple irregular cysts of variable size with little intervening hyperechogenic stroma (Fig. 25.21).^{83,84} Affected kidneys are usually extremely enlarged. The hypoplastic or atretic collecting system is undetectable by ultrasound. In the unilateral variant, contralateral kidney and bladder are normal, as is the amount of amniotic fluid. Occasionally, the contralateral renal pelvis appears slightly enlarged owing to compensatory urine flow. Distinction between multicystic kidneys and obstructions at the UPJ in prenatal sonograms can be extremely difficult.⁸⁵ Coronal scans seem to be the most specific because, in UPJ obstructions, they clearly demonstrate the connection between the renal pelvis and the dilated caliceal system. Conversely, in cystic lesions, the cysts are separated. Such a distinction is much easier when ultrasound examination is performed in early pregnancy. Isolated unilateral multicystic kidneys have a good prognosis. The need for postnatal nephrectomy is currently under discussion: it is required when the size of the kidney is inconvenient to the patient, but it should be considered in all cases, because complications, including GI infections, hypertension, and malignant mixed tumors, may originate from a retained affected kidney.^{86,87} Bilateral multicystic dysplastic kidney disease (MDKD) invariably has a poor prognosis.

Figure 25.21 Coronal scan of the trunk of a 33-week fetus with unilateral multicystic dysplastic kidney disease. The cysts are clearly separated by echoic tissue.

Cystic dysplasia

Early and persistent obstruction of the lower GU tract is associated with secondary cystic dysplasia of the kidneys, which appear hyperechogenic, increased in size, and present small cysts that spread through the parenchyma. In these cases, the diagnosis is made by the simultaneous demonstration of obstructive uropathy (distended bladder, convoluted ureters, pyelectasia, oligohydramnios), and these findings can be part of genetic renal disorders.⁸⁸

Autosomal-recessive cystic kidney

Autosomal-recessive cystic kidney (also referred to as infantile polycystic kidney) invariably involves both kidneys, and occurs in 1 in 20 000 live births. A defect in the collecting system seems to be responsible for the anomaly. Kidneys are symmetrically enlarged, and the parenchyma is totally occupied by numerous cysts of minute dimensions. At section, the cysts present a cubic epithelium.

Sonographically, both kidneys usually appear extremely enlarged and hyperechogenic (Fig. 25.22).⁸⁹ In severe cases, the bladder is absent and oligohydramnios is extreme. However, these sonographic appearances may be manifest only in late gestation.⁹⁰ Molecular genetics helps in the diagnosis only when the index case has been clearly identified, and only if DNA from the case is available and can be screened in order to identify the familial mutations.

The prognosis is variable. Cases appearing early in

Figure 25.22 Coronal section of a fetus with recessive-type polycystic kidneys. Kidneys appear extremely enlarged and hyperechogenic.

gestation are associated with oligohydramnios in the second trimester and are usually lethal owing to a combination of renal failure and pulmonary hypoplasia.^{91,92} In other cases, the onset of the disease occurs later in gestation or after birth, and there is variable progression toward renal failure. The infantile and juvenile types result in chronic renal failure, hepatic fibrosis, and portal hypertension; many survive into their teens but require renal transplantation.

Autosomal-dominant cystic kidney

Autosomal-dominant cystic kidney (also referred to as adult polycystic kidney) almost invariably affects both kidneys, although often asymmetrically.^{93,94} It is usually asymptomatic until the third or fourth decade of life.

Autosomal-dominant cystic kidney is a common inherited nephropathy affecting more than 1 in 1000 live births. It may be inherited as an autosomal-dominant trait, or it may be a feature of genetic and nongenetic syndromes. Sporadic diseases have also been reported in the literature.⁹⁵

Using a highly polymorphic DNA probe genetically linked to the mutant gene, prenatal diagnosis is possible.⁹⁶

Sonography does not usually demonstrate abnormalities prior to the second or third decade of life. In a handful of cases, however, affected fetuses have demonstrated findings similar to the autosomal-recessive variety, including enlarged and echogenic kidneys.^{93,95} Kidneys appear grossly enlarged with multiple cysts of variable size intermixed with well-represented, hyperechogenic solid tissue (Fig. 25.23). Dissection shows multiple cysts of variable size filled with fluid within both the medulla and the cortex. Histology demonstrates the

presence of normal renal parenchyma. Nephrons and collecting tubules are poorly defined, as are papillae and calices. The cysts are lined by cuboidal cells.

It is clear that this disease covers a wide spectrum. The experience with prenatal diagnosis is limited. It would not seem that intrauterine presentation is necessarily associated with a poor prognosis.

Cystic kidneys are also found with many mendelian disorders, such as tuberous sclerosis, Jeune syndrome, Sturge-Weber syndrome, Zellweger syndrome, Laurence-Moon-Biedl syndrome, and Meckel-Gruber syndrome.

Obstructive uropathies

Enlargement of the GU tract usually occurs, albeit not exclusively, as a consequence of obstruction. When the obstruction is complete and occurs early in fetal life, cystic renal dysplasia ensues. On the other hand, where intermittent obstruction allows for normal renal development, or when obstruction occurs in the second half of pregnancy, hydronephrosis will result, and the severity of renal damage will depend on the degree and duration of the obstruction. Different entities with variable findings and clinical implications exist depending on the location and severity of the dilatation.⁹⁷

Hydronephrosis refers to dilation of the renal pelvis (Fig. 25.24 and 25.25). Mild hydronephrosis, or pyelectasia, is defined by the presence of an anteroposterior diameter of the pelvis of more than 4 mm at mid-gestation and more than 7 mm in the third trimester. Transient hydronephrosis may be

Figure 25.23 Coronal scan of the fetal trunk demonstrating the polycystic kidneys (PK).

Figure 25.24 Cross-section of the fetal abdomen showing a mildly enlarged renal pelvis and a contralateral normal pelvis.

Figure 25.26 Coronal view of the kidney in a case of ureteropelvic junction obstruction. Pelves and calices appear fairly dilated.

due to relaxation of smooth muscle of the GU tract by high levels of progesterone or maternal–fetal overhydration. In the majority of cases, the condition remains stable or resolves in the neonatal period. In about 20% of cases, there may be an underlying pathology that requires postnatal follow-up and possible surgery. The incidence of surgery with a renal pelvis of 5–10 mm is in the range of 3–4%. Moderate hydronephrosis, characterized by an anteroposterior pelvic diameter of more than 10 mm, is almost invariably associated with caliceal dilation, is usually progressive and, in more than 50% of cases, requires surgery during the first 2 years of life. Sonographically, it may be difficult at times to distinguish severe hydronephrosis with significant caliceal enlargement from a multicystic kidney. A scan oriented along the coronal plane of the kidney is required to demonstrate the radial projection of the calices around the enlarged pelvis (Fig. 25.26). Sections oriented in different planes may create the false impression of multiple cysts separated by parenchymal tissue that is typical of multicystic kidney.

Mild pyelectasia (anteroposterior diameter between 4 and 10 mm) has recently been suggested as a sonographic marker for chromosomal abnormalities⁹⁸ and, in some cases, may reveal vesicoureteric reflux at birth.⁹⁹

Hydroureteronephrosis is the combination of hydronephrosis and an enlarged ureter (Fig. 25.27). Of course, these findings are generally present with megacystis. However, the following discussion refers to hydroureteronephrosis with a normal bladder, which may result from either ureterovesical reflux or ureterovesical junction obstruction. Under normal conditions, the small ureter cannot be visualized with antena-

tal ultrasonography. The dilated ureter appears as a tortuous fluid-filled tubular structure interposed between the renal pelvis, which is variably dilated, and the bladder.^{100,101} Sometimes, it is clearly visible as a ureterocele, which is represented by a thin-walled and fluid-filled small circular area inside the bladder (Fig. 25.28). Amniotic fluid is present in normal amounts. Rarely, a primary megaureter will be present, with a normal renal pelvis. The outcome and management principles are similar to those outlined for hydronephrosis.

Ureteral duplication can be associated with hydronephrosis and megaureter. A specific diagnosis is possible when two distinct renal pelves can be seen within one kidney (Fig. 25.29). Typically, there is some degree of dilation of the upper renal pole.^{102,103}

Megacystis

Megacystis is defined as an abnormal enlargement of the urinary bladder, and is most frequently the consequence of urethral obstruction. Typically, it is seen in the early midtrimester and has been visualized as early as 11 weeks' gestation.¹⁰⁴ The bladder is usually greatly enlarged, occupying most of the abdomen and distending it. Urethral obstruction can be caused by urethral agenesis, persistence of the cloaca, urethral stricture, or posterior urethral valves. Posterior urethral valves occur only in males and are the most common cause of bladder outlet obstruction. The condition is generally sporadic and is found in about 1 in 3000 male fetuses; however, in some cases, it has a genetic basis.¹⁰⁵ In the

Figure 25.27 Coronal scan of the lower abdomen in a fetus with unilateral ureterovesical junction obstruction. Calices and pelvis are dilated, as well as the proximal portion of the ureter (U).

Figure 25.28 Thin-walled, fluid-filled, small, circular area (*) inside the bladder (B), representing a ureterocele in a fetus with ureterovesical junction obstruction.

Figure 25.29 Coronal scan of the abdomen of a fetus with duplication of the kidneys. The two renal pelvises (*) appear moderately dilated.

majority of cases, obstruction is caused by two semicircular membranous plicae at the level of the verumontanum.⁷⁴ As urine flows from the bladder, these plicae adhere and close the upper portion of the urethra.

With posterior urethral valves, there is usually incomplete or intermittent obstruction of the urethra, resulting in an enlarged and hypertrophied bladder with varying degrees of hydroureters, hydronephrosis, a spectrum of renal hypoplasia and dysplasia, oligohydramnios, and pulmonary hypopla-

sia^{106,107} (Figs 25.30–25.33). Diagnosis has been made from as early as 12 weeks' gestation (Fig. 25.34).

In some cases, urinary ascites is associated with rupture of the bladder or transudation of urine into the peritoneal cavity.

When megacystis is found in association with an increased amount of amniotic fluid, the possibility of a megacystis–microcolon–intestinal hypoperistalsis syndrome should be considered. This is a sporadic abnormality characterized by a massively dilated bladder and hydronephrosis in the presence

Figure 25.30 Longitudinal scan of the lower abdomen in a fetus with megacystis. The proximal tract of the ureter is dilated.

Figure 25.31 Longitudinal scan of the trunk of a male fetus affected by megacystis. The insertion of the umbilical vessels on the anterior abdominal wall is demonstrated with color Doppler.

of normal or increased amniotic fluid; the fetuses are usually female. There is associated shortening and dilation of the proximal small bowel, and microcolon with absent or ineffective peristalsis. The condition is usually lethal owing to bowel and renal dysfunction.

The outcome of urethral obstruction depends on how severe it is and how early it occurs. Complete persistent obstruction occurring in the early midtrimester (e.g., urethral atresia, early posterior urethral valves) results in massive distention of the bladder and abdominal wall (prune-belly abdomen), severe oligohydramnios, dysplastic kidneys, and pulmonary hypopla-

Figure 25.32 Severe megacystis. Radiograph of neonate with severe dilation of the urinary bladder.

Figure 25.33 Megacystis: pathological specimen of the urinary bladder which appeared enlarged with thickened walls.

sia.¹⁰⁸ Obstruction occurring in late gestation may be associated with oligohydramnios and hydronephrosis, but does not result in pulmonary hypoplasia and dysplastic kidneys. The management of early-appearing megacystis has been debated.^{109–112} Shunting of the fetal bladder is feasible, although there is no

Figure 25.34 Longitudinal scan of a 12-week fetus with megacystis, obtained using a 6.5-MHz transvaginal probe.

conclusive evidence that such intervention improves renal or pulmonary function beyond what can be achieved by postnatal surgery. Antenatal evaluation of renal function relies on a combination of ultrasonographic findings and analysis of fetal urine obtained by puncture of the bladder or renal pelvis. An attempt to assess the severity of renal compromise should be made before embarking on fetal therapy. Poor prognostic signs are: (1) the presence of bilateral multicystic or severely hydronephrotic kidneys with increased parenchymal echogenicity, suggestive of renal dysplasia; (2) anhydramnios, implying complete urethral obstruction; and (3) decreased output ($< 2 \text{ mL/h}$) of isotonic urine (osmolality $> 210 \text{ mOsm}$; sodium $> 100 \text{ mEq/mL}$; chloride $> 90 \text{ mEq/mL}$, and high levels of beta-2 microglobulin). In these cases, there is little chance of the infant surviving. Conversely, potential candidates for intrauterine surgery are fetuses with: (1) bilateral moderately severe pelvicaliceal dilation and normal cortical echogenicity; and (2) normal levels of urinary sodium, calcium and beta-2 microglobulin. One must remember, however, that normal values cannot exclude renal failure in childhood.¹¹³

Fetal ovarian cysts

Ovarian cysts are one of the most common causes of abdominal masses in the female neonate.^{114,115} They are the most significant genital anomaly presenting in the prenatal period.

Although classically related to hormonal stimulation, the cause of the anomaly is still uncertain. Interestingly, congenital ovarian cysts occur in association with hypothyroidism.¹¹⁶

Prenatal ultrasound diagnosis is possible from the second trimester of pregnancy.^{117–119} Cystic mass in the fetal lower abdomen, integrity of GI and GU tracts, and female sex are the main ultrasound criteria for diagnosis of fetal ovarian cyst. The cyst may be completely fluid or septated,¹²⁰ and sometimes presents with a fluid-solid level (Fig. 25.35). Diagnosis,

however, is always presumptive, as mesenteric and urachal cysts, enteric duplication anomalies, cystic teratoma, and low intestinal obstructions cannot be ruled out with certainty *in utero*. Serial examinations of the anomaly allow the detection of structural changes in the cyst, which prompt the diagnosis of a complication of the cyst.¹²¹

Associated anomalies are uncommon, although increased amniotic fluid is often present, probably secondary to partial GI obstruction.¹²²

Prognosis and management of fetal ovarian cysts depend largely on the natural history of the mass.¹²³ The cyst may increase in size, decrease, or even disappear, or lead to complications such as torsion, infarction, and rupture. In this light, once prenatal ultrasound diagnosis has been made, serial examinations should be performed throughout gestation to detect any structural changes in the mass. Enlargement of the mass, causing distention of the fetal abdomen, is an indication for Cesarean section to avoid the risk of soft tissue dystocia. Ultrasound-guided fine-needle aspiration of large fetal ovarian cysts may eliminate the need for a Cesarean section, theoretically reducing the risk of intrauterine torsion. However, the benefit of such an invasive procedure is unclear, possibly being a cause of intraperitoneal bleeding. Sudden development of intense hyperechogenicity within the mass, followed by a complex, heterogeneous appearance, should be considered to result from an intrauterine torsion of the cyst with infarction. When this occurs, immediate delivery is recommended. Conversely, small cysts detected *in utero* can subsequently disappear and may not be present on a postnatal ultrasound evaluation.

In summary, prenatal diagnosis of fetal ovarian cysts *per se* does not modify standard obstetric management, whereas complications occurring during gestation, such as torsion and rupture, may require active obstetric intervention. Neonates with confirmed diagnosis often require postnatal ovariectomy soon after birth.

Figure 25.35 Cross-section of the abdomen of a 28-week fetus showing a cystic mass. A diagnosis of ovarian cyst was made.

Key points

- 1 Esophageal atresia is suspected when polyhydramnios is present and serial ultrasound examinations fail to demonstrate the fetal stomach, or the stomach appears permanently small ($< 15\%$ of the abdominal circumference). Prenatal diagnosis cannot be made at times, as gastric secretions may be enough to distend the stomach and make it visible. Moreover, in cases of associated tracheal fistula, the stomach may look normal.
- 2 Approximately half of fetuses with duodenal atresia have associated abnormalities, including trisomy 21 in about 40% of cases, skeletal defects (vertebral and rib anomalies), sacral agenesis, radial abnormalities, and talipes), gastrointestinal abnormalities (esophageal atresia/tracheo-esophageal fistula, intestinal malrotation, Meckel diverticulum, and anorectal atresia), and cardiac and renal defects.
- 3 Jejunal and ileal obstructions are imaged as multiple fluid-filled loops of bowel in the abdomen. The more distal the site of the obstruction, the greater the number of anechoic structures. The abdomen is usually distended, and active peristalsis may be observed. In cases of bowel perforation, transient ascites, meconium peritonitis, and meconium pseudocysts can be seen. After 25 weeks, polyhydramnios is rather common, particularly in proximal obstructions.
- 4 As meconium begins to accumulate in fetal bowel at 4 months, any perforation occurring after that time could bring the outflow of meconium into the peritoneal cavity. As a result, an intense reaction occurs, leading to extensive adhesions. If it is localized at the site of perforation, a calcified mass develops (fibroadhesive type). In other cases (cystic type), the continuous outflow of intestinal content into a cavity (pseudocyst) determines the formation of a highly echogenic mass at the site of the perforation. A peritonitis can be suspected when a fetus with intestinal obstruction suddenly shows the presence of ascites or generalized hydrops. Prognosis is generally severe. In stable conditions, without ascites, obstetric management should not change. In case of a deteriorating condition, with developing ascites, preterm delivery should be considered to avoid damage to the bowel.
- 5 Omphalocele is often associated with other abnormalities, such as gut and duodenal obstructions, exstrophy of the bladder, penile anomalies, and undescended testes, and particularly congenital heart diseases, which represent the most important cause of death for the affected child. Chromosomal abnormalities (mainly trisomy 18 or 13) are found in about 30% of cases at midgestation and in 15% of neonates. Beckwith–Wiedemann syndrome (EMG syndrome) is a mostly sporadic genetic syndrome, which includes omphalocele, macroglossia, and macrosomia with hyperplastic fetal visceromegaly; a severe resistant neonatal hypoglycemia and mental handicap are sometimes present. Pentalogy of Cantrell includes a large upper abdominal omphalocele, an anterior diaphragmatic hernia, a sternal cleft, an ectopia cordis, and cardiac anomalies such as ventricular septal defect or tetralogy of Fallot.
- 6 Prenatal diagnosis of omphalocele is based on the demonstration of the midline anterior abdominal wall

defect, the herniated sac with its visceral contents, and the umbilical cord insertion at the apex of the sac. As normal migration of the midgut back into the abdomen occurs between the 9th and the 12th gestational weeks, the diagnosis of ventral wall defects should not be made before 14 weeks. Exceptionally, heart and bladder are contained in the herniated sac. In small defects, umbilical cord insertion is on top of the mass, whereas in large lesions, the cord is attached to its lower border.

- 7 In gastroschisis, the loops of intestine lie uncovered in the amniotic fluid. Occasionally, only a short tract of the intestine is herniated; in most cases, however, all the small and large intestines protrude. Stomach, gallbladder, urinary bladder, testes or uterus, and adnexae are also prolapsed. Chemical peritonitis is an ominous complication due to amniotic fluid exposure of eviscerated abdominal contents. In such cases, the intestine shows marked dilation of the lumen and increased thickness of the walls.
- 8 The impact of the route of delivery on outcome is still debated in the case of gastroschisis and omphalocele. As babies born from elective Cesarean section seem to have a lower risk of sepsis and short-term morbidity, the benefit of Cesarean section versus vaginal delivery is not yet clearly demonstrated. It seems crucial, however, that delivery takes place in tertiary care centers where the neonate can receive intensive care and prompt surgical correction. Long-term follow-up of survivors is excellent.
- 9 Bladder exstrophy is a consequence of impaired development of the caudal fold of the anterior abdominal wall. The anterior wall is absent, and exposure of the posterior bladder wall is common. Omphalocele, as well as epispadias, is frequently associated with incomplete descent of the testicles and imperforate anus. Cloacal exstrophy is associated with omphalocele, exstrophy of the bladder, imperforated anus, and spinal defects such as meningomyelocele.
- 10 Failed visualization of kidneys and bladder, associated with oligohydramnios, prompts the diagnosis of bilateral renal agenesis. Prenatal diagnosis can be rather difficult due to the lack of amniotic fluid and the “crumpled” position adopted by these fetuses. Additionally, adrenals are usually hypertrophic and can be confused with normal kidneys. Identification of the renal capsule and renal pelvis enables the two structures to be distinguished. Failure to visualize the renal arteries with color Doppler is another important clue to the diagnosis. The differential diagnosis includes premature rupture of the membranes, severe uteroplacental insufficiency, and obstructive uropathy or bilateral multicystic or polycystic kidneys. Vaginal sonography with a high-resolution probe may be useful in these cases.
- 11 Multicystic kidneys are usually unilateral and appear as a cluster of multiple irregular cysts of variable size with little intervening hyperechogenic stroma. Affected kidneys are usually extremely enlarged. Distinction between MDKD and obstructions at the UPJ in prenatal sonograms can be extremely difficult. Coronal scans may demonstrate the connection between the renal pelvis and the dilated caliceal system in UPJ, and separation of the cysts in MDKD. Such a distinction is much easier when ultrasound examination is performed in early pregnancy, as the progression of obstructive uropathy results in a sonographic appearance similar to that of MDKD.
- 12 Early and persistent obstruction of the lower urinary tract is associated with secondary cystic dysplasia of the kidneys that appear enlarged, hyperechogenic, and present small cysts that spread through the parenchyma. In these cases, the diagnosis is made by the simultaneous demonstration of obstructive uropathy (distended bladder, convoluted ureters, pyelectasia, oligohydramnios), and the prognosis is poor.
- 13 Autosomal-recessive cystic kidneys (also referred to as infantile polycystic kidney) invariably involves both kidneys, with a recurrence risk of 1 in 20 000 live births. A defect in the collecting system seems to be responsible for the anomaly. Kidneys are symmetrically enlarged, and the parenchyma is totally occupied by numerous cysts of minute dimensions. Sonographically, both kidneys usually appear extremely enlarged and hyperechogenic. The hyperechogenicity seems to be due to multiple minute cysts, which fall below the resolution power of the ultrasound equipment, thus increasing the acoustic transmission. In severe cases, the bladder is absent and oligohydramnios is extreme.
- 14 Autosomal-dominant cystic kidneys is a common inherited nephropathy affecting more than 1 in 1000 live births. It may be inherited as an autosomal-dominant trait, and it may be a feature of genetic and nongenetic syndromes. Sporadic cases have also been reported in the literature.
- 15 Hydronephrosis refers to dilatation of the renal pelvis. Mild hydronephrosis, or pyelectasia, is defined by the presence of an anteroposterior diameter of the pelvis of more than 4 mm at mid-gestation and more than 7 mm in the third trimester. Transient hydronephrosis may be due to relaxation of smooth muscle of the urinary tract by high levels of progesterone or maternal–fetal overhydration. In the majority of cases, the condition remains stable or resolves in the neonatal period. In about 20% of cases, there may be an underlying pathology that requires postnatal follow-up and possible surgery.
- 16 Sonographically, it may be difficult to distinguish severe hydronephrosis with significant caliceal enlargement from a multicystic kidney. Coronal scans demonstrate the radial projection of the calices around the enlarged pelvis enabling the diagnosis. Duplication

of the kidney is commonly associated with dilation of one or both renal pelvises.

- 17 Megacystis is defined as an abnormal enlargement of the urinary bladder, and is most frequently the consequence of urethral obstruction. It is usually seen in the early midtrimester and has been visualized as early as 11 weeks' gestation. A more or less severe oligohydramnios is present.
- 18 Megacystis associated with an increased amount of amniotic fluid raises the suspicion of a megacystis-microcolon-intestinal hypoperistalsis syndrome. This is a sporadic abnormality characterized by a massively dilated bladder and hydronephrosis in the presence of normal or increased amniotic fluid; the fetuses are usually female. There is associated shortening and dilation of the proximal small bowel and microcolon with absent or ineffective peristalsis. The condition is usually lethal owing to bowel and renal dysfunction.
- 19 Prenatal surgical treatment of bilateral urinary obstructive uropathies relies on antenatal evaluation of renal function. Potential candidates for intrauterine surgery are fetuses with: (1) bilateral moderately severe pelvicaliceal dilation and normal cortical echogenicity; (2) normal levels of urinary sodium, calcium, and beta-2 microglobulin. One must remember, however, that normal values cannot exclude renal failure in childhood.
- 20 Prenatal diagnosis of fetal ovarian cyst is based on the ultrasound finding of a cystic mass in the fetal lower abdomen, integrity of GI and GU tracts, and female sex. In the majority of cases, the cyst is completely fluid; sometimes it is septated. Polyhydramnios is often present. Differential diagnosis should be made with other abdominal cystic lesions such as mesenteric and urachal cysts, enteric duplication anomalies, cystic teratoma, and low intestinal obstructions. Serial examinations of the anomaly allow the detection of structural changes in the cyst, which prompt the diagnosis of a complication of the cyst.

Fetal skeletal anomalies

Luís F. Gonçalves, Patricia L. Devers, Jimmy Espinoza, and Roberto Romero

Skeletal dysplasias are a heterogeneous group of disorders that affect the development of chondro-osseous tissues, resulting in abnormalities in the size and shape of various segments of the skeleton. Despite recent advances in imaging modalities and molecular genetics,¹⁻³ accurate prenatal diagnosis of skeletal dysplasias remains a clinical challenge.⁴ Although 253 osteochondrodysplasias and 45 genetically determined dysostoses have been included in the most recent revision of the International Nosology and Classification of Constitutional Disorders of Bone,⁵ the number that can be recognized with the use of sonography in the antepartum period is considerably smaller. This chapter reviews the birth prevalence, classification, and molecular genetics, and provides an approach to prenatal diagnosis of skeletal dysplasias identifiable at birth.

Birth prevalence and contribution to perinatal mortality

Table 26.1 presents a summary of the published prevalence of skeletal dysplasias abstracted from 12 studies.⁶⁻¹⁷ Estimated prevalences ranged from 1.1 to 9.5 per 10 000 births, with the highest prevalence reported from a greatly inbred population.¹⁷

In a large multicentric Italian study, the birth prevalence of skeletal dysplasias recognizable in the neonatal period, excluding limb amputations, was estimated as 2.4 per 10 000 births.⁷ In this large series, 23% of affected infants were stillborn and 32% died during the first week of life. The overall frequency of skeletal dysplasias among perinatal deaths was 9.1 per 1000. This study also reported the birth prevalence of the different skeletal dysplasias and their relative frequency among perinatal deaths (Table 26.2). The four most common skeletal dysplasias were thanatophoric dysplasia, achondroplasia, osteogenesis imperfecta, and achondrogenesis. Thanatophoric dysplasia and achondrogenesis accounted for 62% of all lethal skeletal dysplasias,

whereas the most common nonlethal skeletal dysplasia was achondroplasia.⁷

In another larger series reporting the prevalence and classification of lethal neonatal skeletal dysplasias in the west of Scotland, the prevalence was 1.1 per 10 000 births, and the most frequently diagnosed conditions were thanatophoric dysplasia (1 per 42 000), osteogenesis imperfecta (1 per 56 000), chondrodysplasia punctata (1 per 84 000), campomelic syndrome (1 per 112 000), and achondrogenesis (1 per 112 000).⁸ Rasmussen and colleagues¹⁵ reported a prevalence of 2.14 cases per 10 000 deliveries in a longitudinal study that included elective pregnancy termination, stillborn infants at more than 20 weeks of gestation, and liveborn infants diagnosed by the fifth day of life. The rate of lethal cases was 0.95 per 10 000 deliveries.¹⁵

Classification of skeletal dysplasias

Nosology

Over the past 30 years, the classification of skeletal dysplasias has evolved from one based upon clinical/radiological/pathological descriptions to one that also includes the underlying molecular abnormality for conditions in which the defect is known.¹⁸ In an attempt to develop a uniform terminology, a group of experts met in Paris in 1977 and proposed an International Nomenclature for Skeletal Dysplasias based purely on descriptive findings of either a clinical or radiologic nature.¹⁹ This nomenclature was revised in 1992,²⁰⁻²² when it was reoriented on radiodiagnostic and morphologic criteria, grouping morphologically similar disorders into families of disorders based on presumed pathogenetic similarities. The International Working Group on Constitutional Diseases of Bone met in Los Angeles, California, in 1997, to perform the third revision of the Paris Nomenclature of Constitutional Disorders of Bone.^{23,24} Families of disorders were rearranged based on etiopathogenetic information concerning the gene and/or protein defect. Disorders in which the defect was well docu-

Table 26.1 Birth prevalence of osteochondrodysplasias: summary of 12 studies.

Reference	Rate per 10 000	Comment
Gustavson and Jorulf ⁶	4.7	In newborns
Camera and Mastroiacovo ⁷	2.4	In neonates
Connor and colleagues ⁸	1.1	Lethal skeletal dysplasias in neonates
Weldner and colleagues ⁹	7.5	—
Orioli and colleagues ¹⁰	2.3	First 3 days of life
Stoll and colleagues ¹¹	3.2	First 8 days of life
Andersen and Hauge ¹²	7.6	Diagnosed in all ages
Andersen ¹³	1.5	Lethal chondrodysplasias only
Kallen and colleagues ¹⁴	1.6	No details about age
Rasmussen and colleagues ¹⁵	—	—
All cases	2.1	In first 5 days of life
Lethal chondrodysplasias	0.95	—
Gordienko and colleagues ¹⁶	3.1	—
Al Gazali and colleagues ¹⁷	9.5	Newborns and stillbirths > 500 g; prevalence of consanguinity 72%

Table 26.2 Birth prevalence (per 10 000 total births) of skeletal dysplasias.

Skeletal dysplasias	Birth prevalence (per 10 000)	Frequency among perinatal deaths
Thanatophoric dysplasia	0.69	1:246
Achondroplasia	0.37	—
Achondrogenesis	0.23	1:639
Osteogenesis imperfecta type II	0.18	1:799
Osteogenesis imperfecta (other types)	0.18	—
Asphyxiating thoracic dysplasia	0.14	1:3196
Chondrodysplasia punctata	0.09	—
Campomelic dysplasia	0.05	1:3196
Chondroectodermal dysplasia	0.05	1:3196
Larsen syndrome	0.05	—
Mesomelic dysplasia (Langer's type)	0.05	—
Others	0.46	1:800

mented were regrouped into distinct families based on the mutations. These include the “achondroplasia group” of disorders with mutations in the fibroblast growth factor receptor 3 (*FGFR3*) gene, the “diastrophic dysplasia group” of disorders with mutations in diastrophic dysplasia sulfate transporter gene, the “type II collagenopathies” with mutations in the type II collagen gene, and the “type XI collagenopathies” with mutations in the cartilage oligomeric protein (*COMP*) gene. Several new groups were added, including the “lethal skeletal dysplasias,” the group with fragmented bones, and the “miscellaneous neonatal severe dysplasia” group. Other groups were renamed. The classification was revised in 2001 and is now called the International Nosology and Classification of Constitutional Disorders of Bones (2001).⁵ Although the classification remains a combination of morphological and molecular groupings of disorders, genetically determined dysostoses were added to the skeletal dysplasias, as in clinical practice these two groups overlap. Genetically determined dysostoses

have been divided into three groups: those with predominant cranial and facial involvement (e.g., Crouzon syndrome), those with predominant axial involvement (e.g., spondylocostal dysplasia), and those with predominant involvement of the extremities (e.g., Fanconi syndromes). The full version of the 2001 classification⁵ can be downloaded from the website of the International Skeletal Dysplasia Society (<http://www.isds.ch/ISDSframes.html>, last accessed on 06/11/2006).

Nosology of lethal skeletal dysplasias

Of special interest to perinatologists are the lethal osteochondrodysplasias, which were classified by Spranger and Maroteaux²⁵ into 11 groups based on the radioanatomical manifestations (Table 26.3). The purpose of this classification is to facilitate differential diagnosis, and the groups do not necessarily constitute pathogenetic “families.”

Table 26.3 Nosology of lethal osteochondrodysplasias.

<i>Hypophosphatasia and morphologically similar disorders</i>	Short rib–polydactyly syndrome, type IV (Yang)
Hypophosphatasia	Short rib–polydactyly syndromes
Probable hypophosphatasia	Short rib–polydactyly syndrome, type VI (Majewski)
Lethal metaphyseal dysplasia	Short rib–polydactyly syndrome, type VII (Beemer)
<i>Chondrodysplasia punctata and similar disorders</i>	<i>Lethal metatropic dysplasia and similar disorders</i>
Rhizomelic chondrodysplasia punctata	Lethal metatropic dysplasia (hyperchondrogenesis)
Lethal chondrodysplasia punctata, X-linked dominant	Fibrochondrogenesis
Greenberg dysplasia	Schneckenbecken dysplasia
Dappled diaphysis dysplasia	<i>Kniest-like disorders</i>
<i>Achondrogenesis and similar disorders</i>	Dyssegmental dysplasia, Silverman type
Achondrogenesis IA (Houston–Harris)	Dyssegmental dysplasia, Rolland–Desbuquois
Achondrogenesis IB (Fraccaro)	Lethal Kniest disease
New lethal osteochondrodysplasia	Chondrodysplasia resembling Kniest dysplasia
Achondrogenesis II (Langer–Saldino)	Blomstrand chondrodysplasia
Hypochondrogenesis	<i>Lethal osteochondrodysplasias with pronounced diaphyseal abnormalities</i>
<i>Thanatophoric dysplasia and similar disorders</i>	Campomelic syndrome
Thanatophoric dysplasia, type I	Stuve–Wiedemann syndrome
Thanatophoric dysplasia, type II	Boomerang dysplasia
Homozygous achondroplasia	Atelosteogenesis
Lethal achondrodysplasia	Disorder resembling atelosteogenesis
Glasgow variant	de la Chappelle dysplasia
<i>Platyspondylic lethal chondrodysplasias</i>	McAlister dysplasia
Platyspondylic chondrodysplasia, Torrance type	Pseudodystrophic dysplasia
Platyspondylic chondrodysplasia, San Diego type	<i>Osteogenesis imperfecta and similar disorders</i>
Platyspondylic chondrodysplasia, Luton type	Osteogenesis imperfecta type IIA
Platyspondylic chondrodysplasia, Shiraz type	Osteogenesis imperfecta type IIB
Opsismodysplasia	Osteogenesis imperfecta type IIC
Sixth form of platyspondylic chondrodysplasia	Astley–Kendall dysplasia
Seventh form of platyspondylic chondrodysplasia	<i>Lethal disorders with gracile bones</i>
<i>Short rib–polydactyly syndromes</i>	Fetal hypokinesia phenotype
Short rib–polydactyly syndrome, type I (Saldino–Noonan)	Lethal osteochondrodysplasia with gracile bones
Short rib–polydactyly syndrome, type II (Verma–Naumoff)	Lethal osteochondrodysplasia with intrauterine overtubulation
Short rib–polydactyly syndrome, type III (Le Marec)

Molecular–pathogenetic classification of skeletal dysplasias

The process of skeletal formation and growth includes differentiation of mesenchymal cells to form cartilage for future bone endochondral ossification. Long bone growth occurs through differentiation of chondrocytes in the growth plates, whereas the craniofacial skeleton and clavicles develop by intramembranous ossification.^{26,27} Disruption in any of these processes results in skeletal abnormalities.²⁸ A wide range of phenotypes has been described in osteochondrodysplasias. However, recent advances in the understanding of the molecular basis of skeletal dysplasias indicate that a spectrum of phenotypes share a similar genetic basis.^{29,30} Although the familial tendency of chondrodyspla-

sias has been known for many years, the molecular basis for a number of conditions has only recently been clarified.^{2,3,31,31,32}

Therefore, it is anticipated that two parallel but interacting classifications will evolve, one clinical, and the other molecular, to help further understand the pathogenesis of individual disorders. Indeed, a classification of genetic disorders of the skeleton based on the structure and function of implicated genes and proteins has recently been proposed (Molecular–Pathogenetic Classification of Genetic Disorders of the Skeleton – Table 26.4)² to complement the existing International Nosology and Classification of Constitutional Disorders of Bone⁵. In this classification skeletal disorders with a well-documented genetic and biochemical basis were assigned to one of seven groups: (1) defects in extracellular structural

Table 26.4 Molecular–pathogenetic classification of genetic disorders of the skeleton.

Gene or protein	Inheritance	Clinical phenotype	References
<i>Group 1: Defects in extracellular structural proteins</i>

proteins, (2) defects in metabolic pathways (including enzymes, ion channels, and transporters), (3) defects in folding and degradation of macromolecules, (4) defects in hormones and signal transduction mechanisms, (5) defects in nuclear proteins and transcription factors, (6) defects in oncogenes and tumor-suppressor genes, and (7) defects in RNA and DNA processing and metabolism.

Table 26.4 presents a comprehensive list of mutations associated with skeletal dysplasias and the clinical phenotypes associated with them.² The reader is reminded that approximately only one-third of bone dysplasias have had their molecular basis elucidated, and that new genes involved in skeletal dysplasias are continually being discovered.³ We will review the significant mutations associated with each phenotype in subsequent sections of this chapter.

Terminology frequently used in the description of bone dysplasias

Shortening of the extremities can involve the entire limb (micromelia), the proximal segment (rhizomelia), the intermediate segment (mesomelia), or the distal segment (acromelia). The diagnosis of rhizomelia or mesomelia requires the comparison of the dimensions of the bones of the legs and forearm with those of the thigh and arm. Figures 26.1 and 26.2 display the relationship between the humerus and ulna, and the femur and tibia, and can be used in the assessment of rhizomelia and mesomelia. Table 26.5 presents the skeletal dysplasias characterized by rhizomelia, mesomelia, and micromelia.

and feet. The term “polydactyly” refers to the presence of more than five digits. It is classified as *postaxial* if the extra digits are on the ulnar or fibular side, and *preaxial* if they are located on the radial or tibial side. Syndactyly refers to soft-tissue or bony fusion of adjacent digits. Clinodactyly consists of deviation of a finger (or fingers).

The most common spinal abnormality seen in skeletal dysplasias is platyspondyly, which consists of flattening of the vertebrae (Fig. 26.3).^{33–39} Kyphosis and scoliosis can also be identified *in utero* (Fig. 26.4).^{40–44} Prenatal diagnosis of

Biometry of the fetal skeleton in the diagnosis of bone dysplasias

Long-bone biometry has been used extensively for the prediction of gestational age. Nomograms for this purpose use the long bone as the independent variable and the estimated fetal age as the dependent variable. However, the type of nomogram required to assess the normality of bone dimensions uses gestational age as the independent variable and the long bone as the dependent variable. For the proper use of these nomograms, the clinician must accurately know the gestational age of the fetus. Therefore, patients at risk for skeletal dysplasias should be advised to seek prenatal care at an early gestational age to assess all clinical estimators of gestational age. Tables 26.6 and 26.7 present nomograms for the assessment of limb biometry for the upper and lower extremities, respectively. Comparisons between limb dimensions and the head perimeter can be used for patients presenting with uncertain gestational age (Figs 26.6 and 26.7). Although some investigators have employed the biparietal diameter for this purpose, the head perimeter has the advantage of being shape independent. A limitation of this approach is that it assumes that the cranium is not involved in the dysplastic process, and this may not be the case in some skeletal dysplasias.

The nomograms and figures in this chapter provide the mean and the 5th and the 95th percentiles of limb biometric parameters. The reader should be aware that 5% of the general population would fall outside these boundaries. Ideally, a more stringent criterion, such as the 1st percentile of limb growth for gestational age, should be used for diagnosis. Unfortunately, none of the currently available nomograms has been based on enough patients to provide an

accurate discrimination between the 5th and the 1st percentiles. However, most skeletal dysplasias diagnosed *in utero* or at birth are associated with dramatic long bone shortening, and, under these circumstances, the precise boundary used (1st or 5th percentile) is not critical. An exception to this is achondroplasia, in which limb biometry is mildly affected until the third trimester, when abnormal growth can be detected by examining the slope of growth of femur length.⁴⁸ In a study including 127 cases of 17 skeletal dysplasias, Gonçalves and Jeanty⁴⁹ conducted discriminant analysis and showed that the femur length is the best biometric parameter to distinguish among the five most common disorders: thanatophoric dysplasia, osteogenesis imperfecta type II, achondrogenesis, achondroplasia, and hypochondroplasia. Gabrielli and colleagues⁵⁰ evaluated the possibility of an early diagnosis of skeletal dysplasias in high-risk patients. A total of 149 consecutive, uncomplicated singleton pregnancies at 9–13 weeks after amenorrhea were included in the study. Transvaginal ultrasound was used to establish the relationship between biparietal diameter and crown–rump length using polynomial regression. Eight patients with previous skeletal dysplasias were evaluated with serial examinations every 2 weeks between 10 and 11 weeks, and femur length correlated significantly with both biparietal diameter and crown–rump length. Of the five cases with skeletal dysplasias, only two (one with recurrent osteogenesis imperfecta and one with recurrent achondrogenesis) were diagnosed in the first trimester. This study suggests that an early evaluation of the fetus and the correlation of femur length with crown–rump length and of femur length with biparietal diameter may be useful for early diagnosis of severe skeletal dysplasias. In less severe cases, biometric evaluation appears to be of limited value. Nomograms have recently been published for long bone measurements according to crown–rump length in a large population of normal fetuses that were examined between 11 and 14 weeks of gestation, and they may help in the early assessment of pregnancies at risk for skeletal dysplasias.⁵¹

Figure 26.7 Relationship between the head perimeter and the length of the femur.

Clinical presentation

The challenge of antenatal diagnosis of skeletal dysplasias generally presents itself in one of two ways: (1) a patient who has delivered an infant with a skeletal dysplasia and desires antenatal assessment of a subsequent pregnancy or (2) the incidental finding of a shortened, bowed, or anomalous extremity during a routine sonographic examination. In patients at risk, the examination is easier when the particular phenotype is known. The inability to obtain reliable information about skeletal mineralization and the involvement of other systems (e.g., skin) using sonography is a limiting factor in the establishment of an accurate diagnosis after the identification of an incidental finding. Another limitation is the paucity of information about the *in utero* natural history of these disorders.

Despite these difficulties and limitations, there are good medical reasons for attempting an accurate prenatal diagnosis of skeletal dysplasias. A number of these disorders are uniformly lethal (Table 26.3), whereas others are associated with mental retardation.⁵² In addition, there is a group of disorders associated with thrombocytopenia in which vaginal delivery may expose these infants to the risk of intracranial hemorrhage. Therefore, accurate diagnosis of skeletal dysplasias is important for prenatal counseling.

Diagnostic imaging and the prenatal diagnosis of skeletal dysplasias

Despite the increasing availability of molecular testing, a comprehensive molecular diagnostic search for all skeletal dysplasias is not possible at this time. Indeed, only about one-third of skeletal dysplasias have had their molecular basis defined.³ Therefore, the roles of diagnostic imaging in the prenatal investigation of skeletal dysplasias are: (1) to narrow the differential diagnosis of skeletal dysplasias so that appropri-

ate confirmatory molecular tests can be selected; (2) to predict lethality; and (3) to identify the fetus with a skeletal dysplasia early enough in pregnancy so that the diagnostic workup can be completed before the limit of fetal viability.^{53–57}

Ultrasound is the primary imaging modality used for the initial diagnostic evaluation of an affected fetus, and several studies have explored the role of ultrasound in the detection of skeletal dysplasias.^{33,48,58–68} A prospective analysis of a high-risk population (15 women, 16 cases) carrying a genetic risk for skeletal dysplasias was conducted by Kurtz and Wapner.⁴⁸ Based on ultrasonographic findings in the second trimester, they were able to diagnose five abnormal fetuses among the 16 fetuses at risk. Weldner et al.⁹ screened 12453 patients in the second and third trimesters and estimated the prevalence of skeletal dysplasias as 7.5 per 10000. Sharony and colleagues⁶⁴ studied fetuses and stillbirths referred from other centers for suspected skeletal dysplasia. Most of the cases were sporadic, and the most common final diagnoses were osteogenesis imperfecta (16%) and thanatophoric dysplasia (14%). Table 26.8 summarizes the diagnostic accuracy of two-dimensional ultrasound for prenatal diagnosis of skeletal dysplasias.^{4,16,68–71} An accurate diagnosis was made in 31–73% of cases.

The introduction of three-dimensional ultrasound and rendering algorithms to reconstruct the fetal skeleton may improve diagnostic accuracy as additional phenotypic features not detectable by two-dimensional ultrasound may be identified.^{72–84} For example, Garjian and colleagues⁷⁵ and Krakow and colleagues⁸² reported the diagnosis of additional facial^{75,82} and scapular anomalies,⁷⁵ as well as abnormal calcification patterns⁸² in fetuses with skeletal dysplasias, whereas Moeglin and Benoit⁷⁸ used the multiplanar visualization method to

demonstrate the “pointed appearance” of the upper femoral diaphysis in a case of achondroplasia. Three-dimensional reconstruction of the fetal bones is best performed using the “maximum intensity projection” mode, a rendering algorithm that prioritizes the display of voxels with the highest gray levels contained within a region of interest selected by the user.^{75,78} If the fetus is examined early enough during pregnancy, the entire skeleton can be included within the region of interest of the three-dimensional volume dataset and, therefore, panoramic visualization can be achieved.⁷⁵ However, the diagnosis may be missed as the phenotypic characteristics of some skeletal dysplasias do not manifest until later in pregnancy. Case reports and small series of several skeletal dysplasias have been published describing phenotypic characteristics or skeletal features (Table 26.9).^{73,75–78,80–83,85}

Three-dimensional helical computed tomography (3DHCT) has recently been proposed as an adjunctive imaging

Table 26.8 Accuracy of prenatal ultrasound for diagnosis of skeletal dysplasias.

Author	Year	No. of cases	Correct diagnosis*
Gordienko and colleagues ¹⁶	1996	26	73% (9)
Gaffney and colleagues ⁶⁸	1998	35	31% (11)
Tretter and colleagues ⁷⁰	1998	27	48% (13)
Hersh and colleagues ⁷¹	1998	23	48% (11)
Doray and colleagues ⁶⁹	2000	47	60% (28)
Parilla and colleagues ⁴	2003	31	65% (20)

*Numbers in parentheses indicate the number of fetuses with the correct diagnosis.

Table 26.9 Additional phenotypic findings and improved visualization in cases of skeletal dysplasias by prenatal three-dimensional ultrasound compared with two-dimensional ultrasound in published reports.

Skeletal dysplasia	Phenotypic characteristics identified better by three- rather than two-dimensional ultrasound
Platyospondylic lethal chondrodysplasia ⁷³	Enhanced visualization of femoral and tibial bowing, better characterization of the facial soft tissues with surface rendering
Campomelic dysplasia ^{75,83}	Micrognathia, flat face, hypoplastic scapulae, bifid foot
Thanatophoric dysplasia ^{75–77,82}	Improved characterization of frontal bossing and depressed nasal bridge, demonstration of redundant skinfolds, low-set dysmorphic ears
Achondroplasia ^{78,82}	Improved characterization of frontal bossing and depressed nasal bridge; superior evaluation of the epiphyses and metaphyses of the long bones, with demonstration of a vertical metaphyseal slope; caudal narrowing of the interpedicular distance; clear visualization of trident hand; better visualization of disproportion between limb segments
Chondrodysplasia punctata, rhizomelic form ⁸²	Improved characterization of the Binder facies (depressed nasal bridge, midface hypoplasia, small nose with upturned alae); identification of laryngeal stippling
Achondrogenesis ⁸²	Panoramic demonstration of short neck and severe shortening of all segments of the limbs
Jarcho-Levin syndrome ⁸¹	Vertebral defects with absence of ribs and transverse process
Larsen syndrome ⁸⁵	Genu recurvatum, midface hypoplasia, low-set ears

Phenotypic characteristics of osteogenesis imperfecta,⁷⁵ short rib–polydactyly syndrome,⁸⁰ and Apert syndrome⁸² have also been described using three-dimensional ultrasound, although no additional findings with two-dimensional ultrasound were observed.

modality for the prenatal diagnosis of skeletal dysplasias (Fig. 26.8).⁸⁶ Similar to three-dimensional ultrasound, postprocessing techniques such as “maximum intensity projection,” “surface rendering,” and “volume rendering” can be used for three-dimensional reconstruction.^{87–89} Long bone measurements obtained by postmortem helical computed tomography studies have been compared with those obtained within 24 h of delivery by ultrasound, and a significant correlation between the two methods was observed.⁹⁰ Excellent panoramic images of the fetal skeleton can be obtained by 3DHCT without superimposition of the maternal skeleton (which occurs with radiography). Ruano and colleagues⁸⁶ compared the phenotypic characteristics of three skeletal dysplasias [achondroplasia ($n = 3$), osteogenesis imperfecta ($n = 2$), and chondrodysplasia punctata ($n = 1$)] visualized by prenatal 3DHCT, and three-/two-dimensional ultrasound. Deformation of the fetal pelvis and an increase in the intervertebral space of the lumbar vertebrae were diagnosed more often using 3DHCT than two- and three-dimensional ultrasound. In contrast, some phenotypic characteristics of fetuses with skeletal dysplasias were demonstrated only by ultrasound: phalangeal hypoplasia (by both two- and three-dimensional ultrasound), facial dysmorphism (by three-dimensional ultrasound only), and point-calcified epiphysis (by both two- and three-dimensional ultrasound). Although the overall count of correct phenotypic characteristics detected prenatally favored 3DHCT over three-dimensional ultrasound [94.3% (33 out of 35) vs. 77.1% (27 out of 35), $P = 0.03$, McNemar’s test for correlated samples], the diagnostic performance of 3DHCT was not superior to that of three-dimensional ultrasound, as the correct prenatal

diagnosis was established by both modalities in all cases. Provided that the two diagnostic methods have similar diagnostic accuracy, three-dimensional ultrasound has two important advantages over 3DHCT, namely lack of radiation exposure and wider availability in the clinical setting. It is also noteworthy that the overall experience with three-dimensional ultrasound for the diagnosis of skeletal dysplasias is still limited.^{72–85} Nevertheless, even in this study, three-dimensional ultrasound performed better than two-dimensional ultrasound, both in the identification of phenotypic characteristics [77.1% (27 out of 35) vs. 51.4% (18 out of 35), $P = 0.004$, McNemar’s test] as well as in establishing an accurate diagnosis.

Approach to the diagnosis of skeletal dysplasias

Our proposed systematic approach to the prenatal diagnosis of skeletal dysplasias is summarized in Table 26.10.

Evaluation of long bones

Measurements

All long bones should be measured in all extremities. Comparisons with other segments should be performed to establish whether the limb shortening is predominantly rhizomelic, mesomelic, or acromelic, or whether it involves all segments (Fig. 26.9). A detailed examination of each bone is necessary to exclude the absence or hypoplasia of individual bones (fibula, tibia, scapula, radius).^{65,91–94}

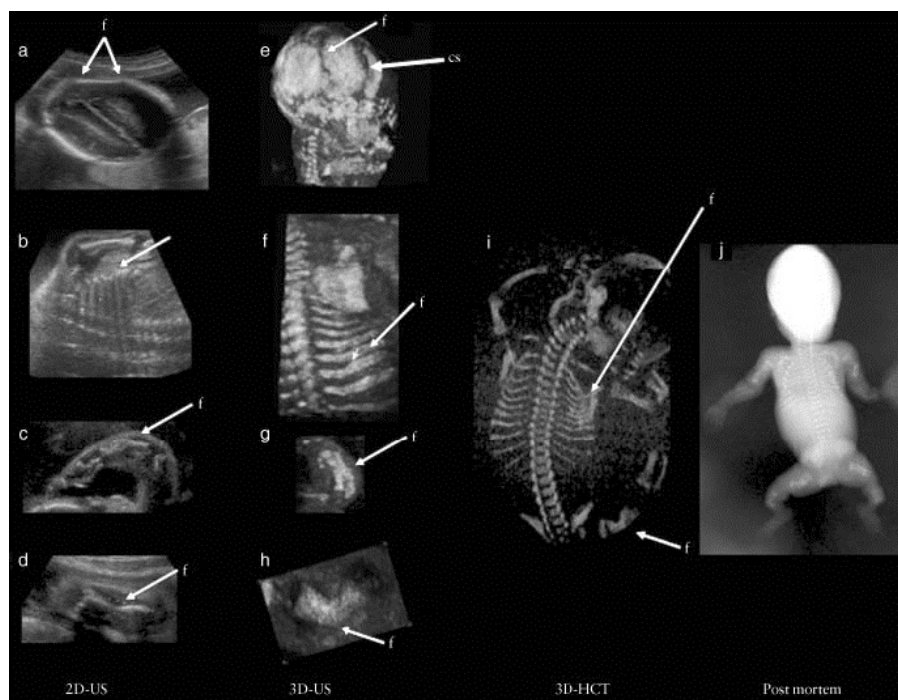

Figure 26.8 Comparison of phenotypic features of osteogenesis imperfecta by 3DHCT, three- and two-dimensional ultrasound, and postmortem radiographs.

Table 26.10 Steps for examination of the fetus with a suspected skeletal dysplasia by two- and three-dimensional ultrasound.

1. Measure all long bones
2. Compare with other segments and classify the limb shortening as:
 - Rhizomelia
 - Mesomelia
 - Acromelia
 - Severe micromelia
3. Qualitative assessment of long bones:
 - Demineralization
 - Fractures
 - Bowing
 - Metaphyseal flaring
 - Absence of bones
4. Measure chest dimensions to determine risk of pulmonary hypoplasia
5. Evaluate hands and feet:
 - Digits (polydactyly/syndactyly)
 - Positional deformities
6. Evaluate the cranium:
 - Macrocrania
 - Frontal bossing
 - Cloverleaf skull
 - Hypertelorism/hypotelorism
7. Evaluate for facial clefts
8. Examine the spine:
 - Platyspondyly
 - Demineralization
 - Hemivertebrae

Degree of mineralization

An attempt should be made to characterize the degree of mineralization. This can be assessed by examining the acoustic shadow behind the bone and the echogenicity of the bone itself. Signs of demineralization include the visualization of an unusually prominent falx and the absence of or decreased echogenicity of the spine. It should be stressed that there are limitations in the sonographic evaluation of mineralization of long bones and that other structures, such as the skull, may be better suited for this assessment (Fig. 26.10).

Degree of long bone curvature

At present, there is no objective means of assessing long bone curvature, and experience is the only tool to assist the

Figure 26.9 Varieties of short limb dysplasia according to the segment involved.

Figure 26.10 Demineralization of the skull in a case of osteogenesis imperfecta.

operator to discern the boundary between normality and abnormality. Campomelia (excessive bowing) (Fig. 26.11) is a characteristic of certain disorders (e.g., campomelic dysplasia).

Metaphyseal flaring

Metaphyseal flaring denotes widening at the level of the metaphyseal growth plate. It can be observed in many conditions, including achondroplasia, hypochondroplasia, hypochondrogenesis, asphyxiating thoracic dysplasia, chondrodysplasia punctata, diastrophic dysplasia, hypophosphatasia, Kniest dysplasia, kyphomelic dysplasia, metatropic dysplasia, and osteogenesis imperfecta.⁹⁵

Fractures

The possibility of fractures should be considered, as they can be present in some conditions (e.g., osteogenesis imperfecta) (Fig. 26.12). The fractures may be extremely subtle or may

lead to angulation and separation of the segments of the affected bone (Fig. 26.13).

Prediction of pulmonary hypoplasia

Several skeletal dysplasias are associated with a hypoplastic thorax. This finding is extremely important because chest

restriction leads to pulmonary hypoplasia, a frequent cause of death in these conditions (Table 26.3). A number of ultrasonographic parameters have been investigated for the prediction of pulmonary hypoplasia. These include measurements of the thorax and lungs, a series of ratios between thoracic measurements and other biometric parameters, Doppler velocimetry of the pulmonary arteries, Doppler evaluation of tracheal fluid flow, and, more recently, three-dimensional volumetric measurements of the fetal lungs by either ultrasound or MRI. Below we briefly review studies that have attempted to use ultrasonographic or MRI parameters for prenatal prediction of lung hypoplasia.

Evaluation of thoracic and lung dimensions by two-dimensional ultrasound

Thoracic and lung biometry have been extensively studied to identify fetuses at high risk for pulmonary hypoplasia.^{96–107} Table 26.11 lists skeletal dysplasias associated with altered thoracic dimensions, and Figs 26.14 and 26.15 illustrate features associated with a hypoplastic thorax.

The methods used to measure the bony thorax, chest, lungs, and heart by two-dimensional ultrasound are illustrated in Fig. 26.16. Thoracic dimensions in fetuses with known gestational age can be evaluated by the nomograms in Tables 26.12 and 26.13. When gestational age is uncertain, age-independent ratios, such as the thoracic–abdominal circumference ratio (normal value 0.77:1.01) and the thoracic–head circumference ratio (normal value 0.56:1.04), can be used.⁹⁷

Figure 26.16 The various methods to measure thoracic, lung, and heart dimensions.

A summary of the diagnostic accuracy of biometric parameters for the diagnosis of pulmonary hypoplasia is presented in Table 26.14.^{98–104,107–113} Of particular interest are the measurements of the right lung diameter or the ratio between right lung diameter and bony thoracic circumference proposed by Merz and colleagues.¹⁰⁵ In a study of 32 fetuses with a post-natal diagnosis of pulmonary hypoplasia (skeletal dysplasias, $n = 7$; renal agenesis, $n = 11$; diaphragmatic hernia, $n = 7$; and hydrothorax, $n = 2$), all had a right lung diameter below the 5th percentile for age, regardless of the primary disorder.¹¹⁰ In a subsequent study of 19 fetuses with congenital diaphragmatic hernia, Bahlmann and colleagues¹¹¹ demonstrated that the right lung diameter–bony thoracic circumference ratio detected all fetuses with pulmonary hypoplasia with 100%

sensitivity and 100% specificity. Whether the same degree of accuracy for this test can be replicated in a uniform population of fetuses with osteochondrodysplasias remains to be determined.

Short femur length and the prediction of lethality in skeletal dysplasias

Rahemtullah and colleagues¹¹⁴ studied 18 cases of skeletal dysplasias and all lethal cases were associated with a femur length–abdominal circumference ratio ≤ 0.16 . Although the test detected lethal cases with 100% sensitivity, two cases of achondroplasia were erroneously identified as lethal with this method. A less pragmatic approach has been proposed by Hersh and colleagues,⁷¹ who correctly predicted lethality in 23

out of 25 cases of skeletal dysplasias with a femur length below the 1st percentile for age by combining this information with other sonographic findings (i.e., bell-shaped thorax, decreased bone echogenicity, or both).

Doppler velocimetry of the pulmonary arteries for the prediction of pulmonary hypoplasia

Underdevelopment and structural changes of the pulmonary vascular bed in cases of pulmonary hypoplasia may result in increased pulmonary vascular resistance and reduced pulmonary arterial compliance.¹¹⁵ Therefore, several investigators have attempted to use Doppler measurements of the pulmonary arteries and/or its branches as a test to identify fetuses at risk for pulmonary hypoplasia.^{113,116–120} Mitchell and colleagues¹¹⁶ evaluated the resistance index of the peripheral pulmonary arteries for the prediction of pulmonary hypoplasia in 10 fetuses with bilateral multicystic dysplastic kidneys. The resistance index of the peripheral pulmonary arteries was above the 95th percentile for gestational age in 80% of the cases with pulmonary hypoplasia.

Subsequent studies have yielded contradictory results. For example, Achiron and colleagues¹¹⁷ found that the pulsatility

index of the peripheral pulmonary arteries was within normal limits in four fetuses with proven pulmonary hypoplasia, suggesting that the pulsatility index of the lung circulation is a poor test to predict lung hypoplasia. Chaoui and colleagues¹¹⁸ reported that only six out of nine fetuses with lung hypoplasia had an elevated pulsatility index in the main branches of the left and right pulmonary arteries. Similarly, Laudy and colleagues¹¹³ studied 40 fetuses at risk for pulmonary hypoplasia and found that Doppler velocimetry indices of the proximal and middle pulmonary branches were not better than chest biometry to predict pulmonary hypoplasia.

In contrast, Yoshimura and colleagues¹¹⁹ reported low peak systolic velocities in four out of five fetuses and an increased pulsatility index in five out of five fetuses with confirmed pulmonary hypoplasia (thanatophoric dysplasia, $n = 2$; nonimmune hydrops, $n = 2$; and bilateral renal agenesis, $n = 1$). Rizzo and colleagues,¹²⁰ in a population of 20 fetuses with prolonged preterm premature rupture of the membranes, found that an elevated pulsatility index in a peripheral pulmonary artery observed 2 weeks after membrane rupture detected the subsequent development of pulmonary hypoplasia with a sensitivity of 62.5%, a specificity of 94.6%, a

†All fetuses had pulmonary hypoplasia.

positive predictive value of 83.3%, and a negative predictive value of 78.5%. Finally, Fuke and colleagues¹²¹ proposed the use of acceleration time/ejection time at the main branches of the pulmonary arteries to identify fetuses at risk for pulmonary hypoplasia. The normal ratio is 0.17 ± 0.04 for the right and 0.15 ± 0.04 for the left pulmonary arteries, and this ratio did not change with gestational age. Five out of six fetuses with pulmonary hypoplasia among 17 fetuses at risk were correctly identified by the test. All 11 normal fetuses had a normal acceleration time/ejection time of the pulmonary arteries.

Evaluation of lung volume by three-dimensional ultrasound

Fetal lung volumetry by three-dimensional ultrasonography has been performed using two techniques: multiplanar^{122–126} (Fig. 26.17) and VOCAL (Virtual Organ Computer-aided AnaLysis, General Electric Medical Systems, Kretztechnik, Zipf, Austria) techniques (Fig. 26.18).^{127–132}

Kalache and colleagues¹²⁷ demonstrated that both the three-dimensional multiplanar and three-dimensional VOCAL modes can be used to measure pulmonary volumes in fetuses, an observation that has been subsequently confirmed by

Moeglin and colleagues¹³² A potential advantage of the VOCAL technique is the possibility of obtaining fine contours of the lungs, which may be particularly valuable when the outline of the lung is irregular, such as in cases of congenital diaphragmatic hernia. In contrast, lung volume measurements obtained by the three-dimensional multiplanar technique are faster, usually taking less than 5 min to perform.¹³² Volumes are best estimated when datasets are acquired using a transverse view of the fetal thorax.¹²⁴

Nomograms for lung volume by three-dimensional ultrasound have been proposed by several investigators.^{122–124,129,132–134} A brief description of the studies with the largest number of cases is described herein. Ruano and colleagues¹²⁹ determined nomograms for lung volume calculated using the VOCAL technique in 109 normal fetuses. The observed/expected fetal lung volume ratio was significantly lower in fetuses with congenital diaphragmatic hernia than in control subjects (median 0.34, range 0.15–0.66, vs. median 1.02, range 0.62–1.97, $P < 0.001$). Moeglin and colleagues¹³² proposed an alternative approach to calculate lung volumes using two-dimensional ultrasound. The method uses the assumption that the lung is a geometrical

Figure 26.17 Measurement of fetal lung volume using three-dimensional multiplanar ultrasonography.

A

B

Figure 26.18 Fetal lung volume measurement using the VOCAL technique.

pyramid and the total pulmonary volume is calculated as: [surface area of right lung base (cm^2) + surface area of left lung base (cm^2)] \times (height of right lung/3) (cm). Surface area of lung bases is measured on the transverse thoracic view containing the four chambers of the heart, and the height of the right lung is measured on a right sagittal paramedical view. Although lung volumes calculated by this method are significantly smaller than volumes calculated using the VOCAL technique, Moeglin and colleagues¹³² have proposed an equation to extrapolate three-dimensional volumes from two-dimensional measurements using the formula $\text{RPVE (mL)} = 4.24 + (1.53 \times 2\text{DGPV})$, where RPVE is the re-evaluated pulmonary volume equation. Preliminary results in nine fetuses with pulmonary hypoplasia are encouraging, with

all of them having lung volume estimates below the 1st percentile for gestational age.¹³²

Evaluation of lung volume or signal intensity by MRI

Parameters proposed to evaluate lung volume by MRI include the relative lung volume (observed lung volume–expected lung volume ratio), lung volume–estimated fetal weight ratio (LV/EFW), and the lung–spinal fluid signal intensity ratio (L/SF).^{135–142}

Rypens and colleagues¹³⁵ determined normal lung volume biometry across gestational age in 336 fetuses with normal lungs. Normal fetal lung volume increased with gestational age. However, there was a constant ratio between the volume of the left and right volumes, with right lung volume account-

ing for 56% of the total fetal lung volume. MRI volumes corresponded to 90% of the volumes measured by pathologic examination.

Williams and colleagues¹³⁸ calculated relative lung volume in a group of 91 fetuses with sonographically normal lungs and compared the measurements with 28 fetuses at risk for pulmonary hypoplasia. The mean relative lung volume was significantly smaller in the group of fetuses at risk for pulmonary hypoplasia ($34\% \pm 15\%$ vs. $102\% \pm 17\%$, $P < 0.001$). Tanigaki and colleagues¹³⁹ compared the diagnostic performance of LV/EFW determined by MRI with three ultrasonographic parameters commonly used to assess the risk of pulmonary hypoplasia at birth. In a population of 17 fetuses at risk for pulmonary hypoplasia, a fetal LV/EFW below the 5th percentile for age was the most accurate diagnostic parameter.

Signal intensity ratios to predict lung hypoplasia have also been evaluated.¹⁴⁰⁻¹⁴² Kuwashima and colleagues¹⁴⁰ proposed that the lungs of fetuses with pulmonary hypoplasia would have low-intensity signals compared with fetuses with normal lung development. Osada and colleagues¹⁴¹ compared LV/EFW between 58 normal fetuses and 29 fetuses at risk for pulmonary hypoplasia. In addition to LV/EFW, the authors also evaluated lung signal intensities expressed as a proportion of the spinal fluid signal intensity (L/SF). Although diagnostic indices were not reported in this study, receiver-operator characteristic (ROC) curve analysis showed that simultaneous measurement of fetal lung volume and signal intensity by MRI had an area under the curve of 0.990 to predict lung hypoplasia, compared with 0.930 and 0.955 for lung volume or L/SF ratio alone. Keller and colleagues¹⁴² evaluated signal intensities of lung/liver, lung/amniotic fluid, lung/muscle, liver/fluid, and liver/muscle for the prediction of lung hypoplasia. In contrast with the study of Osada and colleagues,¹⁴¹ these signal intensity ratios did not differ significantly from those in the normal population.

Doppler assessment of tracheal fluid flow

Kalache and colleagues¹⁴³ have proposed that the volume of lung fluid displaced in the trachea could be useful for the analysis of fetal lung function. The investigators tested this hypothesis in a case-control study that included six cases of congenital diaphragmatic hernia diagnosed prenatally and a control group of five healthy fetuses matched for gestational age to each case. Parameters analyzed included: (1) the length of the inspiratory phase, (2) the length of the expiratory phase, (3) the peak velocities during inspiration and expiration, and (4) the volume estimation of the displaced fluid in the trachea during breathing [calculated as volume = velocity time integral (VTI) $\times \pi \times (d \times 0.5)^2$]. The estimated breathing-related tracheal volume flow in uncomplicated pregnancies increased with gestational age (from 0.21 ± 0.10 mL/breath at 26 weeks to 1.37 ± 0.48 mL/breath at 36 weeks of gestation), and was significantly lower in fetuses with diaphragmatic hernia who died of pulmonary hypoplasia. Tracheal volume flow in survivors was similar to that in control subjects.

Evaluation of hands and feet

Hands and feet should be examined to exclude polydactyly (Fig. 26.19), brachydactyly, and extreme postural deformities such as those seen in diastrophic dysplasia. Table 26.15 shows a nomogram of the fetal foot size throughout gestation. Table 26.16 displays disorders associated with hand and foot deformities. Disproportion between hands and feet and the other parts of the extremity may also be a sign of a skeletal dysplasia. Figure 26.20 illustrates the relationship between femur

Figure 26.19 Three-dimensional rendered volume using the maximum intensity (skeletal) mode showing postaxial polydactyly.

length and foot length. The femur–foot length ratio is nearly constant from 14 to 40 weeks of gestation, with a mean value of 0.99 ± 0.06 (SD). A ratio below 0.87 is considered abnormal.¹⁴⁴ Although fetuses with skeletal dysplasias have been reported to have abnormally low ratios, more experience is required to test the diagnostic value of this method.¹⁴⁵ It is expected that a small proportion of normal fetuses may have an abnormal ratio. As in the case of other limb biometric parameters, large deviations from the lower limit of normal are likely to be significant.

Evaluation of the fetal cranium

Several skeletal dysplasias are associated with defects of membranous ossification and, therefore, affect skull bones. Examination of the skull bones may reveal poor ossification (see Fig. 26.10), frontal bossing (Fig. 26.21), or cloverleaf deformity (Fig. 26.22). Table 26.17 presents abnormalities of the skull and face in the different skeletal dysplasias.

Evaluation of the fetal face

Sonographic examination of fetal facial features is of major importance in the assessment and diagnosis of fetuses with skeletal dysplasias as many of these disorders are associated with typical facial abnormalities.¹⁴⁶ Sonographic evaluation of

the fetal face is easily performed in a high percentage of patients from 16 to 20 weeks of gestation onward. The single most reliable view in detecting facial abnormalities is the sagittal view. This view permits determination of midface hypoplasia, which occurs in several skeletal dysplasias, such as thanatophoric dysplasia, achondroplasia, campomelic dysplasia, osteogenesis imperfecta type I, and spondyloepiphyseal dysplasia congenita.^{61,147}

In median clefting, the central portion of the upper lip is absent, and on the midline sagittal view no upper lip will be demonstrated. In bilateral cleft lip, the midline view will show a variable appearance, depending on the amount of residual premaxillary tissue present in the midline. In unilateral cleft lip, the midline sagittal scan may be relatively normal; the parasagittal view will reveal the cleft. This should subsequently be confirmed by scanning the coronal plane.

Cleft palate occurs in 66% of patients with cleft lip. Isolated cleft palate is more difficult to diagnose with ultrasound because of shadowing of facial bones. Three-dimensional ultrasonography has been shown to be superior to two-dimensional ultrasonography for the prenatal diagnosis of cleft lip and palate.^{148–150} Potential advantages of three- over two-dimensional ultrasound include: (1) a true coronal view of the lips can be displayed, even when the original scanning plane was obtained from a different orientation; (2) three-

dimensional standardized multiplanar imaging makes it easier to successfully demonstrate the maxillary tooth-bearing alveolar ridge in suspected cases; and (3) the maxillary tooth-bearing alveolar ridge can be more accurately localized by the multiplanar technique because this region can be easily mistaken for the mandibular ridge.^{151,152} Rendered views of the cleft lip/palate have been described as being particularly useful for patient counseling.^{151,153,154} A novel technique for visualization of the fetal palate, the “three-dimensional reverse face view,” has been proposed recently for the antenatal characterization of facial clefting, in particular for clefting of the hard palate.¹⁵⁵ This technique entails rotating the volume dataset 180° around the vertical axis in order to examine the secondary palate. Campbell and colleagues¹⁵⁶ reported preliminary results of this technique in eight cases of suspected orofacial clefting. A cleft in the soft palate was missed in only one case.

Micrognathia is also frequent in cases of skeletal dysplasia (Table 26.18).^{157–159} The jaw index [(anteroposterior mandibular diameter/BPD) × 100] has been proposed as an objective and accurate parameter to diagnose micrognathia *in utero*. In a population of 198 malformed fetuses, 11 of which had micrognathia at necropsy or birth, a jaw index below 23 detected 100% of the cases with micrognathia with 98.1% specificity. In comparison, only 72.7% of the cases were detected by subjective evaluation of the fetal profile.

Intraorbital and interorbital diameters should be measured as hypertelorism may occur in cases of skeletal dysplasia (Table 26.19).

Evaluation of the fetal spine

Sonographic assessment of the fetal spine is a component in the examination of a fetus with suspected skeletal dysplasia. The following parameters should be assessed.

Vertebral bodies

Fetal vertebral bodies are composed of three ossification centers representing the vertebral body and two laminae.^{160–163} Abnormalities of the ossification center of the fetal vertebral

body may result in bony defects, such as hemivertebrae (see Fig. 26.5), butterfly vertebrae, or block vertebrae causing congenital scoliosis (see Fig. 26.4). A study of the associated anomalies of 27 cases in which prenatal ultrasound detected hemivertebrae noted that, although 11 fetuses had no other abnormal findings, 16 fetuses had associated anomalies.¹⁶⁰ These anomalies included cardiac, gastrointestinal, renal, facial, extremity, and cranial malformations. Seven fetuses had bilateral renal agenesis (Potter sequence). Only five of the fetuses with additional anomalies survived. Usually these anomalies are not a risk factor for aneuploidy.

Platyspondyly may be diagnosed with current high-resolution sonography (Fig. 26.3).¹⁶⁴ Objective evaluation may be performed by computing a ratio between measurements of the vertebral interspace to vertebral body height.³³ Rib defects are often associated with thoracic vertebral body anomalies.

Clefting of the vertebrae may be complete or incomplete, coronal, or sagittal.⁴³ Coronal vertebral clefts are a result of missed fusion between the anterior and posterior primary ossification centers beyond 16 weeks of gestation. It can be observed by sonography *in utero*.^{165,166} Sagittal clefts in the vertebral bodies are believed to represent a localized splitting of the notochord due to adhesions between the ectoderm and endoderm during the embryonic period. These clefts range from a single cleft to multiple clefts as part of a malformation syndrome. The role of vertebral clefting in the diagnosis of skeletal dysplasias was assessed by searching the database at the International Skeletal Dysplasia Registry in a study conducted by Westvik and Lachman.¹⁶⁶ Coronal and sagittal clefts were present in 40 different conditions. Coronal clefts were more common than sagittal clefts and were mainly located in the thoracolumbar region. Clefts were most frequently observed in atelosteogenesis (88%), followed by chondrodysplasia punctata (79%), dyssegmental dysplasia (73%), Kniest dysplasia (63%), and short rib-polydactyly syndrome (53%).¹⁶⁶ The authors concluded that vertebral clefts are of major diagnostic value in these groups of skeletal dysplasia.

Spinal curvature

The most common osseous anomaly causing scoliosis is unilateral unsegmented bar with contralateral hemivertebrae.^{160,167-170} Spinal dysraphism may occur with congenital scoliosis and this possibility should be examined carefully. An apparent etiologic relationship exists between neural tube defects and other vertebral anomalies. Siblings of infants with congenital scoliosis have a 4% risk of neural tube defects.¹⁷¹ This increased risk is present in siblings of children with a single hemivertebra as well as multiple vertebral anomalies

(with or without neural arch defects). The differential diagnosis of fetal scoliosis includes neural tube defects, large abdominal wall defects, amniotic band syndrome, caudal regression, and hemivertebrae. Nonossification of the lumbar vertebral bodies has been detected in achondrogenesis and other diseases.¹⁷²⁻¹⁷⁴

Evaluation of the internal organs

A detailed examination of the cardiovascular, genitourinary, gastrointestinal, and central nervous system organs should be performed in all fetuses with skeletal anomalies. Some syndromes present with specific abnormalities of the internal organs, thus helping in the differential diagnoses of these entities. For example, congenital heart disease is a prominent feature of Ellis-van Creveld and Holt-Oram syndromes.

Newborn evaluation

Despite all efforts to establish an accurate prenatal diagnosis, a careful study of the newborn is always required.⁶⁷ The evaluation should include a detailed physical examination performed by a geneticist or an individual with experience in the field of skeletal dysplasias and radiographs of the skeleton. The latter should include anterior, posterior, lateral, and Towne views of the skull and anteroposterior views of the spine, extremities, and scapula,¹⁷⁵ with separate films of the hands and feet. Examination of the skeletal radiographs will permit precise diagnoses in a large proportion of cases, since the classification of skeletal dysplasias is largely based on radiographic findings. In lethal skeletal dysplasias, histologic examination of the chondro-osseous tissue should be performed, as this information may help reach a specific diagnosis. Chromosomal studies should be included, as there is a specific group of constitutional bone disorders associated with cytogenetic abnormalities. Biochemical studies are helpful in rare instances (e.g., hypophosphatasia). DNA restriction and enzymatic activity assays should be considered in cases in which the phenotype suggests a metabolic disorder, such as a mucopolysaccharidosis. The recent significant advance in identifying several mutations responsible for dysplasias is useful for prenatal diagnosis by amniocentesis or chorionic villus sampling (CVS) in patients at risk.^{2,3,176} DNA should be saved in all cases.

Increased nuchal translucency and skeletal dysplasia

In chromosomally normal pregnancies, increased nuchal translucency thickness is associated with increased risk of major anomalies.¹⁷⁷⁻¹⁸⁰ Skeletal dysplasias have been associated with increased nuchal translucency thickness in fetuses with a normal karyotype.¹⁸⁰⁻¹⁸⁴ In the multicenter screening project for trisomy 21 using the combination of maternal age

and nuchal translucency, 100 000 pregnancies were included.¹⁷⁷ An association between nuchal translucency and a wide range of skeletal dysplasias was found among these patients. Several case reports and small series have also suggested that in chromosomally normal fetuses there may be an association between increased nuchal translucency thickness and skeletal anomalies. Table 26.20 summarizes these data.

Osteochondrodysplasias

A growing number of skeletal dysplasias have been recognized *in utero*. A complete account of each disorder is beyond the scope of this chapter. The following discussion presents only a few of the most common disorders relevant to prenatal diagnosis.

Achondroplasia, thanatophoric dysplasia, and hypochondroplasia

These three chondrodysplasias are discussed in the same section since they are caused by different mutations in the *FGFR3* gene.^{185–192} Mutations in *FGFR3* are gain-of-function mutations that produce a constitutively active protein capable of initiating intracellular signal pathways in the absence of ligand binding.^{193,194} This activation leads to premature maturation of the bone.¹⁹⁴

Achondroplasia

The most common nonlethal skeletal dysplasia is achondroplasia, an autosomal dominant condition with a prevalence of 1 per 66 000. It is characterized by rhizomelic shortening, limb bowing, lordotic spine, and enlarged head.¹⁹⁵ This disease is the result of anomalous growth of cartilage, followed by abnormal endochondral ossification, which is responsible for the shortness of long bones. The bones of the hands and feet are short (brachydactyly). The head is large; a flattened nasal bridge, frontal bossing, and broad mandible are frequent features. The problems in the prenatal diagnosis of this condition have been discussed in detail by Kurtz and colleagues.¹⁹⁶ Moreover, Modaff and colleagues¹⁹⁷ provided data about the frequency of prenatal misdiagnosis of achondroplasia and illustrated the difficulty of making this specific prenatal diagnosis. They collected data retrospectively from 37 consecutive referrals of infants with achondroplasia in whom ultrasound was performed prenatally: 9 out of 37 (24%) had a positive family history of achondroplasia; all nine were correctly diagnosed prenatally. Out of the 28 with no family history of achondroplasia, 16 (57%) were recognized to have abnormalities on ultrasound but none was diagnosed with certainty. Five received an appropriate diagnosis of “most likely” achondroplasia and four others were given a nonspecific (but appropriate) diagnosis of some skeletal dysplasia, not otherwise specified. In seven instances (25%), an incorrect diagnosis of a lethal or very severe disorder was assigned.

The major difficulty in the antenatal diagnosis is that the long bone growth in this disease is not recognized in most cases until the third trimester of pregnancy.^{49,198} Therefore, it is usually not possible to detect this disorder in time to allow for pregnancy termination.¹⁹⁹ However, prenatal diagnosis of achondroplasia is possible and has been reported.^{200–202} The trident hand is a specific finding for achondroplasia.^{203,204} A distinct difference in the femoral length growth curves of homozygous, heterozygous, and unaffected children of achondroplastic parents has been described by Patel and Filly.²⁰⁵

More than 99% of individuals with achondroplasia have one of two mutations in the *FGFR3* gene. The more common mutation, found in approximately 98% of patients, is a G → A point mutation at nucleotide 1138. About 1% of affected individuals have a G → C point mutation at the same nucleotide. The G380R mutation has been shown to result in constitutive activation of the fibroblast growth factor receptor. Prenatal diagnosis in pregnancies in which one or both parents has achondroplasia is possible by molecular diagnosis, using CVS or amniocentesis.^{206–208} Molecular analysis can also be used to identify mutations in fetuses suspected to have achondroplasia based on ultrasound findings. As discussed, achondroplasia would typically present in the late second or third trimester of pregnancy, limiting available methods of prenatal diagnosis to amniocentesis.

Heterozygous achondroplasia is compatible with a normal life and intellectual development. However, cervicomedullary junction abnormalities, which may lead to compression, put the infant with achondroplasia at risk for lethal sequelae.²⁰⁹ Although the disease is lethal in the homozygous state, a case of a 37-month survivor has been reported.²¹⁰ The radiologic characteristics of homozygous achondroplasia lie between those of thanatophoric dysplasia and heterozygous achondroplasia. Administration of growth hormone has been proposed for the treatment of achondroplasia.²¹¹

SADDAN (severe achondroplasia with developmental delay and acanthosis nigricans)

Tavormina and colleagues²¹² identified a *FGFR3* missense mutation in four unrelated individuals with skeletal dysplasias, which approaches the severity observed in thanatophoric dysplasia type I. Three out of the four individuals developed extensive areas of acanthosis nigricans (beginning in early childhood), suffered from severe neurological impairments, and have survived past infancy without prolonged life-support measures. The *FGFR3* mutation (A1949T:Lys650Met) occurs at the nucleotide adjacent to the thanatophoric dysplasia type II mutation (A1948G:Lys650Glu) and results in a different amino acid substitution. They referred to the phenotype caused by the Lys650Met mutation as “severe achondroplasia with developmental delay and acanthosis nigricans” (SADDAN) because it differs significantly from the phenotypes of other known *FGFR3* mutations. It is also associated with unusual bone

deformities, such as femoral bowing with reverse (i.e., posterior apex), tibial and fibular bowing, and “ram’s horn” bowing of the clavicle. This condition has not been associated with cloverleaf skull or craniosynostosis.²¹³

Thanatophoric dysplasia

Thanatophoric dysplasia is the most common lethal skeletal dysplasia in fetuses and neonates.⁷ It is characterized by extreme rhizomelia, a normal trunk length with a narrow thorax, and a large head featuring a prominent forehead. It occurs in 0.24–0.69 of 10000 births.^{8,15,187,214} Two subtypes have been identified: type I, with typical bowed “telephone receiver” femurs²¹⁵ (Fig. 26.23) and without cloverleaf skull; and type II, with severe cloverleaf skull (Fig. 26.22) and short, straight long bones.^{21,216} However, mild cloverleaf skull has been described in type I.^{217–219} Cloverleaf skull may result from premature closure of the coronal and lambdoid sutures, defective development of the cranial base with secondary synostosis, or a primary developmental disorder of the brain with secondary deformation of the skull. The differential diagnosis between the two types depends on the radiographic findings and histology. Both types of thanatophoric dysplasia are inherited in an autosomal dominant manner.²²⁰ The majority of cases of thanatophoric dysplasia (all type I and most cases of type II) are sporadic. Some familial cases of type II have been reported.^{220–225}

Distinct mutations in *FGFR3* cause each one of the two types of thanatophoric dysplasia.^{221,222,226,227} Three common mutations (R248C, Y373C, and S249C) are found in approximately 90% of the patients with thanatophoric dysplasia type I.^{193,228} One mutation, K650E, is found in almost all cases of thanatophoric dysplasia type II.^{229–231} Camera and col-

Figure 26.23 Bowed and short femurs in thanatophoric dysplasia.

leagues²³² reported an individual with the common thanatophoric dysplasia type I mutation and the clinical phenotype of achondroplasia. Mosaicism was thought to be a possible explanation for the milder phenotype. However, mosaicism was not found in buccal mucosal cells or blood.

The prenatal sonographic findings depend on the specific type of thanatophoric dysplasia.¹⁶⁵ The association of cloverleaf skull and micromelia is specific for thanatophoric dysplasia. Campomelic syndrome is also associated with cloverleaf skull. Micromelia, however, is not a feature of that condition. Ventriculomegaly, macrocranium, and polyhydramnios are frequently seen. There is a relatively large calvarium with a prominent forehead (Fig. 26.21), a saddle nose, and hypertelorism. Additional findings are short ribs, platyspondyly (see Fig. 26.3), and short and broad tubular bones in the hands and feet. The differential diagnoses include short rib-polydactyly syndrome, homozygous achondroplasia (in which both parents are typically affected), and asphyxiating thoracic dysplasia (differentiated by slight shortening of long bones and normal vertebrae). On review of the radiologic findings of several cases of thanatophoric dysplasia, Horton and colleagues²³³ were able to discern a group of distinct entities characterized by severe platyspondyly. These disorders include the Torrance, San Diego, Lutton, and Shiraz types of platyspondylic lethal osteochondrodysplasias. Differential diagnosis among these entities is based on histologic and radiologic characteristics. Individuals with platyspondylic lethal skeletal dysplasia – San Diego type – have been reported to have *FGFR3* mutations that were previously reported in association with thanatophoric dysplasia type I.²³⁴

Thanatophoric dysplasia is a uniformly lethal disorder, although survival of several months has been reported in some isolated cases.^{225,233,235–238} Prenatal sonographic diagnosis has been documented on several occasions,^{77,173,239–256} and in one case of a triplet pregnancy.¹⁹² Prenatal diagnosis by CVS or amniocentesis is available.^{76,257–259}

Hypochondroplasia

Hypochondroplasia is an autosomal dominant disorder that resembles achondroplasia.²⁶⁰ It can result from a mutation in the *FGFR3* gene,^{261,262} although genetic heterogeneity is suspected.²⁶³ The incidence and prevalence have not been determined, at least in part because of lack of agreement on a definitive set of diagnostic criteria, which makes it difficult to review data from many studies reported in the literature. Most cases occur sporadically as a result of a new mutation.²⁶⁴

Two *FGFR3* mutations (C1620A and C1620G) result in a lysine for asparagine substitution at codon 540 (N5400K0) and have been shown to cause hypochondroplasia.^{186,265} Several other *FGFR3* mutations have been proposed to cause a small number of cases of hypochondroplasia. In addition, the insulin-like growth factor-1 (IGF-1) gene has been proposed to be linked to hypochondroplasia in a subset of cases, although no pathogenetic mutations have been reported.²⁶³

The differential diagnosis between this condition and achondroplasia is based on the sparing of the head and the lack of tibial bowing in hypochondroplasia.^{260,266–270} Although this condition is generally first detected during childhood, prenatal diagnosis has been reported in fetuses at risk for the condition.^{267,271} DNA-based diagnosis via CVS or amniocentesis may be possible.

Fibrochondrogenesis and atelosteogenesis

Fibrochondrogenesis and atelosteogenesis have a clinical presentation similar to that of thanatophoric dysplasia. The differential diagnosis between these disorders *in utero* is extremely difficult. Fibrochondrogenesis and atelosteogenesis are extremely rare, and only a few cases of each have been reported.

Fibrochondrogenesis

Fibrochondrogenesis is a very rare lethal chondrodysplasia inherited with an autosomal recessive pattern and characterized by micromelia with significant metaphyseal flaring, normal head size, undermineralized skull, platyspondyly, cleaving of the vertebral bodies, and narrow, bell-shaped thorax.^{272,273} Metaphyseal flaring is not a feature of thanatophoric dysplasia.^{274–277} This condition has been described in a consanguineous family.²⁷⁸ Other conditions to be considered in the differential diagnosis include metatropic dysplasia and Kniest dysplasia. Prenatal diagnosis of fibrochondrogenesis by ultrasound has been reported as early as 17 weeks of gestation.^{279–281} The molecular defect involved in fibrochondrogenesis is not known.²⁸²

Atelosteogenesis

Atelosteogenesis is also a lethal chondrodysplasia characterized by severe micromelia (with hypoplasia of the distal segments of the humerus and femur), bowing of long bones, narrow chest with short ribs, coronal and sagittal vertebral clefts,⁴³ and dislocations at the level of the elbow and knee. Clubfoot deformities may also be present.²⁸³ Three subtypes of atelosteogenesis have been described based on radiologic and pathologic findings.^{284–287} Atelosteogenesis types I and III are sporadic and caused by mutations in the gene encoding filamin B.²⁸⁸ Atelosteogenesis type II is inherited with an autosomal recessive pattern and is caused by mutation in *DTDST*.^{289–292} It overlaps phenotypically and genetically with diastrophic dysplasia and achondrogenesis type IB.^{287,293,294}

Differential diagnosis includes diastrophic dysplasia and de la Chapelle dysplasia.^{295,296} Three cases of a lethal dysplasia termed *boomerang syndrome* (“boomerang-like tibia”) may actually represent the same disorder as atelosteogenesis type I.²⁹⁷ There are now more than three reported cases.^{43,298–302}

Achondrogenesis

Achondrogenesis, or anosteogenesis, is a lethal chondrodys trophy that is characterized by extreme micromelia, short trunk, and macrocrania. The birth prevalence is 0.09–0.23 in 10 000 births.^{8,15,64,68,70} Traditionally, this disorder has been classified into two types: the more severe form, which is type I achondrogenesis (Parenti–Fraccaro), and type II achondrogenesis (Langer–Saldino). In 1998, type I was subdivided into two subtypes: type IA (Houston–Harris) and type IB (Fraccaro).^{303,304} Hypochondrogenesis had been considered a separate disorder from achondrogenesis. However, evidence now suggests that hypochondrogenesis and achondrogenesis type II are phenotypic variants of the same disorder.^{305–307} Indeed, clinically and radiologically, achondrogenesis type II, hypochondrogenesis, and neonatal spondyloepiphyseal dysplasia congenita form a continuous spectrum of disease.³⁰⁸ The fundamental biochemical disorder seems to be allelic mutations of the gene coding for type II procollagen.³⁰⁹ A different classification dividing achondrogenesis into four types has been proposed by Whitley and Gorlin,³⁰⁹ but this proposal has not gained wide acceptance.

Type IA achondrogenesis (Houston–Harris) is characterized by micromelia, lack of ossification of vertebral bodies but ossification of the pedicles in the cervical and upper thoracic region, and short ribs with multiple fractures. The calvarium is demineralized. Type IB (Fraccaro), which is a recessively inherited chondrodysplasia, is caused by mutation in the *DTDS* gene^{310–312} and is similar to type IA, but the calvarium is ossified, and fractured ribs are not seen. Although the ver-

tebral bodies are minimally or not at all ossified, the pedicles show some ossification. Type II achondrogenesis is characterized by micromelia, lack of mineralization of all or many of the vertebral bodies, sacrum, and ischium, enlarged calvarium with normal ossification, variable shortening of the ribs, and absence of fractures (Fig. 26.24).³¹³ Table 26.21 illustrates the characteristics of the different types of achondrogenesis.^{305,314,315}

Prenatal diagnosis should be suspected on the basis of micromelia, lack of vertebral ossification, and a large head with various degrees of ossification of calvarium.^{172,313–326} Polyhydramnios and hydrops have been associated with achondrogenesis. However, sonographic examinations of affected fetuses do not demonstrate fluid accumulation in body cavities. The hydropic appearance of these fetuses and neonates is probably attributable to redundancy of soft-tissue mass over a limited skeletal frame. An association between cystic hygromas and achondrogenesis has been reported in a fetus with normal chromosomal constitution.^{313,314,327}

Achondrogenesis type IA and IB are inherited in an autosomal recessive pattern, whereas most cases of achondrogenesis type II and hypochondrogenesis have been sporadic (new autosomal dominant mutations). Some severe cases of type II achondrogenesis follow an autosomal recessive pattern.³²⁸

The primary defect in achondrogenesis type IA has not been identified. The only gene known to be associated with achondrogenesis type IB is *SLC26A2* (*DTDST*), which encodes a sulfate transporter protein.³²⁹ As the basic defect in achondrogenesis type IB is known, molecular diagnosis is possible. The distinction between achondrogenesis type IB (which has a risk of 25% for recurrence) and the more frequent

Figure 26.24 Frontal and lateral views in a case of achondrogenesis type II. There is no mineralization of the spine and ischial bones. The thorax is bell shaped, with short and straight ribs and no fractures. Long bones are short, with metaphyseal flaring and cupping.

Table 26.21 Radiologic differences of achondrogenesis types IA/IB, type II, and hypochondrogenesis.

Site	Type IA (Houston–Harris)	Type IB (Fraccaro)	Type II (Langer–Saldino)	Hypochondrogenesis
Skull	Membranous calvarium	All parts of ossified skull well seen	Normal ossification	Normal ossification
Long bones	Extremely shortened with metaphyseal cupping and spurs, “rectangular bones”	Arms and legs shorter than with type IA with minimal ossification; abundant metaphyseal spiking or spurring in lower leg bones, “square or stellate bones”	Short and bowed with metaphyseal flaring and cupping, “mushroom stem bones”	Less bowed and shortened with irregular or smooth metaphyses
Spine	Vertebral bodies unossified, with partly ossified pedicles	Vertebral bodies minimally or not ossified, pedicles ossified	Variable pattern of ossified or unossified vertebral bodies and pedicles	Thoracic and upper lumbar vertebral bodies ossified but still platyspondylic Cervical and lower lumbar bodies unossified
Pelvis	Poorly formed and ossified, with crenated iliac bones, ischial bones poorly ossified, pubic bones unossified	Iliac bones same aspect as in type IA, ischial and pubic bones unossified	Halberd-like iliac bones with unossified ischial and pubic bones	Near normally developed iliac bones with partial ossification of ischial bones and unossified pubic bones
Thorax	Short and barrel shaped, short ribs with cupped metaphyses and multiple fractures	Same as in type IA with unfractured ribs	Short and barrel/bell shaped with short unfractured ribs	Near normal but shallow cage with short unfractured ribs

autosomal dominant achondrogenesis type II, which has a lower recurrence risk, is important for genetic counseling. A couple at risk of having a child with achondrogenesis type IB may take the advantage of molecular prenatal diagnosis by CVS or amniocentesis.^{289,293,310} Achondrogenesis type II and hypochondrogenesis result from mutations in the *COL2A1* gene.³³⁰ Prenatal diagnosis by molecular analysis of the *COL2A1* gene is available.

Osteogenesis imperfecta and hypophosphatasia

Osteogenesis imperfecta and hypophosphatasia are discussed together because they are characterized by skeletal demineralization.

Osteogenesis imperfecta

The term “osteogenesis imperfecta” was introduced over a century ago to describe a newborn with extremely brittle bones (see Figs 26.12 and 26.13). At present, the term refers to a heterogeneous group of disorders caused in most cases by mutations in one or two structural genes for type I procollagen.^{331–337} Extraskelatal malformations are variably associated

with the disorder and include blue sclera, dentinogenesis imperfecta, hyperlaxity of ligaments and skin, hearing impairment, and presence of wormian bones on skull radiographs.³³⁷ Advanced paternal age is a risk factor for osteogenesis imperfecta,³³⁸ and its prevalence is 0.18 per 10 000 births.^{8,15}

The most popular classification is that proposed by Silience and colleagues.³³⁹ A modification of this classification has been recently reported by Rauch and Glorieux³³⁷ and includes three additional types (V, VI, and VII; Table 26.22). Clinically, the most relevant characteristic of osteogenesis imperfecta is bone fragility, with severity increasing in the following order: (1) type I; (2) types IV, V, VI, and VII; (3) type III; and (4) type II.³³⁷

In type I (autosomal dominant), patients have bone fragility, blue sclerae (all ages), and hearing loss. There is osteoporosis, a normal calvarium, and no dentinogenesis imperfecta; fractures range from none to multiple. Mutations that cause type I osteogenesis imperfecta result in premature termination codons that lead to decreased production of type I procollagen.³³³

Type II is an autosomal dominant condition.³⁴⁰ It is also known as the perinatal variety and is uniformly lethal. There is almost no ossification of the skull, beaded ribs, shortened, crumpled long bones, and multiple fractures *in utero* (see Figs 26.12 and 26.13). The thorax is short but not narrow. Type

Table 26.22 Expanded Sillence classification of osteogenesis imperfecta.

Type	Clinical severity	Typical features	Typically associated mutations
I	Mild non-deforming osteogenesis imperfecta	Normal height or mild short stature, blue sclerae, no dentinogenesis imperfecta	Premature stop codon in <i>COL1A1</i>
II	Perinatal lethal	Multiple rib and long bone fractures at birth, pronounced deformities, broad long bones, low density of skull bones on radiographs, dark sclerae	Glycine substitutions in <i>COL1A1</i> or <i>COL1A2</i>
III	Severely deforming	Very short, triangular face, severe scoliosis, grayish sclerae, dentinogenesis imperfecta	Glycine substitutions in <i>COL1A1</i> or <i>COL1A2</i>
IV	Moderately deforming	Moderately short, mild to moderate scoliosis, grayish or white sclerae, dentinogenesis imperfecta	Glycine substitutions in <i>COL1A1</i> or <i>COL1A2</i>
V	Moderately deforming	Mild to moderate short stature, dislocation of radial head, mineralized interosseous membrane, hyperplastic callus, white sclerae, no dentinogenesis imperfecta	Unknown
VI	Moderately to severely deforming	Moderately short, scoliosis, accumulation of osteoid in bone tissue, fish-scale pattern of bone lamellation, white sclerae, no dentinogenesis imperfecta	Unknown
VII	Moderately deforming	Mild short stature, short humeri and femora, coxa vara, white sclerae, no dentinogenesis imperfecta	Unknown

Reproduced with permission from ref. 337.

II is subclassified into three subtypes (IIA, IIB, and IIC) according to radiologic criteria: group A – short, broad, ‘crumpled’ long bones, angulation of tibias, and continuously beaded ribs; group B – short, broad, crumpled femurs, angulation of tibias but normal ribs or ribs with incomplete beading; and group C – long, thin, inadequately modeled long bones with multiple fractures and thin beaded ribs.³⁴¹

Type III (autosomal recessive, rare) is a nonlethal variety characterized by blue sclerae and multiple fractures present at birth. The sclerae become white with time. The membranous skull is severely deossified and the long bones are mildly shortened but with marked angulations. Type IIB and type III osteogenesis imperfecta are difficult to distinguish and may represent different degrees of severity of the same disorder.³⁴²

In type IV (autosomal dominant) the long bones and sclerae are normal. There is mild to moderate osseous fragility, and 25% of the newborns have fractures. There is significant heterogeneity in the expression of the disease even within the same family.³⁴³ From this heterogeneous group, Rauch and Glorieux and colleagues^{337,344–346} have recently identified three separate clinical entities based on distinct clinical and bone histological features. These disorders have been classified as osteogenesis imperfecta types V, VI, and VII (Table 26.22).

Osteogenesis imperfecta type I is caused by a premature stop codon in *COL1A1*.³³² Types II, III, and IV typically result from mutations that lead to substitutions for glycine within the triple-helical domain of the pro- α chain, disrupting the

normal folding of the molecule and leading to the production of abnormal collagen.^{347,348} Approximately 90% of patients with a clinical diagnosis of osteogenesis imperfecta have a mutation in either the *COL1A1* or *COL1A2* gene, resulting in abnormal molecular constitution of procollagen type I.^{337,349–351} Gene mutations associated with types V, VI, and VII have not been identified.³³⁷

Collagen biosynthesis in cell culture from chorionic villi has been demonstrated and may serve as a way for prenatal diagnosis.³⁵² In a large study, Pepin and colleagues³⁵³ completed prenatal diagnosis of collagen synthesized by cells cultured from CVS in 107 cases, and in 22 cases they used direct mutation identification or analysis of polymorphic restriction sites in the *COL1A1* gene of type 1 collagen. There were neither false-negative nor false-positive results. The time needed for diagnosis was 20–30 days when the biopsy was taken using biochemical techniques and 10–14 days when molecular strategies were used.

The natural history of osteogenesis imperfecta *in utero* is quite variable. Prenatal diagnosis of type II osteogenesis imperfecta has been reported several times,^{75,354–375} even as early as 12 weeks of gestation by either two- or three-dimensional ultrasonography.^{376–379} It is important, however, to note that in some cases fractures and limb shortening may not be observed until the second or even the third trimester.^{380–382} Prenatal diagnosis of osteogenesis imperfecta types I, III, and IV has also been reported using either ultrasound, biochemistry, or molecular techniques.^{353,383–386}

Hypophosphatasia

Hypophosphatasia is a rare autosomal recessive inherited disorder characterized by demineralization of bones and low alkaline phosphatase in serum and other tissues.³⁸⁷ Alkaline phosphatase acts on pyrophosphate and other phosphate esters, leading to the accumulation of inorganic phosphates that are critical for the formation of bone crystals. Bone fragility is thought to be the result of deficient generation of bone crystals.³⁸⁸

Hypophosphatasia is a condition that has been subdivided into three clinical types according to the age of onset: congenital/infantile, childhood, and adult.^{389,390} The congenital/infantile and childhood varieties have an autosomal recessive pattern of inheritance, whereas the adult form can be transmitted as either an autosomal dominant or autosomal recessive trait.³⁸⁷ The congenital (neonatal) form is associated with early neonatal death or stillbirth.³⁹¹

Fetuses with congenital hypophosphatasia have generalized demineralization of the skeleton, with shortening and bowing of tubular bones. Multiple fractures are present. The marked demineralization of the cranial vault results in deformation of the skull after external compression. This sonographic sign is also present in some cases of type II osteogenesis imperfecta and type IA achondrogenesis. Prenatal diagnosis of this condition has been reported with ultrasound^{390,392–401} and by assaying alkaline phosphatase in tissue obtained by CVS⁴⁰² or amniotic fluid culture. Alkaline phosphatase measurement in amniotic fluid is not a reliable means of making a diagnosis of hypophosphatasia because most of the alkaline phosphatase in amniotic fluid is of intestinal origin.^{403,404} The involved enzymes in hypophosphatasia are bone and liver alkaline phosphatases. These isoenzymes contribute only 16% of the total amniotic fluid enzymatic activity.⁴⁰⁵

Hypophosphatasia has been shown to be caused by mutations in the alkaline phosphatase liver gene [*ALPL*, also called the tissue non-specific alkaline phosphatase (*TNSALP*) gene] on chromosome 1.⁴⁰⁶ There is a large spectrum of mutations in the Caucasian population.^{407,408} Therefore, although prenatal diagnosis by DNA analysis is possible,⁴⁰⁹ this requires sequencing the entire gene, which increases the complexity of the process. Missense mutations in the gene lead to variable residual enzymatic activity and the extremely high phenotypic heterogeneity observed in hypophosphatasia.^{188,410}

Diastrophic dysplasia

Diastrophic dysplasia is characterized by micromelia, clubfoot, hand deformities, multiple joint flexion contractures, and scoliosis.⁴¹¹ Because of phenotypic variability, the diagnosis may be difficult at birth, and milder cases are diagnosed later.⁴¹² The clinical features include rhizomelic-type micromelia, contractures, hand deformities with abducted position of the thumbs (“hitchhiker thumb”: Figs 26.25 and

26.26), and severe talipes equinovarus. The shape of the head is normal, but micrognathia and cleft palate may be present. This dysplasia is a generalized disorder of cartilage, involving destruction of the cartilage matrix with formation of fibrous scar tissue and subsequent ossification. The ossification is responsible for the contractures. Mutation in the diastrophic dysplasia sulfate transporter gene (*SLC26A2/DTDST*) is associated with impaired sulfation of proteoglycan and causes this disorder.^{413–416} Five common *SLC26A2* mutations (*R279W*, *IVS1+2T→C*, *DELV340*, *R178X*, and *C653S*) account for approximately 65% of disease alleles.⁴¹⁴ Sequence analysis of the coding region can detect mutations in greater than 90% of alleles in individuals with typical clinical, radiologic, and histologic features.⁴¹⁴

The prenatal diagnosis of diastrophic dysplasia has been made in patients at risk,^{42,44,412,417–420} based on severe shortening and bowing of all long bones. Sepulveda and colleagues⁴²¹ reported clearer visualization of the limbs and face deformities using three-dimensional ultrasound. Prenatal diagnosis in at-risk pregnancies in which the familial mutations have been identified can be accomplished by DNA analysis of fetal cells obtained by CVS or amniocentesis.⁴²² Biochemical studies of fibroblasts and/or chondrocytes are available and may be useful for cases in which molecular genetic tests fail to identify *SLC26A2* mutations.⁴²³ This disorder has a wide spectrum, and some cases may not be diagnosable *in utero*.

Diastrophic dysplasia is not universally lethal. Intelligence and sexual development are unaffected. However, death in the neonatal period due to respiratory/spinal abnormalities and mental retardation has been reported in some patients.

Differential diagnoses include arthrogryposis multiplex congenita, type II atelosteogenesis, and pseudodiastrophic dysplasia. Pseudodiastrophic dysplasia has a similar presentation as diastrophic dysplasia⁴²⁴ and is inherited in an autosomal recessive pattern.¹⁵ Histologic examination is required for a differential diagnosis. The distinctive morphologic abnormalities of the growth plate noted in diastrophic dysplasia have not been observed in pseudodiastrophic dysplasia. Cetta and colleagues⁴²⁵ demonstrated that a patient with pseudodiastrophic dysplasia had no defect in the *DTDST* gene. Sulfate uptake by skin fibroblasts was normal, indicating normal sulfate transport. Sulfation of proteoglycans was also normal.

Kniest-like disorders

The term “Kniest-like disorders” is used to refer to a group of conditions that share histologic and radiologic characteristics with Kniest syndrome but differ in terms of clinical presentation and inheritance.⁴²⁶

Kniest syndrome

In 1952, Dr. Wilhelm Kniest⁴²⁷ published a case of a 3.5-year-old girl with “skeletal changes showing a certain relationship

Figure 26.25 Three-dimensional rendered volume of a fetus with diastrophic dysplasia showing a hitchhiker thumb.

to classical chondrodystrophy but differing in many of its manifestations.” His publication clarified the confusion of this disorder with other chondrodystrophies and it is known today as one of the type II collagenopathies.^{428–431} Kniest dysplasia is characterized by involvement of the spine (platyspondyly and coronal clefts) and the tubular bones (shortened and metaphyseal flaring), with a broad and short thorax. There is a wide spectrum of disease.⁴³² The patient described by Dr. Kniest is still alive, although severely handicapped with short stature and blindness.⁴³² Molecular analysis of the patient’s DNA showed a single base (G) deletion of the *COL2A1* gene. Most commonly, the disorder is compatible with life. However, lethality in the neonatal period has been reported.⁴³³

Abnormalities of type II collagen are involved in the pathogenesis of the disease.⁴³⁴ The disorder is inherited in an autosomal dominant pattern.²²⁰

Dyssegmental dysplasia

Dyssegmental dysplasia is another entity related to Kniest dysplasia. Two distinct types of dyssegmental dysplasia have been recognized: the mild, Rolland–Desbuquois form and the lethal

Silverman–Handmaker.^{435–438} The latter is characterized by anarchic ossification of the vertebral bodies, metaphyseal flaring, and severe bowing of the long bones. The Rolland–Desbuquois type has essentially the same features, but the defects are much milder. Prenatal identification has been made in patients at risk.^{439,440} Other conditions associated with vertebral disorganization are Jarcho–Levin syndrome and mesomelic dysplasia. A cephalocele is present in 50% of cases of Silverman–Handmaker type and has been attributed to defective segmentation at the level of the occiput. The disease is autosomal recessive.²²⁰ The Silverman–Handmaker type of dyssegmental dysplasia is caused by a functional null mutation in the gene encoding perlecan (*HSPG2*).⁴⁴¹

Campomelic dysplasia

Campomelic dysplasia is a rare lethal disorder first described by Maroteaux in 1971.⁴⁴² The prevalence varies between 0.05 and 1.6 per 10 000.^{443,444} A unique aspect of campomelic dysplasia is that 75% of affected infants with a male karyotype present sex reversal syndrome and have female or ambiguous genitalia.^{445,446} The histology of the gonads

Figure 26.26 Hitchhiker thumb in diastrophic dysplasia.

varies from gonads with testicular differentiation to dysgenetic gonads with primary follicles. Mutations in the *SOX9* gene have been reported in several patients with this disorder.^{445–449} Campomelic dysplasia arises by mutations that interfere with DNA binding by *SOX9* or truncate the C-terminal transactivation domain, and thereby impede the ability of *SOX9* to activate target genes during organ development.⁴⁴⁹

Campomelic syndrome is characterized by a bowing of the long bones of the lower extremities, an enlarged and elongated skull with a peculiar small facies, hypoplastic scapulae, and several associated anomalies such as micrognathia, cleft palate, talipes equinovarus, congenital dislocation of the hip, macrocephaly, hydrocephalus, hydronephrosis, and congenital heart defects.³⁴⁰ The most significant features are bowing of the femur and tibia; other tubular bones are normal in length. The thorax is narrow and can be “bell shaped.” Cervical vertebrae are hypoplastic and poorly ossified.⁴⁵⁰ In the largest clinical and genetic study, which included 36 patients with this disorder, Mansour and colleagues⁴⁴³ concluded that campomelic dysplasia is an autosomal condition, as females and males are both affected, and their data suggested a sporadic autosomal dominant mode of inheritance.

There are two “short-bone varieties” of campomelic dysplasia, representing distinct syndromes: the normocephalic form is known as *kyphomelic dysplasia*, and the craniostenotic type appears to be identical to the Antley–Bixler syndrome. Differential diagnoses include osteogenesis imperfecta,

thanatophoric dysplasia, and hypophosphatasia. Antenatal diagnosis of campomelic dysplasia has been reported many times in the literature, mainly in patients at risk.^{70,451–459} At the time of this writing, only one laboratory offers prenatal molecular diagnosis for campomelic dysplasia.⁴⁶⁰ The test is available for families in which a mutation has previously been identified. The difficulties in the diagnosis are discussed by Norgard⁴⁶¹ and by Sanders and colleagues.⁴⁵⁸ The condition is frequently lethal in infancy, but some survivors have been reported.^{451,462–466} The cause of death is respiratory distress due to tracheomalacia. However, cleft palate, micrognathia, hypotonia, and small chest are also associated with this condition.⁴⁵¹

Skeletal dysplasias characterized by a hypoplastic thorax

The dysplastic process involves the ribs and other bones of the rib cages in many skeletal dysplasias. A reduction in thoracic dimensions leads to restriction of lung growth and, consequently, pulmonary hypoplasia. Lung hypoplasia is the main cause of death in lethal skeletal dysplasias. There are specific groups of dysplasias in which thoracic hypoplasia is a cardinal feature. These include asphyxiating thoracic dysplasia, Ellis–van Creveld syndrome, short rib–polydactyly syndrome, and campomelic syndrome. Table 26.23 illustrates the criteria for the differential diagnoses of the first three of these conditions. Other disorders presenting with altered thoracic dimensions are thanatophoric dysplasia, atelosteogenesis, fibrochondrogenesis, achondrogenesis, and Jarcho–Levin syndrome (Fig. 26.27).⁴⁶⁷

Asphyxiating thoracic dysplasia

Asphyxiating thoracic dysplasia, originally described by Jeune and Carron⁴⁶⁸ and known as Jeune syndrome, is a rare autosomal recessive skeletal disorder. Its prevalence is 0.14 in 10 000 births.^{469–471} It is characterized by a narrow and “bell-shaped” thorax, with short, horizontal ribs. Long bones are normal or mildly shortened. Polydactyly and cleft lip and/or palate can occur in association and the presence of a proximal femoral ossification center at birth is a characteristic finding.⁴⁷² Asphyxiating thoracic dysplasia has a wide spectrum of clinical manifestations, varying from lethal to mild forms; long-term survivors have been reported.^{470,473,474} The clinical course of individuals surviving the neonatal period is complicated by respiratory distress of varying severity, nephropathy, and hepatic and pancreatic problems.^{475–477} Prenatal diagnosis has been reported.^{478–490} A locus for asphyxiating thoracic dystrophy maps to chromosome 15q13. However, mutation analysis of two candidate genes (*GREMLIN* and *FORMIN*) did not reveal pathogenic mutations.⁴⁹¹ Molecular diagnosis for this condition was not available clinically at the time of this writing.⁴⁶⁰

Table 26.23 Disorders with thoracic dysplasia and polydactyly.

	Asphyxiating thoracic dysplasia (Jeune)	Chondroectodermal dysplasia (Ellis-van Creveld)	Short rib–polydactyly syndrome type I (Saldino–Noonan)	Short rib–polydactyly syndrome type II (Majewski)	Short rib syndrome type III (Naumoff)	Short rib syndrome type IV (Beemer–Langer)

Short rib–polydactyly syndromes

Short rib–polydactyly syndromes are a group of disorders characterized by micromelia, constricted thorax, and post-axial polydactyly (Fig. 26.28).^{492–495} Traditionally, three different types have been recognized (Saldino–Noonan, Majewski, and Naumoff). These conditions have been identified prenatally by two-^{496–517} and three-dimensional⁸⁰ ultrasonography, as well as by fetoscopy.⁵¹⁸ Table 26.23 illustrates

the differential diagnosis and features of these conditions. Recently, some authorities have expanded the definition of short rib–polydactyly syndrome to encompass at least seven disorders, including the three previously mentioned entities along with the Yang, Le Marec, and Beemer varieties, as well as asphyxiating thoracic dysplasia.^{519–522} Spranger and Maroteaux²⁵ and colleagues^{507,510,523} have indicated that the absence of polydactyly does not exclude the diagnosis of this entity.

Figure 26.27 Jarcho–Levin syndrome. There is dramatic spinal shortening with disorganization of the vertebral bodies, a characteristic chest deformity (“crab-like appearance”, with posterior fusion and anterior flaring of the ribs), and unaffected long bones.

Chondroectodermal dysplasia

Chondroectodermal dysplasia, also known as Ellis–van Creveld syndrome, is inherited with an autosomal recessive pattern.^{524–529} It is characterized by acromesomelia, with normal spine and skull, postaxial polydactyly (Fig. 26.29), long and narrow thorax with short ribs, and congenital heart disease (60% of cases).^{530–536} Polydactyly is a consistent finding. The supernumerary digit usually has well-formed metacarpal and phalangeal bones. Survivors who reach adulthood present with short stature but normal intelligence. Prenatal diagnosis has been reported.^{535,537–547} One-third of affected individuals die in the postnatal period as a result of cardiopulmonary disease.^{531–536,539–541,544–546}

Figure 26.28 Short rib–polydactyly syndrome. There is severe shortening of all long bones, very short and horizontal ribs, and postaxial polydactyly in all four extremities. Note the angulation of the bones in the forearm.

Ellis–van Creveld syndrome is caused by mutations in the Ellis–van Creveld syndrome gene (*EVC* gene), which maps to the short arm of chromosome 4 in humans (4p16).^{527,548} Ellis–van Creveld syndrome can also be caused by mutation in a nonhomologous gene, *EVC2*, located close to the *EVC* gene in a head-to-head configuration.^{549,550}

Limb deficiency or congenital amputations

On occasion, the only identifiable anomaly is the absence of an extremity (limb deficiency) or a segment of an extremity (congenital amputation) (Table 26.24).⁵⁵¹ These constitute a group of disorders different from osteochondrodysplasias. The overall incidence of congenital limb reduction deformities is approximately 0.49 in 10 000 births (Table 26.25).⁵⁵² It has been estimated that 51% of these limb reduction defects are simple transverse reduction deficiencies of one forearm or hand without associated anomalies. The remainder consists of multiple reduction deficiencies, with an approximate 23%

Table 26.24 Congenital amputations.

<i>Absent limbs only</i>
Single absent limb
Multiple absent limbs
<i>Absent limbs with rings</i>
Congenital ring constriction syndrome
<i>Absent limbs and face anomaly</i>
Aglossia–adactylia syndromes
Möbius syndrome
<i>Absent limbs with other anomalies</i>

incidence of additional anomalies of the internal organs or craniofacial structures.⁵⁵¹

Limb deficiencies can present alone or as part of a specific syndrome. An isolated limb deficiency of the upper extremity (e.g., distal segment of an arm) is generally an isolated anomaly. In contrast, congenital amputation of the leg generally occurs within the context of a syndrome, as do bilateral amputations or reduction of all limbs.⁵⁵³

Isolated amputation of an extremity can be due to amniotic band syndrome, exposure to a teratogen, or a vascular accident. In most cases, the anomaly is sporadic, and the risk of recurrence is negligible. The sonographic findings were reviewed recently.⁵⁵⁴

The following section reviews syndromes in which a limb amputation or deficiency is associated with other anomalies. We will follow the classification proposed by Goldberg.⁵⁵¹

Syndromes with absent limbs and facial anomalies

The aglossia–adactylia syndrome consists of transverse amputations of the limbs and malformations of the mouth, including micrognathia, vestigial tongue (hypoglossia), dental abnormalities, as well as ankylosis of the tongue to the hard palate, the floor of the mouth, or the lips (glossopalatine ankylosis). The spectrum of anomalies of the extremities is variable, ranging from absent digits to severe deficiencies of all four extremities. Intelligence is generally normal. The condition is sporadic and has been attributed to a vascular accident.^{555,556} It includes the Möbius sequence, Hanhart syndrome, glossopalatine ankylosis syndrome, limb deficiency–splenogonadal fusion syndrome, and Charlie M syndrome.^{557–562} There is confusion in the classification of these patients because of the associated anomalies and the frequency

of overlapping features. Although some authors have considered Hanhart syndrome and glossopalatine ankylosis syndrome as distinct entities, differential diagnosis is extremely difficult.⁵⁶³

The Möbius sequence consists of a number of facial anomalies attributed to paralysis of the sixth and seventh cranial nerves.⁵⁶⁴ Limited jaw mobility and micrognathia are present.^{565,566} Ptosis is also a common feature. The Möbius sequence is generally sporadic, but autosomal dominant, autosomal recessive, and X-linked recessive forms have been described.^{567–569} The associated limb reduction anomalies (25% of cases) are generally present in the upper extremities and range from transverse deficiencies to absent digits. Mental retardation occurs in 10% of the cases.⁵⁶⁷ The Möbius, Poland, and Klippel–Feil syndromes have been considered to occur as a result of subclavian artery supply disruption, based on the hypothesis that interruption of the early embryonic blood supply to the subclavian artery, vertebral artery, and/or their branches may lead to these conditions.^{568,570–575}

Limb reduction defects associated with other anomalies

Congenital hemidysplasia with ichthyosiform erythroderma and limb defects (CHILD syndrome) is a defect characterized by strict demarcation of the skin lesions to one side of the midline.^{576–578} The presence of unilateral defects of long bones is an important feature of the syndrome.⁵⁷⁹ Limb deficiencies may vary from hypoplasia of phalanges or metacarpals to complete absence of an extremity. The calvarium, scapulae, or ribs may also be involved. Zellweger syndrome, chondrodysplasia punctata, and warfarin embryopathy may present with similar findings. Visceral anomalies include congenital heart disease,^{579,580} unilateral hydronephrosis, hydroureter, and unilateral absence of the kidney, fallopian tube, ovaries, adrenal gland, and thyroid. CHILD syndrome predominantly affects females (by a ratio of 19:1)^{581,582} and is caused by mutations in the gene *NSDHL* (NAD[P]H steroid dehydrogenase-like protein), located at Xq28 and encoding a β -hydroxysteroid dehydrogenase that is involved in the cholesterol biosynthetic pathway.^{583–585}

Fibula aplasia complex brachydactyly (Du Pan syndrome) is an extremely rare condition characterized by bilateral agenesis of the fibula with abnormalities of the metacarpals and proximal phalanges. Limb reduction defects can involve the lower extremities.⁵⁸⁶ An autosomal recessive pattern of inheritance has been suggested.⁵⁸⁷ Faiyaz-Ul-Haque and colleagues⁵⁸⁸ have recently examined genomic DNA from a family with Du Pan syndrome for mutations in the *CDMP1* gene. Affected individuals were homozygous for a missense mutation, T1322C, in the coding region of the *CDMP1* gene.

The splenogonadal fusion syndrome is characterized by limb reduction defects and splenogonadal fusion.^{589,590} Most reported cases have occurred in males.⁵⁹¹ Typically, a

mass is detectable in the scrotum, and an ectopic spleen is identified during surgery.⁵⁹² There is a continuous type in which the normally located spleen is connected to the gonad by bands or cords of splenic tissue.⁵⁹³ A review of 14 reported cases indicates some overlap between this syndrome and the aglossia–adactylia syndrome or Hanhart syndrome.⁵⁹⁴

The Adams–Oliver syndrome is a group of disorders characterized by the association of limb reduction defects and scalp anomalies (aplasia cutis and deficiency of bony calvarium).⁵⁹⁵ Sporadic and familial cases have been reported.⁵⁹⁶ Other organ systems may be involved and there are reports of associated cardiovascular, brain, pulmonary, and renal anomalies.^{597–603} Becker and colleagues⁶⁰⁴ reported prenatal diagnosis, using ultrasound, of two cases of Adams–Oliver syndrome in the same family, the first at 13 weeks and the second at 23 weeks of gestation. Both cases showed limb reduction defects and, in the second case, the scalp defect was diagnosed as an echo-free space between the scalp and bone.

Phocomelia

In phocomelia the extremities resemble those of a seal. Typically, although the hands and feet are present, the intervening arms and legs are absent. Hands and feet may be normal or abnormal. Three syndromes must be considered in the differential diagnosis of phocomelia: Roberts syndrome, some varieties of the thrombocytopenia with absent radius (TAR) syndrome, and Grebe syndrome. Phocomelia also can be caused by exposure to thalidomide, but this is only of historical interest.⁶⁰⁵ Prenatal diagnosis of phocomelia has been reported by three-dimensional ultrasound.⁶⁰⁶

Roberts syndrome

Roberts syndrome is an autosomal recessive disorder characterized by the association of tetraphocomelia and facial dysmorphisms (hypertelorism, facial clefting defects, hypoplastic nasal alae).^{607–609} The upper extremities are generally more severely affected than the lower extremities. The spine is not involved. Polyhydramnios has been noted, and other anomalies associated with the syndrome include horseshoe kidney, hydrocephaly, cephalocele, and spina bifida.⁶¹⁰ Prenatal diagnosis has been reported.^{4,610–619}

Grebe syndrome

Grebe syndrome (Grebe–Quelle–Salgado chondrodystrophy) is an autosomal recessive nonlethal disorder of limb development. It was first described in two girls by Grebe,⁶²⁰ and in 47 Brazilian individuals by Quelle–Salgado.⁶²¹ The prevalence at birth has been estimated as 5 in 1 000 000.⁶²² Affected individuals have normal head, neck, and trunk skeleton, relatively normal humeri and femora, short and deformed radii, ulnae, tibiae, and fibulae, and severe abnormalities of hands and feet.

Polydactyly is frequent. Digits are very small and have been variously described as “bulbous,”⁶²³ “bud-like,”⁶²⁴ “mere knobs,”⁶²⁵ “globular appendages,”⁶²⁶ or “stubby toe-like fingers.”⁶²⁷ The proximal and middle phalanges of the fingers and toes are invariably absent, whereas the distal phalanges are present.⁶²⁶ Radiographic documentation has provided information on subtle clinical characteristics for obligate heterozygotes: polydactyly, brachydactyly, hallux valgus, and metatarsus adductus.^{626,628,629} The disease is caused by a missense mutation in the gene encoding cartilage-derived morphogenetic protein-1 (CDMP-1).⁶³⁰ Most patients reported to date are from Brazil. Survivors have normal intelligence and develop normal secondary sexual characteristics. Prenatal diagnosis of Grebe syndrome by ultrasound has been reported.^{623,631}

TAR syndrome is discussed in detail in the section on radial clubhand deformities.

Congenital short femur

Proximal femoral focal deficiency, or congenital short femur, refers to a group of disorders encompassing a wide range of congenital developmental anomalies of the femur. The disorder has been classified into five groups: type I, simple hypoplasia of the femur; type II, short femur with angulated shaft; type III, short femur with coxa vara (the most common); type IV, absent or defective proximal femur; and type V, absent or rudimentary femur.^{632,633} One or both femurs may be affected. The right femur is more frequently involved. Anomalies of the upper limbs can also be present and do not exclude the diagnosis.⁸ The proximal femoral focal deficiency syndrome may be associated with umbilical or inguinal hernias. If both femurs are affected, it is important to examine the face carefully, as the disorder may be bilateral femoral hypoplasia and unusual face syndrome,^{634,635} which consists of bilateral femoral hypoplasia and facial defects, including short nose with broad tip, long philtrum, micrognathia, and cleft palate. Long bone abnormalities can extend to other segments of the lower extremities (absent fibula) and to the upper extremities. The syndrome is sporadic and has been associated with maternal diabetes mellitus. A familial form has been described. The diagnosis has been made *in utero*.^{635–639}

If the defect is unilateral, it may correspond to the femur–fibula–ulna or femur–tibia–radius complex. These two syndromes have different implications for genetic counseling: the former is nonfamilial, whereas the latter has a strong genetic component.⁶⁴⁰

Split hand and foot deformities

The term “split hand and foot syndrome” is used to refer to a group of disorders characterized by splitting of the hand and

foot into two parts. Other terms include “lobster claw deformity,” “ectrodactyly,” and “aborted fingers.”^{582,641} The conditions are classified into typical and atypical varieties.⁶⁴² The typical form consists of absence of both the finger and metacarpal bone, resulting in a deep, V-shaped central defect that clearly divides the hand into ulnar and radial parts. It occurs in 1 per 90 000 live births and has a familial tendency (usually inherited with an autosomal dominant pattern).⁶⁴³ The atypical variety is characterized by a much wider cleft formed by a defect of the metacarpals and the middle fingers. As a consequence, the cleft is U-shaped and wide, with only thumb and small finger remaining. This occurs in 1 per 150 000 live births.⁶⁴⁴

A complex system for the classification of these disorders, based on the distribution of remaining fingers, has been proposed.⁶⁴⁵ However, this system is not helpful in differential diagnosis and syndrome classification. Split hand and foot deformities can occur as isolated anomalies or as part of a more complex syndrome. The syndromic types are more frequently encountered.

The split hand and foot and absent long bones syndromes include two conditions in which there is split hand and aplasia of the tibia or split foot with aplasia of the ulna. However, skeletal anomalies are not limited to these bones; the clavicle, femur, and fibula can also be affected. The pattern of inheritance of these disorders has not been clearly determined. Autosomal dominant, recessive, and X-linked recessive patterns have been proposed.⁶⁴⁶

The ectrodactyly–ectodermal dysplasia–cleft lip/palate syndrome is an autosomal dominant condition which generally involves the four extremities, with more severe deformities of the hands.^{647,648} The spectrum of ectodermal defects is wide, and includes hypopigmentation, dry skin, sparse hair, and dental defects.^{649–652} Tear duct anomalies and decreased lacrimal secretions lead to chronic keratoconjunctivitis and severe loss of visual acuity.^{653,654} The cleft lip is generally bilateral. Obstructive uropathy often occurs in this condition.⁶⁵⁵ Intelligence is generally normal.⁶⁵⁶

A different group of syndromes involves associations of the split hand and foot deformity with other anomalies. These entities include split foot and triphalangeal thumb, split foot and hand and central polydactyly, Karsch–Neugebauer syndrome (split hand and foot with congenital nystagmus), acrorenal syndrome, and mandibulofacial dysostosis (Fontaine syndrome).⁶⁵⁷

Clubhands

Clubhand deformities are classified into two main categories: radial and ulnar. Radial clubhand includes a wide spectrum of disorders that encompass absent thumb, thumb hypoplasia, thin first metacarpal, and absent radius (Table 26.26). Ulnar clubhand is much less frequent than radial clubhand and ranges from mild deviations of the hand on the ulnar side of

Table 26.26 Radial ray defects: a differential diagnosis of congenital deficiency of the radius and radial ray.*Isolated: nonsyndromic**Syndromes with blood dyscrasias*

Fanconi's anemia

Thrombocytopenia with absent radii syndrome

Aase syndrome: congenital anemia, nonopposable triphalangeal thumb, scaphoid and distal radius hypoplasia, radioulnar synostosis, short stature with narrow shoulders, autosomal recessive (see Diamond–Blackfan syndrome for a similar, perhaps identical, syndrome)

Syndromes with congenital heart disease

Holt–Oram syndrome

Lewis upper limb–cardiovascular syndrome: more extensive arm malformations and more complex heart anomalies than with Holt–Oram, but probably not a separate syndrome, autosomal dominant

Syndromes with craniofacial abnormalities

Nager acrofacial dysostosis

Radial clubhand and cleft lip and/or cleft palate: sporadic

Juberg–Hayward syndrome: cleft lip and palate, hypoplastic thumbs, short radius, radial head subluxation, autosomal recessive

Baller–Gerold syndrome: craniosynostosis, bilateral radial clubhand, absent/hypoplastic thumb, autosomal recessive

Rothmund–Thomson syndrome: prematurely aged skin changes, juvenile cataract, sparse gray hair, absent thumbs, radial clubhands, occasional knee dysplasia (see progeria syndromes)

Duane radial dysplasia syndrome: abnormal ocular movements, inability to abduct and eyeball retraction with adduction, radius and radial ray hypoplasia, vertebral anomalies, renal malformation, autosomal dominant (see Klippel–Feil variants)

IVIC syndrome (Instituto Venezolano de Investigaciones Científicas): radial ray deficiency, hypoplastic or absent thumbs and radial clubhands, impaired hearing, abnormal movements of extraocular muscles with strabismus, autosomal dominant

LARD syndrome (lacrimo-auriculo-radial-dental; Levy–Hollister): absent lacrimal structures, protuberant ears, thumb and radial ray hypoplasia, abnormal teeth, autosomal dominant

Radial defects with ear anomalies and cranial nerve VII dysfunction

Radial hypoplasia, triphalangeal thumb, hypospadias, diastema of maxillary central incisors, autosomal dominant

Syndromes with congenital scoliosis

The VATER association

Goldenhar syndrome (oculoauriculovertebral dysplasia)

Klippel–Feil syndrome

*Radial aplasia and chromosome aberrations**Syndromes with mental retardation*

Seckel syndrome (bird-headed dwarfism): microcephaly, beak-like protrusion of nose, mental retardation, absent/hypoplastic thumbs, bilateral dislocated hips

Thalidomide embryopathy (of historical interest, but some 60% had radial clubhand)

Reproduced with permission from ref. 551.

the forearm to complete absence of the ulna. Although radial clubhand is frequently syndromic, ulnar clubhand is usually an isolated anomaly. Table 26.27 shows conditions that present with ulnar ray defects.

Whenever a clubhand is identified, it is important to conduct a thorough examination of the fetus and newborn to delineate associated anomalies that may suggest a syndrome. Fetal blood sampling procedures and fetal echocardiography are recommended. A complete blood cell count, including platelets, is important to establish the diagnoses of Fanconi's pancytopenia, TAR syndrome, and Aase syndrome. A fetal karyotype is indicated because several chromosomal

abnormalities (e.g., trisomy 18, trisomy 21, and other structural aberrations) have been reported in association with clubhand deformities. Congenital heart disease is an important feature of the Holt–Oram syndrome, of the Lewis upper limb–cardiovascular syndrome, and of some cases of TAR syndrome.

Radial clubhand

The term “isolated radial clubhand” indicates that the clubhand is not part of a recognized syndrome.^{658,659} However, this does not exclude the possibility that other anomalies may be

Table 26.27 Ulnar ray defects: a differential diagnosis of congenital deficiency of the ulna and ulnar ray.*Isolated: nonsyndromic absent ulna**Ulna hypoplasia and skeletal deficiency elsewhere*

Ulna aplasia with lobster claw deformity of hand and/or foot, autosomal dominant

Femur–fibula–ulna complex

Syndromes with ulna deficiency

Cornelia de Lange syndrome

Miller syndrome (postaxial acrofacial dysostosis): absent ulna and ulnar rays and absent fourth and fifth toes; Treacher–Collins mandibulofacial hypoplasia, autosomal recessive, distinguish from Nagai preaxial acrofacial dysostosis

Pallister ulnar–mammary syndrome: hypoplasia of ulna and ulnar rays, hypoplasia of the breast and absence of apocrine sweat glands, autosomal dominant

Pillay syndrome (ophthalmomandibulomelic dysplasia): absent distal third of ulna, absent olecranon, hypoplastic trochlea and proximal radius, fusion of interphalangeal joints in ulnar fingers, knee dysplasia, corneal opacities, fusion of temporomandibular joint, autosomal dominant

Weyers' oligodactyly syndrome: deficiency of ulna and ulnar rays, antecubital webbing, short sternum, malformed kidney and spleen, cleft lip and palate, sporadic

Schnitzel syndrome: absent/hypoplastic fourth, fifth metacarpals and phalanges, hypogenitalism, anal atresia, autosomal dominant

Mesomelic dwarfism, Reinhardt–Pfeiffer type (ulno–fibula dysplasia): a generalized bone dysplasia but with a disproportionate hypoplasia of the ulna and fibula, autosomal dominant

Mesomelic dwarfism, Langer's type: a generalized bone dysplasia, but with aplasia of the distal ulna and proximal fibula and hypoplasia of the mandible

Reproduced with permission from ref. 551.

present (e.g., scoliosis, congenital heart disease). Isolated nonsyndromic radial clubhand is generally a sporadic disorder.^{659–662}

Radial clubhand may be part of the three syndromes characterized by hematologic abnormalities: Fanconi's pancytopenia, TAR syndrome, and Aase syndrome.

Fanconi's anemia

Fanconi's anemia (pancytopenia) is an autosomal recessive disease characterized by the association of bone marrow failure (anemia, leukopenia, and thrombocytopenia)⁶⁶³ and skeletal anomalies, including a radial clubhand with absent thumbs, radial hypoplasia, and a high frequency of chromosomal instability (demonstrated in amniotic fluid cells or fetal lymphocytes as a high frequency of chromosomal breakage after incubation with diepoxybutane).^{664–667} Approximately 25% of affected individuals do not have limb reduction anomalies. Associated findings include microcephaly, congenital

dislocation of the hip, scoliosis, and cardiac/pulmonary/gastrointestinal anomalies.^{668–670} Intrauterine growth restriction is common. Up to 25% of patients with this condition will show some degree of mental deficiency. It is assumed that the basic defect is related to the ability to repair DNA damage, in particular that of so-called DNA crosslinks. At present, at least 11 complementation groups have been defined in Fanconi's anemia (A, B, C, D1/BRCA2, D2, E, F, G, I, J, and L)⁶⁷¹ and eight associated genes have been identified: *FANCA*, *FANCC*, *FANCD2*, *FANCE*, *FANCF*, *FANCG/XRCC9*, *FANCL*, and *FANCD1 (BRCA2)*.^{672–679} About 200 mutations have been described and, among these, mutations in the gene for complementation group FA-A (*FANCA*) account for approximately 65% of the cases.⁶⁷¹ Prenatal diagnosis has been reported many times.^{639,680–688} Molecular genetic testing is currently available for mutation analysis of the common Ashkenazi Jewish *FANCC* mutation and sequence analysis for *FANCA*, *FANCC*, *FANCF*, and *FANCG*.⁶⁸⁹

Thrombocytopenia with absent radius (TAR syndrome)

TAR syndrome is an autosomal recessive disorder characterized by thrombocytopenia (platelet count of less than 100 000/mm³) and bilateral absence of the radius.^{690–694} The thumb and metacarpals are always present. The ulna and humerus may be absent, and clubfoot deformities may be present. Congenital heart disease is present in 33% of the cases (e.g., tetralogy of Fallot and septal defects). Delivery by Cesarean section is recommended, as these fetuses are at risk for intracranial hemorrhage.^{695,696} TAR has been successfully diagnosed *in utero* many times.^{695–708}

Aase syndrome

Aase syndrome is an autosomal recessive condition characterized by congenital hypoplastic anemia and a radial clubhand with bilateral triphalangeal thumb and a hypoplastic distal radius.^{709–712} Cardiac defects (ventricular septal defects, coarctation of the aorta) may be present.⁷¹³ Triphalangeal thumbs are a feature of several bone dysostoses and malformation syndromes. They may also occur in random association with other defects, and as isolated, often familial, anomalies.⁷¹⁴ The differential diagnoses of this condition include Holt–Oram syndrome, Diamond–Blackfan syndrome,^{715,716} chromosomal abnormalities, and the fetal hydantoin syndrome.

Holt–Oram syndrome

Holt–Oram syndrome is an autosomal dominant disorder characterized by congenital heart disease (mainly atrial septal defects, secundum type, and ventricular septal defects),^{715,717–720} aplasia or hypoplasia of the radius, and triphalangeal or absent thumbs.^{721,722} Limb defects are often asymmetric, with the left side being more affected than the right side. There is no correlation between the severity of the limb defects and the cardiac anomaly.^{723,724} Indeed, some individuals only have a skeletal anomaly.⁷²⁴ Other findings include hypertelorism, chest wall, and vertebral anomalies.^{725–728} This

condition has been diagnosed prenatally by two- and three-dimensional ultrasonography.^{725,729–732} Holt–Oram syndrome is caused by mutations in the *TBX5* gene,^{733,734} and pre-implantation diagnosis of this condition has been reported recently.⁷³⁵ The upper limb–cardiovascular syndrome described by Lewis and colleagues⁷³⁶ is probably not a separate entity from the Holt–Oram syndrome.

Radial clubhand and scoliosis

Radial clubhand is also associated with congenital scoliosis. The three syndromes that should be considered part of the differential diagnosis include VATER association, some cases of Goldenhar syndrome, and Klippel–Feil syndrome.⁷³⁷

VATER association

The VATER association is the result of defective mesodermal development during embryogenesis before the 35th day of gestation.^{738–741} The typical findings are vertebral segmentation defects (70%), anal atresia (80%), tracheoesophageal fistula (70%), esophageal atresia, and radial and renal defects (65% and 53% respectively).^{742,743} Other anomalies include a single umbilical artery (35%) and congenital heart disease, occurring in nearly 50% of the patients.^{744–749} The VATER association occurs sporadically, although recurrence within a sibship has been reported.⁷⁴⁷ Prenatal diagnosis using sonography has been reported.^{46,749–759}

Goldenhar syndrome

Goldenhar syndrome is characterized by hemifacial microsomia, vertebral anomalies, and radial defects.^{760–764} Alterations in the morphogenesis of the first and second brachial arches result in hypoplasia of the malar/maxillary/mandibular regions, microtia, and ocular/oropharyngeal anomalies.^{764–769} Prenatal diagnosis has been reported.^{765,770–773}

Klippel–Feil syndrome

The Klippel–Feil syndrome is characterized by fusion of any two of the cervical vertebrae, resulting in a short neck, a low posterior hairline, and restricted mobility of the upper spine. Several associated anomalies may be present, including spina bifida, cleft palate, rib abnormalities, lung disorders, congenital heart disease, and limb anomalies.⁷⁷⁴ Prenatal diagnosis of this condition has not been reported.

Other conditions associated with radial clubhand

Radial clubhand has been reported in association with several chromosomal anomalies, including trisomies 18 and 21, deletion of the long arm of 13, and ring formation of chromosome 4.^{667,775,776}

Some disorders present with craniofacial abnormalities and radial clubhand deformities. These conditions are sporadic and have common features that make a prenatal differential diagnosis difficult. The most common craniofacial anomaly is cleft lip and palate. Uuspaa's study⁷⁷⁷ of 3225 cases with oro-

facial cleft showed a 2.8% association with upper extremity deformities.

Ulnar clubhand occurs as an isolated, nonsyndromic anomaly in most cases. It can also be associated with a variety of syndromes (e.g., Poland complex) (Table 26.27).⁷⁷⁸

Polydactyly

Polydactyly is the presence of an additional digit (Fig. 26.19).^{779,780} The extra digit may range from a fleshy nubbin to a complete digit with controlled flexion and extension (Figs 26.29 and 26.30). Polydactyly can be classified as postaxial (the most common form), preaxial, or central (Table 26.16). Postaxial polydactyly occurs on the ulnar side of the hand and fibular side of the foot.^{781–783} Preaxial polydactyly is present on the radial side of the hand and the tibial side of the foot (Fig. 26.31).⁷⁸⁴ Central polydactyly consists of an extra digit that is usually hidden between the long and the ring finger.^{785–787}

The majority of cases of polydactyly are isolated and inherited as an autosomal dominant trait. The preaxial type, especially a triphalangeal thumb, is most likely to be part of a syndrome. Central polydactyly is often bilateral and may be associated with other hand and foot malformations.^{785–787}

Arthrogryposis

The term “arthrogryposis multiplex congenita” (AMC) refers to multiple joint contractures present at birth in an intact skeleton.^{788–790} Normal fetal movement between 7 and 8 weeks of gestation onward is important for the development of the joints; limitation of the fetal joint motion leads to the development of contractures and AMC.^{791,792} This has been confirmed in animal models,⁷⁹³ for example chick and rat

Figure 26.30 Sonographic image of the hand shown in Fig. 26.29. Note the abnormal angulation of the extra digit on the ulnar side of the forearm.

Figure 26.31 Unusual facies–femoral hypoplasia syndrome. Note the absence of the left femur and only a tiny portion of ossified bone on the right side. There is partial fusion of the tibia and fibula. Of interest is the presence of preaxial polydactyly in both feet.

embryos, using tubocurarine and botulism toxins,^{794,795} inducing viral myopathy by coxsackie A viruses⁷⁹⁶ and cross-section of the spinal cord.⁷⁹⁷ Therefore, AMC is a syndrome, not a specific disorder. The incidences of the different underlying causes of AMC are variable in the literature. Neurological, muscular, connective tissue, or skeletal abnormalities or intrauterine crowding can lead to impaired fetal motion and AMC.^{791,792} Table 26.28 shows motor systems that can lead to AMC. In a series of 74 children, Banker⁷⁹⁸ found that the most common cause of AMC was a neurogenic disorder, followed by myopathic disorders. Swinyard and Bleck⁷⁹⁹ reported CNS disorders as a cause in 75% and muscle disorders in 10–15%, based on autopsies of 75 cases of fetuses and newborns. Quinn and colleagues⁸⁰⁰ reported that only 5 out of 21 cases of lethal AMC were of neurogenic cause, 11 were myogenic, and five were of uncertain pathology. The condition is present in 0.03% of live births.^{801,802} The etiology of AMC may derive from hereditary conditions,^{803–810} infectious agents, drugs, toxins, and fetal alcohol syndrome.^{791,792,811} Maternal hyperthermia has also been associated with AMC.⁸¹² Maternal antibodies specific for a fetal acetylcholine receptor have been reported to

Figure 26.32 Arthrogryposis multiplex congenita. There is flexion of the upper limbs with hyperextension of the lower limbs.

cause fetal AMC without evidence of maternal myasthenia gravis.^{813,814} In addition, plasma from human mothers of fetuses with AMC, when injected into pregnant mice, causes deformities in the offspring.⁸¹⁵ The pattern of inheritance depends on the specific cause of AMC.⁸¹⁶ In a series of 350 cases, Hall⁸¹⁷ found that 46% of cases corresponded to a syndrome with no recurrence risk, 23% corresponded to disorders inherited with a mendelian pattern (autosomal dominant, recessive, or X linked), 20% were unknown conditions, 6% were associated with environmental disorders, 3% were chromosomal, and 2% were multifactorial in origin.

The recurrence risk varies depending on the underlying cause. Hall and Reed⁸¹¹ found that in 20% of 350 patients no diagnosis was made. They concluded that, in this situation, the risk for recurrence is 4.7% if the limbs only were affected, 7% if the CNS was involved, and 1.4% if the limbs and another area were involved.

The deformities are usually symmetric. In most cases of AMC, all four limbs are involved (Fig. 26.32), followed by deformities of the lower extremities only, or bilimelic involvement. The severity of the deformities increases distally in the

Disorders of brain development (e.g., porencephaly or brain disease)
Congenital encephalopathy

involved limb, with the hands and feet typically being the most deformed.

Many congenital anomalies are associated with AMC. The most frequent are cleft palate, Klippel–Feil syndrome, meningocele, and congenital heart disease. In total, 10% of patients with AMC have associated anomalies of the central nervous system.⁷⁸⁹

The prenatal diagnosis of AMC with ultrasound has been reported.^{818–831} The cardinal findings are absent fetal movement on real-time examination and severe flexion deformities.⁸²¹ Four-dimensional ultrasonography may help in better characterization of the phenotype prenatally.⁸³²

The prognosis of AMC depends on the specific cause. Although some cases are uniformly lethal, others are associated with mild to moderate handicap. Fahy and Hall,⁸³³ in a retrospective study, included 828 cases of AMC and found that polyhydramnios is a poor prognostic sign.

Key points

- 1 Skeletal dysplasias are a heterogeneous group of disorders with an estimated prevalence of 1.1 to 9.5 per 10 000 births; the highest prevalence was reported in a greatly inbred population.
- 2 The most common skeletal dysplasias are achondroplasia, thanatophoric dysplasia, osteogenesis imperfecta type II, and achondrogenesis.
- 3 Despite the tremendous advances in the understanding of genetic causes and molecular mechanisms involved in skeletal dysplasias, approximately only one-third have had the molecular basis elucidated.
- 4 The role of diagnostic imaging in the prenatal investigation of skeletal dysplasias is (1) to narrow the differential diagnosis so that appropriate confirmatory molecular tests can be offered, (2) to predict lethality, and (3) to identify the fetus with a skeletal dysplasia early enough in pregnancy so that the diagnostic workup can be completed before the limit of fetal viability.
- 5 Three-dimensional reconstruction of the fetal bones is best performed using the maximum intensity mode (skeletal mode).
- 6 Panoramic images of the fetal skeleton without superimposition of maternal structures can be obtained by three-dimensional helical computed tomography.
- 7 No parameter has yet been identified to detect pulmonary hypoplasia with 100% sensitivity and specificity. Measurements of the right lung diameter and the ratio between the right lung diameter and the circumference of the bony thorax are easy to perform and have demonstrated good accuracy in the detection of pulmonary hypoplasia in preliminary studies. The role of three-dimensional ultrasound and MRI for the prediction of pulmonary hypoplasia remains to be determined.
- 8 Achondroplasia may not be diagnosed until the third trimester, as long bone shortening may not manifest until later in pregnancy.
- 9 Achondroplasia, hypochondroplasia, and thanatophoric dysplasia are caused by mutations in the *FGFR3* gene. Molecular diagnosis is possible.
- 10 The main differential findings between thanatophoric dysplasia types I and II are as follows: type I has typical bowed “telephone receiver” femur and no cloverleaf skull, whereas in type II cloverleaf skull is present and the long bones are straight.
- 11 The three most common mutations in the *FGFR3* gene in thanatophoric dysplasia type I are R248C, Y373C, and S249C.
- 12 The most common mutation in the *FGFR3* gene in thanatophoric dysplasia type II is K650E.
- 13 A peer-reviewed source with continuously updated information regarding availability of molecular diagnosis for skeletal dysplasias and contact

information for laboratories offering testing is available at the website of GeneTests (<http://www.genetests.org>).

- 14 The main differential diagnoses for thanatophoric dysplasia are fibrochondrogenesis and atelosteogenesis. Metaphyseal flaring is a feature of fibrochondrogenesis but not of thanatophoric dysplasia, and the molecular basis of fibrochondrogenesis is unknown. Coronal and sagittal vertebral clefts are a feature of atelosteogenesis.
- 15 In achondrogenesis, the spine is usually unossified or poorly ossified. Long bones are extremely short and the head is relatively large.
- 16 A hallmark of diastrophic dysplasia is the “hitchhiker thumb.”
- 17 Anarchic ossification of the spine is observed in dyssegmental dysplasia.
- 18 Bowing of the long bones and hypoplastic scapulae are features of campomelic dysplasia. In this disorder, 75% of the affected infants with a male karyotype have female or ambiguous genitalia.
- 19 Short rib–polydactyly syndromes are characterized by micromelia, constricted thorax, and polydactyly.
- 20 In cases of congenital amputation, limb deficiencies of the upper extremity are generally isolated, whereas limb deficiencies involving the lower extremity, bilateral amputations, or reduction of all limbs generally occur in the context of a syndrome.
- 21 In unilateral femoral hypoplasia, consider the diagnosis of proximal femoral focal deficiency syndrome. In bilateral femoral hypoplasia, examine the face carefully and consider the possibility of femoral hypoplasia with unusual facies syndrome.
- 22 The differential diagnosis of radial clubhands includes Fanconi’s anemia, thrombocytopenia with absent radius syndrome, Aase syndrome, and Holt–Oram syndrome.
- 23 In cases of radial clubhands associated with scoliosis, consider VATER association, Goldenhar syndrome and Klippel–Feil syndrome as differential diagnoses.
