There are some cases in which the spinal fluid examination is not diagnostic. In these women, bacteria are not present in the fluid, and the glucose level is not reduced. There are a number of possible pathogens. One differential diagnosis is a viral meningitis such as coxsackievirus B₂. Viral cultures should be done on the cerebrospinal fluid and antibiotics discontinued if the study results of the fluid are positive for a virus.

If a brain abscess is found on imaging studies of a woman with central nervous system symptoms, the HIV antibody status of the patient should be investigated if it is not known, and *Toxoplasma gondii* should be suspected.⁸⁵ The treatment is spiramycin and TMP-SMX or clindamycin.

In endemic areas, cryptococcal meningitis should be considered. The diagnosis should be suspected if encapsulated organisms are present on an India ink preparation and confirmed by culture. The treatment of choice is amphotericin given intravenously.⁸⁶

Bacterial endocarditis

Bacterial endocarditis is another rare, but serious infection for a pregnant woman. In 1983, Pastorek et al.⁸⁷ reported three cases and estimated an incidence of 1 in 4000 deliveries. In 1988, Cox et al.⁸⁸ reported seven cases, of whom four were

from their clinic population, with an incidence of 1 in 16 500 deliveries. Both these reports stress the increasing frequency of this disease in urban pregnant women with an increasing number of intravenous drug abusers.

The starting point in the care of these patients is prevention. There are no prospective clinical studies to demonstrate the effectiveness of antibiotic prophylaxis.⁸⁹ Observations indicate that endocarditis follows bacteremia, and the bacteria that cause endocarditis are usually susceptible to antibiotics. Making a decision about prophylaxis usually involves two considerations. The first is the risk of infective endocarditis associated with pre-existing cardiac disorders. For the obstetrician, the largest single category of patients for consideration is those with mitral valve prolapse without regurgitation, a low-risk population, but the risk is not zero. The second consideration is the procedure. While bacteremia can occur in 1–5% of women during uncomplicated delivery, most medical authorities recommend prophylaxis only for vaginal delivery complicated by infection.^{90,91}

The American Heart Association (AHA) issued revised guidelines for antibiotic prophylaxis of bacterial endocarditis in 1997.⁹² These guidelines stratify cardiac conditions into high-, moderate-, and negligible-risk categories according to the potential outcome if endocarditis occurs. Endocarditis prophylaxis is recommended for the high- and moderate-risk groups. In the high-risk group are those with: (1) prosthetic cardiac valves (bioprosthetic and homograft); (2) previous bacterial endocarditis; (3) complex cyanotic congenital heart disease (e.g., transposition of the great vessels, tetralogy of Fallot); and (4) surgically constructed systemic pulmonary shunts or conduits. The moderate-risk category includes: (1) most other congenital cardiac malformations; (2) acquired valvar dysfunction (e.g., rheumatic heart disease); (3) hypertrophic cardiomyopathy; and (4) mitral valve prolapse with valvar regurgitation or thickened leaflets. Endocarditis prophylaxis is not recommended for the negligible-risk group which includes: (1) isolated secundum atrial septal defect; (2) surgical repair of atrial septal defect, ventricular septal defect or patent ductus arteriosus; (3) previous coronary bypass surgery; (4) mitral valve prolapse without valvar regurgitation; (5) physiologic, functional, or innocent heart murmurs; (6) previous Kawasaki disease without valvar dysfunction; (7) previous rheumatic fever without valvar dysfunction; and (8) cardiac pacemakers (intravascular and epicardial) and implanted defibrillators.

Mitral valve prolapse is the most common cardiac abnormality seen in obstetric and gynecologic patients. The AHA guidelines provide for a clinical approach to determining the need for bacterial endocarditis prophylaxis.⁹² If there is a murmur of mitral regurgitation, prophylaxis is recommended. In instances in which the presence or absence of mitral regurgitation is not determined or unknown, and if confirmation is not available, prophylaxis is indicated when an immediate need for the procedure exists. In nonemergency situations, referral to a cardiologist for echocardiography and/or Doppler

flow studies should be done for evaluation and determination of the need for prophylaxis.

For obstetric or gynecologic procedures, the AHA recommends that women undergoing cystoscopy or urethral dilation receive endocarditis prophylaxis.⁹² Prophylaxis is not recommended for vaginal delivery, Cesarean section, vaginal hysterectomy, or procedures involving uninfected tissues including: (1) urethral catheterization; (2) dilation and curettage (D&C); (3) therapeutic abortions; (4) sterilization procedures; and (5) insertion or removal of intrauterine devices (IUDs).⁹² However, the AHA notes that, for high-risk women undergoing vaginal delivery or Cesarean section, prophylaxis is optional. Obviously, for patients with infected intrauterine tissue undergoing D&C or for removal of an IUD in the presence of pelvic inflammatory disease (PID), prophylaxis is indicated.

Endocarditis prophylaxis for obstetric and gynecologic procedures is primarily directed against enterococci (e.g., *Streptococcus faecalis*). While Gram-negative bacteria are commonly the cause of bacteremia in obstetric and gynecologic patients, they rarely cause endocarditis. According to the AHA recommendations, high-risk patients should receive ampicillin plus gentamicin as follows: ampicillin 2 g i.m. or i.v. plus gentamicin 1.5 mg/kg within 30 min of starting the procedure; 6 h later, ampicillin 1 g i.m. or i.v. or amoxicillin 1 g orally. High-risk patients allergic to ampicillin should receive vancomycin plus gentamicin with vancomycin given 1.0 g i.v. over 1–2 h within 30 min of the procedure. Moderate-risk patients should be prophylaxed with amoxicillin or ampicillin with amoxicillin 2.0 g orally 1 h prior to the procedure or ampicillin 50 mg/kg i.m. or i.v. within 30 min of the procedure. For those allergic to ampicillin, vancomycin 1.0 g i.v. over 1–2 h with infusion complete within 30 min of the procedure is recommended.

The population of pregnant women who develop bacterial endocarditis is different than it was in the past. Formerly, we focused on women with rheumatic or congenital heart disease. Now, our concerns have to include women with mitral valve prolapse and those patients who are intravenous drug users. Although rarely seen, bacterial endocarditis is life-threatening; maternal death has been reported in pregnant women with this infection.⁸⁷ This is a difficult diagnosis for the obstetrician. It is an uncommon disease, and the clinical and laboratory findings are subtle. It should be suspected in a febrile patient who is lethargic with no localizing signs of infection. There are clues that bacterial endocarditis could be the problem. The patient should be questioned and examined for evidence of intravenous drug abuse. Cutaneous manifestations can be seen, particularly splinter hemorrhages under the fingernails or nontender purpuric spots on the heels or palms. A diagnostic sign of significance is a new or changing heart murmur. A number of tests should be employed to confirm the diagnosis. At least three blood cultures should be drawn, 30–60 min apart. An electrocardiogram and an echocardiogram should be done to determine if there is any vegetation on any of the heart valves.

The treatment of these women is much more intense than the usual antibacterial regimens in pregnancy. These are difficult infections to treat successfully. Cure requires eradication of all the organisms. The usual strategy involves the use of penicillins, cephalosporins, or vancomycin intravenously for 2–6 weeks. The length of time of treatment depends on the susceptibility of the bacteria. The addition of aminoglycosides produces synergistic killing of streptococci, particularly the enterococci. Women with bacterial endocarditis are at risk of preterm labor and the delivery of a premature infant.⁹⁰ In addition to the focus on the mother, careful monitoring of uterine activity and fetal well-being is important in this population.

Antepartum mastitis

In contrast to postpartum mastitis, antepartum mastitis is a rare event. Reports of this entity appear as case reports.⁹³ Because it is so rare, it is difficult to identify predisposing factors, although many of these women have skin disorders in which the skin surface is not intact. When mastitis occurs, cultures should be obtained. The initial choice of antibiotics is empirical, but a cephalosporin is a good starting point. Susceptibility studies can dictate changes. The formation of an abscess requires operative drainage.

Gastrointestinal infections

Gastrointestinal infections in a pregnant woman present in many forms. Physicians can be asked to evaluate chronic cases, for example a persistent diarrhea, or, at the other end of the spectrum, a woman with an acute life-threatening emergency, such as a ruptured appendix.

Appendicitis

Acute appendicitis is an illustration of how pregnancy can modify the clinical manifestations of intra-abdominal disease. The large uterus, hormonal changes, and immunologic suppression change patient symptomatology. For example, a pregnant patient with appendicitis usually presents with no fever, no leukocytosis, and right midquadrant pain, instead of right lower quadrant pain.⁹⁴ New imaging techniques such as a CT scan are not applicable to the pregnant patient. Based on clinical acumen and imaging findings, an operative exploration should be carried out if appendicitis is suspected. It is far better to explore a few patients with inconclusive signs and subsequently discover a ruptured appendix. If intraperitoneal rupture does occur, these women are at high risk of premature labor and delivery.

Cholecystitis

Acute cholecystitis is another gastrointestinal problem sometimes seen in pregnant women. It should be suspected in the

patient with nausea, vomiting, and right upper quadrant pain. New imaging techniques (e.g., ultrasound) without radiation can be used to detect the presence of stones in the gallbladder or the collecting ducts.

Infections of the liver

Hepatitis is an infection caused by a broad range of microbiological agents that can cause morbidity for both the mother and the fetus. Except for hepatitis E, viral hepatitis does not occur with more frequency or severity during pregnancy.^{95,96} Physicians associate hepatitis with the various hepatitis viruses, but this condition has been seen with other viruses and bacteria. The underlying health of the pregnant woman influences maternal morbidity.

Hepatitis A is a significant infectious disease that occurs worldwide. Transmission of the virus is usually by the fecal–oral route. It is unique among the hepatitis viruses because the infection resolves without a carrier state. The impact of this disease on pregnant women varies. In the United States, no increase in maternal mortality with hepatitis A has been noted,⁹⁵ whereas in the Third World countries, an increase in maternal death rate has been documented. Prevention is now possible with the development of an inactivated virus vaccine. The selection of pregnant patients for the administration of the vaccine is limited to high-risk groups as previously described.

Hepatitis B is a serious medical problem for pregnant women. It is still a common disease in the United States. It can cause serious maternal morbidity, although maternal mortality is rarely seen. Approximately 5% of women become chronic carriers of the virus and, in turn, have the capability of infecting their newborn with this virus. This risk applies to women infected with the virus before they become pregnant. As mentioned earlier in this chapter, prevention is the starting point of care. The hepatitis B vaccine is available and should be made available to pregnant women. Because this is not a live virus vaccine, it can be administered during pregnancy.

Obstetricians have become cognizant of hepatitis C. In 1989, the genome of the hepatitis C virus⁹⁷ was cloned, and tests were developed for antibodies against this agent. Subsequent studies have demonstrated that 88–90% of posttransfusion nonA, nonB hepatitis is due to hepatitis C.⁹⁸ The acute hepatitis C infection poses few problems for the obstetrician, for it is usually a subclinical infection. In prospective studies, only 20–30% of the patients have symptoms, and only half of this symptomatic group develop jaundice.⁹⁹ There are exceptions. Fulminant hepatitis secondary to hepatitis C virus infection can occur in pregnancy.¹⁰⁰ In these seriously ill women, hepatitis A, B, and C antibody testing should be done to determine the etiology. Supportive medical care should be offered until the symptoms of hepatitis resolve. The main problem with hepatitis C virus is that chronic infection results in a majority of cases, with progressive chronic liver disease leading to hepatocellular carcinoma.¹⁰⁰ Clearly, prevention is

the preferred approach to this problem. Blood is the most important source of spread. Although transfusion-associated hepatitis C still occurs, its incidence has been dramatically reduced through the screening of blood for hepatitis C virus antibody.¹⁰¹ Intravenous drug abusers remain at risk. Although the risk of sexual transmission of hepatitis C virus is small, there is evidence that it occurs,¹⁰² as does mother-to-child vertical transmission,¹⁰³ particularly among women co-infected with HIV. Each of these modes of transmission is less than with hepatitis B. For prevention, condoms can be suggested.

Hepatitis D infection is sometimes a concern among patients who are positive for hepatitis B antigen. When this occurs, the acute infection resembles uncomplicated hepatitis B. In fewer than 15% of these cases, the disease may be severe, and fatalities have been reported.¹⁰⁴ Treatment is supportive.

Other hepatitis viruses have been identified, and more will be known to us in the future. Outside of hepatitis A, B, C, and D, hepatitis due to hepatitis E virus is more dangerous in pregnant women, with a reported mortality rate of 15–20%. To date, this disease has been reported in India, Africa, and the Middle East.^{105,106}

Hepatitis can be caused by other viruses, notably herpes simplex virus (HSV), CMV, Epstein–Barr virus, and coxsackie B virus. HSV hepatitis is uncommon, with fewer than 20 cases reported in the literature,^{107,108} but it is a serious disease with a maternal mortality rate of close to 50%.¹⁰⁷ This is a difficult disease to diagnose, because of its rarity, but it should be included in the differential diagnosis of a patient with hepatic dysfunction in the third trimester.¹⁰⁸ The physician's suspicions should be aroused by the patient presenting with onset of disease in the third trimester, a prodromal illness, vulvar or pharyngeal vesicular lesions, and an anicteric presentation. It is important to confirm the diagnosis by liver biopsy¹⁰⁸ and begin treatment with acyclovir. This significantly reduces maternal mortality.¹⁰⁷ Hepatitis due to CMV, Epstein–Barr virus, and coxsackievirus can be suspected when other causes of hepatitis cannot be confirmed. Liver biopsy and culture help to confirm the diagnosis.

Occasionally, a pregnant woman will be seen with a liver abscess secondary to *Entamoeba histolytica* (amebiasis). They usually present with a sudden onset with right upper quadrant pain and a fever. Ultrasound confirms the diagnosis. These abscesses respond to medical treatment with metronidazole. This avoids intraperitoneal rupture and usually results in a cure.

Peritonitis

Primary bacterial peritonitis is a rare but life-threatening condition in pregnant women. In nonpregnant women, such problems are usually secondary to bacteremia with Gram-positive aerobic cocci, such as group A β -hemolytic streptococci or pneumococci. In pregnant women, it has been associated with underlying disease or acute salpingitis.^{109,110} The diagnosis should be considered in any pregnant woman with fever

and abdominal tenderness. If more common entities such as chorioamnionitis and appendicitis have been ruled out and if the patient has evidence of liver disease, primary peritonitis should be considered as a diagnosis. Paracentesis and microscopic examination of peritoneal fluid should confirm this diagnosis, and the treatment should be with systemic antibiotics. Some of these women are critically ill and should be monitored closely for evidence of premature labor.

Diarrhea

Diarrhea is seen with some frequency in any large obstetric practice. Fortunately, it is usually self-limited and without complications. When it is explosive in nature or persists beyond 24h, the associated dehydration can be accompanied by premature labor. Close communication must be kept with these patients.

The diagnostic and therapeutic care of these patients requires a knowledge of the etiologies and pathophysiology of diarrheal disease. Table 50.4 provides an outline of the physician considerations when viewing these patients.¹¹¹

The obstetrician can adapt a wait and see approach to pregnant patients who have diarrhea. The patients should be advised to take adequate oral fluids, solid food as tolerated, and to limit the use of medications in the first 24h to nonabsorbed local medications such as loperamide (Kaopectate), which do not alter intestinal motility. Because most cases have a mild self-limited course, neither a stool culture nor treatment is necessary. Antimicrobial therapy should be based on antibiotic susceptibility studies. Antimotility drugs, such as loperamide, can be used to control moderate to severe diarrhea. In patients beyond the 12th week of pregnancy, without a contraindication to the use of salicylates, bismuth subsalicylate can be used. It is helpful for it has antimicrobial properties because of the bismuth and antisecretory properties of the salicylate moiety. Nearly all these women will be managed as out-

patients because it is rare in the United States to have a case so severe that admission is needed.

Women with chronic diarrhea need to be evaluated for ova and parasites, particularly *Giardia lamblia* and *E. histolytica*. These symptomatic women should be treated with quinacrine and metronidazole, respectively, after the 12th week of pregnancy.^{112,113} The influx of refugees from South-east Asia, the Caribbean, and Central America, plus immigrants from South America, has increased the pool of pregnant patients in the United States with intestinal parasites.^{112,113} In one evaluation of 97 South-east Asian refugees in Philadelphia, 65% were colonized with gastrointestinal parasites. The most common isolates in the study were hookworm, *Trichuris trichiura*, *Clonorchis sinensis*, *Ascaris lumbricoides*, *Strongyloides stercoralis*, *E. histolytica*, *G. lamblia*, *Endolimax nana*, *Taenia*, and *Plasmodium vivax*.¹¹² Despite the high infection rate, this population had uncomplicated pregnancy outcomes with the usual pregnancy care and treatment of symptomatic patients. Lee¹¹⁴ counsels therapeutic conservatism if obstetricians discover intestinal parasites in their pregnant patients. He suggests two major indications for therapy: gastrointestinal problems that persist and interfere with maternal health; and parasite-related extraintestinal abnormalities. A detailed description of treatment for parasitic diseases in pregnancy is reviewed in reference 112.

Malaria

Malaria is a serious infection in pregnant women. In endemic areas, peripartum infection increases the risk of perinatal death and low birthweight.^{112,115} Chloroquine prophylaxis protected against maternal and fetal malaria, low birthweight, and perinatal death, even in areas where chloroquine-resistant *Plasmodium falciparum* is endemic.¹¹⁵ Fortunately, this is a rare disease in the United States. In these days, when more people are involved in international travel, more cases will be seen by American physicians.

Lyme disease

Lyme disease is a new infection for obstetricians. It was first described in 1977 and given its name because of a clustering of children with suspected juvenile rheumatoid arthritis in Lyme, CT, USA.¹¹⁶ It is caused by a tick-borne spirochete, *Borrelia burgdorferi*, and is spread by the bite of infected ticks, including *Ixodes dammini*, or related ixodid ticks.¹¹⁷ It is a multisystem disorder that usually begins in the summer with a spreading skin eruption to be followed weeks to months later by cardiac, neurologic, or arthritic abnormalities. Unfortunately for the obstetrician, this is a transplacental infection that can result in intrauterine fetal death or impairment of cerebral function because of *in utero*-acquired central nervous system infection.^{118,119} Fortunately, this pathogen is susceptible to antibiotics so that cure can be achieved, particularly when an early diagnosis is made.

Table 50.4 Classification of diarrhea.

Toxicogenic diarrhea	Caused by <i>Vibrio cholerae</i> and toxigenic <i>Escherichia coli</i>
Invasive bacterial diarrhea	Caused by <i>Shigella</i> species, nontyphoidal <i>Salmonella</i> species, enterohemorrhagic <i>E. coli</i> , enteroinvasive <i>E. coli</i> , <i>Campylobacter jejuni</i> , <i>Vibrio parahaemolyticus</i> , <i>Yersinia enterocolitica</i> , noncholera vibrios
Viral diarrhea	Caused by rotavirus, caliciviruses, including the Norwalk virus, astrovirus, and enteric adenovirus
Parasitic diarrhea	Caused by <i>Giardia lamblia</i> , <i>Entamoeba histolytica</i> , <i>Cryptosporidium parvum</i> , <i>Cyclospora cayetanensis</i> , <i>Isospora belli</i> , and <i>Balantidium coli</i>

The diagnosis of Lyme disease depends on the obstetrician's clinical awareness, backed up by appropriate laboratory testing. In the United States, most of the cases to date have been clustered in three areas: the north-east, from Massachusetts to Maryland; the Midwest in Wisconsin and Minnesota; and the west in California and Oregon. Clinically, the disease begins as a red macule or papule at the site of the tick bite, and this lesion spreads. Concomitant with this, the patient complains of malaise, fatigue, headache, chills, and fever. This is not the flu to be dismissed by physician admonitions "to take fluids and acetaminophen, get to bed, and let nature take its course." These women need to be examined meticulously for skin lesions. Blood should be drawn for IgM antibodies. One study indicated that immunoblotting was superior to indirect enzyme-linked immunosorbent assay (ELISA) tests for diagnosing early Lyme disease.¹²⁰ Patients with Lyme disease do not have a positive regain test result for syphilis (e.g., a Venereal Disease Research Laboratory test), but they can crossreact with other treponemal tests and have a positive fluorescent treponemal antibody absorption test result.¹²¹ In non-pregnant women, the treatment of choice would seem to be tetracycline, which gives superior results to erythromycin, particularly in the prevention of the major late complications, myocarditis, meningitis, and arthritis.¹²² In pregnancy, phenoxymethyl penicillin would seem to be the drug of choice for early disease. For patients who are first diagnosed with late-onset arthritis, ceftriaxone seems to be the drug of choice because of its long half-life.¹²³

Other tick-borne diseases

There are a number of other tick-borne diseases seen in the United States. These are identified in Table 50.5.¹²⁴ Prevention is the approach of choice. Pregnant women should be advised to wear long-sleeved shirts, long pants, and closed-toe shoes in areas where tick exposure is likely. Walking on cleared trails away from bush vegetation is also helpful. If a tick bite occurs, an embedded tick should be removed by tweezers, with a slow steady pressure, perpendicular to the skin. If symptoms occur, the obstetrician should be consulted. Table 50.5 provides some general treatment guidelines. Tetracycline, frequently the drug of first choice, is not used in pregnant women.

HIV in pregnancy

A quarter of a century after first coming to national attention, the HIV epidemic has entered a phase that can be described in a paraphrase of the famous opening line of Dickens' *Tale of Two Cities*, "it is the best of times, it is the worst of times." This is particularly true of maternal-child issues. In the developed world, where access to the full array of antiviral therapies can be assured, the prognosis for infected individuals has improved dramatically, and the birth of an HIV-infected child has become a relative rarity. Unfortunately, the same cannot be said for those areas of the world where 95% of HIV-infected individuals reside. In those settings, where the epidemic continues to expand, most HIV-infected individuals are condemned to substandard care and a concomitant poor prognosis. However, great efforts are being expended to alter that trend, and there are success stories even in the developing world. Obstetricians in the United States, by dint of their ability to utilize the most effective therapies, have an obligation to keep abreast of this rapidly changing field in order to guarantee their patients the best prognosis and the greatest likelihood of giving birth to an uninfected child. In this section, we will briefly review the epidemiology and pathophysiology of HIV, but will focus on the clinical aspects of the disease in order to enable clinicians to provide state of the art care to their patients.

Epidemiology

According to United Nation statistics, close to 30 million people were alive with HIV infection in 2003. During that year, nearly five million new infections were recorded, and almost three million people died. Women now comprise about half of all HIV-infected individuals, and there are approximately 2000 new infections of children under the age of 15 years (the vast majority secondary to mother-to-child transmission) every day. These infections are not evenly dispersed across the globe. Over 95% of infections occur in sub-Saharan Africa. However, if recent projections prove correct, the bulk of new infections will be occurring in other parts of the world by the end of this decade. It is now predicted that India,

Table 50.5 Other tick-borne diseases in the USA.

Disease	Causative agent	Classification	Region	Treatment
Rocky Mountain spotted fever	<i>Rickettsia rickettsii</i>	Bacteria	South-east, West, south central	Chloramphenicol
Ehrlichiosis	<i>Ehrlichia chafeenis</i>	Bacteria	south central, south Atlantic	Chloramphenicol
Relapsing fever	<i>Borrelia</i> sp.	Bacteria	West	Erythromycin
Tularemia	<i>Francisella tularensis</i>	Bacteria	Arkansas, Missouri, Oklahoma	Gentamicin
Colorado tick fever	<i>Coltivirus</i> sp.	Virus	West	Supportive care
Babesiosis	<i>Babesia</i> sp.	Protozoa	North-east	Oral quinine plus clindamycin
Tick paralysis	Toxin	Neurotoxin	North-west, south	Removal of tick

Nigeria, China, Ethiopia, and Russia (in decreasing order of new infections) will have as many as 70 million infected individuals within 5 years.

Perhaps as important as these numbers are the opportunities that exist to alter the course of the epidemic. It has been projected that, if several preventive steps are taken, as many as 29 million infections (63% of all new infections) can be avoided by the year 2010.¹²⁵ These interventions include voluntary HIV counseling and testing in order to raise awareness of the need for risk reduction and to help to bring the disease into the open, behavioral interventions to build motivation and risk-reduction skills, treatment of sexually transmitted diseases to reduce the likelihood that unprotected sex will result in HIV transmission, antenatal antiretroviral regimens to decrease mother-to-child transmission (MTCT), and drug treatment and programs to distribute sterile needles and syringes to help prevent the spread of HIV among injecting drug users. It is estimated that preventive services currently reach only a small minority of people at risk in developing countries. Achieving the aforementioned preventive goals will require at least a fourfold increase in global spending to US\$4.8 billion in developing countries by 2005, and US\$5.85 billion by 2007. In contrast, total spending from all sources in 2002 on HIV prevention efforts in those countries was approximately US\$1.2 billion.

In the United States, the CDC estimates that 40 000 new HIV infections occur every year.¹²⁶ From the beginning of the epidemic in 1981 to 2000, an estimated 1.3–1.4 million Americans have been infected with HIV, and approximately one-third (450 000) of those have died. Despite declines in the number of new infections since the 1990s, the number of individuals alive with HIV infection is greater than ever before. It is further estimated that, as of 2000, between 850 000 and 950 000 people are alive with HIV. While the number of HIV-infected children born in the United States has dropped dramatically in the wake of new antiretroviral therapies and modifications in obstetrical practices (*vide infra*), challenges remain. As many as one in eight HIV-infected women do not receive prenatal care, and one in nine is not tested for HIV before giving birth.

Virology and pathophysiology

HIV-1 and HIV-2 are members of the lentivirus subfamily of Retroviridae and are single-stranded ribonucleic acid (RNA) enveloped viruses that have the ability to become incorporated into cellular deoxyribonucleic acid (DNA).¹²⁷ HIV preferentially infects cells with the CD4 antigen, particularly helper lymphocytes, but also macrophages, cells of the central nervous system and, according to some evidence, cells of the placenta.¹²⁸ At least two other cell-surface molecules help HIV to enter the cells. These coreceptors for HIV, called CXCR4 and CCR5, are receptors for chemokines.¹²⁹ It has also been reported that individuals who are homozygous for a 32-basepair deletion at the CCR5 gene are less likely to acquire

HIV, while those who are heterozygous for the deletion progress less rapidly if infected. Once the virus is internalized, its RNA is released from the nucleocapsid, and is reverse transcribed into proviral DNA. The provirus is inserted into the genome and then transcribed into RNA; the RNA is translated, and virions assemble and are extruded from the cell membrane by budding. The virus is composed of core (p18, p24, and p27) and surface (gp120 and gp41) proteins, genomic RNA, and the reverse transcriptase enzyme surrounded by a lipid bilayer envelope.

Untreated, HIV infection leads to progressive debilitation of the immune system, rendering infected individuals susceptible to opportunistic infections (e.g., *Pneumocystis carinii* pneumonia and central nervous system toxoplasmosis) and neoplasias (e.g., Kaposi's sarcoma) that rarely afflict patients with intact immune systems. For an HIV-infected patient with one of several specific opportunistic infections, neoplasia, dementia encephalopathy, or wasting syndrome, the diagnosis of acquired immunodeficiency syndrome (AIDS) is assigned. In 1993, the CDC changed the case definition to include all individuals with HIV infection whose CD4 counts drop below 200 CD4 lymphocytes/ μ L as well as HIV-infected individuals with advanced cervical cancer, pulmonary tuberculosis, and recurrent pneumonia.¹³⁰

At the time of initial infection, there is an immediate viremia of substantive proportions (up to a billion viral particles turned over per day) and an equally impressive immune response with similar levels of T-cell turnover.¹³¹ After the initial viremia, the level of virus returns to a "set point." The level of virus in the plasma at that time can provide an estimate of the probability that an individual, if left untreated, will develop AIDS within 5 years. Antibodies are usually detectable 1 month after infection and are almost always detectable within 3 months. Evidence of immune dysfunction may be followed by clinical conditions ranging from fever, weight loss, malaise, lymphadenopathy, and central nervous system dysfunction to infections such as herpes simplex virus or oral candidiasis. Studies of infected individuals have noted that, 5 years after infection was confirmed, up to 35% had progressed to AIDS.^{132,133} It should be noted that these statistics antedate the use of highly active antiretroviral therapy (HAART), which has been shown to have a significant effect on the course of HIV disease.

Management of the HIV-infected pregnant women

Appropriate management of HIV-infected pregnant women requires an understanding of testing, monitoring, and medical therapy. The last issue is the most complex and the most rapidly changing. In order to stay abreast of those changes, the International AIDS Society¹³⁴ and the Public Health Service¹³⁵ provide continuing updates, the latter on a website, to which the reader should refer as new drugs and protocols emerge. The Public Health Service ("AIDSinfo") website also

provides guidelines specifically for the care of pregnant women.

Testing

A great deal can now be offered to HIV-infected individuals. As will be detailed below, therapy is now available that can reliably reduce both disease progression and MTCT. All the available treatments work best when they are initiated before clinical disease or advanced immune compromise occurs. It is a bit disheartening to realize that many people still do not learn their serostatus until they have reached an advanced stage of illness. Similarly, while some MTCT can be prevented even when HIV infection is not diagnosed until labor, success rates are much higher if longer term therapy is employed. Thus, it is essential that obstetricians ascertain the serostatus of all their patients as early in pregnancy as possible. "Opt-in" testing is the most common testing strategy employed in the United States. It requires counseling and written consent. However, it is neither the most successful nor the currently recommended strategy for testing. In the antepartum setting, identification of infected women is best accomplished using a "routine" right-of-refusal approach and employing standard ELISA and Western blot technologies. The use of standard testing technologies provides among the most sensitive and specific testing algorithms available for any infection. The right-of-refusal ("opt-out") approach respects pregnant women's autonomy, but does not explicitly or implicitly either stigmatize women who are offered the test or dissuade women from being tested. The opt-out approach is associated with greater testing rates than the opt-in approach. Medical record surveys, laboratory data, and population-based surveys (1998–2001) report 85–98% HIV testing rates in surveyed areas using the opt-out approach, compared with testing rates ranging from 25% to 83% in surveyed areas using the opt-in approach.¹³⁶

Despite the implementation of routine testing protocols in prenatal settings, there will still be circumstances in which rapid testing will play an important role. It is estimated that 40–85% of infants infected with HIV are born to women whose HIV infection is unknown prior to delivery.¹³⁷ A number of studies have been published that demonstrate the ability of antiretroviral therapy, even when first introduced in the intrapartum or immediate neonatal period, to prevent some cases of pediatric HIV infection.¹³⁸ In the intrapartum period, the testing technology involves rapid testing. A rapid test is an HIV screening test with results available within hours. When selecting a rapid HIV test for use during labor and delivery, it is important to consider the accuracy of the test and the site (i.e., hospital laboratory versus point of care testing in labor and delivery) at which testing will be performed. Tests that require serum or plasma (e.g., Reveal) are more suitable for use in the laboratory, whereas tests that can be performed with whole blood (e.g., OraQuick, Uni-Gold) without specimen processing can be performed more easily in the labor and delivery unit.¹³⁹ Performance evaluations on

three United States Food and Drug Administration (FDA)-approved rapid HIV tests (OraQuick, Reveal, and Uni-Gold) indicate a sensitivity of 100%, 99.8%, and 100% [95% confidence interval (CI)], respectively, and a specificity of 99.9%, 99.1% (serum), and 99.7% (95% CI) respectively.¹⁴⁰ Despite the fact that rapid tests may be associated with more false-positive results than standard tests (particularly in low-prevalence communities), there are several steps that should be taken whenever a positive result is received. The patient should be informed that the preliminary screen suggests that she might be positive and her neonate might therefore be exposed so that a follow-up is being performed. Consent should be obtained to initiate therapy immediately for her and her neonate, and advice should be offered not to breastfeed. Finally, her pediatrician should be informed of her status.

Monitoring

The advent of HAART has made HIV, in many ways, a chronic illness similar to diabetes. Just as no clinician would think about managing a diabetic woman without ongoing assessments of their disease state and the impact of their therapy (e.g., monitoring of blood glucose levels), so no HIV specialist would be able to manage his/her patient without tracking their immune status, viral status, and viral resistance as appropriate. The first two measures let the provider know how far advanced the disease is and how rapidly it is progressing. The last test, used in circumstances in which there is evidence that treatment is not being met with complete success, can help the clinician to choose the best regimen to use in a variety of clinical circumstances.

During pregnancy, viral load status should be determined every month until the virus is no longer detectable. Viral load should drop by approximately 1–2 logs per month if effective therapy is being used. Once the virus is no longer detectable, testing can be performed every 3 months. The higher the viral load, the longer it will take to become undetectable. However, in all circumstances, the viral load should become undetectable within 6 months of starting therapy. The CD4 count can be used to decide when it is necessary to institute prophylaxis for opportunistic infections. No such medications are required if the CD4 count is higher than 200/ μ L. If such therapy is begun at a lower count, but the CD4 count rises back above 200/ μ L consequent to HAART, the prophylaxis can be discontinued once the count has remained over that threshold for 6 months.

Failure to achieve the "undetectable" benchmark often reflects the development of a resistant organism. The life cycle of HIV predisposes to mutations and, hence, resistance because of the combination of the rapid turnover of HIV (10^7 – 10^8 rounds of replication/day) and the high error rate of reverse transcriptase when replicating the nearly 10 000 nucleotides present in the HIV genome. When incompletely suppressive drug regimens are used, they provide the evolutionary pressure that selects those mutations that cause resistance to antiretroviral agents. The number of mutations

required to cause a clinically relevant effect varies with the agent in question. Thus, the rate at which resistance develops will depend on the number of mutations necessary to create a significant change in susceptibility.

While obstetricians have often used culture and sensitivity testing in order to choose appropriate antimicrobials, antiviral resistance testing can be a bit more complicated. However, as randomized trials have demonstrated that individuals assigned to study arms with access to resistance test results have a greater reduction in viral load after the initiation of salvage therapy, obstetricians should familiarize themselves with these tools.¹⁴¹ Currently, two types of testing are available, genotypic and phenotypic, each with distinct advantages and disadvantages.¹⁴²

Phenotypic testing is a measure of the activity of the virus under a particular set of conditions, whereas genotyping provides a molecular biologic snapshot of the viral structure. Phenotypic tests compare the ability of the virus to replicate in various concentrations of an antiretroviral drug with its ability to replicate in the absence of the drug.¹⁴³ Resistance is related to the ability of the virus to overcome treatments aimed at viral activities needed for replication, i.e., reverse transcription and at the protease gene. Genotypic testing seeks to detect mutations in the genes that encode reverse transcriptase and protease formation by the virus. These tests establish the nucleotide sequence (ergo the amino acid sequence) of the portion of the viral genome coding for reverse transcriptase and protease. Point mutations in the virus result in the substitution of amino acids in the proteins produced, i.e., reverse transcriptase or protease. The significance of these point mutations is determined by correlating specific mutations with phenotypic resistance, as measured by viral susceptibility assays and correlation with clinical response to therapy. Obstetricians should interpret and act upon the results from both types of tests in consultation with an expert in the field.

Certain limitations are present for both genotypic and phenotypic assays. As most HIV-infected individuals have several circulating viral quasiespecies, the assays may not detect resistant species that constitute 20% or less of the population. This issue may be especially important for evaluating resistance to drugs that a person took in the past but is no longer receiving, as wild-type virus, being fitter, may have overgrown the mutant strain in the interim. It also means that resistance testing is more useful for ruling out, than for ruling in, therapies to be utilized in a given patient. That is because the absence of resistance may merely reflect the re-emergence of the wild-type strain. In that circumstance, the assays will not detect the minority mutant strain. However, if the patient is re-exposed to the offending agent, the resistant strain may again attain dominance. Drug resistance testing is not advised for persons with viral load of < 1000 copies/mL, as amplification of the virus is unreliable.

There are several defined circumstances in which clinicians should utilize these tests. The most common indication for testing is treatment failure. Treatment failure is defined as the

failure to attain an undetectable level of virus or the persistent presence of virus after it had become undetectable. If it has been determined that failure has occurred, resistance testing should be performed *before* the failing regimen is discontinued. This is to prevent the overgrowth of wild-type strains that might occur after the regimen is discontinued, such that resistant strains would not be detected even though they might be “lying in wait” for the reinstitution of some components of the regimen. Resistance testing can also be helpful in the setting of an individual who has recently seroconverted. It has been reported that a substantial percentage of new infections are with organisms that are resistant.¹⁴⁴ If testing can be performed before a wild-type virus overgrows the infecting strain, the clinician will have an opportunity to choose an initial regimen that will have a high probability of success against the infecting virus.

Medical therapy: when to start

Once a diagnosis of HIV infection has been made and the individual's clinical, virologic, and immune status has been assessed, the clinician must determine whether antiretroviral therapy is appropriate. Given the cost, toxicities, and inconveniences of therapy, a clear advantage in prognosis should be shown before the commitment to lifetime treatment is made.

If the patient has severe immune compromise or a clinical diagnosis of AIDS, then the decision is clear. Randomized clinical trials have demonstrated a survival benefit with the use of antiretroviral therapy in those circumstances.¹⁴⁵ For less severely compromised individuals (i.e., asymptomatic individuals with CD4 cell counts $\geq 200/\mu\text{L}$), the data are not as clear cut; there are no definitive data from prospective, randomized, controlled studies. Instead, inferences must be drawn from observational studies, as well as what is known about the consequences of moderate degrees of immune deficiency, and the long-term safety of antiretroviral drugs. The largest study, which analyzed data from more than 10 000 patients, concluded that prognosis could be best predicted by CD4 cell count and HIV RNA response after 6 months of treatment, independent of pretreatment values.^{146,147} Another study analyzed data from 1464 patients from several clinics in the United States and found that, after 4 years of follow-up, patients with baseline CD4 cell counts between 200/ μL and 350/ μL who started antiretroviral therapy had lower mortality rates than those who waited until their CD4 cell count was below 200/ μL .¹⁴⁸ These data agreed with the results of another study that reported the outcomes of 1173 patients who had received therapy for at least 90 days.¹⁴⁹ Again, those who initiated therapy with a CD4 cell count below 200/ μL had a higher risk of disease progression even if a durable virologic suppression was achieved. A Canadian cohort found a similar association between lower CD4 cell count and prognosis, but also noted that a baseline HIV RNA level higher than 100 000 copies/mL was independently associated with death.¹⁵⁰

Thus, delay in the initiation of therapy carries with it some risk of poorer prognosis. However, there are countervailing considerations. These include concerns over the long-term safety of therapy, toxic effects, potential cardiovascular consequences, and the negative impact of fat maldistribution on quality of life. These outcomes may be present at different frequencies dependent upon the drug regimen employed.^{151,152} Additionally, some treatment complications (e.g., lipoatrophy) may be more frequent and severe when therapy is initiated at lower CD4 cell counts.¹⁵³

In sum, these data from observational cohorts strongly suggest that antiretroviral therapy may decrease the incidence of potentially life-threatening conditions. That finding in conjunction with long-term safety data on some regimens, and the availability of newer drugs that are safer and easier to take, would support the initiation of therapy before HIV-related disease becomes clinically manifest.

In reviewing all the aforementioned data, the International AIDS Society drew several conclusions.¹³⁴ They felt that therapy should be recommended for all patients with symptomatic HIV disease, although in rare circumstances initiation can be delayed. For example, treatment of potentially life-threatening opportunistic diseases, or conditions that require drugs that are difficult to co-administer with antiretroviral drugs (e.g., tuberculosis or hepatitis C virus co-infection), or can lead to an immune reconstitution syndrome following the initial CD4 cell count increase, may take precedence over immediate initiation of antiretroviral therapy. They also recommend antiretroviral treatment initiation before CD4 cell counts reach 200/ μ L. However, initiation of therapy in patients with CD4 cell counts below 350/ μ L but above 200/ μ L should be individualized. They cite as an example of an individual in whom it would be reasonable to defer therapy, someone with a low HIV RNA level, stable CD4 cell count (or one that is declining slowly, e.g., a loss of fewer than 50/ μ L per year), and someone who is reluctant to start therapy. Conversely, they would be more aggressive with an individual with

plasma HIV RNA levels above 100 000 copies/mL or a CD4 cell count loss of more than 100/ μ L/year. Finally initiation of therapy is generally not recommended for patients with CD4 cell counts between 350/ μ L and 500/ μ L, but it may be considered in cases with high plasma viral load or a rapid decline in CD4 cell count.

More recently, the Panel on Clinical Practices for Treatment of HIV Infection convened by the Department of Health and Human Services¹³⁵ modified their recommendations for when to initiate therapy for asymptomatic treatment-naïve patients with CD4 cell counts > 350 cells/ μ L. The viral load recommendation at which to defer or to consider therapy was increased from 55 000 to 100 000 copies/mL. They based this change on the belief that, even at those CD4 and viral load levels, the chance of disease progression is relatively low.

Medical therapy: what to start (see Table 50.6)

Over the last several years, arrays of antiretroviral therapies have come on the market. They vary in price, efficacy, and toxicity. Some are inappropriate for use in pregnancy. The obstetrician should be comfortable with a few regimens that are most appropriate for use in pregnancy and be liberal in consulting with experts in HIV infection in those circumstances (e.g., resistance) in which their usual choices are no longer appropriate.

While the choice of initial regimen is influenced by several factors that may be unique to a given patient, including comorbid conditions and concomitant medications, in general, certain initial regimens are preferable to others, at least as evidenced by data from controlled clinical trials. Additionally, some of the newer formulations of medications should improve adherence.

A HAART regimen using a non-nucleoside reverse transcriptase inhibitor (NNRTI) is often the initial regimen of choice because of convenience, superior virological suppression, lower rates of toxic effects, and fewer interactions between drugs than seen with regimens that utilize a boosted

Table 50.6 Currently used antiretroviral drugs.

Drug	Dosage	Side effects	Pregnancy category
Zidovudine	100 mg 6 times per day	Anemia, gastrointestinal upset, headache, myopathy	C
Didanosine	> 60 kg: 200 mg b.i.d.; < 60 kg: 125 mg b.i.d.	Pancreatitis, diarrhea, peripheral neuropathy	B
Zalcitabine	0.75 mg t.i.d.	Peripheral neuropathy, pancreatitis, stomatitis	C
Lamivudine	150 or 300 mg b.i.d.	Minimal toxicity	C
Stavudine	> 60 kg: 40 mg b.i.d.; < 60 kg: 30 mg b.i.d.	Peripheral neuropathy, pancreatitis	C
Indinavir sulfate	800 mg q8h	Nephrolithiasis, drug interactions, hyperbilirubinemia	C
Saquinavir mesylate	600 mg t.i.d.	Gastrointestinal disturbances	B
Ritonavir	600 mg b.i.d.	Gastrointestinal disturbances, paresthesias, drug interactions	B

protease inhibitor. However, during pregnancy, that approach may require modification because the preferred NNRTI, efavirenz, is contraindicated in women who are or wish to become pregnant because of potential teratogenicity. Nevirapine (NVP), which is a reasonable option under other circumstances, has the disadvantage of potential toxic effects that are particularly common among pregnant women with relatively high CD4 counts ($> 250/\mu\text{L}$). Delavirdine, another NNRTI, is not generally recommended for initial regimens because of insufficient data.

The alternative to an NNRTI backbone in a HAART regimen is a protease inhibitor backbone. Some of these regimens involve two PIs with one drug acting to “boost” the availability of the other. Regimens that are ritonavir boosted are often recommended because of the improvement in PI pharmacokinetics and potency. That combination has good rates of sustained response and low rates of viral resistance. The boosted regimen with the most supporting literature is lopinavir/ritonavir,¹⁵⁴ although there is no compelling evidence that this combination is dramatically superior to other boosted regimens such as atazanavir and low-dose ritonavir, and the latter regimen may have less metabolic toxicities (plasma lipid abnormalities). Other choices such as nelfinavir, unboosted atazanavir, and the combination of fosamprenavir and low-dose ritonavir have lower potencies and, consequently, less utility as first-line therapy.

A large number of nucleoside reverse transcriptase inhibitor (NRTI) combinations are available for use as the backbone of HAART regimens in nonpregnant women. These include zidovudine (ZDV) plus lamivudine or emtricitabine, tenofovir plus lamivudine or emtricitabine, or emtricitabine plus didanosine. In pregnancy, the first choice is ZDV plus lamivudine. There are a few combinations that should be avoided. Combining stavudine and ZDV is contraindicated; combinations of stavudine and didanosine or combinations with zalcitabine are not recommended because of increased toxic effects.

Prevention of transmission

Drugs

Since the results of ACTG 076 were first reported in 1994 (monotherapy with ZDV reduced MTCT from 25.5% to 8.3%), it has been apparent that antiretroviral therapy can substantially reduce the rate of MTCT. Those initial reports demonstrated that single drug therapy that is administered over a long period of time (it was administered from 14 weeks’ gestation until term) could prevent two-thirds of transmissions. Since that time, research has advanced in two directions. In the developing world, there have been a large number of studies designed to see whether cheaper, shorter regimens could have benefits similar to those seen with more expensive, cumbersome approaches. In the developed world, the focus has been on improved efficacy, as opposed to reduced cost. Both avenues of research have borne fruit.

Abbreviated regimens of ZDV alone, as well as ZDV in conjunction with 3TC (lamivudine), have been shown to prevent some cases of MTCT.¹⁵⁵ The most dramatic result, from the perspective of simplicity and cost, came from the HIVNET 012 trial, which documented the efficacy of oral NVP when given just twice, once in the intrapartum period and once to the neonate.¹⁵⁶ Subsequent studies have highlighted the public health risks attendant on this approach. Fairly high frequencies of resistant virus in the postpartum period have been reported among mothers who have used NVP in the intrapartum period and, more alarmingly, there is some evidence that women who took NVP to prevent MTCT were more likely to fail NVP-based HAART when they became eligible for treatment later in life.¹⁵⁷

In the United States, data accumulated fairly quickly demonstrating that the results obtained with monotherapy could be exceeded with more aggressive antiretroviral therapy. As HAART became the standard of care for HIV infection, several authors noted that those pregnant women who were on HAART for their own care had remarkably low rates of MTCT, independent of the mode of delivery (*vide infra*). These data were all the more dramatic because those women on HAART were, by definition, women with more advanced disease and thus those who would otherwise be expected to have relatively high rates of MTCT. In fact, there are now preliminary data, summarized in the next section, indicating that HAART therapy *per se* may be as efficacious as Cesarean section in preventing MTCT.

In determining which regimen should be used for the prevention of MTCT, the first question to be asked is what regimen does the mother need for her own health, and is there any need to modify that regimen in order to minimize rates of MTCT? If the patient meets the criteria for antiretroviral therapy (as detailed above), then she should be on a HAART regimen. There is no place for monotherapy for women who have advanced immune compromise, high viral load, or clinical illness. The obstetrician should review the regimen that the patient is taking. If it is effective (viral load is undetectable), then it should only be changed if some component of the regimen is contraindicated in pregnancy (e.g., efavirenz). If it is failing, then it should be changed, taking into consideration both the results of resistance testing and the safety of individual agents for use during pregnancy.

Mode of delivery

When considering the optimal mode of therapy for HIV-infected women, the obstetrician must be cognizant of both maternal interests and fetal interests. Therefore, the clinician must consider minimizing the risks of both perinatal transmission of HIV-1 and the potential for maternal and neonatal complications. Evidence of the potential benefit of Cesarean section for reducing MTCT antedates the use of antiretroviral therapy. Studies from that era showed substantive reductions in transmission (55–80%) when surgery was performed before labor or rupture of membranes occurred.

The most compelling data from that time were observational data from a meta-analysis and from an international randomized study. The former included observations from 15 prospective cohort studies, including more than 7800 mother-child pairs, and found that the rate of perinatal HIV-1 transmission among women undergoing elective Cesarean delivery was significantly lower than that among similar women having either nonelective Cesarean or vaginal delivery, regardless of whether they received ZDV, the only antiretroviral in use at the time.¹⁵⁸ In the latter, transmission was 1.8% among women randomized to elective Cesarean delivery, many of whom received ZDV.¹⁵⁹ Because the trial was underpowered (it began prior to ZDV treatment, and a background rate of transmission of 25% was anticipated), significant differences in the subgroup analysis (mode of delivery stratified by receipt of ZDV) could not be obtained. However, in all analyses, the differences between rates of transmission by mode of delivery were dramatic and consistent. Finally, in both the meta-analysis and the trial, nonelective Cesarean delivery (performed after the onset of labor or rupture of membranes) was not associated with a significant decrease in transmission compared with vaginal delivery. The American College of Obstetricians and Gynecologists' (ACOG) Committee on Obstetric Practice, after reviewing these data, issued a Committee Opinion concerning route of delivery recommending consideration of scheduled Cesarean delivery for HIV-1-infected pregnant women. However, as data were also available demonstrating low rates of transmission, independent of mode of delivery, when the viral load was < 1000 copies/mL, the committee limited their recommendation to those women with HIV-1 RNA levels > 1000 copies/mL near the time of delivery.¹⁶⁰

Transmission, viral load, and combination antiretroviral therapy

As noted, the studies mentioned above were performed on the cusp of the era of HAART. Give the dramatic reductions in MTCT that have followed in the wake of these therapies, it is becoming increasingly difficult to document an effect of operative delivery above and beyond that which can be obtained with medical therapy alone. For example, independent of the specific regimen used, when a woman has a viral load under 1000 copies/mL and is on some therapy, her transmission rate apparently drops into the low single digits. In a study of women with HIV RNA levels below 1000 copies/mL at or near delivery, maternal antiretroviral therapy, primarily ZDV, was the most significant predictor of transmission risk [adjusted odds ratio (AOR) 0.12, $P < 0.001$], but any Cesarean delivery, scheduled or urgent, was also associated with a reduced risk of transmission (AOR 0.09, $P = 0.028$).¹⁶¹ The association between Cesarean section and lower transmission did not control for the receipt of ZDV, and it is not counter-intuitive to think that those providers who used Cesarean section may also have been more likely to employ antiretroviral therapy. However, current standard for medical therapy

is no longer ZDV alone, and it is far from certain that HAART cannot replicate the benefits of operative delivery.

That is not to say that there are not some data that continue to suggest a benefit for Cesarean section even in the HAART era. In an Italian study evaluating risk factors for transmission, the risk of transmission was reduced with elective Cesarean delivery (AOR 0.54, 95% CI 0.29–1.02) compared with other modes of delivery even after adjustment for type of antiretroviral therapy and other risk factors, but not including HIV RNA levels. Among women receiving any antiretroviral therapy, transmission occurred among 13 (2.4%) of 553 women undergoing elective Cesarean delivery and 10 (4.4%) of 229 with other modes of delivery ($P = 0.13$).¹⁶² In the European Collaborative Study, elective Cesarean delivery was associated with a reduced risk of transmission (AOR 0.42, 95% CI 0.27–0.67) even after adjustment for antiretroviral therapy and maternal CD4+ lymphocyte count. HIV RNA levels were not included in the model. Of note, the transmission rate among women on combination antiretroviral therapy regardless of mode of delivery was 1.7% (2/118).¹⁶³ Taken together, these studies suggest a benefit from elective Cesarean delivery among women on antiretroviral therapy, but the majority of the women in all these studies were receiving ZDV monotherapy rather than current combination regimens. Where specified, the risk of transmission among women on HAART was under 2%, making it difficult to detect potential differences in transmission by mode of delivery in this subset.

Even the most recent data fail to clarify the proper role for Cesarean section in the era of HAART, with some suggesting a role for Cesarean section even in the presence of HART, and others seeming to demonstrate that HAART alone will have maximal benefits. Thus, data from PACTG 367,¹⁶⁴ including 2756 women, do not demonstrate any benefit from elective Cesarean delivery among either women with HIV RNA levels below 1000 copies/mL or those on multiagent antiretroviral therapy. Specifically, women with HIV RNA levels under 1000 copies/mL on multiagent therapy had transmission rates of 0.8% with elective Cesarean delivery and 0.5% with all other delivery modes (OR 1.4, 95% CI 0.2–6.4), and those on single-agent therapy, usually ZDV, had a transmission rate of 4.3% after elective Cesarean delivery and 1.8% with all other delivery modes (OR 2.5, 95% CI 0.04–50.0). Women on multiagent therapy with HIV RNA levels over 1000 copies/mL near delivery had a transmission rate of 3.6% with elective Cesarean and 2.3% with other delivery modes (OR 1.6, 95% CI 0.6–4.3). The transmission rate among all women on multiagent antiretroviral therapy was 1.3% (34/2539). Data from the 4377 women who participated in the European Collaborative Study¹⁶⁵ yielded strikingly divergent results, suggesting a reduction in perinatal transmission of HIV with scheduled Cesarean delivery even among women on HAART or with undetectable HIV RNA levels. While the overall transmission rate among women on HAART was a reassuringly low 10 out of 678 (1.5%), a logistic regression, adjusting for antenatal antiretroviral therapy, CD4+ lymphocyte count, gender, and

time period, revealed that scheduled Cesarean delivery was still associated with a reduced risk of transmission (AOR 0.51, 95% CI 0.31–0.82). Even among the 481 women with undetectable HIV RNA levels at delivery, 51% of whom were on HAART, scheduled Cesarean delivery was associated with an OR of transmission of 0.11 (95% CI 0.03–0.37). Thus, despite accumulating experience with Cesarean section in the HAART era, it is still unclear whether there are uniform benefits of elective Cesarean delivery. Hence, consideration must be given to the increased risk to the mother of Cesarean compared with vaginal delivery.

Maternal risks by mode of delivery

Obstetricians are fully familiar with a rich literature that details the excess morbidity, specifically infectious and hemorrhagic, attendant on Cesarean birth relative to vaginal delivery among HIV-uninfected women. In general, postpartum infections are approximately five to seven times more common after Cesarean delivery performed after labor or membrane rupture compared with vaginal delivery.^{166,167} The risks associated with elective surgery, while still greater than for vaginal deliveries, are much less dramatic, to the point that more and more women are electing that mode even for uncomplicated births.¹⁶⁸

In recent years, the types of studies that demonstrated the relative risk of morbidity associated with Cesarean section have been repeated among HIV-infected women. Not surprisingly, Cesarean section was still associated with greater rates of infectious morbidity, although the severity of the morbidity was not remarkable. For example, in the European trial in which HIV-1-infected women were randomized to Cesarean section or vaginal delivery, no major complications occurred in either the Cesarean or the vaginal delivery group, although postpartum fever occurred in fewer women who delivered vaginally (1.1%) than in women who delivered by Cesarean delivery (6.7%; $P = 0.002$).¹⁵⁹ Similarly, an analysis of nearly 1200 women enrolled in an American cohort of HIV-infected pregnant women (WITS) demonstrated an increased rate of postpartum fever among women undergoing elective Cesarean delivery compared with spontaneous vaginal delivery, but hemorrhage, severe anemia, endometritis, or urinary tract infections were not increased.¹⁶⁹ In PACTG 185, only endometritis, wound infection, and pneumonia were increased among women delivered by scheduled or urgent Cesarean delivery, compared with vaginal delivery.¹⁷⁰ In these studies, elective Cesarean sections were performed for obstetrical indications (e.g., previous Cesarean delivery or severe preeclampsia), not for prevention of HIV-1 transmission. That factor may have contributed to higher complication rates than might be seen when scheduled Cesarean delivery is performed solely to reduce perinatal transmission. However, even in cohorts weighted toward women who underwent elective surgery expressly to reduce rates of MTCT, fever was still increased after Cesarean compared with vaginal delivery.¹⁷¹ In a multi-

variate analysis adjusted for maternal CD4+ count and antepartum hemorrhage, the relative risk of any postpartum complication was 1.85 (95% CI 1.00–3.39) after elective Cesarean delivery and 4.17 (95% CI 2.32–7.49) after emergency Cesarean delivery, compared with that for women delivering vaginally. Febrile morbidity was increased among women with low CD4+ counts.

Some researchers have now included comparisons of HIV-infected and -uninfected women in their assessments of operative risk. A European study performing such an analysis found that, among HIV-infected subjects, minor complications (anemia, fever, wound infection, curettage, endometritis, urinary tract infection) occurred in 16.8% of women delivering vaginally and 48.7% of those with Cesarean delivery, while major complications occurred in none of the women with vaginal delivery and 3.2% (5/158) of those with elective Cesarean delivery.¹⁷² These frequencies were increased compared with matched HIV-uninfected women, but the relative difference between vaginal and Cesarean deliveries was similar in HIV-infected and HIV-uninfected women.

Several other studies have compared postoperative complications between HIV-infected women and similar HIV-uninfected women.^{172–179} While two studies found similar outcomes among HIV-infected women compared with control subjects,^{180,181} many more detected an increased risk of one or more complications, albeit predominantly minor complications, among the HIV-infected women. Cases of pneumonia were seen among HIV-infected women in four of the studies, while no cases occurred in the HIV-negative women. In those studies that included an assessment of immune status, an increased risk of complications was seen among women with a lower CD4+ lymphocyte count or percentage.

Timing of scheduled Cesarean delivery

Once a decision has been made to perform an elective Cesarean delivery for the purpose of preventing HIV-1 transmission, it should be scheduled at 38 weeks, as per current ACOG guidelines. This recommendation stands in contrast to that organization's recommendations for HIV-1-uninfected women, in which case ACOG recommends that scheduled Cesarean delivery without confirmation of fetal lung maturity should be scheduled at 39 completed weeks or the onset of labor in order to minimize the chance of complications in the neonate.¹⁸² Delivery at 38 weeks, as is currently recommended for HIV-infected women, rather than at 39 weeks, entails a small absolute increase in risk of development of infant respiratory distress requiring mechanical ventilation.^{183,184} This increased risk must be balanced against the potential risk of labor or membrane rupture, and attendant increased rates of MTCT, if delivery is delayed until 39 weeks of gestation. Theoretically, the risks associated with births a week earlier than standard could be mitigated by maturity studies. However, amniocentesis is not recommended in these circumstances for fear of contamination of the amniotic sac by maternal HIV, which could pose a risk of consequent fetal infection. Thus,

ACOG also recommends that the timing of delivery be based on the best clinical estimate of dating.¹⁶⁰ Women should be informed of the potential risks and benefits to themselves and their infants in choosing the timing and mode of delivery.

Intrapartum management

If a decision has been made to effect delivery via scheduled Cesarean delivery, then antiretroviral therapy should be part of the preoperative protocol. Intravenous ZDV should begin 3 h before surgery, according to standard dosing recommendations, and the infant should receive ZDV for 6 weeks after birth.¹⁸⁵ Other maternal drugs should be continued on schedule as much as possible to provide maximal effect and minimize the chance of development of viral resistance. Oral medications may be continued preoperatively with sips of water. Medications requiring food ingestion for absorption could be taken with liquid dietary supplements, but consultation with the attending anesthesiologist should be obtained before administering in the preoperative period. If maternal antiretroviral therapy must be interrupted temporarily in the peripartum period, all drugs (except for intrapartum intravenous ZDV) should be stopped and reinstituted simultaneously to minimize the chance of resistance developing.

As noted above, infectious morbidity is an important consideration, and consideration should be given to the initiation of prophylactic antibiotics. If vaginal delivery is planned, and if labor is progressing and membranes are intact, artificial rupture of membranes or invasive monitoring should be avoided. These procedures should be considered only when obstetrically indicated, and the length of time for ruptured membranes or monitoring is anticipated to be short.

The most problematic clinical dilemmas involve circumstances in which the fetus may be exposed to prolonged periods of membrane rupture. If a vaginal delivery had been planned, i.e., the viral load is low, then continuing antiviral therapy and aggressively moving toward vaginal delivery seems the most appropriate management plan. However, if a Cesarean section was planned, it is unclear how long after membranes rupture that Cesarean section will continue to offer a benefit with regard to a lowered MTCT rate. Much of the data linking duration of rupture to increased risk of transmission antedate the use of antiretroviral therapy, and their utility for predicting events in the HAART era is therefore limited.^{186,187} The data from more recent studies are less uniform in conclusion. Among women receiving ZDV, some studies have shown an increased risk of transmission with ruptured membranes for four or more hours before delivery,¹⁸⁸ but others have not.¹⁸⁹ If a Cesarean section had been indicated and the patient appears shortly after ruptured membranes, it would seem reasonable to proceed expeditiously toward operative delivery, making sure that intravenous ZDV is started as quickly as possible. If the patient ruptures membranes when she is preterm, then the clinician must balance the potential gain in reduced prematurity-related morbidity from an anticipated latent phase versus the risk of MTCT that

would be encountered by waiting. The further forward from the time of periviability the rupture occurs, the more Cesarean delivery shortly after rupture would be favored.

Postpartum management

The first management decision that the obstetrician and parturient confront in the immediate postpartum period is whether to continue the medications the woman had been on during pregnancy. If the woman had been on HAART prior to pregnancy and her viral load had continued to be suppressed throughout gestation, then she should be maintained on the same regimen at least until she re-establishes contact with her primary HIV care provider. Alternatively, if the patient had not met criteria for HAART during the prepregnancy period, but had been started merely as part of a strategy to reduce the risk of MTCT, the discontinuation of therapy would be appropriate. In that circumstance, all medications should be discontinued simultaneously to avoid prolonged exposure to monotherapy and the consequent risk of development of resistant virus. It should be noted that certain agents have much longer half-lives than others so that, even if all drugs are stopped concurrently, the possibility of a period of *de facto* monotherapy cannot be completely dismissed.

After the patient has been discharged, with suitable instructions about antiviral medication, the obstetrician must assure appropriate follow-up both by an HIV specialist and by a provider who can provide family planning advice.

Summary recommendations

- All pregnant women should be given the opportunity to ascertain their HIV serostatus as early in pregnancy as possible. The preferred testing algorithm involves the “opt-out” approach, in which women are routinely informed that they will be tested unless they specifically request to opt out.
- The physician’s primary responsibility is to maximize the health of his/her pregnant patient. Women’s viral load and CD4 counts should be monitored and HAART administered per standard recommendations. If her viral load and CD4 results do not, unto themselves, justify HAART therapy, consideration should still be given to aggressive therapy in order to minimize the likelihood of MTCT.
- While HAART is probably the most effective regimen for MTCT prevention, there are circumstances (e.g., viral load less than 1000 copies/mL) in which alternatives might be acceptable. As a minimum for the reduction of perinatal HIV-1 transmission, ZDV prophylaxis according to the PACTG 076 regimen is recommended unless the woman is intolerant of ZDV.
- Plasma HIV-1 RNA levels should be monitored during pregnancy according to the guidelines for management of HIV-1-infected adults. The most recently determined viral load value should be used when counseling a woman regarding mode of delivery.
- Perinatal HIV-1 transmission is reduced by scheduled

Cesarean delivery among women with unknown or high HIV-1 RNA levels who are not receiving antiretroviral therapy or are receiving only ZDV for prophylaxis of perinatal transmission. The benefit among women on HAART is unproven. Given the low rate of transmission among this group, it is unlikely that scheduled Cesarean delivery would confer additional benefit in the reduction of transmission.

- Management of women originally scheduled for Cesarean delivery who present with ruptured membranes or in labor must be individualized based on duration of rupture, progress of labor, plasma HIV-1 RNA level, current antiretroviral therapy, and other clinical factors. The woman's autonomy to make an informed decision regarding route of delivery should be respected and honored.

Sexually transmitted diseases in pregnancy

Although STDs have been recognized for more than three millennia and have played major roles in the history of civilization, the last three decades have brought the greatest progress in our understanding of this rapidly expanding field. Advances in microbiology and immunology have made our comprehension of their pathogenesis and amplified treatment options more sophisticated.

Despite these breakthroughs, the epidemic of STDs remains unabated in America.^{190–192} In 1993, the Institute of Medicine (IOM) in their report, *The Hidden Epidemic: Confronting Sexually Transmitted Diseases*, estimated that 12 million new cases of STDs occurred annually in the United States at an estimated annual cost of US\$17 billion.¹⁹⁰ Subsequently, in 1998, the American Social Health Association (ASHA) suggested that 15 million new cases of STDs were occurring each year in the United States.¹⁹¹ Recently, Weinstock et al.¹⁹² increased the estimate of new STD cases to nearly 19 million annually. In particular, this trend has had far-reaching implications on the reproductive health of women.

Not only is there a resurgence of traditional STDs, but new ones have been added to the list (Table 50.7). Unfortunately, many of these new STDs are either incurable or associated with serious sequelae in women. *Chlamydia trachomatis* has been associated with infertility,¹⁹³ ectopic pregnancy,^{191,194–196} and a host of adverse perinatal outcomes;¹⁹⁷ human papillomavirus (HPV) is associated with genital squamous cell carcinomas;¹⁹⁸ HSV becomes a chronic infection; and HIV is ultimately fatal and had become one of the five leading causes of death in women of reproductive age by 1991.¹⁹⁹ Many of these infections have been associated with abortion, preterm delivery, premature ruptured membranes, and amnionitis. Finally, many of these agents, including HIV, HSV, *N. gonorrhoeae*, *Chlamydia*, and *Treponema pallidum*, can be transmitted to the fetus or newborn.

As might be expected, all the STDs regularly occur in pregnancy, with varying effects on mother, fetus, and neonate. This

section focuses on issues related to gonorrhea, syphilis, *Chlamydia*, HPV, HSV, and *Trichomonas* in pregnant women and their fetuses.

Gonorrhea

Gonorrhea is perhaps the oldest known STD, with references to its symptoms dating back to numerous ancient civilizations. It was not until relatively recent times that the disease's effects in women were first described.

Gonorrhea, caused by the Gram-negative diplococcus, *Neisseria gonorrhoeae*, is the second most commonly reported communicable disease in the United States with over 335 000 cases reported in 2003.²⁰⁰ As a result of under-reporting, it is estimated that approximately 750 000 cases actually occur annually in the United States. In 2003, for the first time, the reported gonorrhea rate among women (118.8 per 100 000) was greater than that reported for men (113 per 100 000).²⁰⁰

N. gonorrhoeae infects both columnar and transitional epithelium, including the endocervix, urethra, anal canal, pharynx, and conjunctivae. Local spread in women results in endometritis, salpingitis, and bartholinitis; systemic manifestations include arthritis, dermatitis, endocarditis, meningitis,

myocarditis, and hepatitis. Humans are the only natural host for this organism, and the only known forms of transmission are sexual and vertical.

Epidemiology

A number of risk markers for gonorrhea have been identified. These include young age (younger than 25 years), nonwhite race, early onset of sexual activity, low socioeconomic status, unmarried status, urban dwelling, illicit drug use, and prostitution. According to the CDC, 60% of reported cases of gonorrhea occur in the 15- to 24-year age group with the gonorrhea rate among women (125/100 000) similar to that of men (124/100 000).²⁰⁰ From 1975 through 1997, a dramatic (74%) decrease in gonorrhea was reported. However, in 1998, an 8.9% increase occurred and, since that time, rates have plateaued until 2003 when they began to increase again.

Increasingly resistant strains of *N. gonorrhoeae* have occurred.²⁰¹ These resistant strains include penicillinase-producing *N. gonorrhoeae* (PPNG), high-level chromosomal resistance to penicillin, plasmid-mediated tetracycline resistance (TRNG), chromosomally mediated resistance to cephalosporins, tetracycline, spectinomycin, and aminoglycosides and, most recently, *N. gonorrhoeae* resistant to fluoroquinolones.

Pathogenesis

Similarly to other infections, the initial step in the pathogenesis of gonococcal infection is adherence of *N. gonorrhoeae* to mucosal cells lining the genitourinary tract. Pili and other surface proteins, including porin protein (Por), opacity-associated proteins (Opa), and reduction modifiable protein (RmP), mediate this attachment.^{202–204} Additional gonococcal virulence factors include lipopolysaccharides,²⁰⁴ immunoglobulin A,²⁰² and iron-repressible proteins involved in iron uptake.²⁰⁴ After the organism attaches to mucosal cells, it enters the cell by endocytosis. It releases endotoxins, causing widespread cell damage.

Clinical manifestations

The clinical presentation depends on the site of inoculation, duration of infection, and whether the infection has remained local or has spread systemically. The percentage of women with asymptomatic infection ranges between 25% and 80%.^{205,206} Gonococcal infections in pregnant patients are commonly asymptomatic.

Anogenital gonorrhea

Acute symptomatic anogenital infections in women are characterized by dysuria, increased urinary frequency, increased vaginal discharge secondary to an exudative endocervicitis, abnormal menstrual bleeding, or anorectal discomfort. Most women who become symptomatic do so within 3–5 days of inoculation or during menstruation. Inflammation of the Skene's or Bartholin's glands is usually unilateral and acute in nature. Only 15% of all women with gonorrhea have exten-

sion of infection to the upper genital tract, although this is rarely seen during pregnancy.

Localized extragenital gonorrhea

The majority of patients with pharyngeal infections are asymptomatic. The most common signal is a mild sore throat, and erythema, lesions, and a tonsillar or pharyngeal exudate may be present. Pharyngeal infection is more common during gestation.²⁰⁷

Gonococcal conjunctivitis, as the result of direct sexual contact or indirect autoinoculation, is rare and heralded by the acute onset of severe inflammation and purulent exudate.

Disseminated gonococcal infection

Disseminated gonococcal infection (DGI) occurs in 1–3% of adult infections, and 80% of these cases are in women.^{208,209}

Most women with DGI develop symptoms either during pregnancy or while menstruating. The majority of *N. gonorrhoeae* isolates recovered from patients with DGI are sensitive to antibiotics but resistant to complement-mediated bactericidal activity in normal serum.

There are two distinct clinical syndromes found in DGI: an early bacteremic and a later arthritic stage. Patients with disseminated infection rarely complain of genital symptoms. Bacteremic patients complain of fever, chills, malaise, and skin lesions. The initial dermatologic manifestation most frequently involves the distal extremities, including the palms and soles, with up to 20 lesions. Lesions are characterized as small vesicles that become first pustular, then necrotic, and finally heal spontaneously. Endocarditis, meningitis, and toxic hepatitis are infrequent complications of this phase. The arthritic phase is typically symptomatic and involves the knees, ankles, and wrists, with purulent tenosynovitis. The pain is thought to be secondary to deposition of immune complexes. Without treatment, symptoms usually resolve in approximately a week; the infection may either become chronic or progress to septic arthritis and joint destruction.

Maternal and fetal risks

The association between maternal gonorrheal infection and ophthalmia neonatorum has been appreciated for over a century. Before routine administration of silver nitrate, this disease occurred in 10% of newborns. The institution of routine neonatal prophylaxis reduced this rate dramatically. Gonococcal infection is transmitted to 30–35% of babies who pass through an infected cervix.²¹⁰ After an incubation period of between 4 and 21 days, bilateral purulent conjunctivitis is the usual manifestation, with rapid progression to corneal ulceration, scarring, and blindness in the absence of treatment.

Subsequently, gonococcal infection during gestation has been linked to a wide variety of perinatal complications. Postabortal and postpartum endometritis occur more frequently in women with untreated gonococcal cervicitis at the time of delivery. Intra-amniotic infection has also been described and is characterized by inflammation of the fetal

membranes, placenta, and umbilical cord; it results in maternal fever, leukocytosis, and fetal infection.^{211–214} A chronic, low-grade infection may ensue, with resultant intrauterine growth retardation (IUGR).²¹⁴ Whether infection predisposes to or is the result of premature rupture of the membranes (PROM) remains controversial. Preterm delivery is the customary outcome, and both mother and infant are at risk of continued infection and sepsis. The incidence of preterm delivery in women with untreated cervical gonorrhea has been recorded to be as high as 67%.²¹¹

Laboratory diagnosis

Although the Gram stain of urethral discharge is both sensitive and specific in men, it has two major disadvantages in women: asymptomatic patients are not tested, and the test has poor sensitivity in women. Thus, the diagnosis of gonococcal infection in women requires the identification of *N. gonorrhoeae* at infected sites. Available methods include culture, immunochemical detection, or molecular diagnostic techniques.

Selective plates, such as Thayer–Martin, provide optimal conditions for isolation of the organism. *N. gonorrhoeae* forms oxidase-positive colonies that can be differentiated from other *Neisseria* species by their ability to dissimulate glucose but not maltose, sucrose, or lactose.

The traditional method of gonorrhea detection in women was culture of the cervix and any other symptomatic site. During pregnancy, cultures should be obtained from all patients at the first antenatal visit and again in the third trimester in those at high risk of infection. Factors identifying those at high risk include sex with a symptomatic partner, multiple sex partners, other STDs, bleeding induced by cervical swab, Medicaid as a method of payment, age at first intercourse less than 16 years of age, and low abdominal or pelvic pain.²¹⁵

With the introduction of nonculture assays for the detection of *N. gonorrhoeae*, these newer methodologies have replaced culture.²⁰⁴ Nonamplified DNA probe tests (e.g., Gen-Probe Pace 2) were the first widely accepted alternative to culture and became the most common nonculture method for the detection of *N. gonorrhoeae* in the United States.²⁰⁴ Non-amplified DNA probes have a sensitivity of 89–97% and a specificity of 99%. Nucleic acid amplification tests have become available more recently and include PCR, ligase chain reaction (LCR), and transcription-mediated amplification (TMA). These amplification methods have excellent sensitivity and specificity.

Treatment

Anogenital and pharyngeal infection

The factors to consider in the treatment of uncomplicated anogenital gonococcal infection are: (1) the incidence in many urban areas of resistant strains of *N. gonorrhoeae*; (2) the availability of effective single-dose agents against *N. gonor-*

rhoeae; (3) the coexistence of chlamydial infection in up to 30% of patients; and (4) the absence of a rapid, reliable, inexpensive means of making the diagnosis of *C. trachomatis*.²¹⁶ Patients with gonococcal infections should be treated with regimens effective against both pathogens. The CDC recommendations are listed in Table 50.8.²⁰¹ For pregnant women, the recommended regimens include ceftriaxone or cefixime plus erythromycin.

Alternative cephalosporins for the pregnant patient include cefotaxime, ceftizoxime, cefotetan, and cefoxitin. For patients who cannot tolerate cephalosporins, spectinomycin is the preferred alternative. It covers resistant strains of *N. gonorrhoeae*; unfortunately, it is ineffective against pharyngeal infection. Both doxycycline and the quinolones are contraindicated during pregnancy because of their effects on the fetus.

The incidence of treatment failure among those treated with ceftriaxone or cefixime is extremely rare, obviating the need for test-of-cure for *N. gonorrhoeae*. These women should be screened for reinfection after 2–3 months. Women undergoing other treatment regimens should have follow-up cultures performed 7–14 days after completion of therapy. These cultures should be obtained from the rectum as well as the cervix, because 25% of female treatment failures harbor organisms only in the rectum. Any gonococcal isolate recovered after treatment failure should be tested for antibiotic sensitivity, because the incidence of resistance is high. These patients should be treated with a single dose of ceftriaxone.

All women diagnosed with gonorrhea should undergo serologic testing for syphilis and screening for *C. trachomatis*, and be offered confidential counseling and testing for HIV infection.

Extragenital disseminated infection

Inpatient treatment is advisable for patients with DGI, particularly those with endocarditis, meningitis, synovial effusions,

Table 50.8 Centers for Disease Control 2002 recommended treatment guidelines for uncomplicated anogenital gonorrhea during pregnancy.

Recommended regimens

- Ceftriaxone, 125 mg i.m. once
- or
- Cefixime, 400 mg p.o. in a single dose
- plus
- Erythromycin, 500 mg p.o. q.i.d. for 7 days
- or
- Amoxicillin 500 mg p.o. q.i.d. for 7 days

Alternative regimens

- Spectinomycin, 2 g i.m. in a single dose
- Cefotaxime, 500 mg i.m. once
- Ceftizoxime, 500 mg i.m. once
- Cefotetan, 1 g i.m. once
- Cefoxitin, 2 g i.m. once

Table 50.9 Centers for Disease Control 2002 recommended treatment guidelines for disseminated gonococcal infection during pregnancy.

Recommended inpatient regimen
Ceftriaxone, 1 g i.m. or i.v. q.d.
Alternative inpatient regimen
Ceftizoxime, 1 g i.v. q8h
or
Cefotaxime, 1 g i.v. q8h
or
Spectinomycin, 2 g i.m. q12h
Recommended ambulatory follow-up regimen
Cefixime, 400 mg p.o. b.i.d.

or compliance problems. CDC recommendations for treatment include ceftriaxone, ceftizoxime, cefotaxime, or spectinomycin (Table 50.9).²⁰¹ All regimens should be continued for 24–48 h after improvement begins. Therapy can then be switched to oral cefixime to complete a 7-day course. Although the value of continued inpatient observation of pregnant patients to reduce the risk of adverse perinatal outcomes has not been demonstrated, it may be advisable. The treatment of meningitis and endocarditis infections due to *N. gonorrhoeae* involves high-dose intravenous treatment with ceftriaxone (1–2 g every 12 h) for 2 and 4 weeks respectively.

Syphilis

Syphilis is a chronic, debilitating systemic infection caused by the spirochete *Treponema pallidum* and characterized by infrequent but severe and varied exacerbations.

When untreated, the natural history of this infection may encompass several decades. Two major stages are designated, early and late, and each of these is further separated. The phases of early syphilis are incubating, primary, secondary, and early latent. Late syphilis progresses from late latent to tertiary.

Epidemiology

Globally, there has been a steady decline in the incidence of syphilis since 1960. Both the United States and Europe experienced syphilis epidemics during World War II. Starting in 1982, there was an overall reduction in its incidence, due primarily to the fear of HIV and the use of safer sexual practices in men having sex with men.²¹⁷ Alarming, the incidence among inner city heterosexuals, particularly in New York City, Florida, Texas, and California, began rising in 1987 and peaked in 1990.²¹⁷ A disproportionate number of these cases were women, which led to a dramatic rise in the prevalence of congenital syphilis.^{218–220} Since the peak in 1990, the reported primary and secondary syphilis rates declined by

90% from 20.34 cases per 100 000 population to 2.12 per 100 000.²⁰⁰ The 2000 rate was the lowest since reporting of syphilis began in 1941. Unfortunately, since 2000, the rate of primary and secondary syphilis has increased for three consecutive years, and the 2003 rate (2.5 per 100 000) was 19% higher than that reported for 2000.²⁰⁰ The good news is that, despite a 62% increase among men, there has been a 43% decrease among women.²²¹ In 2003, there were 34 270 total reported cases of syphilis in the United States.²⁰⁰

Gestational and congenital syphilis tend to occur in young, nonwhite, unmarried, poor, inner city dwellers with insufficient antenatal care.

As with primary and secondary syphilis, the rate of congenital syphilis declined sharply from the peak of 107.3 per 100 000 population in 1991.²²¹ During 2003, a total of 413 cases of congenital syphilis were reported in the United States compared with 412 cases in 2002.²⁰⁰

Pathogenesis

Syphilis is efficiently transmitted during sexual contact, with 60% of partners acquiring the infection after a single sexual encounter. Spirochetes require a break in the integument in order to gain access to the host. Microscopic tears in genital mucosa occur almost universally during sexual intercourse. There follows a mean incubation period of 21 days, with a range of 10–90 days. The organism sets up a local infection and eventually disseminates widely via lymphatic drainage. Wherever it lodges, it stimulates an immune response.

Clinical manifestations

The manifestations of syphilis are wide ranging, involving nearly every organ system. The degree of clinical expression clearly reflects the immune status of the host. With an intact immune system, 60% of patients remain in the latent phase.

Primary

The first sign of primary infection is the development of a single, nontender lesion (chancre) at the site of entry. The most customary sites of infection in women include the vulva, introitus, or cervix. Extragenital sites include the lips, tongue, tonsils, breasts, and fingers. The syphilitic chancre is a painless, dull red macule, which becomes a papule and then ulcerates. Ulcers are rounded, with a well-defined margin and a rubbery, indurated, weeping base. The ulcer persists for 3–6 weeks without treatment and then heals spontaneously. Painless unilateral or bilateral inguinal lymphadenopathy often develops a week after the appearance of the lesion. Nodes are small, rubbery, and nonsuppurative.

Secondary

The symptoms of secondary syphilis typically emerge 3–6 weeks later. By this time, the infection is widely disseminated, and most symptoms are due to immune complex deposition. Nonspecific complaints include fever, malaise, sore throat, headache, musculoskeletal pains, and weight loss.

A classic faint macular rash develops over the trunk and flexor surfaces in the vast majority of infected individuals. Its lesions are pink, rounded, and ordinarily less than 1 cm in diameter. The rash spreads over the whole body, including the palms and soles, and becomes first dull red and papular, then squamous. Superficial ulcerations called mucous patches appear in the mucous membranes in 30% of patients. Also, generalized lymphadenopathy is present in the majority.

Latent

By definition, this stage lacks clinical manifestations. The early latent phase (less than 1 year) has been associated with recurrence of secondary mucocutaneous lesions, and these lesions are infectious. Although late latent syphilis (more than 1 year) cannot be transmitted sexually, vertical transmission to the fetus persists.

Tertiary

One-third of untreated patients develop tertiary syphilis. This is characterized by involvement of the cardiovascular, central nervous, or musculoskeletal systems. The presence of gummas in various tissues designates late benign tertiary syphilis. Aortic aneurysms and aortic insufficiency are characteristic cardiovascular lesions, whereas generalized paresis, tabes dorsalis, and optic atrophy with the Argyll Robertson pupil that accommodates, but does not react to, light are all features of neurosyphilis.

Laboratory diagnosis

The gold standard for diagnosis of early syphilis is the detection of treponemes on darkfield examination of ulcer scrapings or tissue samples. The test is inexpensive and easy, and provides immediate results. The reliability of this test is proportional to the skill of the person performing it. The lesion should be cleansed thoroughly with saline and scraped firmly to collect serum. If no spirochetes are apparent, the test should be repeated twice to increase sensitivity. Although a positive test result is diagnostic, a negative one does not preclude the possibility of infection.

Indirect diagnosis of syphilis can be made with the use of two types of serologic tests. Nontreponemal tests such as the Venereal Disease Research Laboratory (VDRL) test and rapid plasma regain (RPR) show reactive results approximately 2 weeks after development of the initial lesion. Both measure anticardiolipin antibody. In secondary syphilis, the VDRL titer is usually greater than or equal to 1 to 16. After successful treatment, the VDRL should decrease fourfold in 3 months and eightfold in 6 months. It should be nonreactive 1 year after therapy for primary infection, and 2 years for secondary disease.

Treponemal-specific tests include the fluorescent treponemal antibody absorbed (FTA-ABS) assay and microhemagglutination assay for antibody to *T. pallidum* (MHATP). More sensitive (70–90%) than nontreponemal tests, these tests become reactive at approximately the same time as the primary lesion

develops and are used to confirm the serologic diagnosis of syphilis. Unfortunately, these test results remain positive for life.

The diagnosis of latent syphilis is made on the basis of two elevated nontreponemal serologic test results taken at least 1 year apart. A further diagnostic workup includes evaluation of the cerebrospinal fluid (CSF).

The CDC recommends that all pregnant women should be screened for syphilis at their first prenatal visit.²⁰¹ Where prenatal care is problematic, the RPR card test screening (a rapid screen for syphilis) is recommended when pregnancy is diagnosed and treatment given if positive.²⁰¹ For women at high risk of syphilis and in populations with a high prevalence of syphilis, additional serologic testing at 28 weeks' gestation and at delivery is recommended.²⁰¹

Patients with neurologic or ophthalmic signs of symptoms, evidence of tertiary syphilis, treatment failure, or HIV infection with late latent syphilis of unknown duration should have CSF obtained to test for neurosyphilis.

The diagnosis of neurosyphilis is challenging, because no one test is reliable. The CSF should be tested for cell count, protein, and with the VDRL test. An elevated count of greater than 5 white blood cells/ μ L is a relatively sensitive indicator of active infection. A positive CSF VDRL result is diagnostic for neurosyphilis.

Treatment

In 1943, penicillin was found to be effective in treating syphilis. To date, no resistance has developed. The goal in therapy is to provide continuous, low-level concentrations of penicillin in infected tissues. It is still the preferred drug in gestational and congenital syphilis, as well as neurosyphilis. Women with history of penicillin allergy should undergo skin testing to validate the sensitivity and proceed with desensitization and penicillin therapy for optimal results.^{222,223}

Treatment regimens in pregnancy are listed in Table 50.10. Alternative regimens in nonpregnant patients include tetracy-

Table 50.10 Centers for Disease Control 2002 recommended treatment guidelines for syphilis in pregnancy.

Early syphilis recommended regimen (primary, secondary, and early latent syphilis)

Benzathine penicillin G, 2.4 million units (U) i.m. once
(1.2 million U in each buttock)

Late latent and tertiary syphilis recommended regimen

Benzathine penicillin G, 7.2 million U total administered as three doses of 2.4 million U i.m. given 1 week apart for three consecutive weeks

Neurosyphilis recommended regimen

Aqueous crystalline penicillin G, 12–24 million U administered
2–4 million U i.v. q4h for 10–14 days

Neurosyphilis alternative regimen

Procaine penicillin, 2.4 million U i.m. daily with
Probenecid, 500 mg p.o. q.i.d., both for 10–14 days

cline and doxycycline, both contraindicated during pregnancy. Pregnant patients who are allergic to penicillin should be treated with penicillin after desensitization.^{222,223}

The Jarisch–Herxheimer reaction is an acute reaction, apparently provoked by the release of prostaglandins during the initiation of treatment for primary or secondary infection.²²⁴ The reaction must be differentiated from penicillin allergy. It occurs within 24h of receiving the first dose of antibiotic and is characterized by fever, malaise, headache, musculoskeletal pain, nausea, tachycardia, and exacerbation of skin lesions. Although the reaction is more common in primary disease, its symptoms are more severe with secondary disease. Fluids and antipyretics are recommended for symptomatic relief. Pregnant women are at risk of preterm labor and intrauterine fetal demise.

Maternal and fetal risks

Pregnancy does not appear to alter the course of syphilis; however, *T. pallidum* adversely affects pregnancy. It crosses the placenta and has been associated with preterm delivery, stillbirth, congenital infection, and neonatal death, depending on the timing of infection. The majority of infants with congenital syphilis are born to mothers with early syphilis or secondary infection. Fetal infection during the first and second trimesters carries significant morbidity, whereas third-trimester exposure results in asymptomatic infection.^{225,226} Paley²²⁵ initially reported that approximately 50% of the pregnancies in which the untreated syphilitic infection was of less than 2 years' duration resulted in living nonsyphilitic infants. On the other hand, Fiumara et al.²²⁷ reported that, with untreated primary or secondary syphilis, 50% of the infants were premature, stillborn, or died as neonates, and the remaining 50% developed congenital syphilis. With early latent syphilis, 20–60% of infants were normal, 20% premature, and 16% stillborn; 40% had congenital syphilis. For late untreated syphilis, the congenital syphilis rate was 10%, stillbirth rate was 10%, premature rate was 9%, and healthy infants made up 70%. More recently, studies have confirmed the significant adverse effect of untreated syphilis on pregnancy outcome.^{228,229} Rici et al.,²²⁸ in Miami, reported a 34% incidence of stillbirth, 85% prematurity, and 21% IUGR. Overall, 68% of liveborn infants in this series had significant clinical disease. MacFarlin et al.,²²⁹ in Detroit, noted a 28% incidence of preterm birth. In this report, eight (75%) out of 12 women who received no antibiotic treatment for syphilis were delivered of stillborn infants; overall, stillbirth complicated 10 out of 72 (13.9%) women in the congenital syphilis group. These authors also documented an alarmingly high rate of failure of current therapy to prevent the development of congenital syphilis.

Infants with early congenital syphilis are usually asymptomatic at birth, but develop symptoms at 10–14 days of life. A maculopapular rash arises and often desquamates or becomes vesicular. Many develop a flu-like syndrome with a copious nasal discharge, commonly referred to as “snuffles.” Other

symptoms include oropharyngeal mucous patches, lymphadenopathy, hepatosplenomegaly, jaundice, osteochondritis, iritis, and chorioretinitis.^{226,227} Untreated early congenital syphilis progresses to the late phase, marked by Hutchinson teeth, mulberry molars, deafness, saddle nose, saber shins, mental retardation, hydrocephalus, general paresis, and optic nerve atrophy.

Pregnant women undergoing treatment for syphilis are at minimal risk of intrauterine fetal demise. Those who develop Jarisch–Herxheimer reactions are at increased risk of preterm labor.

Prevention

As noted previously, the accessibility of early and complete antenatal care with routine screening and adequate treatment for this infection is critical for prevention. Careful post-treatment follow-up is essential for controlling the spread of syphilis. Treatment failure is difficult to distinguish from reinfection. Patients should be examined and tested serologically at 3 and 6 months. If signs and symptoms persist or if non-treponemal antibody test results have not decreased appropriately after therapy, patients should undergo evaluation of their CSF and be retreated as warranted.

Partner tracing is particularly important in syphilis, given its prolonged course and multiple asymptomatic phases. In women with primary syphilis, all partners in the last 3 months should be evaluated; this time period should extend to 12 months for those diagnosed with secondary syphilis.

All patients with syphilis should be screened for other STDs, including confidential counseling and testing for HIV. Patients with coexistent HIV infection should be evaluated more frequently and treated for neurosyphilis in the event of any signs of persistent infection.

Chlamydial infections

Chlamydia trachomatis is the most frequently diagnosed bacterial STD in the United States, with an estimated prevalence of more than 4 million cases and an annual cost of more than US\$1 billion.^{200,230,231} In addition, chlamydia is the most commonly reported infectious disease in the United States with 877 478 cases of genital chlamydial infection reported in 2003.²⁰⁰ Lower genital tract infection predisposes nonpregnant women to pelvic inflammatory disease (PID), and pregnant women to a variety of maternal and neonatal infections.

Epidemiology

C. trachomatis is the causative agent of trachoma, the leading preventable cause of blindness in the developing world. In the United States, it is most frequently manifested as genital tract infections in the adult and inclusion conjunctivitis and pneumonia in the neonate.

It has been estimated that between 20% and 40% of sexually active women in the United States have been exposed to *C. trachomatis*. Cervical infection rates range from 5.5–22.5%

of asymptomatic women attending family planning clinics to 34–63% of women with mucopurulent cervicitis.²³² The prevalence among pregnant women depends on the population sampled, varying from 2% to 37%.²³²

Chlamydial infections tend to occur in women at high risk of other STDs, with infection rates proportional to the number of sexual partners and inversely proportional to age. Risk markers in pregnant women include age less than 20 years, unmarried status, low socioeconomic status, residence in inner cities, late presentation for prenatal care, the presence of other STDs, and the findings of mucopurulent endocervicitis or non-bacteriuric pyuria.^{233–236} Up to two-thirds of women with cervical chlamydial infection are asymptomatic, creating a large reservoir for both horizontal and vertical transmission.²³²

Pathogenesis

There are 15 recognized *C. trachomatis* serotypes, eight of which appear to cause oculogenital infection.²³³ The organism is classified as an obligate intracellular bacterium, requiring viable columnar or pseudostratified columnar epithelial cells for survival and multiplication. The bacterium has an interesting life cycle lasting 48–72 h. The elementary body is the form of the organism capable of infecting cells, whereas the reticulate body is the metabolically active, multiplying form responsible for producing the characteristic inclusions. The long growth cycle of *C. trachomatis* requires long-term therapy.

Clinical manifestations

The incubation period for genital chlamydial infections ranges from 6 to 14 days. A variety of clinical manifestations, from Bartholinitis to PID with peritonitis and perihepatitis, have been described. The most common perinatal syndromes are described briefly here.

Endocervicitis

The most commonly infected site in the female genital tract is the endocervix. As mentioned previously, the majority of infected women are asymptomatic. Findings on physical examination extend from normal to cervical erosion and mucopurulent cervicitis. Requisite components of the diagnosis of mucopurulent cervicitis include endocervical friability, erythema or edema, the presence of yellow or green endocervical mucus, and more than 10 polymorphonuclear leukocytes (PMNs) per high-power field of a cervical Gram stain.

Acute urethral syndrome

Chlamydial infection has also been implicated in the etiology of 25% of patients with acute urethral syndrome. Such women present with dysuria and increased urinary frequency in the face of sterile urine. Also, many report oral contraceptive use, recent contact with a new sexual partner, and a prolonged symptom duration of up to 14 days.²³⁷ Although *C. trachomatis* can sometimes be cultured from the urethra, it is

more frequently recovered from the endocervix of these patients.

Endometritis

It has been well established that the incidence of postabortion endometritis is higher among women with chlamydial cervicitis.^{238–242} Because up to 35% of women with chlamydial cervical infection who undergo elective termination develop endometritis, antibiotic prophylaxis is recommended for high-risk women.

The association between chlamydial infection and postpartum endometritis is more controversial. Although some authors have found such an association,^{243–246} others have not.^{247–249}

Acute pelvic inflammatory disease

The association between maternal lower genital tract *C. trachomatis* infection, neonatal inclusion conjunctivitis, and the subsequent development of postpartum PID has been recognized for 70 years.²⁵⁰ Chlamydial PID can also occur during pregnancy, although its incidence appears to be extremely rare.^{251–254} Pregnancy confounds the diagnosis, given the frequency of adverse gastrointestinal complaints and a physiologic leukocytosis among normal pregnant women, and the low prevalence of gestational PID. Because the rate of fetal wastage approximates 50% in pregnancies complicated by PID, prompt administration of appropriate broad-spectrum antibiotic coverage should be initiated once the diagnosis has been entertained.²⁵⁴

Maternal and fetal risks

Vertical transmission rates secondary to passage through an infected cervix are as high as 60–70%.²³² Inclusion conjunctivitis develops during the first 2 weeks of life in 25–50% of these neonates, whereas another 10–20% develop chlamydial pneumonia within 4 months of birth. Although the use of erythromycin eye prophylaxis has markedly decreased the incidence of conjunctivitis, this topical preparation gives no protection against pneumonia.

The role of endocervical *C. trachomatis* infection in the development of spontaneous abortion, fetal death, PROM, preterm delivery, and IUGR is debated. An association with spontaneous abortion, preterm delivery, and perinatal mortality was initially noted by Martin et al.²⁵⁵ These contentions have remained unsubstantiated in subsequent larger studies.^{247,248,256} Interestingly, however, both Harrison et al.²⁴⁸ and Sweet et al.²⁵⁷ have identified a subgroup of pregnant women with chlamydial infection, those with IgM seropositivity, who may be at increased risk of PROM and preterm delivery. One recent retrospective study compared the pregnancy outcomes of women with chlamydial infection who underwent successful treatment with both untreated infected and uninfected women and found a higher incidence of PROM and preterm delivery in the untreated infected group.²⁵⁸ Ryan et al.²⁵⁹ reported that pregnant women with chlamydial infec-

tion treated with erythromycin had significantly lower incidences of PROM, low birthweight and perinatal death compared with untreated infected women or uninfected control subjects.

Laboratory diagnosis

The diagnosis of chlamydia has seen phenomenal evolution. In the past, culture was considered the optimal means of making the diagnosis of chlamydial infection. However, isolation of *C. trachomatis* was challenging, because the organism requires a susceptible tissue culture cell line, using a technically arduous procedure whereby these cells are inoculated with specimen and then examined 24–72 h later for the development of inclusions.

The first major advancement in making *Chlamydia* testing more available was the introduction of chlamydial antigen detection products in the late 1980s. One is fluorescent monoclonal antibody staining of chlamydial elementary bodies (MicrotracSyva Co., Palo Alto, CA, USA), and the other is an ELISA (Chlamydiazyme, Abbott Laboratories, Chicago, IL, USA). The sensitivities and specificities of both products are comparable, at more than 90%.²³² Their most appropriate use is in populations with a high prevalence of chlamydial infection because their positive predictive value decreases markedly in low-prevalence populations.

These antigen detection tests were largely replaced in the 1990s by methods using DNA probe hybridization (PACE 2 test; Gen. Probe, San Diego, CA, USA). An important advantage of the DNA probe is that it can be used in conjunction with a probe for the detection of *N. gonorrhoeae* in a single swab. As a result, it became the most widely used diagnostic test for *C. trachomatis* in the United States.²⁶⁰

Most recently, DNA amplification methodology has been introduced into clinical practice. Both PCR and LCR tests for *C. trachomatis* have excellent sensitivity, specificity, and positive predictive value.^{261–263} In comparative studies, PCR and LCR have performed better than culture, antigen detection, or DNA probe techniques for the detection of *Chlamydia*. A major advantage of these amplification techniques is that they identify patients with a low inoculum of *C. trachomatis*.

Treatment

The CDC recommendations for the treatment of chlamydial genital tract infection during pregnancy are provided in Table 50.11.²⁰¹ As doxycycline and fluoroquinolones are contraindicated for pregnant women, erythromycin base and amoxicillin are the CDC-recommended regimens for the treatment of chlamydial infection during pregnancy. Crombleholme et al.²⁶⁴ were the first group to demonstrate the efficacy of amoxicillin in preventing vertical transmission of *C. trachomatis*. In addition, amoxicillin was well tolerated. Subsequent, randomized, prospective trials comparing amoxicillin and erythromycin for the treatment of chlamydial infection in pregnancy demonstrated treatment success in 85–99% of amoxicillin-treated patients compared with 72–88% of eryth-

Table 50.11 Centers for Disease Control 2002 recommended treatment guidelines for chlamydial infections in pregnancy.

Recommended regimen
Erythromycin base, 500mg p.o. q.i.d. for 7 days
or
Amoxicillin 500mg p.o. t.i.d. for 7 days
Alternative regimens
Erythromycin base, 250mg p.o. q.i.d. for 14 days
or
Erythromycin ethylsuccinate, 800mg p.o. q.i.d. for 7 days
or
Azithromycin 1g p.o. as a single dose

romycin-treated cases (Table 50.12). At the time when the current CDC guidelines for the treatment of chlamydial infection were published, the safety and efficacy of azithromycin in pregnant and lactating women had not been established.²⁰¹ Thus, azithromycin was suggested as an alternative regimen for pregnant women. Other alternatives include erythromycin ethylsuccinate or the option of reducing by half the dose of erythromycin base or ethylsuccinate but doubling the length of therapy for patients not able to tolerate the larger dose of erythromycin.²⁰¹ Erythromycin estolate is contraindicated in pregnancy because it is associated with drug-induced hepatotoxicity.²⁰¹

Prevention

The risks of vertical transmission to newborns, horizontal transmission to sexual partners, and possible adverse perinatal outcomes underscore the need for large-scale screening programs to detect and eradicate cervical chlamydial infections. The CDC recommends diagnostic testing for *C. trachomatis* at the first prenatal visit and, for those at high risk of contracting this infection, again during the third trimester. Finally, as with other STDs, it is important to emphasize the importance of partner screening and treatment, as well as education about safe sexual practices to avert reinfection.

Human papillomavirus

HPV is a member of the papovavirus family and is composed of double-stranded DNA. More than 100 types have been identified, of which 35 primarily infect the genital tract. Genital HPV types are generally divided into two major groups based upon their oncogenic potential.^{265,266} The high-risk or oncogenic group includes HPV types 16, 18, 31, 33, 35, and 39. The low-risk group includes HPV types 6, 11, 42, 43, and 44. These low-risk HPV types are associated with genital warts (condyloma acuminata), cervical condyloma, and some cases of low-grade squamous intraepithelial lesions (LGSIL).

Table 50.12 Amoxicillin versus erythromycin for the treatment of antenatal *Chlamydia* infection.

Authors	Percentage with treatment success		
	Amoxicillin	Erythromycin	P-value
Crombleholme et al. 1990 ²⁶⁴	63/64 (98%)	55/58 (95%)	NS
Magat et al. 1993 ³²⁷	55/65 (85%)	47/65 (72%)	NS

Among women in the United States today, genital warts caused by HPV is the most common viral STD.¹⁹⁰ Difficulties in deciphering the molecular biology of HPV slowed our progress in understanding this infection. Since the 1970s, however, the association of HPV with genital intraepithelial neoplasias and squamous cell carcinomas has been widely publicized, resulting in an increased public awareness of the problem.

Epidemiology

Sexual transmission of HPV is the primary route of transmission and results in urogenital and anorectal lesions. The highest risk groups are sexually active teenagers and young adults. Transmission rates are high, with 65% of sexual contacts becoming infected.²⁶⁷ Although sexual transmission predominates, vertical transmission can occur, particularly with HPV types 6 and 11.

According to the CDC, an estimated 24 million Americans are infected with HPV and between 500 000 and one million new cases of HPV-induced genital warts occur each year in the United States.²⁶⁸ Use of PCR technology has shown that the prevalence of subclinical HPV is higher, and recent studies have suggested that at least 50% of sexually active women have been infected with one or more HPV types.^{265,269} Host immunity plays an important role in the development of this infection. Immunosuppressed patients, such as renal transplant recipients and pregnant women, have a higher incidence of genital warts, and their symptoms are more severe.²⁷⁰

Clinical manifestations

The majority of HPV lesions are subclinical, identified only with colposcopy, cytology, tissue examination, or *in situ* hybridization techniques. They can be found on the vulva, vagina, cervix, and anorectal region. More recently, PCR technology has been utilized for the detection of HPV. Exophytic warts, also called condyloma acuminata, are typically caused by HPV types 6 and 11. They appear as friable, pink, fleshy skin appendages that vary greatly in size and are either broad based or pedunculated. Many lesions, however, are not visible

to the naked eye. These flat endophytic condylomata are found with the use of colposcopy on the cervix, vagina, and vulva.

Colposcopy uses a lighted, magnification system to view genital epithelium. A 3–5% solution of acetic acid is applied to the area to be examined and allowed to absorb. Common colposcopic findings in HPV infection are irregularly defined patches that appear shiny and white and are not confined to the transformation zone. Any suspicious lesion should be biopsied.

Laboratory diagnosis

The diagnosis of condyloma acuminata is usually made on clinical grounds. Given the high prevalence of subclinical disease, cytology, tissue biopsy, and *in situ* hybridization techniques are often necessary to make the diagnosis.

In the least sensitive of laboratory methods available, cytologic evidence in the form of koilocytosis has been found in approximately 2% of women receiving Pap smears.²⁷¹ Cervical biopsies tested for both koilocytosis and HPV antigen found that 20% were positive by both methods.²⁷² The most sensitive detection method for HPV has been DNA *in situ* hybridization. One study tested routine Pap smears using this technique and found that 16% had evidence of HPV types 6, 11, 16, or 18.²⁷³

Treatment

Treatment for HPV infection of the genital tract depends upon the anatomic location of disease (external genitalia/perianal, cervical, vaginal, or urethral), the clinical presentation of disease (clinical versus subclinical), and the extent of disease. The primary goal of treatment of external genital warts (condyloma acuminata) is to eliminate warts that cause physical or psychological symptoms or distress.²⁷³ However, elimination of genital warts may or may not decrease infectivity because internal sites (vagina or cervix) and clinically normal skin may act as reservoirs for infection.²⁷⁴

In most patients, treatment will include wart-free periods of varying lengths. The CDC notes that there is no evidence indicating that currently available treatment modalities eradicate

Table 50.13 Centers for Disease Control 2002 recommendations for treatment of external genital warts.**Recommended treatments***Patient applied*

Podofilox 0.5% solution or gel. Apply podofilox solution with a cotton swab, or podofilox gel with a finger, to visible genital warts twice a day for 3 days, followed by 4 days of no therapy. Cycle may be repeated as necessary for a total of four cycles or

Imiquimod 5% cream. Apply with finger at bedtime, three times a week for up to 16 weeks

Provider administered

Cryotherapy with liquid nitrogen or cryoprobe. Repeat every 1–2 weeks

or

Podophyllin resin 10–25% in compound tincture of benzoin.

Repeat weekly if necessary

or

TCA or BCA 80–90%. Repeat weekly if necessary

or

Surgical removal by tangential scissors excision, tangential shave excision, curettage, or electrosurgery

Alternative treatments

Intralesional interferon

or

Laser surgery

or affect the natural history of HPV infection.²⁰¹ Visible genital warts that are not treated may resolve spontaneously, remain unchanged, or increase in size or number.

For external genital/perianal warts (condyloma acuminata), the recommended therapeutic measures are listed in Table 50.13. According to the CDC, none of the currently available treatments is superior to other treatments, and no single treatment is ideal for all patients or all warts.²⁰¹ Available treatments for visible genital warts are divided into two categories: (1) patient-applied therapies (i.e., podofilox and imiquimod); and (2) provider-administered treatments (i.e., cryotherapy, podophyllin resin, trichloroacetic acid (TCA), bichloroacetic acid (BCA), interferon, and surgery). Factors influencing choice of treatment include wart size, wart number, anatomic site, wart morphology, patient preference, cost of treatment, convenience, side-effects, and provider experience.²⁰¹ Many patients require a course of therapy rather than a single treatment and, thus, it is important that providers have a treatment plan or protocol for the management of genital warts. The CDC suggests that the treatment modality should be changed if the patient has not improved substantially after three provider-administered treatments or if warts have not completely cleared following six treatments.²⁰¹

The use of podophyllin, podofilox, and imiquimod are contraindicated in pregnancy. During pregnancy, the best

approach to treatment is removal of lesions by excision, electrocautery, or cryosurgery. TCA application has been used in pregnancy without adverse effects.²⁷⁵ Laser therapy is another alternative among pregnant women with extensive disease.

For the treatment of vaginal exophytic warts, the recommendations include: (1) cryotherapy with liquid nitrogen; (2) TCA or BCA 80–90%; or (3) podophyllin 10–25% in compound tincture of benzoin.²⁰¹ Because of concern about potential systemic absorptions, it is best not to use podophyllin in the vagina. Podophyllin is contraindicated in pregnancy. Podofilox is not approved for vaginal use as the patient cannot visualize the lesions for application. For urethral meatus warts, either cryotherapy with liquid nitrogen or podophyllin is recommended.²⁰¹

Maternal and fetal risks

Warty lesions have a tendency to grow and become more vascularized during pregnancy. The only contraindications to a vaginal delivery are extensive lesions that might result in dystocia and lesions that might bleed heavily with birth trauma. Although some suggest removal of large warts during pregnancy, this practice is of uncertain benefit. Vertical transmission of HPV is rare, but can result in respiratory papillomatosis in the exposed infant. The exact mode of spread is unknown. Thus, Cesarean section is not recommended in the presence of genital warts in order to prevent vertical transmission of HPV.

Prevention

Given the fact that transmission rates are low, and adverse perinatal outcome unknown, it is not recommended that pregnant patients be routinely screened for HPV. Sexual partners of infected women should be examined for the presence of warts, and those infected should be schooled in safe sexual practices to avoid transmission to uninfected partners.

Herpes simplex virus

HSV is a double-stranded DNA virus that is a member of the Herpesviridae family. Two major serotypes are recognized: HSV-1 and HSV-2. Genital herpes is an infection caused by sexual transmission of HSV-1 and HSV-2. Following primary infection, HSV ascends to the dorsal root ganglion where it persists in a latent form throughout the host's lifetime. Subsequently, active viral replication and recurrent infection may or may not occur.

Epidemiology

There are an estimated one million new cases of genital HSV in the United States each year.¹⁹¹ While approximately 5 million American adults have a history of genital herpes, serologic surveys utilizing type-specific HSV-2 antibodies to glycoprotein G have demonstrated a seroprevalence for HSV-2 in 30% of adults; thus, an estimated 45 million Americans have been infected with HSV-2.^{191,276–278}

Three types of genital herpes infections are recognized on the basis of clinical history, serologic testing, and HSV typing. Primary infection is an initial infection with either HSV-1 or HSV-2 in an individual without serologic evidence of prior exposure to either HSV-1 or HSV-2. Nonprimary first clinical episode is an initial episode (clinical or subclinical) with HSV-1 or HSV-2 in an individual with serologic evidence of prior exposure to the other serotype. Recurrent genital herpes is reactivation of latent virus.

The prevalence of genital herpes based on culture of HSV in the obstetric population has been estimated at 0.1–4.0%.^{279–282} However, as noted above, use of specific HSV-2 antibody has demonstrated that 30% of adults in the United States have had genital herpes infection. Thus, these older studies underestimate the prevalence in pregnant women. A concomitant increase in the incidence of neonatal herpes infections paralleled the sharp rise in genital herpes infection among adults in the United States.²⁸³ Risk markers for herpes describe a population much different from the ones at risk for other STDs; this infection tends to occur in older, well-educated, married, white individuals.

Pathogenesis

The majority of genital herpetic infections are caused by HSV-2, although up to 15% may be due to HSV-1.^{284,285} HSV infects susceptible mucosal surfaces. It has an incubation period of 2–10 days, which is followed by a primary infection characterized by focal vesicle formation and a pronounced cellular immune response. The infection enters a latent phase, with the virus ascending peripheral sensory nerves and coming to rest in nerve root ganglia. Recurrent exacerbations occur intermittently, stimulated by poorly understood mechanisms.

Clinical manifestations

As noted above, there are three types of herpetic episodes. Primary infections occur in previously unexposed hosts and are characterized by multiple, painful, vesicular lesions that ulcerate, with inguinal lymphadenopathy and flu-like symptoms, including fever, malaise, nausea, headaches, and myalgias. Symptoms usually persist for approximately 2 weeks, with viral shedding for approximately 12 days. Nearly 4% progress to viral meningitis.²⁸⁶

First-episode nonprimary genital herpes occurs in an individual with previous nongenital exposure to HSV-1 or HSV-2. Its presentation is generally much milder than primary infections.

Recurrent HSV is more frequent after HSV-2 infection. Approximately one-half of infected individuals experience a recurrence within 6 months.²⁸⁶ Most of these episodes are prefaced by a 1- or 2-day prodrome consisting of localized pruritus, pain, and paresthesias. Systemic manifestations are absent. The episode usually lasts approximately half as long as the primary outbreak, with only 4–5 days of viral shedding.

Laboratory diagnosis

Until recently, viral culture was the gold standard for diagnosis of HSV infection. HSV grows rapidly, and results are generally available within 48–72 h. Cultures are more likely to be positive among patients with first episodes of HSV infection and those with vesicles or pustules rather than ulcerative or crusted lesions. Detection of HSV in culture has been facilitated by the use of monoclonal antibodies in immunofluorescence or immunoassay tests.²⁸⁷

The introduction of nucleic acid amplification tests such as PCR has revolutionized the laboratory diagnosis of HSV. Compared with culture, PCR has excellent sensitivity and specificity for the detection of HSV. The clinical implications of PCR detection of low viral load, especially among pregnant women at term, remain to be determined.

Diagnosis of HSV infection has been further enhanced by the introduction of type-specific serology.^{286,288} Identifiable proteins for each HSV type are present in a characteristic protein coat; glycoprotein G-1 is associated with HSV-1 and glycoprotein G-2 with HSV-2. Detection of HSV-2 antibodies using glycoprotein G technology is virtually diagnostic of genital herpes infection. Type-specific serologic assays are now commercially available. United States FDA-approved type-specific assays include HerpeSelect-1 ELISA IgG and HerpeSelect-2 ELISA IgG and HerpeSelect 1 and 2 Immuno-blot IgG (Focus Technologies, Cypress, CA, USA).

While serologic screening for HSV-1 and HSV-2 infection in the general population is not recommended,²⁰¹ screening may be useful in counseling couples in which one partner has a history of genital herpes and the other does not, especially pre-conception or in pregnant couples.

Maternal and fetal risks

Neither the frequency nor the severity of recurrent genital herpes is increased during pregnancy.²⁸⁹ Primary episodes of genital herpes may be more severe during pregnancy.²⁸⁹ Initial reports demonstrated a threefold increase in spontaneous abortion with primary maternal HSV infection in early pregnancy.²⁹⁰ This association has been questioned more recently.²⁹¹ In 1997, Brown et al.²⁹¹ reported no overall differences in mean birthweight, gestational age at birth, incidence of IUGR, stillbirth, or neonatal death with acquisition of HSV infection during pregnancy. However, these investigators did demonstrate that acquisition of primary genital herpes in the third trimester of pregnancy was associated with preterm birth, IUGR, and substantial risk of neonatal herpes infection.²⁹¹

The major adverse impact of genital herpes in pregnancy is the development of neonatal herpes infection. An estimated 700–1000 cases of neonatal herpes infection occur each year in the United States, resulting in an incidence ranging from 1 in 3500 to 1 in 5000 births.²⁸⁹ Infection may be transmitted vertically either transplacentally or perinatally. Fortunately, transplacental transmission is rare. Neonatal symptoms typically arise during the first 7 days of life. Death occurs in

approximately one-third of infants, and neurologic sequelae are noted in most survivors.²⁹³ Perinatal acquisition occurs either with passage through an infected birth canal or from contact with orolabial lesions in the parents or hospital workers.²⁸⁹ The vast majority (> 85%) of neonatal herpes infection is acquired from an infected maternal genital tract during the process of labor and delivery.²⁹²

During the past two decades, risk factors associated with transmission of HSV from mother to neonate have been elucidated.^{289,292} These include: (1) HSV type (HSV-2 > HSV-1); (2) maternal clinical stage of infection (primary > recurrent); (3) anatomic site of viral shedding (cervix > labia); (4) use of fetal scalp electrode; and (5) presence and specificity of transplacental passively transferred HSV antibodies from mother to infant. With recently acquired first-episode genital HSV infection, neonates have a 10-fold greater risk of acquiring HSV infection than infants born to mothers with recurrent infection. First-episode genital herpes infection, whether primary or nonprimary, is associated with neonatal infection rates of 40% and 31% respectively. Prober et al.²⁹⁴ demonstrated that passive transplacental passage of maternal antibodies to HSV-2 (but not HSV-1) are protective in a study reporting that, following exposure to HSV during labor and delivery, none of 34 infants with antibody present developed neonatal herpes infection (95% CI 0–8).

Primary HSV infection during pregnancy ranges from asymptomatic to severe, and may result in transplacental or intrapartum neonatal infection. It results in a 40% or higher risk of neonatal HSV infection, depending upon the presence or absence of maternal antibody to heterologous HSV type.²⁸⁹ With nonprimary first-episode genital herpes, maternal symptoms also range from asymptomatic to severe. However, mainly intrapartum acquisition occurs, and the risk of neonatal HSV infection is up to 40%.²⁸⁹ While with recurrent genital herpes symptoms also range from asymptomatic to severe, only neonatal infection secondary to intrapartum or postpartum acquisition occurs, and the estimated risk of neonatal infection is < 1–4%.²⁸⁹ The estimated risk of neonatal herpes occurring from an asymptomatic mother with a history of recurrent genital HSV is less than 1 in 1000.²⁸⁹

Until the mid-1980s, the approach for prevention of neonatal herpes focused on the use of weekly cultures for HSV starting at 34–36 weeks' gestation in women with a history of recurrent genital herpes.

Because weekly maternal vaginal cultures in the third trimester do not predict viral shedding at the time of delivery, this approach was abandoned. The Infectious Disease Society for Obstetrics and Gynecology developed a position paper on the peripartum management of women with a history of HSV.²⁹⁵ They made the following suggestions:

- Weekly antenatal cultures should be abandoned.
- In the absence of genital lesions, Cesarean sections should be performed for obstetric considerations only.
- A culture should be obtained from mother or neonate at delivery in order to identify exposed infants.

- Women with genital lesions should undergo Cesarean section, preferably within 6 h of membrane rupture, to prevent HSV exposure in the neonate.
- The mother should not be isolated from her infant.

Shortly thereafter (November, 1988), the ACOG issued a Technical Bulletin, which basically concurred with these recommendations.²⁹⁶ ACOG stated: (1) cultures should be done when a woman has active HSV lesions during pregnancy to confirm the diagnosis; (2) if there are no visible lesions at the onset of labor, vaginal delivery is acceptable; (3) weekly surveillance cultures of pregnant women with a history of HSV infection, but no visible lesions, are not necessary and vaginal delivery is acceptable; and (4) amniocentesis, in an attempt to rule out intrauterine infection, is not recommended for mothers with HSV infection at any stage of gestation. Until recently, limited experience with active herpetic lesions in the face of preterm premature rupture of membranes (PPROM) suggested that expectant management may be successful.^{297,298} More recently, Major²⁹⁹ reported a series of 29 patients with PPRM complicated by active recurrent genital HSV infection. The mean gestational age of the women was 28.7 weeks (range 24.6–31 weeks), and the mean latency from development of herpes lesions to delivery was 13.2 days (range 1–35 days). There were no cases of neonatal herpes infection among the delivered newborns, and all neonatal cultures for HSV were negative (95% CI 0–10.4).

Treatment

Because there is no known cure for this virus, HSV becomes a chronic and usually recurrent infection. Fortunately, there are antiviral medications now available that reduce the duration and frequency of HSV outbreaks, reduce symptomatic HSV shedding, and reduce the transmission of HSV.^{300–304} Acyclovir (Zovirax) is an antiviral agent that inhibits viral DNA synthesis by interfering selectively with viral thymidine kinase. Because of its selectivity for HSV-infected cells, acyclovir has a high margin of safety. It has been shown to ameliorate the symptoms of primary infections and, when given prophylactically, may reduce the frequency and intensity of recurrences. The drug is available in three forms: topical, oral, and intravenous. The oral preparation is considerably more effective than its topical counterpart. Oral acyclovir is recommended by the CDC for the treatment of genital herpes.³⁰⁰ Intravenous treatment should be reserved for severe infection or immunocompromised hosts. More recently, two additional antiviral agents, valacyclovir and famciclovir, have been approved for the treatment and suppression of HSV infection.³⁰⁰

The current CDC-recommended treatment guidelines for herpes simplex virus infections are listed in Table 50.14. If lesions of first-episode herpes infection are not fully healed, treatment with antiviral agents can be extended beyond 10 days. Intravenous acyclovir should be reserved for severe primary outbreaks or disseminated herpes infections. In these instances, the recommended treatment is acyclovir i.v.

Table 50.14 Centers for Disease Control and Prevention 2002 recommended treatment guidelines for genital herpes.**Recommended regimens: first clinical episode**

Acyclovir 400 mg orally, three times a day for 7–10 days
 Acyclovir 200 mg orally, five times a day for 7–10 days
 Famciclovir 250 mg orally, three times a day for 7–10 days
 Valacyclovir 1 g orally, twice a day for 7–10 days

Recommended regimens: episodic recurrent regimens

Acyclovir 400 mg orally, three times a day for 5 days
 Acyclovir 200 mg orally, five times a day for 5 days
 Acyclovir 800 mg orally, twice a day for 5 days
 Famciclovir 125 mg orally, twice a day for 5 days
 Valacyclovir 500 mg orally, twice a day for 3–5 days
 Valacyclovir 1 g orally, once a day for 5 days

Recommended regimens: suppression of recurrent episodes

Acyclovir 400 mg orally, twice a day
 Famciclovir 250 mg orally, twice a day
 Valacyclovir 500 mg orally, once a day*
 Valacyclovir 1 g orally, once a day

*Valacyclovir 500 mg once a day might be less effective than other dosing regimens in patients who have frequent (≥ 10 episodes per year) recurrences.

5–10 mg/kg every 8 h for 2–7 days or until clinical improvement followed by oral antiviral therapy to complete at least 10 days of therapy.³⁰⁰

Following the first clinical episode of genital herpes, two alternative approaches are available: episodic therapy with signs of recurrent outbreak or continuous suppressive therapy. Episodic treatment has been shown to decrease the proportion of patients with outbreaks, reduce the duration of symptoms, and shorten the duration of viral shedding.²⁸⁸ Suppressive therapy reduces the frequency of genital herpes recurrences by 70–80% among patients with frequent recurrences and, in many patients, no symptomatic outbreaks occur.²⁸⁸

Interest has focused on the use of acyclovir prophylaxis during late pregnancy to prevent recurrent herpes simplex virus infection at delivery.³⁰⁵ Acyclovir is well tolerated in pregnancy with minimal fetal drug accumulation.³⁰⁶ The Acyclovir in Pregnancy Registry assessed data from over 1200 pregnant women exposed to acyclovir with no increases in drug-related fetal abnormalities attributed to acyclovir use.³⁰⁵ However, long-term developmental outcomes were not evaluated. While the CDC suggested that insufficient data exist to recommend prophylaxis in pregnancy,³⁰⁰ the ACOG suggest that use of acyclovir to suppress recurrent HSV infection in late pregnancy is acceptable.³⁰⁷ ACOG notes that, for women at or beyond 36 weeks of gestation who are at risk of recurrent HSV infection, antiviral therapy may be considered. However, they caution that such therapy may not reduce the likelihood of Cesarean delivery. Recently, Sheffield and colleagues³⁰⁵ performed a meta-analysis of acyclovir prophylaxis

to prevent HSV recurrence at delivery. They demonstrated that acyclovir prophylaxis commencing at 36 weeks' gestation was effective in reducing clinical HSV recurrences at the time of delivery [odds ratio (OR) 0.25, 95% CI 0.15–0.40], Cesarean deliveries for clinical recurrence of genital herpes (OR 0.30; 95% CI 0.13–0.67), total HSV detection at delivery (OR 0.11; 95% CI 0.04–0.31), and asymptomatic HSV shedding at delivery (OR 0.09; 95% CI 0.02–0.39).

Prevention

The following recommendations have been suggested for the management of genital herpes infection in pregnancy.²⁸⁹

- Women with primary HSV infection during pregnancy should be treated with antiviral therapy.
- Cesarean delivery should be performed on women with first-episode HSV infection who have active lesions at the time of delivery.
- For women ≥ 36 weeks' gestation with a first episode of HSV infection during the current pregnancy, antiviral therapy should be considered.
- Cesarean delivery should be performed on women with recurrent herpes who have active lesions or prodrome at labor and delivery.
- Expectant management of patients with preterm labor or PPRM and active HSV lesion(s) may be warranted.
- For women ≥ 36 weeks' gestation who are at risk of recurrent HSV infection, antiviral therapy may also be considered.
- In women with no active lesions or prodrome during labor, Cesarean delivery should not be performed on the basis of a history of recurrent herpes.

Trichomonas vaginalis

Trichomoniasis is a localized genitourinary infection caused by the protozoan *Trichomonas vaginalis*.³⁰⁸ It was first described in 1836 by Donne³⁰⁸ as a nonpathogenic resident of the genital tract. Its pathogenicity was recognized during the twentieth century in a novel set of experiments in which healthy male and female volunteers were inoculated with organisms and followed to describe the natural history of the infection.^{309,310} One of the most prevalent parasites in humans, it has been found in nearly 10% of healthy women and in up to 50% of patients screened at STD clinics. It has been estimated that 2–3 million women in the United States contract the infection annually.³¹¹ More recently, Cates¹⁹¹ estimated that 5 million new cases of trichomoniasis occur each year in the United States.

Epidemiology

Sexual contact is the primary mode of transmission for *T. vaginalis*, although the infection can be passed from mother to female infants during vaginal delivery. Because trichomoniasis is not a reportable infection, its epidemiology is difficult to ascertain. As noted above, as many as 5 million new cases of trichomoniasis occur annually in the United States.¹⁹¹ Screen-

ing studies comparing various populations have discerned that prevalence parallels the degree of sexual activity ranging from 2–3% in middle-class women to over 50% in women attending STD clinics.^{312,313} Prior to the introduction of metronidazole, *T. vaginalis* was responsible for approximately 25% of clinically evident cases of vulvovaginitis.³¹⁴ As a result of effective therapy, approximately 5–10% of vulvovaginitis is currently attributed to *T. vaginalis*.³¹³ As might be expected, barrier contraception has a protective effect, as do oral contraceptives.

It appears that asymptomatic infected men may serve as reservoirs for their female partners. Although only 30–40% of male partners of infected women carried *T. vaginalis*, it was recovered in 85% of female partners of infected men.³¹⁵ Finally, carriage of this STD is a risk marker for other STDs, especially gonorrhea, which is 1.4–3.0 times more frequent among women with trichomoniasis.^{315,316}

Pathogenesis

T. vaginalis is an oval-shaped, moderately anaerobic protozoon. The presence of four flagella and an undulating membrane render it motile. Multiple serotypes, which may correlate with virulence, have been identified. The parasite attaches to mucous membranes, but neither enters nor kills the cells. Instead, it induces a moderate cellular immune response.

Clinical manifestations

It appears that this pathogen confines itself to the genitourinary system. Although most men are asymptomatic, anywhere from 50% to 90% of infected women become symptomatic at some time. Host factors, such as vaginal pH, circulating hormonal levels, the integrity of the normal vaginal flora, and the presence of menstrual blood, appear to play important roles in the development of symptoms.

An abnormal vaginal discharge is noted by 50–75% of symptomatic women. In only 10% of these women is the exudate malodorous. Pruritus, dysuria, and dyspareunia are experienced in up to half of them. Low abdominal pain and lymphadenitis are relatively uncommon complaints.^{313,315}

Physical examination findings are normal in 15% of infected patients. Vaginal erythema and an excessive vaginal discharge are present in up to 75%, whereas vulvar inflammation is much less common. The so-called classic findings of a yellowish-green frothy discharge and strawberry cervix are relatively uncommon, seen in 25% and 2% respectively.^{313,315}

Laboratory diagnosis

Because clinical manifestations are so nonspecific, the clinician must rely on laboratory parameters to make the diagnosis. Most commonly, the diagnosis is made by light microscopic examination of a saline wet mount. The vaginal pH is ≥ 4.5 in the majority of patients. Performance of a Pap smear makes the diagnosis nearly 70% of the time.^{313,315,316}

Collection of a sample of vaginal discharge for wet mount or culture is the diagnostic procedure of choice. Because the

organism attaches only to squamous cells, evaluation of the endocervical columnar epithelium is positive in only 13% of women. A cotton swab should be used to wipe both anterior and posterior fornices. In the preparation of a wet mount, the swab should then be rubbed across a slide containing a drop of sodium chloride and immediately overlaid with a coverslip. Low to medium (100–400 \times) magnification with a light- or darkfield microscope should be used to examine the material. More recently, *T. vaginalis* has been identified as a risk factor facilitating the transmission and acquisition of HIV.³¹⁷ Large numbers of PMNs are generally present. *T. vaginalis* can be seen as motile ovoids that appear slightly larger than PMNs.³¹⁸ The sensitivity of the wet mount ranges between 40% and 80%, matching that of the Pap smear.^{313,319,320} Culture is the optimum method currently available for detecting the presence of *T. vaginalis*.³¹³ While easily performed, culture for *T. vaginalis* requires the use of special medium such as Diamond or Kupferberg. Culture, using a number of selective media, promotes growth in 2–7 days, and is 95% sensitive.³¹³ PCR technology has also been demonstrated to be an effective method for the diagnosis of trichomoniasis. However, no FDA-approved PCR test for *T. vaginalis* is currently available. An FDA-approved DNA probe-based test for *T. vaginalis* (Affirm VP III; Becton Dickinson, Sparks, MD, USA) is also available.³²¹

Treatment

Until 40 years ago, trichomoniasis was a chronic, relapsing urogenital infection. In the 1960s, the 5-nitroimidazoles, including metronidazole, were developed and found to be effective in the treatment of this infection.³²² Recent years have seen the development of isolated clusters of resistant organisms.³²³

Given the colonization of both genital and urinary tracts, a systemic agent is needed. The original regimen for metronidazole therapy lasted 7 days. This has been shortened to a single oral dose in order to improve compliance, decrease the total dose, and deal with the problems of alcohol use during treatment (Table 50.15). Cure with this regimen is achieved in 82–88% of cases, and this increases to 95% when partners are treated empirically.

Relative resistance of *T. vaginalis* to metronidazole is documented.³²⁴ For treatment failures, the CDC recommends

Table 50.15 Centers for Disease Control 2002 recommended treatment guidelines for trichomoniasis in pregnancy.

Recommended regimen
Metronidazole,* 2 g orally in a single dose
Alternative regimen
Metronidazole,* 500 mg twice daily for 7 days

*Metronidazole cannot be recommended for use in the first trimester.

retreatment with metronidazole 500mg twice daily for 7 days.²⁰¹ If failure occurs again, a single 2-g dose once daily for 3–5 days is recommended. For patients still having persistent trichomoniasis, the CDC suggests excluding reinfection, evaluating the *in vitro* susceptibility of the isolate, and managing in consultation with an expert.²⁰¹ In May 2004, tinidazole (Tindamax) was approved by the FDA for the treatment of trichomoniasis with a suggested treatment regimen of a single 2-g oral dose.

Metronidazole freely crosses the placenta. Studies of limited numbers of pregnant women have shown no increased risk of spontaneous abortion or adverse perinatal outcomes.³¹³ Thus, the use of metronidazole in pregnancy appears to be safe. However, some experts prefer to wait until the second trimester to use metronidazole.²⁰¹

Maternal and fetal risks

Studies with conflicting results have been published on the potential association of *T. vaginalis* with adverse pregnancy outcomes. In an adolescent, inner-city population with a *T.*

vaginalis prevalence of 34%, Hardy et al.³¹² noted that *T. vaginalis* was associated with low birthweight and preterm birth. In contradistinction, Mason and Brown,³²⁵ in a similar high-prevalence population, found no association with adverse pregnancy outcome. In a similar vein, Minkoff et al.³²⁶ failed to find a significant association between *T. vaginalis* and preterm labor. Conversely, the Vaginal Infection and Prematurity Study demonstrated that *T. vaginalis* in midpregnancy was significantly associated with preterm low birthweight (OR 1.6, 95% CI 1.3–1.9).³¹³ However, a recent prospective randomized trial of metronidazole versus placebo sponsored by the NIH demonstrated that metronidazole treatment of asymptomatic pregnant women with trichomoniasis (identified by culture) during the midtrimester resulted in an increased risk of preterm birth.³³

Prevention

Because this infection is sexually transmitted, its diagnosis should serve as a reminder to test carefully for the coexistence of other, more dangerous STDs.

Key points

- 1 Determine the HIV serostatus of all women as early in pregnancy as possible. The preferred testing algorithm involves the “opt-out” approach, in which women are routinely informed that they will be tested unless they specifically request to opt out.
- 2 Women’s viral load and CD4 counts should be monitored and HAART administered per standard recommendations. If the woman’s viral load and CD4 results do not, unto themselves, justify HAART therapy, consideration should still be given to aggressive therapy in order to minimize the likelihood of MTCT.
- 3 While HAART is probably the most effective regimen for MTCT prevention, there are circumstances (e.g., viral load less than 1000) when alternatives might be acceptable. At a minimum, for the reduction of perinatal HIV-1 transmission, ZDV prophylaxis according to the PACTG 076 regimen is recommended unless the woman is intolerant of ZDV.
- 4 Plasma HIV-1 RNA levels should be monitored during pregnancy according to the guidelines for the management of HIV-1-infected adults. The most recently determined viral load value should be used when counseling a woman regarding mode of delivery.
- 5 If HAART is successful, then viral load will drop by more than 1 log per month, not rebound, and be undetectable within 6 months.
- 6 If HAART fails, resistance testing should be performed before discontinuing the initial regimen and choosing a new one.
- 7 Perinatal HIV-1 transmission is reduced by scheduled Cesarean delivery among women with unknown or high HIV-1 RNA levels who are not receiving antiretroviral therapy or are receiving only ZDV for prophylaxis of perinatal transmission. The benefit among women on HAART is unproven. Given the low rate of transmission among this group, particularly among those with a low viral load, it is unlikely that scheduled Cesarean delivery would confer additional benefit in reduction of transmission.
- 8 Management of women originally scheduled for Cesarean delivery who present with ruptured membranes or in labor must be individualized based on duration of rupture, progress of labor, plasma HIV-1 RNA level, current antiretroviral therapy, and other clinical factors. The woman’s autonomy to make an informed decision regarding route of delivery should be respected and honored.
- 9 Women who present in labor with unknown HIV status should be offered rapid HIV testing.
- 10 If a woman was placed on antiretroviral therapy solely to prevent MTCT (i.e., she did not meet the criteria for therapy based on her own clinical, immunologic, or virologic status), then all medications should be discontinued once she has given birth.

Rheumatologic and connective tissue disorders in pregnancy

Gustavo F. Leguizamón and E. Albert Reece

Rheumatologic and connective tissue disorders are multisystem conditions that occur most commonly in women of reproductive age. Therefore, it is not unusual for the obstetrician to be challenged by patients with autoimmune disorders seeking preconception counseling or antenatal care. This chapter addresses the effect of systemic lupus erythematosus, scleroderma, rheumatoid arthritis, and ankylosing spondylitis on perinatal outcomes as well as the impact of pregnancy on the natural course of these conditions. Furthermore, drugs commonly used to treat these disorders during pregnancy and lactation are reviewed.

Systemic lupus erythematosus

Systemic lupus erythematosus (SLE) is a chronic autoimmune disorder of unknown etiology. It has an overall incidence in the United States of approximately 7 per 100 000.¹ A strong predilection for women is observed with a female to male ratio of 7:1. Furthermore, African-Americans and Hispanics have an excess risk of two- to fourfold over the background population.²

The onset of SLE is often subtle and can compromise one or multiple organ systems. Frequently, the disease is characterized by periods of disease activity alternating with quiescence. Systemic signs and symptoms are common and usually involve fatigue, fever, malaise, and weight loss. The frequency of involvement of major systems is depicted in Table 51.1.

Recently, the American College of Rheumatology (ACR) has reviewed and modified the 1982 revised criteria for the diagnosis of SLE (Table 51.2). Positive LE cell preparation was removed from the classification, and “positive finding of antiphospholipid antibodies” was included among the immunologic criteria.^{3,4} If at least four of the 11 ACR criteria are met (either simultaneously or serially), the diagnosis of SLE is achieved.

Laboratory evaluation

Antinuclear antibodies (ANA) are the most sensitive screening laboratory tool for evaluating patients with the clinical suspi-

cion of SLE. Approximately 90% of patients with SLE will present a positive test for ANA. False positives have been reported in normal subjects and those with chronic inflammatory disorders, other autoimmune diseases, certain drugs, and viral infections. A negative ANA result makes the diagnosis of lupus very unlikely, whereas a positive result ($> 1/80$) favors the diagnosis. Antibodies directed against double-stranded DNA (ds DNA) and Sm have better specificity; however, they are present in a minority of the patients. Antibodies against ds DNA are present in approximately 60% of patients suffering from lupus and have been associated with disease activity and nephritis.^{5,6} Anti-Sm antibodies are present in Caucasian and black populations with SLE in approximately 10% and 30% of the population respectively. It has also been suggested that these antibodies are associated with disease activity as well as renal and neurological involvement.⁷ Although the ability of antibody testing to predict disease activity is controversial, in general, rising titers of anti-ds DNA antibodies suggest a two- to threefold increased risk of flare in the following 3–4 months.⁶ In some patients, however, decreasing plasma complement together with other laboratory abnormalities such as microscopic hematuria, decreased leukocyte count, and increasing proteinuria are better predictors of lupus exacerbation.⁷

The presence of anti-Ro (SS-A) and anti-LA (SS-B) antibodies is of recognized clinical significance as they were consistently associated with neonatal lupus. These antibodies are present in 20–60% of patients with SLE depending on the techniques used for their detection. Table 51.3 depicts relevant clinical information for different ANA.

Effects of pregnancy on systemic lupus erythematosus

The impact of pregnancy on SLE is not fully elucidated. The fact that this disorder has a clear predilection for female subjects raises the notion that estrogen levels are involved in the pathophysiology of SLE. Therefore, high estrogen level conditions, such as pregnancy, generate significant concern.⁸ Overall, the incidence of lupus flares during pregnancy ranges from 15% to 63%.⁹ Early uncontrolled studies suggested exacerbations during pregnancy or the puerperium. More

Table 51.1 Frequency of organ system involvement in SLE.

System involved	Frequency (%)
Systemic	95
Musculoskeletal	95
Cutaneous	80
Hematologic	85
Neurologic	60
Cardiopulmonary	60
Renal	50
Gastrointestinal	45
Vascular	15

recent reports have shown contradictory results. While some authors report no differences in lupus flares during pregnancy,^{10–13} others observed disease exacerbation.^{14–17}

Lockshin et al.¹³ compared different clinical markers of disease activity in 33 pregnancies of women with SLE with nonpregnant women with SLE matched for age, race, organ involvement, and disease severity. Both groups were followed for periods of up to 1 year after delivery. No differences between pregnant and nonpregnant patients were observed; however, new-onset proteinuria occurred in four pregnant patients compared with one nonpregnant patient, and SLE-related thrombocytopenia occurred more frequently in pregnant patients. The authors concluded that, although

Table 51.2 The 1982 revised criteria for the classification of systemic lupus erythematosus.

Criterion	Definition
1. Malar rash	Fixed erythema, flat or raised, over the malar eminences, tending to spare the nasolabial folds
2. Discoid rash	Erythematous raised patches with adherent keratotic scaling and follicular plugging; atrophic scarring may occur in older lesions
3. Photosensitivity	Skin rash as a result of unusual reaction to sunlight, by patient history or physician observation
4. Oral ulcers	Oral or nasopharyngeal ulceration, usually painless, observed by physician
5. Arthritis	Nonerosive arthritis involving two or more peripheral joints, characterized by tenderness, swelling, or effusion
6. Serositis	a) Pleuritis – convincing history of pleuritic pain or rubbing heard by a physician or evidence of pleural effusion or b) Pericarditis – documented by ECG or rub or evidence of pericardial effusion
7. Renal disorder	a) Persistent proteinuria >0.5 g/day or > 3+ if quantitation not performed or b) Cellular casts – may be red cell, hemoglobin, granular, tubular, or mixed
8. Neurologic disorder	a) Seizures – in the absence of offending drugs or known metabolic derangements, e.g., uremia, ketoacidosis, or electrolyte imbalance or b) Psychosis – in the absence of offending drugs or known metabolic derangements, e.g., uremia, ketoacidosis, or electrolyte imbalance
9. Hematologic disorder	a) Hemolytic anemia – with reticulocytosis or b) Leukopenia – < 4000/mm ³ total on two or more occasions or c) Lymphopenia – < 1500/mm ³ on two or more occasions or d) Thrombocytopenia – less than 100 000/mm ³ in the absence of offending drugs
10. Immunologic disorder	a) Anti-DNA: antibody to native DNA in abnormal titer or b) Anti-Sm: presence of antibody to Sm nuclear antigen or c) Positive finding of antiphospholipid antibodies based on: an abnormal serum level of IgG or IgM anticardiolipin antibodies or a positive test result for lupus anticoagulant using a standard method or a false-positive serologic test for syphilis known to be positive for at least 6 months and confirmed by <i>Treponema pallidum</i> immobilization or fluorescent treponemal antibody absorption test
11. Antinuclear antibody	An abnormal titer of antinuclear antibody by immunofluorescence or an equivalent assay at any point in time and in the absence of drugs known to be associated with “drug-induced lupus” syndrome

From ref 3.

ECG, electrocardiogram.

pregnancy complications are frequent, the assertion that pregnancy causes exacerbation of SLE remains unproven. In a subsequent publication concerning 80 women whose pregnancies were complicated by SLE, these authors observed that, if only SLE-specific abnormalities were counted, disease exacerbation occurred in less than 13%.

Other investigators concluded that pregnancy increases the frequency of flare. Ruiz-Irastorza et al.¹⁶ compared the incidence of flare during pregnancy and puerperium in 78 SLE-complicated pregnancies and 50 consecutive, nonpregnant, age-matched SLE patients. Additionally, 43 of the pregnant patients continued attending the lupus clinic for the year after puerperium, and their course was compared with their course during pregnancy. The incidence of flare was 65% during pregnancy and/or the puerperium and 42% in the control group. The 43 patients controlled after the puerperium flared more frequently during pregnancy than thereafter. Kidney and central nervous system involvement was not different between the pregnancy and control groups. The authors concluded that SLE tends to flare during pregnancy, especially during the second and third trimesters and the puerperium. Finally, when flares occurred, they were not more severe than in nonpregnant patients. Similarly, Petri et al.¹⁵ and Wong et al.¹⁴ observed a significant increase in flare incidence associated with pregnancy. Numerous reasons can explain this lack of consistency: inadequate control, differences in patient cha-

racteristics, proportion of patients with antiphospholipid syndrome (APS), inconsistencies in flare definition, and methods of assessment of disease activity. Furthermore, physiologic changes of pregnancy such as palmar erythema, increased urinary protein excretion secondary to increased renal blood plasma flow, and changes in facial skin pigmentation can often lead to overdiagnoses of lupus flare in pregnancy.¹⁸ Table 51.4 summarizes current studies evaluating the impact of pregnancy on the occurrence of lupus flare.

Patients with lupus nephritis have a small but crucial risk of permanent renal function deterioration following pregnancy. Burkett¹⁹ reviewed six retrospective studies including over 200 pregnancies with lupus nephritis. The authors observed that 7% of the patients had permanent renal failure, 26% had transient renal function deterioration, and 60% had no significant change in renal function parameters. Conditions associated with improved outcomes include prepregnancy remission of at least 6 months, serum creatinine less than 1.5 mg/dL, creatinine clearance of 60 mL/min or more, or proteinuria of 3 g/24 h or less. In a case-control study, Urowitz et al.¹² concluded that inactive disease at conception was protective against the occurrence of flare during pregnancy.

Table 51.5 summarizes relevant information about pregnancy influencing the natural course of SLE.

Effects of systemic lupus erythematosus on pregnancy

SLE can affect pregnancy in different ways. It increases the risk of early and late pregnancy losses owing to hypertension, renal dysfunction, placental insufficiency, and its association with antiphospholipid syndrome APS. Furthermore, it is an important cause of fetal and neonatal heart block. Finally, it also increases the risk of spontaneous as well as medically indicated preterm labor. In the following sections, the relevant aspects of such complications are discussed.

Preeclampsia

Women with SLE have an increased risk of developing preeclampsia with an incidence of 15–32%.^{11,12,20} Several risk factors have been identified, such as lupus nephritis, APAS,

Table 51.3 Antibodies of clinical significance in SLE.

Antibody	Frequency (%)	Feature
Anti-ds DNA	60–90	Specific for SLE Associated with activity and nephritis
Anti-Sm	10–30	Specific for SLE Lupus nephritis?
Anti-La	20–40	Neonatal lupus
Anti-Ro	20–40	Neonatal lupus
Anti-RNP	10	Mixed connective tissue disorder

Table 51.4 Impact of pregnancy on lupus flare.

Authors	Publication year	Patients (n)	Design	Flare incidence
Lockshin et al.	1984	28	Matched	Equal
Mintz et al.	1986	75	Unmatched	Equal
Urowitz et al.	1993	46	Matched	Equal
Wong et al.	1991	22	Unmatched	Increased
Petri et al.	1991	37	Unmatched	Increased
Ruiz-Irastorza et al.	1996	68	Matched	Increased

Table 51.5 Effects of pregnancy on the natural course of SLE.

Increased incidence of flare during pregnancy and puerperium is controversial
Flare is frequent and can occur throughout pregnancy and puerperium
Women with quiescent disease at conception could have better outcome
Although onset of definitive renal failure can occur in pregnancy, patients with lupus nephritis and normal renal function usually have no long-term effects

and chronic hypertension. However, making the differential diagnosis between the onset of preeclampsia and the occurrence of lupus flare could be a difficult challenge for the obstetrician. Making the differential diagnosis is of utmost importance because the therapeutic approach differs substantially; while the lupus flare is treated with high doses of steroids, preeclampsia is most likely treated with seizure prophylaxis, control of hypertension and, eventually, delivery. Both conditions can coexist in a patient with SLE and, even when they present as a single complication, both can cause hypertension, deteriorating renal function, proteinuria, and edema. Laboratory evaluation can be helpful in making the differential diagnosis. Mainly, decreased complement levels (C3-C4-CH50), increased anti-ds DNA, leukopenia, hematuria, and the presence of casts in urine raise the suspicion for SLE flare, while the presence of microangiopathic hemolytic anemia, abnormal liver function tests, and hyperuricemia most likely indicate preeclampsia.

Fetal outcome

Most investigations are consistent with the notion that women with SLE present an excess risk of pregnancy loss. Early retrospective studies^{21–24} as well as more recent prospective investigations are consistent with this finding. Petri et al.²⁵ conducted a case-control study to compare the incidence of pregnancy loss (including spontaneous abortion, miscarriage, or stillbirth) between women whose pregnancies were complicated with SLE and two control groups. The authors found a significantly increased risk of 21% versus 14% and 8% in the control groups. Prospective studies addressing this issue are in agreement with a median incidence of pregnancy loss of approximately 20%.^{11,14,26–31} The incidence of preterm labor in this population has been reported to be from 20% to 50%.³² In a case-control study, Johnson et al.³² evaluated the causes of increased preterm delivery in this population. The authors found that premature rupture of membranes was the most frequent associated finding, and was present in 39% of gestations between 24 and 36 weeks' gestation. The incidence of intrauterine growth restriction (IUGR) is also increased, and has been reported in 12–32% of pregnancies complicated by SLE.^{14,28,33}

SLE complicating pregnancy constitutes a rather heteroge-

neous population, and several risk factors for poor fetal outcome have been described. Cortes-Hernandez et al.³⁴ recently evaluated clinical and laboratory markers of fetal outcomes in 60 patients with SLE and 103 pregnancies. In a multiple regression model, the authors observed that increased levels of anti- β_2 glycoprotein I, hypertension at conception, and hypocomplementemia were significantly associated with pregnancy loss (spontaneous abortions and stillbirth), occurring in 74%, 22%, and 44% of the cases respectively. Furthermore, the presence of anticardiolipin antibodies and hypertension during pregnancy as well as lupus nephritis was associated with IUGR and prematurity. Rahman et al.³⁵ also concluded that hypertension and maternal renal disease are predictors of poor fetal outcomes. In summary, although most pregnancies in women with SLE do well, those presenting with risk factors need to be monitored aggressively throughout pregnancy.

Selected patients with immune diseases have an excess risk of perinatal morbidity and mortality. The most significant factors influencing outcome are most likely activity of disease at conception, renal involvement, and the presence of APAS.

Antiphospholipid syndrome: definition, classification, and epidemiology

APS is an autoimmune disorder frequently associated with other immunologic-related diseases with significant impact on perinatal and maternal outcomes. Primary APS occurs in patients without other immune disorders, whereas the so-called secondary APS occurs in conjunction with autoimmune disease, mainly SLE.

Its diagnosis has been a matter of controversy and is still an ongoing process. Recently, an international consensus has been generated to orient research efforts and aid in clinical diagnosis (Table 51.6).³⁶ At least one clinical and one laboratory criterion must be met to achieve the diagnosis of APS. Clinical criteria consist of either vascular thrombosis or pregnancy complications, such as one or more unexplained deaths of a morphologically normal fetus at or beyond the 10th week of gestation, one or more premature births before 34 weeks of a morphologically normal neonate, or three or more unexplained consecutive spontaneous abortions before 10 weeks of gestation.

Although many antiphospholipid antibodies have been described, only lupus anticoagulant (LAC) and moderate to high levels of IgG and IgM anticardiolipins detected on two occasions separated by no less than 6 weeks are recognized criteria from the 1999 consensus conference. Laboratory detection of LAC must follow the guidelines of the International Society of Thrombosis and Hemostasis³⁷ including: (1) prolongation of at least one phospholipid-dependent coagulation test (e.g., activated partial thromboplastin time, dilute Russell's viper venom time, kaolin clotting time); (2) failure to correct the initial phospholipid-dependent clotting test when mixed with normal plasma; and (3) correction of the abnormal coagulation assay when excess phospholipid is added.

Table 51.6 International consensus statement on preliminary criteria for the classification of the antiphospholipid syndrome.

Clinical criteria
Vascular thrombosis: one or more episodes of arterial, venous, or small vessel thrombosis
Complication of pregnancy:
One or more unexplained deaths of a morphologically normal fetus at or beyond the 10th week of gestation or
One or more premature births before 34 weeks of a morphologically normal neonate or
Three or more unexplained consecutive spontaneous abortions before 10 weeks of gestation
Laboratory criteria
Anticardiolipin antibodies IgG or IgM present in blood at moderate or high levels on two or more occasions at least 6 weeks apart
Lupus anticoagulant antibodies detected in blood on two or more occasions at least 6 weeks apart, according to the guidelines of the International Society of Thrombosis and Hemostasis

From ref. 36.

Among patients with antiphospholipid antibodies, excess vascular and obstetric morbidity is observed when these antibodies react against the phospholipid-binding protein β_2 glycoprotein I. In contrast, antibodies reacting directly against negatively charged phospholipids are commonly transient and associated with intravenous drug exposure.³⁸ Therefore, laboratory detection of the anticardiolipin antibodies must be performed by standardized enzyme-linked immunosorbent assay (ELISA) methods measuring β_2 glycoprotein I-dependent anticardiolipin antibodies.³⁹

To test the Sapporo classification criteria, Lockshin et al.⁴⁰ studied a total of 243 consecutive patients with the clinical diagnoses of primary APS, secondary APS, SLE without clinical APS, and lupus-like disease without clinical APS. The authors reported a sensitivity and specificity of 71% and 98% respectively. Overall, studies show that concordance of antibodies is not always found. In fact, among patients with the syndrome, between 50% and 70% have both LAC and APS.^{39,41} Anticardiolipin antibodies (ACLA) tend to be more sensitive, whereas LAC is more specific. Specificity of ACLA increases with increasing titers and when IgG is present.³⁹ Five percent of healthy individuals present with ACLA;⁴² however, patients with SLE present with these autoantibodies more frequently than the general population, with an incidence of approximately 12–30%.^{43,44} Furthermore, among this group, the occurrence of thrombosis or pregnancy complications has been reported to be between 50% and 70% at long-term follow-up.^{42,45}

Fetal loss in the antiphospholipid syndrome

The association of pregnancy loss and APS has been reported consistently among patients with both primary and secondary APS.^{9,46} Rai et al.⁴⁶ studied the incidence of miscarriages (median 4) among 20 women with APAS and history of recur-

rent pregnancy loss who declined treatment in the next pregnancy and compared them with 100 consecutive women with recurrent miscarriage (median 4) of unknown etiology. The authors found a pregnancy loss rate of 90% among untreated women with APS versus 34% in the control group. In a cross-sectional study, Ginsberg et al.⁴⁷ evaluated the association between pregnancy loss and secondary APS among 42 women. Patients were considered to be positive for LAC and/or ACLA only when at least two tests were positive on separate occasions. Significant associations were found between previous pregnancy loss and both presence of LAC [odds ratio (OR) 4.8] and ACLA (OR 20). Importantly, when patients showed only transient LAC and/or ACLA, this association was lost.⁴⁷ Finally, when fetal loss occurs in association with APS, a high proportion of late (second and third trimester) fetal losses are observed.⁴⁸

Complications secondary to placental insufficiency such as IUGR, stillbirth, preeclampsia, and preterm labor are also commonly observed in this population.^{9,39,49} IUGR has been reported in 15–30% of pregnancies affected by APS.^{50,51} Abnormalities in tests of fetal well-being have been observed in as many as 50% of pregnancies with APS,^{52–54} leading to a preterm delivery rate of approximately 32–65%.^{52,53,55–57} Lockshin et al.⁵⁸ prospectively studied the relationship between ACLA and the presence of midpregnancy fetal distress among women with SLE. The authors found that all women with lupus presenting with abnormal antenatal fetal testing had abnormal ACLA values, while patients with normal antenatal test results had low antibody levels.⁵⁸ Loizou et al.⁵⁹ studied the impact of ACLA on fetal outcome among 84 women with SLE. The authors observed that, when antibodies were present, fetal loss tended to occur at a later gestational age (17.4 ± 7.1 weeks) and that 30% of the pregnancy losses occurred in the third trimester.⁵⁹

Finally, preeclampsia complicates pregnancies in women with APS with a frequency of 32–50%.^{52,53,55–57,60} Although some authors have observed elevated antiphospholipid antibodies among women who develop preeclampsia, especially at early gestational age,⁵⁰ others have not.⁶¹

Neonatal lupus syndrome (NLS)

This syndrome occurs rarely in neonates born to mothers with SLE. It has been described in 1 in 20000 live births in the general population.⁶² One or more of the following findings are characteristic: congenital heart block (CHB), cardiomyopathy, cutaneous lesions, thrombocytopenia, and hepatobiliary disease. The most frequent and severe finding in NLS is CHB. The occurrence of this complication is correlated with the presence of anti-SS-A/Ro and anti-SS-B/La antibodies. Among mothers with SLE, Ramsey-Goldman et al.⁶³ estimated a risk for CHB of 1 in 60; however, when anti-SS-A antibodies were present, the risk increased to 1 in 20. Furthermore, 85% of the mothers whose fetuses had CHB and structurally normal hearts presented with anti-SS-A/Ro and anti-SS-B/La antibodies.^{64,65} In a large series of data obtained from the

National Neonatal Lupus Registry, Buyon et al.⁶⁶ exposed relevant information to both support clinical management and counsel parents. Among 87 pregnancies with CHB and positive anti-SS-A/Ro and anti-SS-B/La antibodies, no major structural abnormalities were observed. The majority of abnormalities (82%) were diagnosed by ultrasound before 30 weeks of gestation. A significant mortality was found (19%), most likely occurring in the first 3 months of life. Although the cumulative 3-year survival was 79%, significant morbidity was present as 63% required pacemaker placement. Finally, for women with a previous child with CHB, the recurrence rate was 16%.⁶⁶

The frequency and characteristics of hepatobiliary disease were reviewed by Lee et al.⁶⁷ Among 219 cases, 19 (9%) had a diagnosis of hepatic disease. Most of them (16) were combined with either cardiac or cutaneous manifestations, and only three were isolated. Three clinical forms were observed: (1) severe liver failure present during gestation or in the neonatal period; (2) conjugated hyperbilirubinemia with mild or no elevations of aminotransferases, occurring in the first few weeks of life; and (3) mild elevations of aminotransferases occurring at approximately 2–3 months of life.

Neiman et al.⁶⁸ reviewed the feature of cutaneous manifestations in 57 infants born to 47 women who were positive for anti-SS-A/Ro, anti-SS-B/La, and/or anti-U1-ribonucleoprotein antibodies. Skin lesions usually emerged after ultraviolet (UV) exposure around 6 weeks of age and lasted an average of 17 weeks. Most frequently, it was manifested as a periorbital rash with secondary extension to the scalp, trunk, and extremities. Most (65%) resolved without sequelae, but 25% had chronic manifestations such as telangiectasia and skin dyspigmentation. Importantly, mothers who delivered a child with a cutaneous lupus manifestation had an increased risk of having a newborn with CHB in future pregnancies.⁶⁸

Clinical management of systemic lupus erythematosus in pregnancy

Preconception period

Frequently, patients seeking preconception counseling have been exposed to cyclophosphamide. This cytotoxic drug has been associated with decreased fertility as well as teratogenicity. Overall, the rate of permanent amenorrhea is approximately 25%,⁶⁹ and certain risk factors have been recognized as being associated with a higher risk. Ioannidis et al.⁷⁰ found that age (≥ 32 years) was a strong predictor of ovarian failure secondary to cyclophosphamide use. Furthermore, the cumulative dose was associated with the successive fertility rate.⁷¹ For those patients under treatment, an adequate method of contraception is mandatory as this drug has been associated with spontaneous abortion and teratogenicity when used during the first trimester.⁷²

Evaluation of renal function is of significant relevance during the preconception period. A 24-h urine collection for proteinuria and creatinine clearance should be obtained.

Furthermore, blood samples for complete blood count (CBC), platelet count, serum creatinine, and liver function tests are recommended. Disease activity should be determined on clinical grounds as well as with laboratory values such as the previously mentioned renal function, ANA, C3, C4, and anti-dsDNA. A remission period of no less than 6 months is recommended. A significant impact on pregnancy management is determined by the presence of APAS; therefore, anticardiolipins and lupus anticoagulant need to be evaluated. Finally, anti-SS-A/SS-B antibodies need to be measured as fetal cardiac conduction anomalies will increase the risk of perinatal death, especially if they are not recognized.

Prenatal care

Although there are no prospective randomized trials assessing the best strategy to enhance fetal and maternal well-being, some general conclusions can be made from the available information. During the first two trimesters of pregnancy, women should be evaluated every 2 weeks and weekly during the last trimester. At each visit, a urinalysis, blood pressure measurements, maternal weight, and evaluation for signs of flare should be obtained. A 24-h urine collection for proteinuria and creatinine clearance as well as serum creatinine and uric acid should be obtained every 1–3 months. Although there is no consistent evidence of the clinical value of serial ANA and complement determinations, some authorities recommend this approach. Normally, complement levels increase during pregnancy and with preeclampsia; therefore, this measurement could help in the early diagnosis of a flare, especially when the differential diagnosis is preeclampsia.^{73,74} An early ultrasound to establish heart activity and accurately date gestational age as well as an anomaly screen between 18 and 22 weeks is recommended. After 22–24 weeks of gestation, fetal growth should be followed with ultrasound every 4–6 weeks. Initiation of nonstress testing is advisable from 28 to 32 weeks according to individual risk factors. Patients who are at increased risk of fetal heart block need to undergo echocardiogram starting during the second trimester. Some authorities recommend performing a serial evaluation every 2 weeks between 16 and 24 weeks of gestation.⁶⁶ In general, the mode of delivery is determined by obstetric indications, and vaginal delivery should be attempted. An exception could be the delivery of the fetus with bradycardia secondary to CHB. In this case, fetal pulse oximetry should be considered for fetal monitoring during labor.⁷⁵ Figure 51.1 describes different levels of intervention in patients with SLE.

Drug therapy

The drugs most commonly used in the treatment of SLE are aspirin and other nonsteroidal anti-inflammatory drugs (NSAIDs), antimalarials such as hydroxychloroquine, corticosteroids, and cytotoxic agents. Many of these drugs present fetal side-effects and, therefore, the benefits should outweigh the risks for them to be administered during pregnancy.

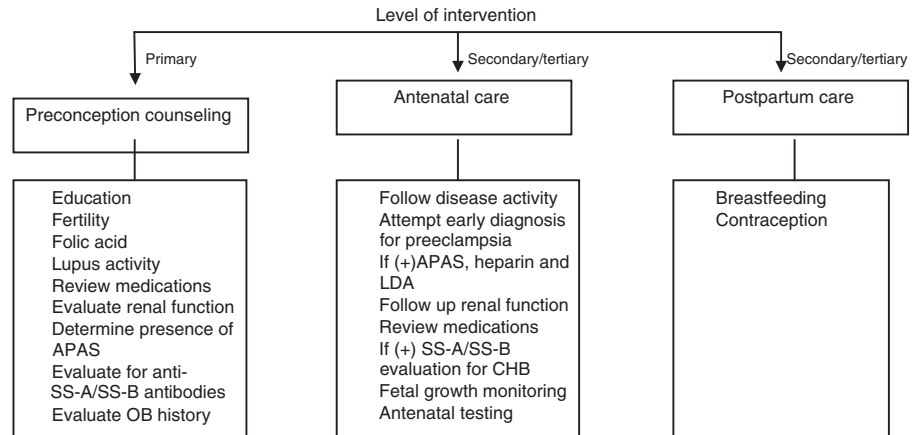

Figure 51.1 Levels of intervention in SLE.

Aspirin is commonly used as an analgesic for patients with rheumatic conditions, and the effects on pregnancy have been studied extensively. When used during the first trimester, no teratogenic effect has been identified;^{76–78} however, aspirin has been associated with increased incidence of miscarriages. Acetaminophen, on the other hand, appears to be safe during the first trimester.⁷⁹

In a population-based cohort study of 1055 pregnant patients recruited immediately after a positive pregnancy test, Li et al.⁷⁹ evaluated the effects of aspirin, NSAIDs, and acetaminophen on pregnancy loss. The authors found an 80% increased risk of miscarriage among women taking NSAIDs and aspirin. The association was stronger if the initial NSAID use was around the time of conception or if NSAID use lasted more than a week. Prenatal use of acetaminophen was not associated with an increased risk of miscarriage regardless of timing and duration of use.⁷⁹ During late gestation, NSAIDs and aspirin have been associated with a reduction in amniotic fluid levels and constriction of the fetal ductus arteriosus.⁸⁰ Therefore, acetaminophen appears to be safe at any trimester during pregnancy, and NSAIDs as well as aspirin are better avoided during the first trimester and after 32 weeks of gestation.

Corticosteroids are the other agents frequently used during pregnancy for patients with SLE. Maternal side-effects secondary to corticosteroids are gastrointestinal discomfort, fluid retention and hypertension secondary to the mineralocorticoid activity, bone demineralization, avascular necrosis, acne, and gestation diabetes. No teratogenic effect in humans has been described with these drugs.¹⁸ In fact, prednisone, prednisolone, and methylprednisone only minimally (~ 10%) cross the placenta, as an enzyme with 11- β -ol hydroxylase activity inactivates these drugs. Fluorinated steroids (β -methasone and dexamethasone) should be avoided when steroids are administered for maternal indications as they readily cross the placenta. Although theoretical risks exist for suppression of the hypothalamic-pituitary axis, no such effect has been consistently described in the literature. Finally, when a pregnant patient receives steroids for at least a month in the year pre-

vious to the delivery, she should receive a stress dose (100 mg of hydrocortisone intravenously) of steroids every 6 h to prevent acute adrenal failure.

Hydroxychloroquine (HCQ) is an antimalarial that has been used in pregnancy and lactation. This drug interferes with phagocytic function, leading to interference in antigen processing. Early reports raised concern regarding potential fetal ear and ocular side-effects;⁸¹ however, recent studies have shown a lack of teratogenicity or other significant fetal effects.^{82–85} Furthermore, recent reports suggest that discontinuing HCQ in high-risk patients may be associated with a poorer prognosis. Levy et al.⁸⁶ randomized 20 pregnant women with SLE to receive either HCQ or placebo. The authors found improvement in clinical disease scores as well as fewer flares and lower prednisone doses in the HCQ group. Gestational age at delivery and Apgar scores were higher in the HCQ-treated group. Finally, no congenital anomalies as well as normal neuro-ophthalmologic and auditory evaluations were observed at 1.5–3 years of age. Based on these data, it would appear prudent to continue HCQ therapy in pregnant patients with SLE.⁸⁶

In general, cytotoxic drugs are contraindicated during pregnancy. Azathioprine, however, has been widely used throughout gestation in patients with renal transplants and is the only cytotoxic agent that can be considered safe during pregnancy. For patients with SLE, azathioprine could be indicated when nephritis is present or in women without renal involvement requiring maintenance therapy of 15 mg or more of prednisone as well as those who have experienced recurrent flares. It is also effective for patients with skin lesions, pneumonitis, thrombocytopenia, or hemolytic anemia.⁸⁷ Early animal⁸⁸ as well as clinical studies^{89,90} suggested an increased incidence of IUGR; however, most recent series have demonstrated that azathioprine is well tolerated during pregnancy⁹¹ with no significant increase in congenital malformations or growth restrictions.⁷¹ Although hematological abnormalities in the offspring such as neonatal lymphopenia have been described, they are transient and disappear as the infant ages.⁹² Cyclosporine A has also been used in pregnant women with

renal transplants and continued during pregnancy in patients with rheumatic disease when other agents failed. Although some degree of fetal growth restriction was reported, no teratogenic effect was observed.⁷² Table 51.7 depicts the maternal and fetal toxicities of frequently used drugs.

Scleroderma

Systemic sclerosis is a connective tissue disorder that affects women four times more frequently than men with the mean age of onset in the early forties. This multisystem disorder is characterized by fibrosis of the skin, blood vessels, gastrointestinal tract, lungs, kidneys, and heart. Different degrees of organ involvement are associated with a wide range of clinical scenarios. Generally, two subsets can be described. In the diffuse cutaneous scleroderma form, symmetric skin thickening of extremities, face, and trunk is observed, frequently accompanied by kidney and other visceral involvement. On the other hand, in limited cutaneous scleroderma, fibrosis is usually confined to the skin of the proximal extremities and face, presenting a symmetrical distribution, and frequently has features of the CREST syndrome (calcinosis, Raynaud's phenomenon, esophageal dysmotility, sclerodactyly, and telangiectasia). In general, the prognosis of the limited form is more positive.

Early data, mainly from case reports, suggested that scleroderma complicating pregnancy carried an ominous prognosis.⁹³ More recent and larger studies suggest that, with careful planning and intensive monitoring, maternal and fetal prognosis are in general favorable.⁹⁴ Generally, scleroderma symptoms remain unchanged or even improve during pregnancy.⁹⁵ Gastroesophageal reflux commonly worsens and, if present, Raynaud's phenomenon tends to improve.⁹⁵ Although some authors suggested that skin thickening could increase postpartum,⁷² others found no evidence to support this belief.⁹⁵ Among pregnant patients with scleroderma, renal crisis is probably the most problematic complication, and its diagnosis represents a difficult challenge. It usually occurs during the first years following the diagnosis of diffuse scleroderma and presents with acute onset of severe hypertension, rapidly progressing renal impairment, daily increases in serum creatinine, and thrombocytopenia. The differential diagnosis includes preeclampsia-hemolysis, elevated liver function, and low platelets (HELLP) syndrome and is based on normal liver function tests, the rapid progression of renal deterioration with daily increases in serum creatinine, lack of proteinuria, as well as a history of diffuse scleroderma diagnosed within 5 years.^{72,95} Although the use of angiotensin-converting enzyme (ACE) inhibitors during the second and third trimesters has been associated with severe fetal toxicity,^{96,97} these drugs dramatically improve short- and long-term outcomes after a renal crisis in patients with scleroderma. Specifically, they increase survival and decrease the need for long-term dialysis after a renal crisis.⁹⁸ Furthermore, if treat-

ment is delayed, irreversible kidney damage or death can still occur.⁹⁹ Steen and Medsger⁹⁹ suggested that, if renal crisis is suspected, treatment should be started with a serum creatinine of less than 3 mg/dL. Finally, there is no evidence suggesting that abortion will reverse renal crisis.⁷⁰ Based on these findings, most authorities suggest that, if renal crisis is diagnosed in pregnancy, the parents should be counseled and ACE inhibitors offered as these therapies could be life-saving.

It is currently not possible to determine the impact of pregnancy on the development of renal crisis in patients with systemic sclerosis.⁹⁵

Overall, perinatal outcomes are good for women who demonstrate stable disease before conception, especially for patients with localized forms. Preterm labor is the most frequent complication, and recent studies show an incidence of approximately 30%.⁹⁵ Although some series have shown an increased incidence of growth restriction,¹⁰⁰ others have not confirmed this finding.⁹⁵ The rate of miscarriages was reported to be increased in older studies. Silman and Black¹⁰¹ in a retrospective study, described a twofold increase in the rate of spontaneous abortion. Recently, Steen and Medsger¹⁰² compared perinatal outcomes in 214 women with systemic sclerosis, in 167 women with rheumatoid arthritis (RA) and 105 healthy control subjects, and found no significant differences in the rate of first-trimester spontaneous abortion.

Rheumatoid arthritis

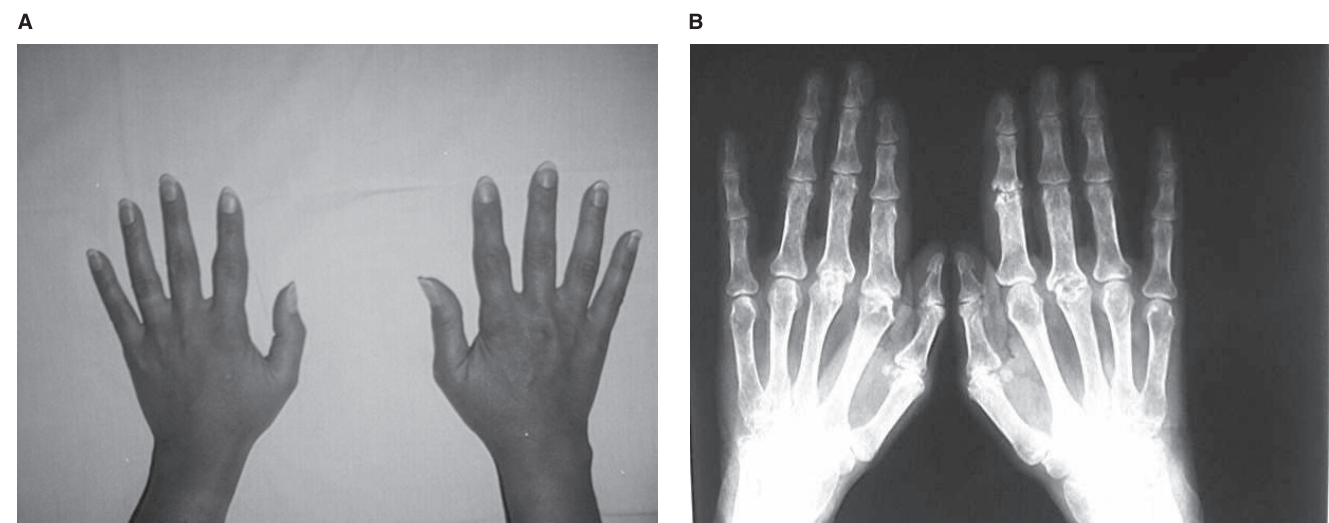

RA affects approximately 1% of the adult population and is three times more common in women, predominantly of reproductive age, complicating 1 in every 1000–2000 pregnancies.¹⁰³ It is a systemic, autoimmune, and inflammatory disorder that primarily affects synovial tissues. Its etiology is unknown, and it is characterized by symmetric involvement of peripheral joints such as metacarpophalangeal, proximal interphalangeal, wrist, and metatarsophalangeal, with characteristic cartilage destruction and eventual joint distortion. The affected joints characteristically present with swelling, and are warm and tender with limitation of movement and morning stiffness (Fig. 51.2A and B). Extra-articular involvement can occur including rheumatoid nodules, vasculitis, uveitis, interstitial lung disease, serositis, and Felty's syndrome. Usually, it has an insidious onset associated with fatigue, weakness, and anorexia. The disease has a chronic fluctuating course with variable degrees of compromise, with some patients having only a few joints affected and others presenting with significant disability. The diagnosis is not made by a single finding, but rather by the combination of clinical and laboratory findings together with the clinical course. The ACR published the revised criteria depicted in Table 51.8. These guidelines have a sensitivity and a specificity of 91–94% and 84%, respectively,¹⁰⁴ and are based on the presence of the following characteristics: morning stiffness, arthritis of three or more joint areas, arthritis of hand joints, symmetric arthritis, rheumatoid

Table 51.7 Side-effects of drugs commonly used in rheumatologic and connective tissue disorders.

Drug	FDA codes for use in pregnancy	Major maternal toxicities	Fetal toxicities	Lactation
Aspirin	C; D in third trimester	Anemia, peripartum hemorrhage, prolonged labor	Premature closure of ductus hypertension	Use cautiously; excreted at low concentration; doses >1 tablet (325 mg) result in high concentrations in infant plasma
NSAIDs	B; D in third trimester	As for aspirin	As for aspirin	Compatible according to AAP
Corticosteroids				
Prednisone	B	Exacerbation of diabetes and hypertension, PROM	IUGR	5–20% of maternal dose excreted in breast milk; compatible, but wait 4 h if dose >20 mg
Dexamethasone	C			
Hydroxychloroquine	C	Few	Few	Contraindicated (slow elimination rate, potential for accumulation)
Gold	C	No data	One report of cleft palate and severe CNS abnormalities	Excreted into breast milk (20% of maternal dose); rash, hepatitis, and hematologic abnormalities reported, but AAP considers it compatible
D-Penicillamine	D	No data	Cutis laxa connective tissue abnormalities	No data
Sulfasalazine	B; D if near term	No data	No increase in congenital malformations, kernicterus if administered near term	Excreted into breast milk (40–60% maternal dose); bloody diarrhea in one infant; AAP recommends caution
Azathioprine	D	No data	IUGR (rate up to 40%) and prematurity, transient immunosuppression in neonate, possible effect on germ lines of offspring	No data; hypothetical risk of immunosuppression outweighs benefit
Chlorambucil	D	No data	Renal angiogenesis	Contraindicated
Methotrexate	X	Spontaneous abortion	Fetal abnormalities (including cleft palate and hydrocephalus)	Contraindicated; small amounts excreted with potential to accumulate in fetal tissues
Cyclophosphamide	D	No data	Severe abnormalities; case report: male twin developed thyroid papillary cancer at 11 years and neuroblastoma at 14 years	Contraindicated; has caused bone marrow depression
Cyclosporine A	C	No data	IUGR and prematurity; one case report: hypoplasia of right leg; not an animal teratogen and unlikely to be a human one	Contraindicated because of potential for immunosuppression

ICH, intracranial hemorrhage; AAP, American Academy of Pediatrics; PROM, premature rupture of membranes; IUGR, intrauterine growth retardation; CNS, central nervous system; IUD, intrauterine device.

Food and Drug Administration (FDA) codes used in pregnancy ratings are as follows: A, controlled studies show no risk. Adequate, well-controlled studies in pregnant women have failed to demonstrate risk to the fetus; B, no evidence of risk in humans. Either animal findings show risk but human findings do not or, if no adequate human studies have been performed, animal findings are negative; C, risk cannot be ruled out. Human studies are lacking, and results from animal studies are either positive for fetal risk or lacking as well. However, potential benefits may justify the potential risk; D, positive evidence of risk. Investigational or postmarketing data show risk to the fetus. Nevertheless, potential benefits may outweigh the potential risk; X, contraindicated in pregnancy. Studies in animals or humans, or investigational or postmarketing reports, have shown fetal risk that clearly outweighs any possible benefit to the patient.

Figures 51.2 Clinical (A) and radiological (B) evidence of RA lesions. Courtesy of Dr Carlos Perandones, Rheumatology Division, CEMIC, Buenos Aires, Argentina.

Table 51.8 1987 criteria for the classification of acute arthritis of rheumatoid arthritis.

Criterion	Definition
1. Morning stiffness	Morning stiffness in and around the joints, lasting at least 1 h before maximal improvement
2. Arthritis of three or more joint areas	At least three joint areas simultaneously have had soft-tissue swelling or fluid (not bony overgrowth alone) observed by a physician. The 14 possible areas are right or left PIP, MCP, wrist, elbow, knee, ankle, and MTP joints
3. Arthritis of hand joints	At least one area swollen (as defined above) in a wrist, MCP, or PIP joint
4. Symmetric arthritis	Simultaneous involvement of the same joint areas (as defined in 2) on both sides of the body (bilateral involvement of PIPs, MCPs, or MTPs is acceptable without absolute symmetry)
5. Rheumatoid nodules	Subcutaneous nodules, over bony prominences, or extensor surfaces, or in juxta-articular regions, observed by a physician
6. Serum rheumatoid factor	Demonstration of abnormal amounts of serum rheumatoid factor by any method for which the result has been positive in < 5% of normal control subjects
7. Radiographic changes	Radiographic changes typical of rheumatoid arthritis on posteroanterior hand and wrist radiographs, which must include erosions or unequivocal bony decalcification localized in or most marked adjacent to the involved joints (osteoarthritis changes alone do not qualify)

From Arnett FC, Edworthy SM, Bloch DA, et al. The American Rheumatism Association 1987 revised criteria for the classification of rheumatoid arthritis. *Arthritis Rheum* 1988;31:315–324.
MCP, metacarpophalangeal; MTP, metatarsophalangeal; PIP, proximal interphalangeal. For classification purposes, a patient shall be said to have rheumatoid arthritis if he/she has satisfied at least four of these seven criteria. Criteria 1 through 4 must have been present for at least 6 weeks. Patients with two clinical diagnoses are not excluded. Designation as classic, definite, or probable rheumatoid arthritis is *not* to be made.

nodules, serum rheumatoid factor, and radiographic changes. Early radiologic changes are less specific and mainly demonstrate joint effusion and evidence of soft-tissue swelling. Later on in the course of the disease, more characteristic findings are observed, such as symmetric involvement, juxta-articular osteopenia, and loss of cartilages with narrowing of joint spaces. Serum rheumatoid factor is present in approximately 80% of affected patients,¹⁰³ but it is not specific. In fact, it is present in 5% of healthy individuals as well as in patients with

SLE, Sjogren syndrome, and syphilis among others. Other frequent laboratory findings during periods of disease activity are normocytic normochronic anemia, increased erythrocyte sedimentation rate, C-reactive protein, as well as other acute-phase reactants.
The beneficial effect of pregnancy on the course of RA has been known for many years.¹⁰⁵ It has been reported that pregnancy induces improvement in RA symptoms in approximately 75% of women.¹⁰⁶ Recently, Barrett et al.¹⁰⁷ examined the influ-

ence of pregnancy on disease activity. The authors prospectively analyzed 140 women, of whom two-thirds reported decreased joint swelling and pain, while 16% experienced total remission during pregnancy. However, the authors considered that the influence of pregnancy on disease activity showed widespread variability. The mechanism for these improvements is complex and still under investigation. One of the leading hypotheses is related to the immunologic changes observed in pregnancy with increased T-helper type 2 responses, which could potentially counterbalance the exacerbated T-helper type 1 response observed in RA.¹⁰⁵ During the puerperium, however, the relapse rate is approximately 90%.¹⁰⁸ Silman et al.¹⁰⁹ conducted a case-control study to determine the relationship between the onset of RA and parturition in 88 women with recent-onset RA and 144 age-matched control subjects. There was an increase during the first 3 months postpartum [OR 5.6, 95% confidence interval (CI) 1.8–17.6], which was greater when RA onset occurred after the first pregnancy. Other investigators have linked this increased risk specifically with breastfeeding.^{110,111} Barrett et al.¹¹¹ prospectively followed and compared disease activity during pregnancy and 6 months postpartum among 49 nonbreastfeeders, 38 first-time breastfeeders, and 50 repeat breastfeeders. The authors found that women breastfeeding for the first time had increased disease activity at 6 months postpartum.¹¹¹ The considerable increase in prolactin secretion during breastfeeding together with its immunoregulatory activity are thought to be involved in the increase in disease activity or onset among susceptible women.¹¹² Finally, the risk of adverse perinatal outcome does not seem to be increased in women with RA.¹¹³ The fertility rate as well as the miscarriage rate is similar to that in the general population,¹¹³ and perinatal outcome is not different from that of healthy women.¹¹⁴ If general anesthesia is needed in patients with upper spinal involvement, caution must be exerted as atlanto-occipital joint luxation is an infrequent but severe complication. As perinatal outcome is not affected and RA activity tends to ameliorate during pregnancy, most concerns during the preconception and antenatal period focus on the safety of the medications.

Treatment

Treatment of RA is usually delivered by a healthcare team involving a primary-care physician, rheumatologist, and a physical therapist. The goal of the treatment is initially to attain remission of symptoms and maintenance of such remission over time together with adequate joint function.¹¹⁵ Non-pharmacologic treatment consists of education regarding the disease and psychological support to help patients to cope with the chronicity of this condition. Physical therapy is necessary to maintain adequate joint range of motion and includes supervised physical activity to improve muscle strength and improvement in emotional adjustment.¹⁰⁴

In nonpregnant individuals, three groups of agents are available for the treatment of RA: NSAIDs, corticosteroids, and

the so-called DMARDs (disease-modifying antirheumatic drugs), most commonly hydroxychloroquine, sulfasalazine, methotrexate, leflunomide, etanercept, and infliximab. Optimal treatment of RA in nonpregnant individuals consists of starting DMARD therapy within the first 3 months following diagnosis as these agents can arrest or delay the progression of the disease.¹¹⁶ NSAIDs are useful in decreasing symptoms especially during the first weeks until a definitive diagnosis is achieved and DMARDs start acting. However, these drugs do not decelerate the rate of disease progression.¹¹⁵ Low-dose oral glucocorticoids (< 10 mg/day) are effective in relieving symptoms¹¹⁶ as well as in slowing joint damage.^{117,118} However, their dose-dependent side-effects limit their long-term effectiveness. During pregnancy and the preconception period, patient education and guidance regarding drug side-effects are of utmost importance in achieving a good perinatal outcome. Frequently, the decreased disease activity during gestation allows patients to treat mild symptoms with analgesics such as acetaminophen, which have been shown to be safe for the fetus.⁷⁹ If NSAIDs are needed, they can be used with caution after the first trimester and up to 32 weeks. As the potential risk of decreased amniotic fluid is well proven, it is recommended that follow-up should include the assessment of amniotic fluid volume with ultrasonography during treatment. When steroids are required to control the symptoms of arthritis, they are generally considered to be safe for use in pregnancy and during lactation. Most DMARDs are contraindicated during pregnancy, lactation, and the preconception period.¹⁰⁴ Methotrexate and leflunomide have significant teratogenicity^{114,119} and therefore should be avoided during pregnancy. If pregnancy is detected in a woman already taking these agents, the agents should be discontinued immediately. When preconception planning is possible, either leflunomide should be stopped 2 years before conception or cholestyramine washout should be attempted in those women who desire to conceive sooner.¹²⁰ Methotrexate should be discontinued 3 months before conception.¹²⁰ Hydroxychloroquine and sulfasalazine can be used cautiously during pregnancy and lactation.¹²¹

Ankylosing spondylitis

Ankylosing spondylitis is an inflammatory condition with unknown etiology, strong genetic predisposition, and a remarkable association with human leukocyte antigen (HLA)-B27. It most frequently affects the axial skeleton; however, 30% of patients can develop peripheral arthritis.¹²² Its onset usually occurs during the reproductive years from adolescence to early adulthood. Characteristically, symptoms arise with insidious lumbar pain and morning stiffness. Later in the disease course, decreased spinal mobility can be observed. Laboratory evaluation has poor specificity and is not diagnostic. If isolated, rheumatoid factor and ANA are negative. Usually, patients are positive for HLA-B27¹²³ and for

Figure 51.3 Radiological evidence of sacroiliitis in a patient with ankylosing spondylitis. Courtesy of Dr Carlos Perandones, Rheumatology Division, CEMIC, Buenos Aires, Argentina.

active-phase reactants such as C-reactive protein. Chest radiographs are characteristic, when the disease is well established, demonstrating evidence of symmetric erosions and sclerosis of sacroiliac joints (Fig. 51.3). Furthermore, loss of the normal spine lordosis and squaring of vertebral bodies with calcification of the outer fibers of the annulus fibrosus giving the “bamboo spine” appearance can be seen. Diagnosis of ankylosing spondylitis is based on the modified New York criteria of 1984 including: (1) history of inflammatory back pain; (2) limitation of motion of the lumbar spine in the sagittal and frontal planes; (3) limited chest expansion; and (4) evidence of radiographic sacroiliitis. The presence of the first with any of the other criteria is sufficient for diagnosis.¹²⁴

Unlike rheumatoid arthritis, ankylosing spondylitis does not usually undergo remission during pregnancy. Ostensen and Ostensen¹²⁵ studied pregnancy performance in 930 patients with ankylosing spondylitis. The authors found that the mean age of onset was 23 years, and 21% had onset during pregnancy. Disease activity was unchanged in 33%, improved in 31%, and worsened in 33%. Interestingly, the group of

patients with symptomatic improvement had a previous history of peripheral arthritis and gave birth to a female fetus. Among patients with active disease at conception, 60% presented with postpartum flares within 6 months of delivery.¹²⁵ Women with ankylosing spondylitis can be reassured that the perinatal outcome is not significantly affected by the disease.^{125,126} Ostensen and Ostensen¹²⁵ observed a rate of miscarriage of 15%, with 93% of the deliveries being at term with a mean birthweight of 3340 g. Cesarean section was performed in 58% of cases. Finally, the authors found no evidence of an increased rate of infertility among women with ankylosing spondylitis.¹²⁵ Among offspring of women with ankylosing spondylitis, 12% had the disease by the age of 18 years. Therefore, children of women with ankylosing spondylitis seem to have an increased incidence of the disease over the general population.¹²⁷

Treatment during pregnancy is oriented to maintaining functional capacity as well as to ameliorating pain. NSAIDs can be used with caution, but must be avoided during the first trimester and during the last 8 weeks of pregnancy.

Key points

- 1 SLE is diagnosed when at least four of the 11 ACR criteria are met. Approximately 90% of the patients will be positive for ANA.
- 2 Either anti-Ro (SS-A) and/or anti-LA (SS-B) antibodies are present in 20–40% patients with the diagnosis of lupus, and they are associated with the occurrence of congenital heart block.
- 3 Whether pregnancy causes exacerbation of SLE is still under debate. However, flares occur frequently during pregnancy and the puerperium, and are not more severe than in nonpregnant patients.
- 4 Although most women with lupus nephritis have no permanent renal deterioration secondary to pregnancy (60%), some will develop permanent renal failure

- (7%). Inactive disease as well as mild renal dysfunction at conception are associated with improved outcome.
- 5 SLE is associated with an increased risk of poor perinatal outcome, such as early and late pregnancy loss, IUGR, preeclampsia, preterm labor, and neonatal complications secondary to complete heart block.
 - 6 The most significant factors influencing outcome are probably activity of disease at conception, renal involvement, and the presence of antiphospholipid syndrome (APS).
 - 7 Primary APS occurs in patients without other immune disorders, and secondary APS occurs in conjunction with autoimmune disease.
 - 8 At least one clinical and one laboratory criteria must be met to achieve the diagnosis of APS. Lupus anticoagulant (LAC) and moderate to high levels of IgG and IgM anticardiolipins detected on two occasions separated by no less than 6 weeks must be present to consider diagnosis.
 - 9 APS complicating SLE increases fetal risks of spontaneous abortion, stillbirth, IUGR, preeclampsia, abnormalities in tests of fetal well-being, and preterm delivery.
 - 10 During prenatal care, efforts should be directed to early detection of maternal complications, such as preeclampsia, lupus flare, renal function deterioration, and to fetal well-being including adequate growth, placental function, and normal heart rate.
 - 11 Women exposed to cyclophosphamide have a rate of permanent amenorrhea of approximately 25% and an increased incidence of infertility. Patient's age at exposure is an important risk factor. Adequate contraception is mandatory while undergoing treatment as this drug is teratogenic.
 - 12 NSAIDs can be used with caution during the second trimester and up to 32 weeks of gestation to relieve symptoms.
 - 13 Corticosteroids have no teratogenic effects. When required, prednisone or prednisolone can be utilized as only 10% of these drugs cross the placenta.
 - 14 When necessary, hydroxychloroquine can be used during pregnancy. It has been shown to have no teratogenic effect or significant neonatal morbidity.
 - 15 Azathioprine can be considered in pregnancy when a cytotoxic drug is necessary. Recent studies demonstrated that it is fairly well tolerated in pregnancy.
 - 16 In general, with careful planning and intensive monitoring, maternal and fetal outcomes are good in women with scleroderma.
 - 17 Among patients with scleroderma, renal crisis is the most severe complication. Although ACE inhibitors have significant fetal toxicity, these drugs could be life-saving and should be offered to pregnant women with scleroderma and renal crisis.
 - 18 The diagnosis of rheumatoid arthritis is based on the modified criteria of the ACR that evaluate the presence of the following characteristics: morning stiffness, arthritis of three or more joint areas, arthritis of hand joints, symmetric arthritis, rheumatoid nodules, serum rheumatoid factor, and radiographic changes.
 - 19 The course of rheumatoid arthritis shows significant improvements throughout pregnancy in the majority of women. However, most (90%) relapse in the puerperium and during breastfeeding.
 - 20 The fertility rate as well as the incidence of miscarriage is not increased in women with rheumatoid arthritis. Furthermore, perinatal outcome is similar to that in the general population.
 - 21 When preconception planning is possible, either leflunomide should be stopped 2 years before conception or cholestyramine washout should be attempted in those women who desire to conceive sooner. Methotrexate should be discontinued 3 months before conception. Hydroxychloroquine and sulfasalazine can be used cautiously during pregnancy and lactation.
 - 22 Diagnosis of ankylosing spondylitis is based on the modified New York criteria of 1984 including: (1) history of inflammatory back pain; (2) limitation of motion of the lumbar spine in sagittal and frontal planes; (3) limited chest expansion; and (4) evidence of radiographic sacroiliitis. The presence of the first with any of the other criteria is sufficient for the diagnosis.
 - 23 Ankylosing spondylitis does not generally undergo remission during pregnancy, and the few exceptions are observed in patients with involvement of the peripheral joints. Fertility and perinatal outcome are not significantly altered by the disease.

Dermatologic disorders during pregnancy

Thomas D. Horn and Jerri Hoskyn

Pigmentary alterations

The most common change in the skin during pregnancy is hyperpigmentation, which is most noticeable in more darkly complexioned individuals.¹ While darkening may affect the normal skin, it is more pronounced in scars, melanocytic nevi, and ephelides, and particularly in skin and mucosal surfaces that contain more melanin – genital and axillary skin, areolae, and the perineum. The linea alba may darken, becoming the linea nigra.

Melasma or chloasma, the latter term confined to pregnant women, occurs commonly in pregnancy or in patients taking oral contraceptive medications. Well-defined hyperpigmented macules arise on the face in a symmetric distribution, particularly on the cheeks and forehead. Wood's lamp examination highlights the affected skin, but is rarely necessary to establish the diagnosis. Ultraviolet light exposure enhances the hyperpigmentation; thus, treatment is directed toward bleaching the epidermal melanin and protecting the skin with sunscreens. Combinations of 4% hydroquinone (pregnancy category C) and sunscreens exist in various formulations. Topical retinoids (pregnancy category C) and azelaic acid (pregnancy category B) are reported to possess bleaching effects beneficial in the treatment of melasma. Delay of treatment until well after delivery is reasonable, as melasma resolves spontaneously in the majority of patients.

Melanocytic nevi, including Spitz nevi, are reported to increase in size during pregnancy. One prospectively performed study of photographic documentation of melanocytic nevi during pregnancy disputes this generally accepted notion by showing that only a small number of nevi change in size, with some nevi decreasing in surface area.² Thus, any melanocytic nevus undergoing significant change should be sampled to explore the possibility of melanoma. The exact incidence of melanoma arising in pregnancy is uncertain, but the event is rare. Prognosis appears to be the same, based upon the characteristics of the tumor, as in nonpregnant women

(Tables 52.1 and 52.2).³ Melanoma is the most common cause of placental metastasis. The risk of fetal metastasis is estimated to be 22%. This level of disease portends a poor prognosis for mother and fetus.^{4,5}

Vascular alterations

Spider angioma, capillary hemangioma, pyogenic granuloma, palmar erythema, varicosities and hemorrhoids, livedo reticularis, gingival hyperemia and hyperplasia, and dependent edema may arise in pregnancy. Spider angiomas are characterized by a central dilated arteriole with a fine meshwork of radiating capillary-sized vessels forming a blanching macule several millimeters in width. Firm pressure on the lesion followed by quick release reveals refilling of the lesion from the central arteriole with rapid spread outward. Persistent lesions may be destroyed using electric current or vascular laser. Pyogenic granuloma is a misnomer for a vascular tumor arising after minor trauma. The lesion is a lobular capillary hemangioma that is exophytic, beefy, and friable. These lesions may arise on mucosal and skin surfaces. Treatment is indicated to stop the nearly constant erosion and bleeding, and is best accomplished by removing the bulk of the tumor surgically followed by destruction of the feeder vessel. Left alone, pyogenic granulomas decrease in size and may involute. Livedo reticularis is asymptomatic, and is recognized by a lacy network of red–purple macules with intervening normal skin. The erythema blanches with pressure. Cold temperatures exacerbate the appearance of livedo reticularis.

Connective tissue alterations

Striae (striae distensae) arise from stretching of the skin from various causes and are common in pregnancy. Initially, they appear as symmetric reddish/purple linear macules with evolution to depressed skin-colored patches. Striae may itch. In

Table 52.1 Melanoma TNM classification.

<i>T classification</i>	<i>Thickness</i>	<i>Ulceration status</i>
T1	≤1.0 mm	a: Without ulceration and level II/III b: With ulceration or level IV/V

*Micrometastases are diagnosed after sentinel or elective lymphadenectomy.

†Macrometastases are defined as clinically detectable nodal metastases confirmed by therapeutic lymphadenectomy or when nodal metastasis exhibits gross extracapsular extension.

association with pregnancy, the lesions arise most commonly on the abdomen, but they may develop on other sites, including breasts, thighs, hips, and buttocks. Striae arise most commonly in the third trimester and have been associated with vaginal lacerations during delivery.⁶ While striae may fade over time, topical therapy with tretinoin cream 0.1% and application of pulsed-dye laser at 585 nm may improve their appearance.^{7,8} Unrelated to the appearance of striae, skin tags, or acrochordons, may proliferate during pregnancy. Skin of the neck, axillae, and groin are typical sites.

Hair and nail alterations

Hirsutism is defined as the development of a male pattern of hair growth (terminal and/or vellus) in a woman, while hypertrichosis is defined as an increased amount of hair. Both conditions may arise during pregnancy, but neither condition warrants concern or treatment. For persistent hair abnormal-

ities after delivery, topical application of eflornithine or the use of hair removal lasers may provide benefit.

Telogen effluvium is a shedding of hair that begins roughly 2–4 months after delivery, lasts for 2–4 months, and resolves over many months without intervention. A minority of patients progress to chronic telogen effluvium. In this disorder, anagen hairs, which normally account for 90–95% of all hairs, cycle into telogen. Telogen hair shafts are wispy, small, and nonpigmented and, thus, the appearance of hair loss ensues.

Changes in the appearance of the nail plate of fingers and toes are common. The nail plate may become brittle, and some patients report an increased rate of nail growth. The most common nail plate abnormality of significance is the development of Beau's lines in one or, more typically, several nails. Beau's lines are transverse depressions in the surface of the nail plate that arise from physiologic changes in the nail matrix. The Beau's lines will grow distally with continued nail growth, resulting in a normal nail plate after many months.

[†]Clinical staging includes microstaging of the primary melanoma and clinical/radiologic evaluation for metastases. By convention, it should be used after complete excision of the primary melanoma with clinical assessment for regional and distant metastases.

[‡]Pathologic staging includes microstaging of the primary melanoma and pathologic information about the regional lymph nodes after partial or complete lymphadenectomy. Pathologic stage 0 or stage IA patients are the exception.

[§]There are no stage III subgroups for clinical staging.

Dermatoses of pregnancy

The dermatoses of pregnancy are a group of skin conditions unique to pregnancy or directly related to the products of conception (Table 52.3).

Polymorphic eruption of pregnancy

Polymorphic eruption of pregnancy (PEP), also known as pruritic urticarial papules and plaques of pregnancy, is the most common of the pregnancy dermatoses.

Clinical presentation

Pruritic urticarial papules appear first on the abdomen, often

in the striae gravidarum, then progress to involve the thighs, buttocks, arms, and trunk (Fig. 52.1).⁹ Periumbilical skin is characteristically spared, as are the face, palms, soles, and mucous membranes. Papules may coalesce into plaques, sometimes surrounded by a pale halo¹⁰ and occasionally surmounted by pinpoint vesicles that do not progress to bullae.¹¹ In some cases, there are annular or target-like lesions. Excoriations are unusual despite the often marked pruritus. PEP presents in the third trimester, most commonly around the 35th week.^{9,10} Occasionally, the presentation is postpartum, usually within 10 days,¹² although in one case, PEP appeared 4 weeks after delivery.¹³ Primigravidas comprise about three-quarters of PEP cases.^{9,11,14} In multiple pregnancies, PEP appears to be more common, and may occur earlier and be more severe.^{10,15–17}

Table 52.3 Key features of the dermatoses of pregnancy.

	Incidence	Key signs/ symptoms	Presentation	Diagnosis	Course	Risks to mother or fetus	Recurrence	Treatment
PEP	1:150–160	Abdominal urticarial papules favoring striae, periumbilical sparing	36–39 weeks, rarely postpartum	Clinical Negative DIF	Self-limited, with resolution in 6 weeks	No	No	Symptomatic Systemic steroids in severe cases
CP	1:100–200	Pruritus ± jaundice	>30 weeks in 80%	Clinical Elevated serum bile salts	Resolution with delivery. Pruritus remits before laboratory values normalize	Yes, fetal distress	Yes	Symptomatic UDCA Delivery
PG	1:40 000– 60 000	Periumbilical urticarial papules, vesicles, bullae	Second and third trimesters	Clinical Skin biopsy Positive DIF	Remission in third trimester with postpartum flare. Resolution in 2–6 months	Yes, low birthweight, small for dates, prematurity	Yes Flare with OCP or menses	Systemic steroids
IH	Rare (case reports)	Grouped sterile pustules, favor flexural areas, constitutional symptoms	Second and third trimesters	Clinical Skin biopsy Negative DIF	Resolution with delivery	Yes, placental insufficiency	Yes Flare with OCP or menses	Systemic steroids Delivery or termination
PP	1:300	Red papules, most excoriated, on trunk and extremities	Third trimester	Clinical	Resolution by 3 months postpartum	No	Rare	Symptomatic
PFP	Case reports	Small follicular papules and pustules on the trunk	Third trimester	Clinical	Resolution with delivery	No	Unknown	Symptomatic

PEP, polymorphic eruption of pregnancy; CP, cholestasis of pregnancy; PG, pemphigoid gestationis; IH, impetigo herpetiformis; PP, prurigo of pregnancy; PFP, pruritic folliculitis of pregnancy; DIF, direct immunofluorescence; OCP, oral contraceptive pills; UDCA, ursodeoxycholic acid.

Course

PEP is self-limited, with most cases clearing prior to or within 1 week of delivery. In a typical course, the eruption evolves over 1–2 weeks and fades over the following 2–4 weeks. PEP rarely lasts beyond 6 weeks postpartum.¹² Resolution is not clearly tied to delivery,¹⁸ although in one severe case, early delivery led to prompt resolution of symptoms.¹⁹ PEP rarely, if ever, recurs in subsequent pregnancies.

Epidemiologic features

With an estimated incidence ranging from 1:150 to 1:240

pregnancies,^{11,20} PEP is the most common of the pregnancy-specific dermatoses. PEP is not thought to be familial, although there is one case report of its occurrence in two sets of sisters.²¹ There has been no association with particular human leukocyte antigen (HLA) subtypes.¹⁰

Pathogenesis

The pathogenesis of PEP is unknown. Given its association with abdominal striae and presentation late in pregnancy, maternal and/or fetal weight gain have been theorized to play a role, but the evidence for this has been contradictory.^{14,22,23}

Figure 52.1 Polymorphic eruption of pregnancy. Erythematous papules on the abdomen, sparing the umbilicus. Excoriations are present here, but are not typical. Image courtesy of Susan Mallory, MD.

Fetal DNA has been identified in the skin lesions of PEP, suggesting that a maternal immune reaction to fetal DNA may play a role in PEP, but this has not been proven.²⁴ Interestingly, fetal microchimerism has been detected in the blood of nonpregnant women as much as 27 years postpartum,²⁵ and there is one report of PEP-like lesions 28 years postpartum in a woman with a prior history of PEP.²⁶

Diagnosis and differential diagnosis

The diagnosis of PEP is a clinical one, as there is no confirmatory diagnostic test. No consistent laboratory or hormonal abnormalities have been associated with PEP,²⁷ and the histopathology is nonspecific, with negative direct immunofluorescence (DIF). The most important differential diagnosis is pemphigoid gestationis (PG), as the urticarial lesions of PG can be clinically and histopathologically indistinguishable from PEP. Only DIF can reliably distinguish these entities when the clinical picture is unclear. Other differential diagnoses include contact dermatitis, drug eruptions, erythema multiforme, and viral exanthems.

Prognosis

The prognosis for mother and baby is excellent. Aside from pruritus, there appear to be no risks to the mother. Likewise, there have been no reports of adverse outcomes for the babies of mothers with PEP. To date, there has been a single case report of a transient PEP-like eruption in a newborn whose mother was diagnosed clinically with PEP; however, because DIF was not done on either the mother or the baby, PG could not be definitively ruled out.²⁸

Management

As PEP is self-limited, treatment is aimed at controlling symptoms. Moderate- to high-potency topical steroids are helpful in the majority of cases. Antihistamines have been variably helpful. In severe cases, systemic steroids may be required. One severe case of PEP was delivered early via Cesarean section, with resolution of symptoms within hours.¹⁹

Pemphigoid gestationis

PG, also known as herpes gestationis and gestational pemphigoid, is an autoimmune blistering disorder similar to bullous pemphigoid, but is unique to pregnancy.

Clinical presentation

In classic PG, pruritic urticarial papules and plaques appear on the periumbilical skin and evolve into vesicles and tense bullae within days to weeks (Figs 52.2–52.5). Eventual palmoplantar involvement is common, but the face and mucous membranes are usually spared. Acute onset has been reported infrequently.²⁹ In some cases, pruritus may precede the rash, or the rash may consist only of urticarial lesions, never developing typical vesicubullous lesions.²⁹ Barring secondary infection, the lesions typically heal without scarring.³⁰

PG typically presents in the second or third trimester, with an average onset at 21 weeks.¹¹ Up to 20% of cases may begin in the postpartum period, usually within 3–5 days after delivery. Although there are case reports of PG presenting up to 35 days postpartum, the diagnosis of PG is suspect if presentation is delayed for more than a few days.^{30–32}

Course

In the third trimester, there may be relative remission or even clearance of the rash, but the vast majority will flare after delivery.^{11,29,30} Most cases will clear within 2–6 months, although postpartum duration of disease varies.^{31,32} In exceptional cases, disease activity has been reported to last one to several years after delivery.^{11,33–35} PG may appear in any pregnancy, but generally recurs thereafter, skipping fewer than 10% of subsequent pregnancies.^{29–31} Thirty percent of PG cases occur in primigravidas.¹¹ Recurrent episodes tend to occur earlier and to be more severe and prolonged.³⁰ Recurrent eruptions may or may not share the same morphology. In

other words, a typical eruption may be followed by one with urticarial lesions only, and vice versa.³⁰ Flares may occur with oral contraceptive pills and menses.³⁶

Epidemiologic features

PG is a relatively rare disorder, and estimations of its incidence

have varied widely from 1:1700²⁰ to 1:50 000–60 000 pregnancies,^{29,30} the latter being the more recent estimates. The incidence has been estimated at 1:4500 in Mexicans,³⁷ and PG is reported to be distinctly uncommon in African-Americans.³⁰ The incidence in different populations appears partly to reflect the prevalence of the HLA haplotypes that have been associated with PG, most prominently the DR3 and DR4 alleles.³⁸ Some authors have reported an increase in other autoimmune diseases in PG patients, particularly Graves' disease.³⁹ PG has also been reported in association with hydatidiform mole and choriocarcinoma,^{40,41} suggesting that placental tissue is a prerequisite for the development of PG.³⁰

Pathogenesis

PG is caused by an autoantibody to a component of the basement membrane zone. Most patients with PG have an antibody to collagen XVII, a hemidesmosomal protein also known as bullous pemphigoid antigen 2. It is unclear what leads to the development of these autoantibodies in pregnancy, but the finding of anti-HLA antibodies in women with PG suggests that a maternal response to the placenta may play a role.^{42,43} Some theorize that abnormal expression of major histocompatibility complex (MHC) class II molecules on the placenta may lead to a maternal immune response against the

Figure 52.5 Pemphigoid gestationis. The characteristic tense bullae seen in PG. Image courtesy of Jeffrey Callen, MD.

placental basement membrane zone, which then leads to cross-reaction in the skin.⁴⁴

Diagnosis and differential diagnosis

Clinically, the diagnosis of PG can suggest itself readily in a case with classic features; however, not all cases are straightforward, and routine laboratory and histopathology data can be unrevealing. The main source of confusion can be in distinguishing the urticarial lesions of PG from those of PEP. Laboratory values tend to be normal in PG, although there may be peripheral eosinophilia.³⁰ Routine histopathology may reveal typical subepidermal bullae with eosinophils, but the urticarial lesions of PG are only reliably distinguished from PEP on the basis of DIF.⁴⁵ DIF reveals C3 deposited in a linear fashion along the basement membrane zone in 100% of patients, and immunoglobulin (Ig)G can be seen in up to 25%.⁴⁶ The main differential diagnosis is PEP, but urticaria, contact dermatitis, erythema multiforme, bullous drug eruption, and other autoimmune blistering disorders such as bullous pemphigoid or dermatitis herpetiformis may also be considered depending on the clinical setting.

Prognosis

Maternal risks include the postpartum flare, sometimes severe, and a high likelihood of recurrence with subsequent pregnancies. But, most importantly, PG has been associated with an increased incidence of fetal risks, including prematurity, low birthweight, and small size for gestational age.^{36,46,47} Early onset or severity of maternal disease does not appear to predict fetal outcome.⁴⁷ In addition, up to 10% of newborns may get a transient, nonscarring bullous eruption¹¹ that usually resolves within 2 weeks.^{29,31,47,48} The eruption in the newborn is thought to be due to passive transfer of the maternal anti-

basement membrane zone antibodies, which are eventually cleared from the baby's circulation.

Management

Systemic steroids are usually required to control symptoms during pregnancy and the postpartum flare, and may be required for up to 6–10 weeks postpartum.²⁹ In milder cases or in newborns, topical steroids alone may be sufficient. A variety of therapies have been reported to be helpful in severe or refractory cases, including plasmapheresis,^{49,50} immunoadsorption (a variant of plasmapheresis),⁵¹ high-dose intravenous immunoglobulin (IVIG),⁵² IVIG in combination with cyclosporine,⁵³ goserelin,⁵⁴ cyclophosphamide,⁵⁵ ritodrine,⁵⁶ and minocycline⁵⁷ or doxycycline⁵⁸ with nicotinamide.

Impetigo herpetiformis

Impetigo herpetiformis (IH) is an extremely rare noninfectious pustular dermatosis that occurs exclusively in pregnancy. There has been considerable debate regarding its status as a disease *sui generis* or variant of pustular psoriasis.⁵⁹

Clinical features

Erythematous patches with groups of pinpoint pustules at the margins appear first in the groin, axillae, and neck, and later generalize. The face, hands, and feet are usually spared, but mucous membranes may be involved. Subungual pustules may lead to nail plate separation and fragmentation.⁶⁰ Pruritus is not prominent. The patient with IH is systemically ill, and may have fever, malaise, diarrhea, and vomiting. IH typically presents early in the third trimester, although presentation in the first trimester⁶¹ and 1 day postpartum⁶² has been reported. Patients with IH rarely provide a personal or family history of psoriasis.

Course

IH typically resolves with delivery, but postpartum exacerbation was reported in one case.⁶³ Lesions dry, then desquamate, and heal without scarring, but postinflammatory hyperpigmentation is typical. Recurrences are common in subsequent pregnancies and generally occur earlier and are more severe than the initial episode.^{60,64} Oral contraceptives may also precipitate a recurrence.⁶⁵

Epidemiologic features

IH is extremely rare, with less than 200 cases reported in the world literature. Although IH has not generally been considered to be a genetic disorder, there have been a handful of familial cases.^{66–68}

Pathogenesis

The etiology of IH is unknown. Although hypocalcemic states, including hypoparathyroidism,^{64,69} have been associated with both IH and pustular psoriasis, it is unclear what role hypocalcemia plays in the disease.

Diagnosis and differential diagnosis

The diagnosis can be confirmed by biopsy, which shows features identical to that of pustular psoriasis. DIF is negative. Elevated leukocyte counts and erythrocyte sedimentation rates are common, with hypocalcemia and hypoalbuminemia less frequently noted. Cultures from intact pustules are negative, although secondary infection can occur. Differential diagnoses may include herpes gestationis, pustular psoriasis, drug eruption, subcorneal pustular dermatosis, dermatitis herpetiformis, and infections. Interestingly, acrodermatitis enteropathica was eventually diagnosed in one patient who was initially thought to have IH.⁷⁰

Prognosis

Patients with IH can be quite ill and must be monitored for secondary infection. When present, hypocalcemia can lead to tetany, seizures, and delirium. With subsequent pregnancies, patients risk earlier and more severe recurrences. In some cases, patients with IH have gone on to develop more typical pustular psoriasis.^{59,71} Risks to the fetus are considerable and are those associated with placental insufficiency, namely stillbirth, neonatal death, and fetal abnormalities.⁶⁰

Management

Systemic steroids are the treatment of choice, along with appropriate supportive care and treatment of secondary infection. Severe or refractory cases may necessitate early delivery or termination.^{72,73} Other treatments reported to be effective have included cyclosporine,⁷⁴ etretinate,⁷⁵ photochemotherapy,⁷⁶ isotretinoin with photochemotherapy,^{59,63,73} methotrexate,⁶² and a mestranol-ethynodiol combination.⁶¹ One patient with hypocalcemia was treated with systemic steroids but improved only after calcium and vitamin D were administered.⁶⁴

Cholestasis of pregnancy

Cholestasis of pregnancy (CP), also known as intrahepatic cholestasis of pregnancy, gestational cholestasis, and prurigo gravidarum, is a condition characterized by pruritus and intrahepatic cholestasis, with or without jaundice, occurring late in pregnancy.

Clinical presentation

Unlike the other dermatoses of pregnancy, CP has no primary skin lesions, but may present with excoriations in more severe cases. CP typically presents with pruritus on the palms and soles that later spreads to include the trunk, extremities, and face. Pruritus can be mild or severe and is often worse at night. There may or may not be associated biochemical abnormalities. In a minority of patients, jaundice can follow the pruritus by 2–4 weeks.⁷⁷ CP presents in the third trimester, with over 80% of cases presenting after 30 weeks,^{77,78} and may follow a previous pregnancy without CP. A personal or family history of gallbladder disease is sometimes noted.⁷⁸

Course

CP usually remits within 1–2 weeks of delivery, with the pruritus resolving before the biochemical abnormalities, which can take 4–6 weeks to normalize. Up to 70% of subsequent pregnancies may be affected by CP.⁷⁷

Epidemiologic features

CP is present in populations worldwide, but with significant geographic variation in frequency. In most European and North American countries, the incidence has ranged from 0.5% to 1%.^{20,79,80} Higher rates have historically been reported in Sweden and Chile,⁷⁷ but this is now thought to reflect nutritional factors.^{81,82}

Diagnosis and differential diagnosis

The diagnosis of CP is largely clinical, with laboratory tests used to support the diagnosis and rule out other diseases. Elevated serum bile acids are the most sensitive and most commonly seen laboratory finding,⁸³ but elevations in transaminases, alkaline phosphatase, and conjugated bilirubin may also be present. Because pruritus can precede laboratory abnormalities by several weeks, repeat testing may be warranted.^{78,84} Skin biopsy is not useful, as there are no primary lesions. A few patients with CP have had liver biopsies, which have showed only mild cholestasis without significant inflammation or necrosis.⁸¹ The differential diagnosis is broad and, depending on the clinical presentation, may include entities such as scabies, eczema, hepatitis, urticaria, other liver or biliary disease, early PEP, or early PG. When jaundice is present, it is essential to rule out viral hepatitis, which is the most common cause of jaundice in pregnancy.⁸⁵

Pathogenesis

The pathogenesis of CP is unclear, but likely to be multifactorial. A genetic component is suggested by the observation of familial clusters of cases⁷⁷ and the finding that sisters and mothers of patients with CP are 12 times more likely to develop CP than control subjects.⁸⁶ In addition, recent work has pointed to an association with the multidrug resistance protein 3 (MDR3) gene.⁸⁷ Hormonal factors are also likely to be important in CP, as estrogens can reduce hepatocyte bile acid secretion, and progesterone metabolites can intensify the estrogen effect by reducing hepatic clearance of estrogens.⁸⁸ Finally, dietary factors have been implicated in studies in Chile, where the seasonal and yearly incidence of CP has correlated with selenium levels.⁸²

Prognosis

The risks to the mother are generally minimal and limited to severe pruritus. However, postpartum hemorrhage has been reported, likely due to vitamin K deficiency as a result of malabsorption in the setting of prolonged cholestasis.⁸⁹ The risk of fetal complications is substantial and may include fetal distress, meconium staining, and preterm labor (up to 44%).^{89,90}

Perinatal mortality has ranged from 3% to 11% of cases.^{89,90} A recent report describes possible “bile acid pneumonia” causing respiratory distress in three newborns born to mothers with severe CP, and suggests that bile acid accumulation may impair the function of surfactant in the lungs.⁹¹ The severity of maternal disease does not predict fetal outcome,⁸⁹ but earlier onset of pruritus has been associated with spontaneous prematurity.⁹²

Management

The goal of treatment is to control the pruritus and minimize fetal complications. In mild cases, symptomatic treatment with emollients, anti-itch lotions, and antihistamines may suffice. In more severe cases, systemic therapy may be required, and those aimed at reducing serum bile acids have had the most success in treating the pruritus and normalizing the laboratory abnormalities. Several recent studies have documented the efficacy of ursodeoxycholic acid (UDCA) in this regard.⁹³⁻⁹⁷ It remains to be seen whether treatment with UDCA will affect fetal outcome. Other treatments have been variably effective in reducing pruritus and/or bile acid levels, including S-adenosyl-L-methionine,⁹³ ultraviolet light (UVB),⁸⁸ activated charcoal,⁹⁸ dexamethasone,⁹⁹ cholestyramine,^{100,101} phenobarbital,^{100,101} ondansetron,¹⁰² and guar gum.^{103,104} Prophylactic vitamin K may decrease the rate of postpartum hemorrhage.⁷⁸ Some authors advocate elective early delivery, as most singleton intrauterine deaths have occurred after 37 weeks of gestation.⁹²

Miscellaneous eruptions in pregnancy

These entities are less well characterized, and it is unclear whether they represent truly separate diseases or are part of a poorly understood spectrum of overlapping disorders.

Pruritic folliculitis of pregnancy

Pruritic folliculitis (PF) of pregnancy was first described in 1981 in six patients with sterile follicular pustules appearing on the trunk in the latter half of pregnancy.¹⁰⁵ No maternal or fetal morbidity has been reported, and the rash has cleared spontaneously after delivery in all cases. The etiology is unknown. Serum androgen levels were elevated in one case,¹⁰⁶ but a more recent study reported normal androgen levels in 12 PF patients.¹⁰⁷ Treatment is symptomatic.

Prurigo of pregnancy

Prurigo of pregnancy (PP) is usually a diagnosis of exclusion. PP presents in the second or third trimester with excoriated papules predominantly on the trunk and extensor aspects of the extremities. Resolution may come quickly after delivery or occur more slowly over weeks to months. The etiology is unknown, but some cases may represent other undiagnosed pregnancy- and nonpregnancy-related dermatoses. Treatment is symptomatic.

Approach to the patient

Pruritus is common in pregnancy,¹⁰⁸ and the differential diagnosis is broad, encompassing not only the specific dermatoses of pregnancy, but many conditions that cause pruritus with or without rash in the nonpregnant population (Tables 52.4 and 52.5). It is especially important to exclude the dermatoses of pregnancy that are associated with fetal complications, chiefly PG and CP (see Fig. 52.6). Given the fetal risks associated with PG and CP, some have recommended a laboratory evaluation in all patients with itching during pregnancy, and a skin biopsy with DIF when there is an associated rash.²⁰

Table 52.4 Common skin disorders that may cause pruritus in pregnancy.

Category	Skin disorder	Clinical features
Allergic/atopic	Urticaria (hives)	Transient wheals
	Atopic dermatitis	Scaly plaques with lichenification. Often coexists with allergic rhinitis and asthma
	Contact dermatitis	Pattern of rash often suggestive
	Drug reactions	History of drug ingestion or change in medication. Morphology varies
Infection/infestation	Scabies	Excoriated papules favor fingerwebs, areola. Burrow is diagnostic
	Infectious folliculitis	Follicle-based pustules. May follow hot-tub exposure
	Tinea (ringworm)	Annular or round scaly plaques. May have affected child or pet
	Other arthropod bites	Scattered excoriated or urticarial papules. Flea bites usually on legs. Chigger bites favor areas where clothing fits tightly. Head or pubic lice in characteristic location
Others	Psoriasis	Scaly red plaques on extensor limbs, scalp. May be generalized
	Pityriasis rosea	Oval plaques with fine scale on trunk. May be preceded by a larger “herald patch”
	Miliaria (prickly heat)	Tiny vesicles appear in hot weather
	Polymorphous light eruption	Pink papules, papulovesicles on sun-exposed areas of arms, chest. Appears in spring or after sunny vacation in winter. Improves over summer
	Xerosis	Dry skin

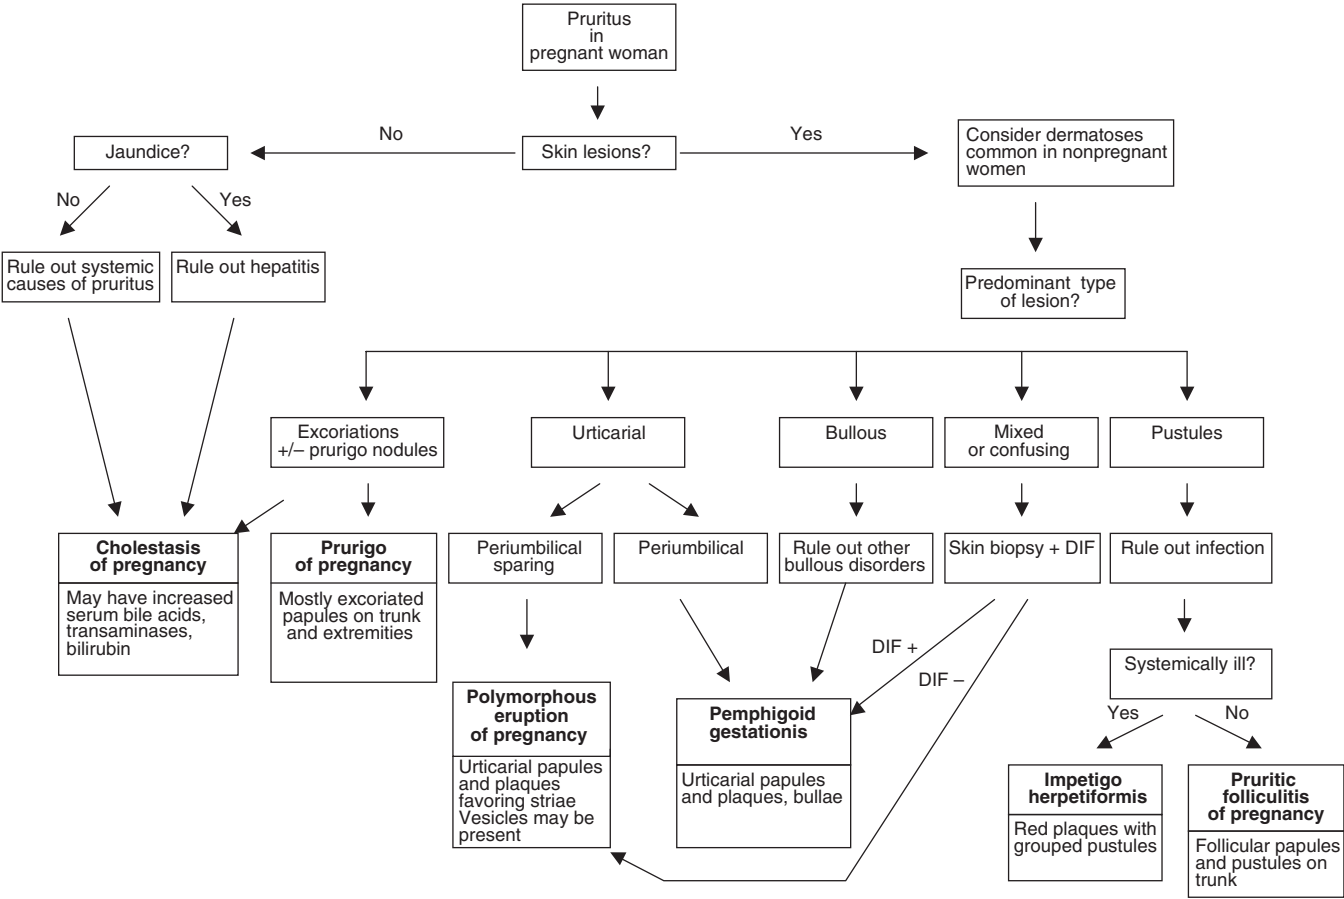

Figure 52.6 Approach to the pregnant patient with pruritus.

Table 52.5 Some causes of pruritus without rash.

Medications (e.g., opiates)
Drug reactions
Hepatitis
Cholestatic or obstructive biliary disease
Chronic renal failure
Malignancy (especially lymphoma)
Hyperthyroidism
Iron deficiency
Acquired immunodeficiency syndrome

Key points

- 1 Hyperpigmentation is the most common pigmentary alteration in pregnancy, and is most pronounced in scars, nevi and ephelides, and genital, mucosal, and axillary skin.
- 2 Melasma or chloasma generally resolves spontaneously after delivery, but may recur with oral contraceptive use.
- 3 Moles or ephelides that change in size during pregnancy should be biopsied to rule out melanoma.
- 4 Bleeding from pyogenic granuloma may require treatment with surgical excision and cautery.
- 5 Striae have been associated with vaginal laceration during delivery.
- 6 Telogen effluvium usually occurs 2–4 months after delivery and resolves over many months.
- 7 Polymorphic eruption of pregnancy (PEP) is characterized by pruritic urticarial papules and plaques favoring the striae and sparing periumbilical skin.
- 8 PEP is more common in primigravidas and presents in the third trimester.
- 9 PEP is not associated with maternal or fetal risk and resolves spontaneously postpartum.
- 10 Pemphigoid gestationis (PG) is characterized by pruritic urticarial plaques that evolve into vesiculobullae, often appearing first on periumbilical skin.
- 11 PG is caused by autoantibodies to components of the basement membrane zone.
- 12 Recurrence of PG with subsequent pregnancies is the rule.
- 13 Fetal risks associated with PG include prematurity and small size for gestational age.
- 14 Diagnosis of PG is confirmed by skin biopsy with direct immunofluorescence.
- 15 Impetigo herpetiformis (IH) is a rare pustular eruption similar to pustular psoriasis that occurs in the latter half of pregnancy.
- 16 Cholestasis of pregnancy (CP) can present with or without jaundice or biochemical abnormalities (chiefly increased serum bile salts).
- 17 CP presents in the third trimester and remits within 2 weeks of delivery.
- 18 Pruritus in CP may resolve before the laboratory values normalize.
- 19 Fetal risks associated with CP include preterm labor, fetal distress, and increased perinatal mortality.
- 20 Evaluation of the pregnant woman with pruritus should include a consideration of the causes of pruritus in nonpregnant women.

Cancer and other neoplasms in pregnancy

Peter E. Schwartz and Masoud Azodi

In the USA, benign gynecologic masses account for more than 1 million hospital admissions per year.¹ Benign masses may occur in pregnancy, and their management is complicated by the risk to the fetus. Knowledge of the natural history of these masses during pregnancy is essential to their proper management. Cancer during pregnancy is unusual. As a result of physiologic changes that normally occur in pregnancy, cancer during pregnancy may be more advanced because the diagnosis is not recognized as early as it might otherwise have been. However, stage-for-stage, cancer during pregnancy is no more virulent than cancer occurring in the nonpregnant state. The routine interruption of pregnancy to influence cancer progression has not been established.

Benign masses in pregnancy

Uterine myomas

Myomas are very common in the general population, especially in nonwhite women.¹ They are a frequent cause of infertility, and are less prevalent among pregnant women than among the same age group of nonpregnant women. Myomas that cause hospitalization are mostly seen in women aged 40–45 years. Complications occur in about 10% of pregnancies with uterine myomas.²

Estrogen receptors are amplified in myomas compared with normal myometrium.³ Several other hormone receptors also appear to be amplified in myomas. Estrogen has been thought to stimulate the growth of uterine myomas, but the precise mechanism is not well understood. Traditionally, it was believed that uterine myomas will grow during pregnancy, but this has been challenged by several prospective studies.^{4–6} Nongrowing myomas can cause symptoms during pregnancy as a result of the enlarging uterus displacing them out of the pelvis. Symptoms may develop as asymptomatic myomas compress abdominal organs.

Uterine myomas can undergo central necrosis and degeneration, causing localized pain at the site of known myoma. Degenerating myomas can provide a culture medium for path-

ogenic organisms with occasional leukocytosis and superimposed infection. Myomas are thought to increase the frequency of preterm labor and premature rupture of membranes. They have been implicated in first-trimester spontaneous abortions,^{7,8} and large cervical and lower uterine segment myomas can cause obstructed labor.^{6,9}

Placental abruption, postpartum hemorrhage, and retained placenta are thought to be complications of uterine myomas during pregnancy. However, several studies failed to show statistically different rates of these complications compared with the general population.^{6,9} One study showed that women with leiomyomata are at increased risk of second-trimester spontaneous abortion.¹⁰

Management of myomas in pregnancy

Myomas can cause pain through degenerative changes or by direct compression of adjacent organs. Most of the symptoms can be managed medically in pregnant women. Symptomatic treatment with acetaminophen or opioid analgesics usually provides relief. Several studies have shown that nonsteroidal anti-inflammatory drugs can be used successfully in pregnancy for management of the symptoms.^{2,11} However, these drugs have known fetal risks and should be used with caution during pregnancy.¹² Hydration and antibiotics can be used if infection is suspected. Medical management is the primary means of treatment in pregnancy. Surgical management is usually avoided during pregnancy. There are very few studies and no randomized trials available on the safety of myomectomy in pregnancy.^{13–15} Myomectomy during pregnancy is best avoided in all but the most extreme circumstances, such as torsion of a pedunculated myoma or when a malignancy is suspected.

Adnexal masses in pregnancy

Benign adnexal tumors are sometimes associated with normal pregnancies. Clinical features suspicious for malignancy, par-

ticularly ovarian cancer, include the presence of a fixed mass, lymphadenopathy, ascites, and constitutional symptoms such as pain, abdominal distention, dyspareunia, frequency, or constipation.^{16,17} Sonographic features of adnexal masses suspicious for malignancy include size greater than 6 cm, thick septations, papillary projections, complex echogenicity, and the presence of ascites.^{18,19} The negative predictive value of sonography as a method of excluding malignancy appears to improve in pregnancy.²⁰ Magnetic resonance imaging (MRI) and computed tomography (CT) have been used to distinguish benign from malignant ovarian masses in pregnancy. These modalities may prove particularly useful in the evaluation of adenopathy and tumor invasion. To date, there is little evidence to link exposure to diagnostic MRI with adverse fetal effects.^{21,22}

The most common benign pelvic masses in pregnancy are persistent corpus luteum cysts, benign cystic teratomas, paratubal cysts, cystadenomas, and pedunculated myomas. Although the vast majority of benign pelvic neoplasms discovered during pregnancy are present before the beginning of the pregnancy, the hormonal changes of pregnancy, particularly the production of human chorionic gonadotropin (hCG), are associated with luteomas, theca-lutein cysts, hyperreactio luteinalis, and large solitary luteinized follicular cyst of pregnancy.

Corpus luteum of pregnancy

The corpus luteum is the most common hormone-producing tumor of pregnancy. The corpus luteum of pregnancy is a physiologic cyst in which granulosa-lutein cells in the post-ovulatory ovarian follicle are stimulated by placental chorionic gonadotropin production to produce progesterone. The corpus luteum maintains progesterone production until approximately 9 weeks' gestation, when placental progesterone production is sufficient to maintain the pregnancy. They are unilateral, sonolucent structures contiguous with the ovary. Corpus luteum cysts can complicate pregnancy if they undergo torsion or spontaneous rupture. Asymptomatic corpus luteum cysts typically regress during the second trimester and are completely absent by the third trimester. If a corpus luteum is removed before 9 weeks' gestation, exogenous progesterone is administered.

Luteoma

Luteomas of pregnancy are solid tumors that are characterized by hypertrophy of ovarian stroma. This hypertrophy may be secondary to stimulation by hCG. They are frequently bilateral and multinodular. Elevated levels of testosterone accompany luteomas in at least 25% of cases, although other hormones may be responsible for maternal virilization.^{23–25} When maternal virilization is present, female fetuses are at risk of virilization. The female fetus is usually not at significant risk of labioscrotal fusion because placental aromatization of

maternal androgens is not usually overwhelmed by androgen production until fusion is complete.^{26,27} There does not appear to be any association between luteomas and multiple gestation or gestational trophoblastic disease. Expectant management is recommended.²⁸ Luteomas can occasionally recur; therefore, preconception counseling is necessary for women with a history of luteoma.²⁹

Hyperreactio luteinalis

Hyperreactio luteinalis is a benign, non-neoplastic enlargement of theca-lutein cysts, most likely due to stimulation by hCG.³⁰ Hyperreactio luteinalis is strongly associated with conditions that produce abnormally elevated hCG, such as multiple gestation, gestational trophoblastic disease, and ovarian hyperstimulation syndrome.³¹ Hyperreactio luteinalis is usually bilateral and multicystic with stromal edema. Ovarian enlargement can be massive. Although maternal androgen excess is occasionally present, virilization of female fetuses rarely occurs.^{32,33} Life-threatening ascites, electrolyte abnormalities, thromboembolism, intravascular depletion, hemolysis, renal failure, and pleural effusion with respiratory difficulties may be present when hyperreactio luteinalis complicates ovarian hyperstimulation syndrome or gestational trophoblastic disease. In addition to supportive measures, uterine evacuation may be necessary to reverse hCG-induced ovarian stimulation in such cases. In milder cases, expectant management is appropriate because hyperreactio luteinalis and theca-lutein cysts usually resolve shortly after delivery.

Cancers in pregnancy

Incidence

Data reflecting the incidence of cancers during pregnancy are scant because of a lack of information accrued by population-based tumor registries. Estimates of cancer during pregnancy vary considerably (Table 53.1). The uterine cervix remains the most common site for neoplasia to develop in pregnancy.³⁴ The breast is the second most common site for malignancy that occurs during pregnancy.³⁵ The frequency distribution of other cancers during pregnancy such as leukemia, lymphoma, and cancers of the ovary, vulva, vagina, skin (melanoma), brain, and gastrointestinal tract reflects that of cancer occurring in all women in their reproductive years.³⁶

The study by Haas³⁷ reporting the incidence of cancer during pregnancy compared with that in control nonpregnant women suggested that there may be a significantly reduced incidence of cancer in pregnancy. These data were from a population-based epidemiologic study in the German Democratic Republic. As women grew older, the 5-year age group observed-to-expected ratios of pregnancy-associated cancers increased from 0.22 for women aged 15–19 years (1.9 cancers per 100 000 live births) to 1.40 (232.4 cancers per 100 000

Table 53.1 Estimate of cancers occurring in pregnancy.

live births) for those aged 40–44 years (Fig. 53.1). The frequency of occurrence, in descending order, was cervical cancer, breast cancer, ovarian cancer, lymphoma, melanoma, brain cancer, and leukemia.

A fear expressed by pregnant patients is that the cancer might spread to the fetus. Information collected during the past two decades suggests that transplacental metastasis is extremely unusual, and metastases to the fetus are so rare as to preclude this as an indication for termination of a pregnancy. The most common malignancy to be associated with fetal metastases is malignant melanoma. The reported number of cases in the literature of such an event is fewer than 30.³⁸

Surgery in pregnancy

Patients may undergo successful surgical procedures when they are pregnant without jeopardizing the fetus. In general, surgery should be delayed until the second trimester, which seems to be the safest time in terms of avoiding patients going into labor. Spontaneous abortion frequently occurs when surgery is performed in the first trimester, and premature labor has been associated with surgery in the third trimester. Corpus luteum function is replaced by the placenta after the 12th week of gestation. Pathologic ovaries may be removed safely once the patient has entered into the second trimester.

Figure 53.1 Overall incidence of cancer occurring in pregnancy by age and incidence of carcinoma *in situ* and invasive cervical cancer (modified from ref. 37).

In preparing the patient for a surgical procedure, simple technical considerations may have an important impact on the success of the operation. For example, placing the patient in a lateral position to avoid vena cava and aortic compression is an important factor in considering the anesthetic consequences of surgery.^{39,40} Anesthesiologists must always act as if a pregnant woman has a full stomach, as progesterone relaxes the gastroesophageal sphincter, and pyloric displacement by the gravid uterus impedes gastric emptying.⁴¹

Radiation in pregnancy

Radiation is commonly employed in the routine management of cancers that may occur in pregnancy. Deleterious effects that the fetus may experience from being exposed to radiation therapy have been recognized for many years.^{42–44} Production of genetic mutations by radiation in the laboratory was documented as early as 1927, but data directly applicable to humans are scant.⁴⁵ Three phases of pregnancy must be considered with regard to radiation damage.⁴⁶ The preimplantation phase lasts for approximately 7–10 days and represents the time from fertilization to the implantation of the blastocyst into the uterine wall. Spontaneous abortion is the most likely consequence of an embryo being exposed to radiation in the preimplantation phase. For many patients, the pregnancy may not be clinically recognized.⁴⁷ Organogenesis, the period from the first to the 10th week of gestation, represents the most sensitive time for the fetus with regard to radiation injury.⁴⁶ This is the time of major organ formation and the time when the fetus is most susceptible to teratogenic agents.

However, the central nervous system, the eyes, and the hematopoietic system remain highly sensitive to the effects of radiation throughout the entire pregnancy. Radiation has been associated with microcephaly, the most common malformation observed in humans exposed to high-dose radiation during pregnancy, and mental retardation.⁴⁸ In general, such effects are seen in fetuses exposed to amounts greater than 50 rad of low-energy-transfer (LET) radiation. Embryonic exposure to 5 rad or less is rarely associated with anomalies.⁴⁸ The actual radiation dose rates are extremely important in assessing the risks to the fetus for developing growth retardation, malformations, or death.

Pregnant women exposed to radiation therapy of 250 rad or greater during the first 2–3 weeks of gestation have an increased risk of spontaneous abortion but not a dramatic risk of severe congenital anomalies.⁴⁹ However, once patients are exposed to such radiation during the third to 10th weeks of gestation, multiple congenital anomalies including low birthweight, microcephaly, mental retardation, retinal degeneration, cataracts, and genital and skeletal malformations have been reported.⁴⁹ Radiation exposure between the 11th and 20th weeks has been associated with a significant decline in anomalies. Exposure after the 20th week of gestation is usually limited to anemia, skin pigmentation changes, and dermal erythema. The risks of growth retardation and abnormalities of the eye and central nervous system (CNS) increase throughout the latter period of fetal radiation exposure. It has been suggested that fetuses exposed to radiation doses higher than 10 rad should be considered for therapeutic abortion.⁴⁶

Pelvic irradiation for the management of malignancies, particularly cervical lesions in pregnancy, will result in fetal demise and will usually lead to spontaneous abortion. The fetus may receive only minor exposure when supradiaphragmatic irradiation is given, particularly if such radiation is tapered so that the internal scatter is minimal during the first trimester of pregnancy. Proper shielding equipment can significantly reduce the radiation dose to the fetus.⁵⁰ However, as the fetus grows, its exposure to supradiaphragmatic radiation increases. Such radiation may not be appropriate in the more advanced stages of pregnancy.

Chemotherapy and pregnancy

Prior experience supported the concept that cytotoxic chemotherapy should not be administered to patients, especially during the first trimester of pregnancy. This was because of the high incidence of spontaneous abortion following exposure to chemotherapy and the teratogenic effects of these agents on the developing fetus.^{51,52} However, as anecdotal and small series reports have accumulated, it appears that, although certain drugs must be avoided during early pregnancy, others might be life-saving and might not cause congenital anomalies in the fetus^{53–56} (Table 53.2). Prematurity

and low birthweight are frequent complications of chemotherapy exposure in any trimester of pregnancy. However, the fear of exposure in the second and third trimesters of pregnancy resulting in congenital anomalies no longer appears to be a major concern, provided that the selection of drugs is appropriate.^{51,52} The long-term neurologic consequences of intrauterine exposure to chemotherapeutic agents has yet to be established. Children who have been born after *in utero* exposure to chemotherapeutic agents during the second and third trimesters have not been noted to have significant congenital abnormalities. One study of 17 children exposed *in utero* to chemotherapy for the management of maternal acute leukemia revealed no fetal malformations. The children's growth and development, school performance, intelligence tests, neurologic examinations, and hematologic evaluations (with a follow-up period ranging from 4 to 22 years) were normal.⁵⁶ Another study of 16 pregnant women treated for non-Hodgkin's lymphoma reported similar results.⁵⁴

Physiologic effects of pregnancy may have an impact on the efficacy and toxicity of chemotherapeutic agents. For example, renal blood flow, glomerular filtration rate, and creatinine clearance increases may lead to increased clearance of drugs from the body.⁵⁷ It has been suggested that amniotic fluid may act as a pharmacologic third space for such drugs as methotrexate, analogous to ascites or pleural effusions which may then increase methotrexate toxicity.⁵⁸ Gastrointestinal absorption of drugs may be decreased owing to delayed gastric motility. The distribution and kinetics of antineoplastic agents may be substantially affected by the physiologic increase in body water in a pregnant woman in association with a 15% increase in plasma volume and changes in plasma protein concentrations.⁵⁹ Drugs that cross the placenta have low molecular weight, high lipid solubility, are nonionized, and are loosely bound to plasma proteins.^{58,60,61}

In assessing the teratogenic effects of chemotherapeutic agents administered in pregnancy, it must be kept in mind that up to 3% of children have associated major congenital anomalies and 9% have minor anomalies in pregnancies not complicated by cancer treatments or exposure to a chemotherapeutic agent.⁶²

Congenital anomalies have been noted in patients treated with alkylating agents in the first trimester of pregnancy but not in the second and third trimesters.⁵¹ Cisplatin has become the most important drug in the management of gynecologic malignancies.⁶³

Antimetabolites are cell cycle specific and interfere with DNA, RNA, and some coenzymes. Aminopterin and methotrexate act as abortifacients for patients when administered during the first trimester.^{34,51} Only one congenital anomaly was observed in 56 patients exposed to other antimetabolites during pregnancy.⁵² Second- and third-trimester exposure to a variety of antimetabolites resulted in no congenital anomalies in 37 fetuses. Thus, antimetabolites other than aminopterin and methotrexate may be relatively

Table 53.2 Chemotherapeutic agents and reported associated anomalies by trimester.

Chemotherapeutic agents	Mechanism of action	Reported significant anomalies by trimester*		
		1st	2nd	3rd
<i>Alkylating agents</i>				
Melphalan, chlorambucil, cyclophosphamide, triethylene thiophosphoramide, cisplatin, carboplatin, carmustine (BCNU), chloroethylcyclohexyl nitrosourea, methyl-CCNU, busulfan	Cell-cycle nonspecific; forms cross linkages with DNA	Yes†	No	No
<i>Antimetabolites</i>				
Amethopterin (methotrexate),‡ aminopterin, 5-fluorouracil,‡ cytosine arabinoside, 6-thioguanine, 5-azacytidine, hydroxyurea, hexamethylmelamine, L-asparaginase	Cell-cycle specific; structural analogue of precursor purine and pyrimidine bases; lead to nonfunctional DNA and cell death	Yes\$	No	No
<i>Antibiotics</i>				
Actinomycin D, doxorubicin, daunorubicin, bleomycin, mitomycin C, mithramycin	Cell-cycle nonspecific; interferes with DNA-dependent RNA synthesis; cell death from lack of RNA and an inability to produce cell proteins	No	No	No
<i>Vinca alkaloids</i>				
Vincristine, vinblastine, etoposide (VP-16), teniposide (VM-26)	Cell phase specific	Yes	No	No
<i>Glucocorticoids</i>				
Cortisone, prednisolone, prednisone, methylprednisolone, dexamethasone	Inhibition of DNA, RNA, and protein synthesis	Yes¶	No	No

*Reports of anomalies are limited and should be viewed with caution.

†Chlorambucil syndrome: renal aplasia, cleft palate, skeletal abnormalities.

‡Abortifacients in first trimester.

\$Aminopterin syndrome: cranial dysostosis, hypertelorism, anomalies of the external ears, micrognathia, cleft palate.

¶Cleft lip, cleft palate.

safely used in the management of cancer during pregnancy.

Antibiotics such as actinomycin D, doxorubicin, daunorubicin, bleomycin, mitomycin C, and mithramycin have been used relatively safely in the second and third trimesters of pregnancy. Recent data suggest that doxorubicin and daunorubicin may be relatively safe when used in the first trimester of pregnancy, but the follow-up information on children exposed *in utero* remains extremely limited.^{64,65}

Vinca alkaloids are cell phase-specific agents that cause mitotic arrest. These agents include vincristine, vinblastine, VP-16, and VM-26. A limited experience with exposure to vinca alkaloids suggests that only one of 15 pregnancies exposed during the first trimester was associated with a congenital anomaly. No anomalies were seen in 11 patients treated later in pregnancy.^{51,52}

The reported rate of fetal malformations when exposed to combination chemotherapy in the first trimester (16%) is similar to that of single-agent therapy.^{51,66–68} Theoretically, the incidence could be reduced to 6% by removing folate antagonists in common with radiation therapy.⁵³ Doll and col-

leagues⁵³ summarized the findings of 71 patients treated with single-agent therapy in the last two trimesters and of 79 patients treated with combination therapy; they identified one child in each treatment group with a congenital anomaly. Thus, second- and third-trimester chemotherapy appears to be safe with regard to teratogenicity in the fetus.⁵³ Nevertheless, a 40% incidence of low birthweight was reported by Nicholson⁵¹ when fetuses were exposed to chemotherapy *in utero*. Other complications may occur in the fetus exposed to cytotoxic chemotherapy in addition to teratogenicity, death, and stunted growth.⁶⁹ Anemia, leukopenia, and thrombocytopenia may occur in the fetus as a result of bone marrow suppression and leukopenia, or immune suppression may lead to secondary infection.⁵⁵ Timing of chemotherapy in relation to the anticipated delivery must be carefully assessed. Deliveries should occur when the mother is not bone marrow suppressed. Breastfeeding is discouraged in patients who are receiving cytotoxic chemotherapy, although the data supporting this are weak.⁶⁹ To date, there have been no reports of children developing leukemia after *in utero* exposure to chemotherapeutic agents.

Assessing fetal maturity

The early delivery of a child has been incorporated into the management strategy in treating pregnant cancer patients. This strategy requires that sophisticated newborn special care units be available for maintaining premature infants. The survival rate for infants treated in the Newborn Special Care Unit at Yale–New Haven Children’s Hospital for the years 1994 through 2003 is presented in Fig. 53.2. The data presented are typical of those reported from newborn intensive care units in the United States.

Antenatal corticosteroid therapy has been shown to decrease complications related to organ immaturity such as respiratory distress syndrome, intraventricular hemorrhage, and necrotizing enterocolitis. They are most effective if delivery occurs from 1 to 7 days after the initiation of therapy. Tests of fetal lung maturity, such as the lecithin/sphingomyelin (L/S) ratio, are important in determining the timing of delivery.⁷⁰

Cervical cancer

Invasive cervical cancer is on the decline in the United States. Effective Pap smear screening techniques in combination with colposcopy for directed biopsies have allowed physicians to recognize the presence of malignancy early and to treat patients with simple office procedures. Although the decline in invasive cancer is evident in the United States, an increase in cervical intraepithelial neoplasia (CIN) has occurred as a result of widescale cytologic screening.^{71,72} The cervix remains the most common site for precancerous and cancerous changes in pregnancy (see Table 53.1 and Fig. 53.1). Epidemiologic studies suggest that women who develop CIN and invasive cancer in pregnancy tend to be married at an earlier age, have

Figure 53.2 Newborn special care unit survival statistics, Yale–New Haven Hospital.

an earlier age of diagnosis of CIN and invasive cancer, and have a higher parity than a control population.^{73–75} The most common histologic types of cancer occurring in the cervix are squamous cell. Four case reports of a small cell neuroendocrine carcinoma arising in the uterine cervix in pregnancy have been reported.⁷⁶

Cervical intraepithelial neoplasia

The presence of CIN in pregnancy is usually identified by Pap smear and confirmed by colposcopically directed biopsies. It is the policy at Yale–New Haven Hospital to use colposcopy to evaluate patients with abnormal Pap smears in pregnancy and to limit the biopsy to the site that has the worst colposcopic appearance. In general, colposcopy will show the entire transformation zone, as the squamocolumnar junction tends to be present well out on the exocervix during pregnancy. Cone biopsies of the cervix are avoided, as they are associated with hemorrhage, abortion, and premature labor.⁷⁷ It has been a successful policy at Yale–New Haven Hospital to biopsy the worst colposcopically identified site and, if the cervical biopsy and Pap smear are consistent, to follow the patient throughout the pregnancy with Pap smears every 3 months. Patients are reevaluated at approximately 36 weeks’ gestation with repeat colposcopy and Pap smears to be as certain as possible that the lesion has not progressed. Cotton-tip applicator sticks are used to obtain endocervical cytologic specimens in pregnancy. The preference for the cotton-tip applicator stick is to avoid disrupting the fetal membranes with the wire-like tip of the cytobrush. Adenocarcinomas arising in association with carcinoma *in situ* of the exocervix are easily visualized in pregnancy and may be readily biopsied.⁷⁷ In the 30 years that this policy has been practiced, only one case of a stage IB cancer of the cervix has occurred in a patient initially assessed to have a precancerous lesion. That patient was recognized at delivery to have an invasive lesion and was subsequently successfully managed with a type III radical hysterectomy and bilateral deep pelvic lymphadenectomy.

If the assessment at 36 weeks remains consistent with CIN, the patient and her physician are advised that the patient may deliver vaginally. No attempt is made routinely to perform Cesarean hysterectomies in the management of CIN if further pregnancies are desired. Assessment of precancerous changes can be readily carried out 8–12 weeks following delivery.

Microinvasive cancer of the cervix

Microinvasive cancer of the cervix is defined as a lesion that has only microscopically penetrated through the basement membrane. The current International Federation of Gynecology and Obstetrics (FIGO) staging system is seen in Table 53.3. Confirmation of the presence of stage IA1 or stage IA2 microinvasive cancer is important in distinguishing it from

Table 53.3 International Federation of Gynecology and Obstetrics (FIGO) cervical cancer staging classification.

0	Carcinoma <i>in situ</i> , intraepithelial carcinoma; cases of stage 0 should not be included in any therapeutic statistics for invasive carcinoma
I	Carcinoma is strictly confined to the cervix (extension to the corpus should be disregarded)
Ia	Preclinical carcinoma of the cervix, i.e., those diagnosed only by microscopy
Ia1	Minimal microscopically evident stromal invasion
Ia2	Lesions detected microscopically that can be measured; the upper limit of the measurement should not show a depth of invasion of more than 5 mm taken from the base of the epithelium, either surface or glandular, from which it originates; a second dimension, the horizontal spread, must not exceed 7 mm; larger should be staged as Ib
Ib	Lesions of greater dimension than stage Ia2, whether seen clinically or not; preformed space involvement should not alter the staging but should be specifically recorded so as to determine whether it should affect treatment decisions in the future
II	Carcinoma extends beyond the cervix but has not extended onto the pelvic wall; the carcinoma involves the vagina, but not as far as the lower third
Ila	No obvious parametrial involvement
Ilb	Obvious parametrial involvement
III	Carcinoma has extended onto the pelvic wall; on rectal examination there is no cancer-free space between the tumor and the pelvic wall; the tumor involves the lower third of the vagina; all cases with a hydronephrosis or nonfunctioning kidney should be included, unless they are known to be due to another cause
IIla	No extension onto the pelvic wall, but involvement of the lower third of the vagina
IIlb	Extension onto the pelvic wall or hydronephrosis or nonfunctioning kidney
IV	Carcinoma has extended beyond the true pelvis or has clinically involved the mucosa of the bladder or rectum
IVa	Spread of the growth to adjacent organs
IVb	Spread to distant organs

Reprinted from Staging Announcement: FIGO Cancer Committee. *Gynecol Oncol* 1986;25:383, with permission.

frankly invasive cancer. In general, patients with microinvasive cancer identified by abnormal Pap smears should undergo routine colposcopic assessment. The confirmation of the extent of disease is extremely important in pregnancy and may require a more extensive biopsy in the form of a hemicone biopsy or a cone biopsy of the cervix. If surgical margins are histologically free of disease on the cervical biopsy, patients may safely continue with the pregnancy as long as they are willing to be assessed with frequent Pap smears and colposcopy. Stage IA2 patients have more extensive microinvasive cancer. Once again, the issue is related to the margins of the biopsy used to establish the diagnosis and the patient's desire to preserve the pregnancy and her fertility. Those patients with stage IA1 microinvasive cancer who wish to undergo prompt therapy are usually successfully managed with a simple hysterectomy and leaving the ovaries in place. Those with stage IA2 cervical cancer are recommended to undergo a type II modified radical hysterectomy. Patients who wish to have definitive surgery performed following completion of pregnancy may be delivered vaginally with a subsequent hysterectomy (stage IA1) or may be delivered by Cesarean section followed by modified radical hysterectomy (stage IA2).

Invasive cancer

The identification of invasive cancer of the cervix requires prompt treatment, except for patients in the late second or

third trimester, when one may briefly delay therapy until fetal viability is established. Sood et al.⁷⁸ reported on 11 women with cervical cancer diagnosed in pregnancy who underwent surgical treatment in the third trimester with a mean planned delay in therapy of 16 weeks. None of these patients experienced a recurrence. Patients with stage IB and stage IIA cervical cancer recognized in the first trimester of pregnancy are routinely recommended to be treated with a type III radical hysterectomy and bilateral deep pelvic lymphadenectomies. This approach affords the patient the opportunity to preserve ovarian function and have a more pliable vagina compared with patients treated with radiation therapy.

Patients with more advanced cervical cancer are routinely recommended to be treated with radiation therapy concurrent with weekly cisplatin.^{79–81} External beam radiation therapy has generally been employed first and will induce spontaneous abortion. Intracavitary radiation follows completion of the external beam radiation regimen. Radiation therapy is a known abortifacient when treating pelvic malignancies. Abortion following initiation of radiation exposure occurs more rapidly in the first trimester than in the second.⁸² In general, the plan of management at Yale–New Haven Hospital for cervical cancer is to use external beam radiation first and not to attempt to deliver the fetus prior to initiation of therapy. There are no data to suggest that delivering the fetus through an irradiated cervix affects the course of the disease. However, 13 pregnant women with squamous cell carcinoma who delivered vaginally were subsequently diagnosed to have the same type of malignancy in episiotomy sites.^{83,84}

Advanced stage cervical cancer has a particularly poor response to standard radiation therapy. A major effort in the past few years has resulted in the development of neoadjuvant chemotherapy protocols for the management of such disease.⁸⁵ It may be appropriate to consider a role for neoadjuvant chemotherapy in the management of locally advanced cervical cancer, particularly in situations where definitive treatment will be excessively delayed in order for the fetus to reach viability. In reviewing the 5-year survival for pregnant women with stage I and II cancers treated in pregnancy compared with those patients not pregnant at diagnosis, the survivals were 74.5% and 47.8%, respectively, compared with 76.5% and 55% for overall 5-year survival in the FIGO annual report.⁸⁶ Stage III and IV disease did worse in pregnancy, with 16.2% compared with 27.9% survival in the FIGO annual report.⁸⁶ The treatment for cervical cancer remains unsatisfactory in the advanced stages, particularly in pregnancy, and bold new initiatives will be necessary for managing this common cancer in pregnant women.

Breast cancer

Breast cancer may be difficult to diagnose during pregnancy and lactation due to the anatomic changes in the breast parenchyma associated with the preparation for lactation. Only 3% of breast cancers occur during pregnancy, but it is the second most common site for invasive cancer in a pregnant woman.⁸⁷

Pregnancy-associated cancers are defined as those diagnosed simultaneously or within 1 year after pregnancy. A number of studies have demonstrated that breast cancer presents at a more advanced stage because of the delay in diagnosis.^{81,88-90} The median duration of symptoms before treatment is 15 months in the pregnant patient compared with 9 months in nonpregnant premenopausal women.⁹¹

The breasts should be examined at the first prenatal visit and thereafter if there have been any concerns noted either by the patient or by the physician during the initial examination. With rare exceptions, any mass discovered during pregnancy should be evaluated.

An ultrasound evaluation may be helpful. If the mass is obvious, a fine needle aspiration (FNA) can be performed.⁹² For most patients, an open biopsy on a day surgery basis under local anesthesia is appropriate. Sedation is not necessary and, therefore, there is no risk to the developing fetus. Because of the increased engorgement and vascularity during pregnancy, absolute hemostasis must be achieved, and a pressure dressing should be applied and left in place for 48 h. Open biopsy can also be performed during lactation. The breasts are emptied early in the morning of the day of surgery, and the procedure is again performed under local anesthesia. A pressure dressing is left in place for a few hours. Temporary leakage may occur during breastfeeding, but this soon disappears.

Biopsy material should be sent to the pathologist in a fresh state, and the tissue should be submitted for estrogen and progesterone receptor analysis as well as DNA studies. Steroid hormone receptors may not be detected during pregnancy. Pregnancy, in fact, may depress levels of detectable estrogen and progesterone receptors, resulting in a false-negative study because high circulating levels of estrogen and progesterone hormones associated with pregnancy result in many more occupied receptor sites.⁹³

Earlier studies of breast cancer diagnosed during pregnancy uniformly suggested a poor prognosis. Data now show a similar prognosis for breast cancer patients who are pregnant compared with their nonpregnant counterparts when controlled for stage.⁹⁴⁻⁹⁸ Other studies have noted that younger women with shorter intervals from pregnancy to cancer diagnosis appear to have a poorer prognosis.⁸⁸ Guinee et al.⁹⁹ evaluated 407 women younger than 30 years of age and found that those cancer patients who were diagnosed during pregnancy had a significantly greater risk of dying from breast cancer than those who had never been pregnant. When adjusted for tumor size and axillary node status, the risk was reduced only slightly.⁹⁷ The authors concluded that concurrent or recent previous pregnancy adversely affects survival of breast cancer in young women. Chung et al.¹⁰⁰ evaluated 6571 breast cancer patients in Rhode Island and divided them into age groups of 10-year intervals. These researchers concluded that women 40 years of age and younger had a worse 5-year cancer-specific survival rate compared with their older counterparts, except in stage I breast cancers (Table 53.4). Anderson et al.¹⁰¹ conducted a retrospective analysis of young women (younger than 30 years of age) and observed them throughout 20-year intervals. Improved survival rates were found in patients treated during the "modern era," probably as a result of less extensive surgical procedures and the introduction of cytotoxic chemotherapy.¹⁰¹

Once the diagnosis of carcinoma has been confirmed, prompt treatment is essential. During the first trimester, modified radical mastectomy is the treatment of choice. Breast conservation treatment poses several problems including potential fetal injury from the effects of radiation.¹⁰² If the patient insists on breast conservation, wide local excision and axillary dissection may be performed and radiation postponed until after delivery. The alternative is termination of the pregnancy and immediate institution of radiation therapy.

During the third trimester, it may be more reasonable to complete local treatment, i.e., wide local excision and axillary dissection, and to delay radiation therapy until after delivery. If the patient chooses modified radical mastectomy, this can be delayed until after delivery if the cancer was diagnosed during the third trimester. Appropriate tests should be obtained to insure maturity of the fetus before delivery. The role of sentinel node evaluation during pregnancy needs to be defined.

If axillary dissection reveals lymph node involvement, adjuvant therapy must be considered. This is standard treatment

for node-positive premenopausal patients and may be considered in selected node-negative patients. Biologic response modifiers have been administered in pregnancy without adverse effects.^{103–106}

The final decision whether to use adjuvant chemotherapy rests with the patient after she has received appropriate counseling. In cases of locally advanced cancer, the decisions are even more difficult because chemotherapy and radiotherapy may be required for palliation. In this situation, pregnancy

termination would be recommended. This is a difficult decision, and there are no absolutely correct answers. In most of these patients, life expectancy is severely limited, and a frank discussion of the issues involved is imperative.

With prompt diagnosis and appropriate treatment, many patients survive the disease and desire further pregnancies. Most recurrences of breast cancer appear within the first 2 years, and pregnancy should be avoided during this period. Some studies have shown no adverse effect of a subsequent

pregnancy even in patients with positive nodes or patients in whom pregnancy occurred earlier than 2 years after completion of treatment.^{107–111} Abortion has not improved survival.¹⁰⁸

Ovarian cancer

Most ovarian cancers complicating pregnancy are either borderline malignant potential epithelial cancers or germ cell malignancies. Invasive epithelial cancers are rare in pregnancy, and sex cord–stromal tumors occur extremely infrequently. It can be expected that the incidence of ovarian neoplasms recognized in pregnancy will increase with the routine use of diagnostic ultrasound in pregnancy. As a result, more patients are now being seen in our institution with ovarian masses. A recent series of adnexal masses reported from the Yale–New Haven Hospital suggests that ultrasound evaluation is a very successful way of assessing the nature of an ovarian tumor.¹¹² MRI is useful in further delineating the nature of the ovarian neoplasm.^{112,113} Our experience suggests, however, that for most patients an ultrasound assessment of an adnexal mass is likely to establish the benign nature of the lesion, with MRI being used in those patients in whom the ultrasound findings are equivocal or the lesion cannot be distinguished from a uterine neoplasm, in particular a uterine leiomyoma.¹¹² Figure 53.3 demonstrates an MRI confirming a uterine fibroid that was ultrasonographically indistinguishable from an ovarian tumor associated with a 15-week pregnancy. Figure 53.4 demonstrates a benign cystic teratoma diagnosed in pregnancy by MRI techniques.

Ovarian malignancies occurring in pregnancy are estimated to complicate 1 in 9000 to 1 in 25 000 pregnancies.¹¹⁴ Ovarian

Figure 53.3 Uterine leiomyoma, T2-weighted sagittal magnetic resonance image. The low signal intensity of this well-circumscribed mass (*large arrows*) and origin from the posterior wall of the gravid uterus (*small arrows*) permit a confident diagnosis of a uterine leiomyoma. (Courtesy of Dr. R. Kier.)

neoplasms are usually observed in the first trimester and are operated upon in the second trimester. These lesions tend to be asymptomatic when recognized. However, torsion is a relatively frequent presentation for a germ cell malignancy of the ovary and requires prompt surgical intervention. Simple cysts of the ovary may be followed with serial ultrasound examinations until the cysts resolve. Lesions greater than 6 cm in diameter, complex cysts (i.e., cysts containing both solid and cystic elements), and solid tumors are the usual indications for operative intervention in pregnancy. Figure 53.5 demonstrates a complex ovarian cyst that proved to be a mucinous carcinoma of the ovary. Germ cell ovarian malignancies occur relatively infrequently in younger women, but must be considered in the differential diagnosis of solid or solid and cystic pelvic masses occurring in pregnancy.¹¹⁵ The more rapidly growing tumors (i.e., the endodermal sinus tumors and embryonal carcinoma) may be associated with hemorrhage and necrosis, giving a rather inhomogeneous appearance to the mass on ultrasound or MRI scans. Elevated levels of circulating tumor markers may help to distinguish germ cell tumors from other ovarian neoplasms. However, elevated α -fetoprotein (AFP) and β -hCG titers are routine in pregnancy, and such assays may be more confusing than informative in the preoperative evaluation of patients with pelvic masses. Similarly, serum lactic dehydrogenase (LDH) and other liver enzyme levels may be elevated in nonpregnant women with solid adnexal tumors that prove to be dysgerminoma.¹¹⁶ However, LDH and other liver enzymes may be elevated in the pregnant state unrelated to the presence of a dysgerminoma. CA 125, an antigenic determinant made by approximately 80% of ovarian cancers, may be elevated in early pregnancy for reasons unrelated to the presence of a malignancy.^{117–119}

In general, surgical management of ovarian neoplasms occurring in pregnancy is delayed until the second trimester, provided the patient is asymptomatic and the tumor is not suspicious for malignancy by diagnostic imaging techniques. Symptomatic patients and patients with tumors suspicious for malignancy should promptly undergo surgery to diagnose and initiate the treatment of the cancer.

Surgical staging

Surgical staging for ovarian cancer in pregnancy should be the same as that recommended for surgical staging in the nonpregnant state. However, the pregnant uterus makes assessment of the retroperitoneum much more difficult. A vertical incision should be used. On entering the abdomen, any free fluid should be aspirated and sent for cytology. If no free fluid is present, washings of the paracolic spaces, the pelvis, and subdiaphragmatic spaces should be obtained. The ovarian lesion should then be removed and sent for frozen section histologic analysis. Every effort should be made to remove the tumor intact. The remaining ovary should be carefully inspected and biopsied. Any peritoneal abnormalities should

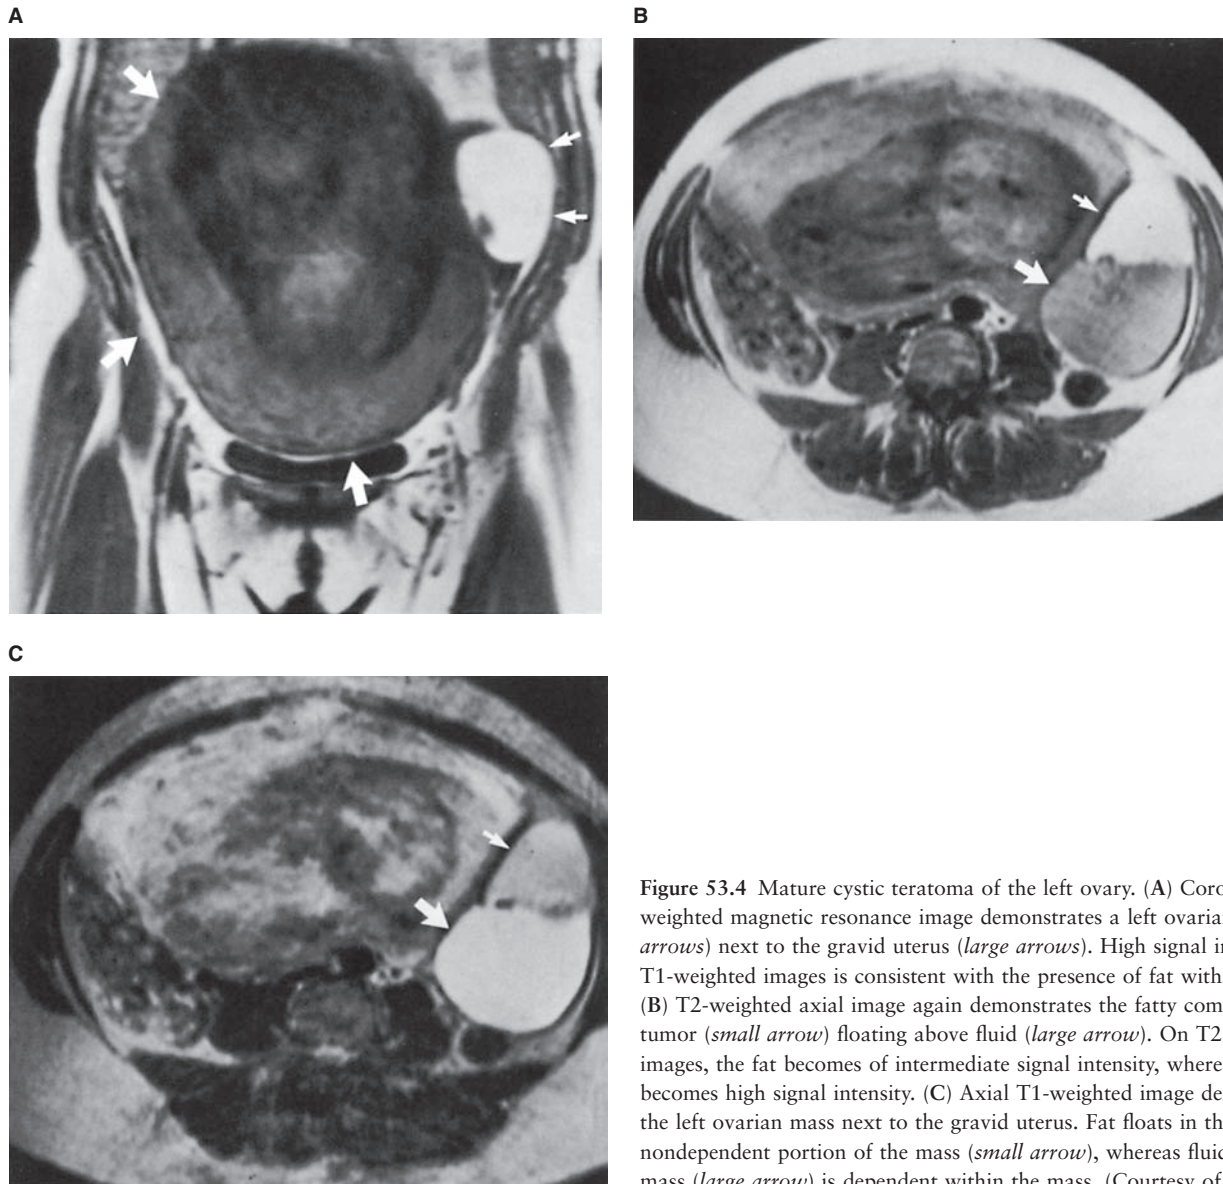

Figure 53.4 Mature cystic teratoma of the left ovary. (A) Coronal T1-weighted magnetic resonance image demonstrates a left ovarian mass (*small arrows*) next to the gravid uterus (*large arrows*). High signal intensity on T1-weighted images is consistent with the presence of fat within the tumor. (B) T2-weighted axial image again demonstrates the fatty component of the tumor (*small arrow*) floating above fluid (*large arrow*). On T2-weighted images, the fat becomes of intermediate signal intensity, whereas the serum becomes high signal intensity. (C) Axial T1-weighted image demonstrates the left ovarian mass next to the gravid uterus. Fat floats in the nondependent portion of the mass (*small arrow*), whereas fluid within the mass (*large arrow*) is dependent within the mass. (Courtesy of Dr. R. Kier.)

be sampled. Any retroperitoneal nodularities should also be sampled. Sampling of periaortic lymph nodes should be attempted. This can be the most difficult part of the procedure in pregnancy because of the bulk of the gravid uterus. It is inappropriate to remove both ovaries when a germ cell ovarian malignancy is diagnosed by frozen section techniques. The most common neoplasm in the contralateral ovary of a woman with a germ cell malignancy is a benign cystic teratoma. However, if both ovaries are involved with malignant growths and the patient is in the second trimester of pregnancy, each ovary should be removed, as the pregnancy will

sustain itself in the second and third trimesters without ovaries being present.⁷⁷ Germ cell ovarian malignancies are almost invariably unilateral. Removing the contralateral ovary does not affect prognosis for the patient. Recent evidence suggests that occult dysgerminomas may be present in a grossly normal contralateral ovary.¹²⁰ In such a circumstance, it is not necessary to remove the entire ovary. Nonpregnant women with microscopic dysgerminoma in the contralateral ovary have subsequently been treated with chemotherapy and have gone on to conceive normal healthy children. The current FIGO staging system for ovarian cancer is presented in Table 53.5.

Epithelial ovarian cancer

Borderline malignant potential tumors are the most common epithelial ovarian cancers in pregnancy.¹²¹ Patients with stage IA and IB borderline malignant potential tumors are adequately treated with surgery alone. More advanced stage ovarian borderline malignant potential tumors are also treated surgically, chemotherapy being reserved only for the unusual group of patients with invasive metastases in association with borderline malignant potential tumors of the ovary.¹²²

Figure 53.5 Mucinous carcinoma of the ovary. Sagittal ultrasonogram demonstrates a complex ovarian mass (arrows) posterior to the lower uterine segment of the gravid uterus. (Courtesy of Dr. M. G. Tompkins.)

Patients found to have stage I invasive cancers of the ovary are generally managed conservatively, and the pregnancy is allowed to go to term. Recent data suggest that, in a non-pregnant state, patients with stages IA and IB, grades 1 and 2, epithelial cancers of the ovary are adequately treated with surgery alone.¹²³ Additional adjuvant chemotherapy appears to play no significant role in improving a very high disease-free survival. Once the cancer is more advanced than stage IB, aggressive cytoreductive surgery is necessary. In general, a total abdominal hysterectomy and bilateral salpingo-oophorectomy, omentectomy, and para-aortic and pelvic lymph node sampling, and resection of all gross tumor is recommended in early-stage ovarian cancer. The patient is subsequently treated with platinum-based combination chemotherapy.

Recent studies with germ cell ovarian malignancies suggest that platinum-based chemotherapy may be given successfully in the second and third trimester prior to the fetus reaching viability.¹²⁴ Such a strategy may be employed for common epithelial cancers as well, first recognized to be present in the second and third trimesters of pregnancy. Malfetano and Goldkrand¹²⁵ treated one patient successfully with cisplatin-based chemotherapy after conservative surgery at 16 weeks' gestation confirmed the presence of an advanced-stage epithelial ovarian cancer. That patient went on to a vaginal delivery and a postpartum laparotomy that revealed no evidence of persistent cancer. In turn, Buckley et al.¹²⁶ reported on a pregnant woman with an advanced ovarian cancer in a pregnancy complicated by human immunodeficiency virus (HIV) infection who failed to respond to cytoreductive surgery and

Table 53.5 International Federation of Gynecology and Obstetrics (FIGO) ovarian cancer staging classification.

I	Growth limited to the ovaries
Ia	Growth limited to one ovary; no ascites; no tumor on the external surface; capsule intact
Ib	Growth limited to both ovaries; no ascites; no tumor on the external surfaces; capsule intact
Ic	Tumor either stage Ia or Ib, but with tumor on the surface of one or both ovaries; or with the capsule ruptured; or with ascites containing malignant cells; or with positive peritoneal washings
II	Growth involving one or both ovaries with pelvic extension
IIa	Extension, metastases, or both to the uterus, tubes, or both
I Ib	Extension to other pelvic tissue
I Ic	Tumor either stage IIa or I Ib but with tumor on the surface of one or both ovaries; or with the capsule ruptured; or with ascites present containing malignant cells; or with positive peritoneal washings
III	Tumor involving one or both ovaries with peritoneal implants outside the pelvis and/or positive retroperitoneal or inguinal nodes; superficial liver metastases equals stage III; tumor is limited to the true pelvis but with histologically proven malignant extension to the small bowel or omentum
IIIa	Tumor grossly limited to the true pelvis with negative nodes but with histologically confirmed microscopic seeding of abdominal peritoneal surfaces
IIIb	Tumor involving one or both ovaries with histologically confirmed implants of abdominal peritoneal surfaces, none exceeding 2 cm in diameter; nodes are negative
IIIc	Abdominal implants greater than 2 cm in diameter and/or positive retroperitoneal or inguinal nodes
IV	Growth involving one or both ovaries with distant metastases. If pleural effusion is present, there must be positive cytology to allot a case to stage IV; parenchymal liver metastasis equals stage IV

cytotoxic chemotherapy and who died within 13 months of her cancer diagnosis.

Germ cell ovarian malignancies

Germ cell ovarian malignancies are infrequently occurring tumors that present in women in their second and third decades of life. The dysgerminoma is the most common malignancy in pregnancy.¹²⁷ Management of dysgerminoma requires removal of the primary tumor and careful surgical staging, as described earlier. Dysgerminomas are the only germ cell malignancies of the ovary to frequently (5–15%) involve both ovaries. Thus, biopsying the contralateral ovary is appropriate even if it appears to be grossly normal. Dysgerminomas also have a tendency to spread to the para-aortic nodes. Every effort should be made to sample the para-aortic lymph nodes surgically at the time of the extirpation for the dysgerminoma.

Dysgerminomas are exquisitely sensitive to radiation therapy and chemotherapy.¹¹⁵ Vincristine, actinomycin D, and cyclophosphamide (VAC) and bleomycin, etoposide, and platinum (BEP) are extremely effective regimens for the management of dysgerminomas.¹²⁸ Stage IA dysgerminoma may be treated very effectively with surgery alone.¹¹⁵ Advanced-stage dysgerminoma should be treated with postoperative chemotherapy.¹¹⁵ Pregnant women should be given the chance to maintain the pregnancy if a dysgerminoma is present. Chemotherapy may be given in the second or third trimesters. BEP and VAC chemotherapy regimens require only short-term administration and are given every 3–4 weeks. A Cesarean section is used to deliver the fetus at the time of fetal viability. A second-look procedure may also be performed at that surgery. The endodermal sinus tumor is the most virulent of all the germ cell ovarian malignancies. It was associated with a 2-year survival of 12–19% in the prechemotherapy era. Our current recommendation for this disease is the BEP regimen.

Other germ cell malignancies include the embryonal carcinoma, the immature teratoma, choriocarcinoma, and mixed germ cell tumors. Their management is based on both the stage of disease and the presence or absence of circulating oncofetal proteins that can be used as markers for response to therapy. In general, these malignancies require aggressive therapy in the form of resection of all viable tumor followed by intense combination chemotherapy.¹¹⁵ Pregnant women found to have these tumors in the second and third trimesters of pregnancy should be offered the opportunity of receiving chemotherapy during pregnancy as a way of being treated and not terminating the pregnancy. Christman and colleagues¹²⁹ have reported a patient with a stage IC, grade 3, immature teratoma who was successfully treated with a unilateral salpingo-oophorectomy at 15 weeks' gestation and one course of cisplatin, vinblastine, and bleomycin in her 19th week of gestation.¹²⁹ The patient delivered a normal term infant, received four more cycles of therapy postpartum, and is alive and well 61 months from diagnosis. The child has developed normally.

Sex cord–stromal tumors

Sex cord–stromal tumors are rare tumors that may complicate pregnancy. The granulosa theca cell tumor is the most common member of this category and is associated with estrogen production.¹³⁰ The Sertoli–Leydig cell tumor is rare and is associated with androgen production. Young and colleagues¹³¹ reported on 36 sex cord–stromal tumors diagnosed in pregnancy. Treatment was limited to removing the tumor. Only one of these patients has subsequently recurred. Advanced-stage sex cord–stromal tumors require more aggressive chemotherapy. Our current recommendation in the nonpregnant state is a carboplatin and paclitaxel combination.

Hodgkin's disease

Hodgkin's disease generally occurs during the reproductive years, the peak incidence being between the ages of 18 and 30 years.¹³² It is estimated that one-third of women with Hodgkin's disease are pregnant or have delivered within 1 year of the diagnosis.^{133,134} As with almost all malignancies associated with pregnancy, Hodgkin's disease has not been reported to be affected by the pregnancy.^{135–137} It is a disease that is extremely sensitive to therapy. The cure rate for localized disease treated with radiation therapy is 80%, and patients with advanced disease treated with chemotherapy can anticipate a long-term disease-free survival of 65%.^{138,139} Peripheral lymphadenopathy is the most common presenting symptom for patients with Hodgkin's disease. Between 60% and 80% of Hodgkin's disease patients have enlarged cervical lymph nodes. In addition, patients may be asymptomatic or may have a history of fever, night sweats, weight loss, malaise, and pruritus.¹⁴⁰

Selection of local radiation or systemic chemotherapy is based on the staging system (Table 53.6). Staging studies recommended for a patient with Hodgkin's disease are done in an attempt to identify extranodal disease. Pregnant women may undergo ultrasound or MRI studies of the liver, spleen, and retroperitoneal lymph nodes to avoid the hazard of diagnostic imaging radiation exposure to the fetus. Strategies for treating patients with stage I and stage II Hodgkin's disease are usually radiotherapeutic, with reported 5-year survivals of 89% and 67% respectively.¹⁴⁰ Radiation is the only modality necessary for patients with stage IIIA lymphocyte-predominant or nodular-sclerosing Hodgkin's disease. Stage IIIA disease with other histologic types is treated with radiation and combination chemotherapy. More advanced disease is treated with combination chemotherapy.¹⁴¹

The standard mantle field for midline mediastinal radiation to doses of 4000 rad results in fetal exposure to a degree that is greater than acceptable.¹⁴² It has been recommended that, in the first trimester of pregnancy, the fetus should not be exposed to more than 10 rad (0.1 cGy). Internal radiation

Table 53.6 Ann Arbor staging classification for Hodgkin's disease.

I	Involvement of a single lymph node region (I) or a single extralymphatic organ or site (I _E)
II	Involvement of two or more lymph node regions on the same side of the diaphragm (II) or localized involvement of an extralymphatic organ or site (II _E)
III	Involvement of lymph node regions on both sides of the diaphragm (III) or localized involvement of an extralymphatic organ or site (III _E), spleen (III _S), or both (III _{SE})
IV	Diffuse or disseminated involvement of one or more extralymphatic organs with or without associated lymph node involvement. The organ(s) involved should be identified by a symbol
A = Asymptomatic	
B = Fever, sweats, weight loss >10% of body weight

scatter from standard mantle fields cannot be shielded and would result in a greater exposure rate to the fetus than the dose recommended for continuation of the pregnancy.¹⁴¹ Patients with pelvic disease or disease localized to the inguinal or abdominal region should undergo therapeutic abortion prior to radiation therapy. Similar disease first recognized in the third trimester would be treated with localized radiation therapy once fetal maturity was achieved and the infant delivered. Patients found to have rapidly progressing disease routinely receive chemotherapy, with the decision for initiating treatment based on the trimester of pregnancy and the patient's desires.

Advanced (stage III and stage IV) Hodgkin's disease has been successfully treated with the MOPP regimen – Mustargen (nitrogen mustard), Oncovin (vincristine), procarbazine, and prednisone.¹⁴⁰ Eighty-one percent of patients in the National Cancer Institute series with previously untreated stage III and stage IV disease were successfully managed with only 6 months of treatment.¹³⁹ The role for chemotherapy in the management of Hodgkin's disease in the first trimester of pregnancy is only beginning to become defined.¹³⁷ Therapeutic abortion should be offered to those patients in the first half of pregnancy who are unwilling to accept an increase in risk of adverse fetal outcome potentially attributable to treatment.

Non-Hodgkin's lymphoma

Fewer than 50 cases of non-Hodgkin's lymphomas during pregnancy have been published.^{54,140,143} The mean age of patients with non-Hodgkin's lymphoma is 42 years, suggesting that most patients are past their childbearing years or are

in a subfertile period of their reproductive life. The most important prognostic features for non-Hodgkin's lymphoma are the histologic type and the stage of disease.¹⁴¹ Non-Hodgkin's lymphomas tend to be widely disseminated at the time of diagnosis and therefore require less elaborate staging than Hodgkin's disease. Breast and ovarian involvement is frequent, and breast metastases have a particularly bad prognosis.^{144,145}

Localized non-Hodgkin's lymphoma is treated with radiation and has a 50% cure rate. Chemotherapy may also be curative in this disease.¹⁴⁶ Disseminated nodular lymphoma and chronic lymphocytic leukemia fall into a favorable group of disseminated non-Hodgkin's lymphomas. They tend to be relatively indolent.¹⁴¹ Palliative treatment results in survivals of about 5 years. The unfavorable types of non-Hodgkin's lymphoma have a much shorter life expectancy, although occasional complete remissions and prolonged survival with chemotherapy have been reported.¹⁴⁷ Because of the aggressive nature of diffuse non-Hodgkin's lymphoma, aggressive therapy should not be delayed until fetal maturity. Aviles and colleagues published the largest experience treating non-Hodgkin's lymphoma in pregnancy.⁵⁴

Acute leukemia

Acute leukemia rarely complicates pregnancy, the incidence being less than one case in 75 000 pregnancies.^{57,148} The disease is usually first recognized in the second or third trimester.¹⁴⁹ A recent review of 72 women with leukemia in pregnancy from 1975 to 1988 revealed that 64 (89%) had acute leukemia. Of these 72 women, 44 had acute myelogenous leukemia, 20 had acute lymphocytic leukemia, five had chronic myelogenous leukemia, one had a hairy cell leukemia, and two had unspecified leukemias.¹⁵⁰ Sixteen (22%) were detected in the first trimester, 26 (36%) were detected in the second trimester, and 30 (42%) were detected in the third trimester of pregnancy. Presenting symptoms are becoming easily fatigued, bleeding diathesis, or recurrent infections that reflect bone marrow failure. Specific physical findings associated with acute leukemia include sternal tenderness, skin pallor, petechiae, ecchymoses, and hepatosplenomegaly. Patients with acute lymphocytic, myelocytic, or monocytic leukemia usually have normocytic anemia, normochromic anemia, mild to marked thrombocytopenia, and leukocytosis.¹⁴⁰

Pregnancy does not influence the natural history of acute leukemia.^{55,150} Substantial improvement in the survival of women with acute leukemia in pregnancy has occurred with the use of chemotherapy, radiation therapy, and supportive care, including blood products, antibiotics, and autologous bone marrow transplantation.¹⁵¹ Virtually all women treated with chemotherapy in pregnancy will survive to delivery, and 87% of the fetuses will also survive.¹⁴⁰ Intense combination chemotherapy leads to multiple complications, including

severe infections secondary to bone marrow suppression and the risk of central nervous system leukemia. The latter is treated with whole brain radiation, intrathecal methotrexate, or cytosine arabinoside. Hyperuricemia is usually treated with allopurinol.¹⁵²

Chronic myelocytic leukemia

Chronic myelocytic leukemia makes up 90% of the chronic leukemias complicating pregnancy.^{153,154} Pregnancy does not adversely affect the natural history of chronic myelocytic leukemia. Treatment is palliative. Median survival is 45 months. All patients eventually die, most from an acute blastic crisis resembling myeloblastic leukemia.¹⁴¹ The median survival is less than 1 year following the development of an acute blastic crisis.¹⁴⁰ Eighty-five percent of chronic myelocytic leukemia patients have a Philadelphia chromosome, a 9:22 translocation.¹⁴⁰ Approximately 96% of pregnant women with chronic myelocytic leukemia survive to delivery. Fetal survival throughout the gestation is 84%.¹⁴⁰

Melanoma

Pigment-producing melanocytes are found in the base layer of the epidermis, the mucosa of the gastrointestinal tract, the vagina, and the pigmented portion of the retina. Malignant melanoma derives from such cells and, in 90% of cases, originates in the skin in pre-existing pigmented nevi.¹⁵⁵ Malignant melanoma localized to superficial layers of the skin is associated with a 50–80% cure rate. Lesions that have infiltrated into the lowest third of the dermis or that have metastasized to regional lymph nodes have a 20% cure rate.¹⁴⁰

Pregnancy frequently induces a darkening in the appearance of pigmented nevi, but a bluish or slightly gray appearance to a nevus requires immediate excisional biopsy. Indeed, pigmented nevi that have become darker or irregular in outline and elevated should always be promptly excised in pregnancy under local anesthesia. Pregnancy does not change the natural history of melanoma.^{156,157} McNammy and colleagues¹⁵⁶ reported on 23 patients pregnant at the time of the diagnosis of melanoma and were unable to show that pregnancy had any significant influence on the survival of those patients. They did recommend that subsequent pregnancies be avoided for the first 3 years following excision of a malignant melanoma. Wong and colleagues reviewed 66 patients with stage I melanoma diagnosed during pregnancy and were unable to identify any significant difference between the pregnant population and a control population with regard to the location of the primary tumor, the age of diagnosis, Clark's level, mean depth of invasion, and histologic type.¹⁵⁷ The 5-year survival for women with melanoma during pregnancy and for the entire population was 86% and 87% respectively. Thus, the pregnancy did not influence the survival of the

patients.¹⁵⁷ Terminating a pregnancy will not initiate a remission.¹⁵⁸ The clinical significance of estrogen receptor protein found in malignant melanoma has yet to be established. Clinical trials with an estrogen agonist–antagonist have yet to demonstrate any benefit in the treatment of malignant melanoma.^{140,159,160}

Most patients with malignant melanoma present with stage I disease, disease limited to a primary cutaneous lesion. Stage I disease is pathologically staged according to Clark's level of deepest anatomic invasion or the Breslow system.^{161,162} Stage I lesions are usually treated with wide local excisions. Adjuvant immunotherapy for completely resected stage I and stage II disease has not shown definite benefit.¹⁵⁵ Surgery should be performed promptly in patients with stage I and stage II disease, whereas patients with stage III disease can only be palliated. Early delivery of the fetus in the third trimester once fetal lung maturation has been achieved should be considered routinely for stage III patients.

Placental or fetal metastases have been reported only 16 times, with four fetal deaths due to transplacental metastases of malignant melanoma.¹⁵⁸ Although malignant melanoma is the most common malignancy to metastasize to the placenta and fetus, this is such a rare event as to preclude the recommendation of pregnancy termination for the management of the disease to avoid transplacental carcinogenesis or to induce a remission.

Gastrointestinal cancer

Colorectal cancers

Cancers of the gastrointestinal tract rarely complicate pregnancy.¹⁶³ There is no evidence that pregnancy changes the natural history of colorectal cancer, the most common of these neoplasms.^{164–168} Most pregnant patients with gastrointestinal cancers have rectal carcinomas. Approximately 20% of patients have carcinoma presenting in the sigmoid colon.¹⁶⁹ Unfortunately, diagnosis is frequently difficult in pregnancy, and there is a considerable delay in diagnosis. Typical presenting symptoms include severe constipation, abdominal distention, and rectal bleeding. As most diagnoses can be made by rectal examination, these symptoms should be promptly evaluated. Delay in diagnosis can be associated with intussusception, obstruction, or perforation.¹⁶⁸ Carcinoembryonic antigen (CEA) is routinely elevated in pregnancy and is of little use in diagnosing colorectal cancers in the gravid state.¹⁷⁰

Early-stage colorectal cancers diagnosed in the first and second trimester should be treated with prompt surgery, and the pregnancy should be allowed to go to term.^{168,171} Patients with large colorectal lesions with metastases suspected or present have been allowed to carry the pregnancy until fetal maturity and have then undergone a Cesarean section and bowel resection, provided they remained relatively asymptomatic.¹⁶⁹ Most colorectal cancer patients are delivered

by Cesarean section, as labor may result in dystocia or hemorrhage. Lesions initially identified in the third trimester are not usually treated until fetal maturity is achieved.¹⁷¹ Standard therapy for curable lesions is definitive surgery, including standard bowel resections, low anterior resections, or abdominal perineal resections.¹⁷²

Pancreatic tumors

Pancreatic carcinoma rarely complicates pregnancy and is difficult to diagnose in the presence of pancreatitis.^{173,174} Three cases of pancreatic carcinoma have been diagnosed in pregnancy, with the mothers dying soon after delivery.^{173,174}

Stomach tumors

Gastric cancers rarely complicate pregnancy, and their symptoms are similar to those normally experienced in pregnancy, including gastrointestinal discomfort, nausea, and vomiting.^{175–178} Diagnosis may be made by gastroscopy, which avoids diagnostic radiation exposure. Maeta¹⁷⁹ reported 14 cases of gastric cancer occurring in pregnancy.

Liver tumors

Hepatocellular carcinomas are rare in women and usually present in postmenopausal women. A literature review revealed only 28 cases of hepatocellular carcinoma reported through 1995.¹⁷⁹ Hepatocellular carcinoma predominantly occurs in males, tends to present at a later age in women, and decreased fertility is associated with advanced cirrhosis (a predisposing factor for hepatocellular carcinoma).¹⁸⁰ One case report of a hepatocellular carcinoma resulted in a maternal death in pregnancy.¹⁸¹ A single case of an extrahepatic biliary tract carcinoma complicating pregnancy has been reported.¹⁸²

Gynecologic malignancies

Uterine carcinoma

Adenocarcinoma of the endometrium is an extremely unusual disease in pregnant women, as only 8% of endometrial cancers have been reported to occur in women under age 40 years.¹⁸³ Infertility has been a factor associated with women who develop adenocarcinoma of the endometrium. Eleven cases of adenocarcinoma of the endometrium associated with pregnancy have been reported.^{184–188} The cases were generally associated with vaginal bleeding and were found to be well-differentiated adenocarcinomas. Only one of the patients has died to date. Standard therapy for patients with adenocarcinoma of the endometrium is a total abdominal hysterectomy and bilateral salpingo-oophorectomy. One patient with a mixed mesodermal tumor of the uterus has also been reported from Yale–New Haven Hospital.¹⁸⁹

Vulvar cancer

Vulvar carcinoma *in situ* has been increasing, according to data from the Connecticut Tumor Registry.¹⁹⁰ Forty percent of patients with vulvar carcinoma *in situ* are under age 40 years. Thus, it can be anticipated that more women will be diagnosed in pregnancy to have vulvar carcinoma *in situ*. The management of a vulvar lesion in pregnancy is a wide local excision. Vulvar carcinoma *in situ* does not progress rapidly to invasive cancer unless associated with an immune deficiency. Definitive therapy in terms of a wide local excision or vulvectomy can be delayed in most cases until after completion of the pregnancy.

Lutz and colleagues¹⁹¹ reported that 5% of women with carcinoma of the vulva seen at the Medical University of South Carolina were diagnosed in pregnancy or within 2–6 months postpartum. Invasive cancer is usually treated with a radical vulvectomy. Recently, less extensive surgery has been quite effective if the tumor is only superficially invasive.¹⁹² Extensive vulvectomies may be performed in pregnancy, but the current trend in the nonpregnant state is to manage microinvasive cancer with wide local excision.^{192,193}

Vaginal cancer

Carcinoma of the vagina occurs infrequently and is usually a squamous carcinoma presenting in a peri- or postmenopausal woman. Its management is similar to that of cervical cancer. Senekjian and colleagues¹⁹⁴ reported on 20 patients who developed clear cell adenocarcinomas of the vagina in pregnancy. These women had been exposed *in utero* to diethylstilbestrol. It was noted that the pregnancy did not have an adverse effect on clear cell carcinomas of the vagina or cervix. Perhaps this is due to the fact that, in a previous report, clear cell carcinomas did not have estrogen and progesterone receptors.¹⁹⁵

Soft tissue sarcoma

Soft tissue sarcomas rarely complicate pregnancy. The overall prognosis is poor. No evidence suggests that, if they were successfully managed, subsequent pregnancies would be deleterious to the patient's health.^{196,197} Osteogenic sarcoma is the most frequent sarcoma reported in pregnancy. No survival differences were noted in 18 cases of osteogenic sarcoma managed in pregnancy when they were matched with nonpregnant women for skeletal tumor location, histologic appearance, and age.¹⁹⁸ Therapeutic abortion has been recommended in the first trimester for patients exposed to intense cytotoxic chemotherapy.¹⁹⁹ However, it is usually recommended that patients diagnosed in the third trimester undergo early delivery once fetal maturity has been established.¹⁹⁹ A case of a Ewing's sarcoma involving the iliac wing diagnosed at 25 weeks' gestation appears to have been successfully

treated with multiagent chemotherapy in pregnancy followed by a Cesarean section at 34 weeks' gestation.²⁰⁰

Endocrine tumors

Thyroid cancer

Disorders of the thyroid gland are common in pregnancy, and thyroid nodules are frequently diagnosed in pregnancy.²⁰¹ However, the thyroid is an infrequent site for cancer to develop in pregnancy. Tan et al.²⁰¹ found three thyroid cancers among 40 nodules assessed in pregnancy. As the population delays childbearing, it is possible that more papillary adenocarcinomas of the thyroid will be diagnosed in the future, as the peak distribution for papillary adenocarcinomas occurs in women aged 30–34 years.²⁰² Patients at high risk of thyroid cancer include women exposed to radiation therapy to the head, neck, or chest during childhood.^{203,204} Most cancers of the thyroid present as solitary nodules. Most thyroid nodules appear in the first and third trimester of pregnancy and are benign.²⁰⁵

The most common type of thyroid cancer to be diagnosed in pregnancy is the papillary carcinoma or mixed papillary follicular carcinoma. Prognosis is not affected by subclinical metastases to regional lymph nodes, which are present in 50–70% of patients. Women under age 49 years are expected to have a 15-year survival rate of 90–95%.^{203,204} Anaplastic carcinomas have fulminant courses and rarely complicate pregnancy, as they occur most commonly in women over 50 years of age. Medullary carcinomas can occur in association with the multiple endocrine neoplasia type II syndrome (medullary thyroid carcinoma, pheochromocytoma, and parathyroid adenoma), are bilateral, and have only once been reported in pregnancy.²⁰⁶

Fine needle aspiration biopsies are used to diagnose thyroid cancer in pregnancy.^{201,207} Radionuclide scans are contraindicated in pregnancy because of the theoretical risk of destroying the fetal thyroid. Fine needle aspiration biopsy is associated with a false-negative rate of only 6%.^{201,208}

As the overwhelming number of thyroid cancers presenting in pregnancy are histologically well differentiated, there is no reason to terminate pregnancy or avoid future pregnancies.^{209,210} Pregnancy does not appear to influence the course of well-differentiated thyroid cancer.^{210,211} Thyroid suppression therapy may be administered until delivery, regardless of the trimester in which the cancer was diagnosed.²⁰² Patients should undergo prompt surgery if metastases develop in regional lymph nodes during suppression therapy or the tumor is fixed to surrounding tissue and enlarges during suppression therapy. A subtotal thyroidectomy is usually performed, and ¹³¹I should be administered postpartum to avoid the surgical complication of permanent hypoparathyroidism.²¹² Extensive surgery should be avoided during pregnancy, as there is a chance of miscarriage occurring as a result.²¹³

Patients diagnosed in the first two trimesters of pregnancy as having a medullary carcinoma should undergo prompt total thyroidectomy and prophylactic neck dissection, whereas those diagnosed in the third trimester can await fetal maturity before definitive surgery. Patients undergoing thyroidectomy in pregnancy are recommended to receive levothyroxine post-operatively in a dose sufficient to keep serum thyroid-stimulating hormone (TSH) low.²¹⁴

Adrenal tumors

Pheochromocytoma is the most common tumor arising in the adrenal gland in pregnancy. In the past, it has been associated with a high maternal mortality (58%) and fetal mortality (55%).¹⁶⁸ However, Harper and colleagues²¹⁵ reviewed the literature from 1980 to 1987 and presented 47 cases with pheochromocytoma diagnosed in pregnancy. The overall mortality was 17% and fetal loss was 26%. MRI may be used to confirm the presence, laterality, and location of the pheochromocytoma.²¹⁶ Figure 53.6 shows a pheochromocytoma diagnosed by MRI in a 25-week-pregnant patient. Provocative tests should not be performed, because these might lead to maternal fatality.²¹⁷

The management of pheochromocytoma has been surgical in the first two trimesters and delivery by Cesarean section followed by tumor resection in the third trimester.¹⁶⁸ Medical management of the disease includes preoperative adrenergic blockade with oral phenoxybenzamine, to lower the blood pressure, and propranolol to reduce the heart rate and prevent arrhythmias through the adrenergic receptor blockade.^{218,219} Stenstrom and Swolin²²⁰ have recommended using alpha receptor-blocking agents for the treatment of patients diagnosed as having pheochromocytomas in the second and third trimester and delaying surgery until fetal viability is accomplished. Armaroli and colleagues²²¹ also reported on the successful management of a mother in this fashion. Lyons and Colmorgen²²² managed a patient throughout her entire pregnancy with adrenergic blockade.

Parathyroid carcinoma

One case of a parathyroid carcinoma complicating pregnancy has been reported.²²³ That patient presented with acute pancreatitis at 31 weeks' gestation, underwent a left parathyroidectomy, subsequently delivered a viable infant, and then had an additional pregnancy.²²³

Urinary tract malignancies

Kidney tumors

Renal cell carcinoma is the most common malignancy arising in the urinary tract in pregnancy. Tydings and colleagues²²⁴ reviewed 37 cases of renal tumors, 22 of which were renal cell

Figure 53.6 Pheochromocytoma in a pregnant patient. The right adrenal mass (*arrows*) is very high signal intensity on this T2-weighted image, consistent with a diagnosis of pheochromocytoma. (Courtesy of Dr. R. Kier.)

carcinoma. Hematuria is the most common presenting symptom. Nephrectomy with or without radiation therapy is standard treatment.

Bladder cancers

Bladder cancers have infrequently been reported in pregnancy.^{225–227} The histologic distribution is similar to that in the nonpregnant state, with an overwhelming majority being transitional cell carcinoma followed by squamous cell and adenocarcinomas.

Central nervous system tumors

Central nervous system tumors rarely complicate pregnancy.²²⁸ Patients present with headaches and visual disturbances. MRI allows for rapid evaluation without radiation exposure. The overall maternal mortality for patients with central nervous system tumors is 60%. Therapeutic abortions have been recommended for patients diagnosed in the first trimester as having malignant brain tumors because of the rapid course of such tumors.

Key points

- 1 Medical management is the primary means of treatment of myoma in pregnancy.
- 2 The hormonal changes of pregnancy, particularly the production of human chorionic gonadotropin (hCG), are associated with luteomas, theca-lutein cyst, hyperreactio luteinalis, and large solitary luteinized follicular cyst of pregnancy.
- 3 Radiation and chemotherapy are commonly employed in the routine management of cancers that may occur in pregnancy, such as cervical cancer, breast cancer, ovarian cancer, uterine cancer, vaginal carcinoma, vulvar cancer, and urinary tract malignancies.
- 4 Surgical staging for ovarian cancer in pregnancy should be the same as that recommended in the nonpregnant state.
- 5 Dysgerminoma is a germ cell ovarian cancer, and is the most common ovarian malignancy in pregnancy.
- 6 Sex cord–stromal tumors, such as Sertoli–Leydig cell tumors, are rare during pregnancy.
- 7 It is estimated that one-third of women with Hodgkin's disease are pregnant or have delivered within 1 year of diagnosis.
- 8 Non-Hodgkin's lymphoma, acute leukemia, gastrointestinal cancers, and thyroid cancers are rare during pregnancy.

Medicosocial Considerations in Pregnancy

Pregnancy before age 20 years and after age 35 years

Helen H. Kay

The problem with pregnancies in younger and older women

The optimal age for childbearing is debatable. Younger and older maternal age are considered to be suboptimal for childbearing, but it is uncertain whether that adversity is due to age itself, to biologic factors, or to socioeconomic factors. It has been taught that older women have more complications because of an increase in medical complications and risks from aneuploidy. Younger parous teens have difficulties because of socioeconomic pressures and, possibly, immature pelvises. In Fig. 54.1, the relative risks of maternal mortality by age in the United States from 1979 to 1986 is demonstrated by a J-shaped distribution with slightly increased risk mortality for those less than 20 years of age and for those beyond 24 years of age, rising exponentially.^{1,2} In actual numbers, pregnancy complications kill 70 000 teenagers a year worldwide.³ At ages greater than 40 years, risk of mortality is 8.6 times that for women between the ages of 20 and 24 years. Additionally, low birthweight is more closely linked with age less than 15 years and age 40 years and older in New Jersey.⁴ Maternal age, either low or high, was included among the list of high-risk factors that Creasy and colleagues suggested using in a screening protocol to identify pregnant women at risk of preterm delivery.⁵ Therefore, pregnancy for women at the extremes of reproductive potential may be more hazardous. Physicians should be aware when counseling patients regarding the optimal timing of pregnancy. A realistic understanding of the true risks and reassurances by healthcare providers would be valuable to women in those reproductive years.

At the same time, it is important to determine whether adverse outcomes are related to physiology, genetics, or psychosocial behaviors. Many epidemiologic studies have not been able to control for a multitude of variables such as smoking, education, socioeconomic status, and race. Consequently, only associations have been identified without direct

cause and effect relationships. Even a focused analysis of outcomes in Nigeria suggests that poor obstetric outcomes are a reflection of poor utilization of prenatal care rather than a biologic factor from maternal age.⁶

The literature also contains studies from a variety of countries with a multitude of unique problems. Therefore, is the problem of obstructed labor due to a patient's young age or to the inability to perform a Cesarean section, which is a problem unique to an environment? Reported complications in the literature worldwide may not be pertinent to the US-based population in our current healthcare system. In this chapter, we will discuss the primary issues pertinent to pregnancies complicated by teenage mothers and women over the age of 35 years, drawing data and experience primarily from Westernized countries' experiences.

Adolescent pregnancies are a cost to society. Public aid programs through Aid to Families with Dependent Children, Medicaid, Food Stamps, WIC programs, home visiting nurses, and others increase costs; these costs add up to billions of dollars per annum.⁷ Older women having pregnancies are also a cost to society, although these mothers tend to be more financially secure. Costs accrued to them include those related to infertility, prenatal diagnosis, and care resulting from medical complications such as diabetes, chronic hypertension, and other medical illnesses. The amount is also likely to be in the billions of dollars annually.

We as physicians should understand the scope of these problems because we will be asked for consultation. During our routine practices, we will have opportunities to identify those at risk of pregnancy at either an early age or a mature age. We should also be aware of those who are deciding whether to proceed or not to proceed with a conception. We should be prepared to provide proper consultation and guidance through wise counsel. Ultimately, whether our advice is heeded or not, it is our responsibility to provide appropriate prenatal care tailored to the age group in order to ensure the best neonatal outcomes.

Adolescent pregnancies

Many resources have been spent on preventing and reducing the incidence of teenage births. The primary reason for doing so is the high-risk nature of these pregnancies, resulting in

Figure 54.1 Relative risk (RR) of maternal death by age group in the United States, 1979–1986 (from ref. 1 with permission).

physical and psychosocial ill-effects to the young mothers. In addition, there are long-term socioeconomic burdens to society from the offspring of these often unplanned pregnancies. One other outcome, not well known, is the ill-effect among the offspring of adolescent mothers. In Sweden, risks of attempted and completed suicide attempts were higher among those offspring of teenage mothers (hazard ratio of 2.09 compared with those age 20 years or older, $P < 0.0001$).⁸ These risks deserve further study.

Incidence

Teenage pregnancy, often termed adolescent pregnancy, is, by definition, pregnancy in a patient who is between the ages of 13 and 20 years. In the USA, teenage births peaked in the 1950s and have declined since then⁹ (Table 54.1). However, over one million teenagers still become pregnant in the US each year.¹⁰ This is a very high rate for an advanced society and underscores the inadequate educational efforts that have been put forth¹¹ (Fig. 54.2). The incidence of unplanned and unwanted pregnancies among the black teenage population is 51.2%.¹³ Approximately half are aborted¹⁴ (Table 54.2). In 2002, Hispanic teenagers had the highest pregnancy rate (82.9 per 1000) compared with other ethnic groups, surpassing black women for the first time¹⁷ (Fig. 54.3). The proportion of births to unmarried Hispanic women increased to 43.4% from 2001 to 2002. In California, Hispanics accounted for the largest percentage of early and late teenage pregnancies (65% and 60% respectively). This phenomenon should be recognized and appreciated in order to better understand its socioeconomic impact.¹⁸

Figure 54.2 UNICEF data. Births per 1000 women aged 15–19 years per country in the industrialized world (from ref. 12).

Table 54.1 Teenage birth rates in the USA.

Year and age of woman	Birth rate	Abortion rate	Pregnancy rate
Women under age 20 years*			
1920	51.4	u.	u.
1930	60.1	u.	u.
1940	47.9	u.	u.
1950	72.3	u.	u.
1960	71.8	u.	u.

1999	49.7	25.6	87.8
2000	48.6	24.8	85.6
2001	46.1	u.	u.

*Statistically significant; u., unavailable data. National Center for Health Statistics (NCHS) of the US Department of Health and Human Services.

Some more recent reports on teenage pregnancies are positive. The teenage birth rate for women aged 15–19 years was 61.8/1000 women in 1991, but declined to 43.0/1000 women in 2002. This is a 30% decrease. In 2002, the teenage birth rate decreased by 50% among the highest risk ages of 15–17 years; rates for black teenagers decreased by 40%. According to recent statistics from national surveys in 2001, sexual activity decreased by 16% from 1991 (54.1%) to 2001 (45.6%); the prevalence of multiple partners decreased by 24%; condom use increased; and sexually transmitted diseases (STD) decreased.¹⁵

Risk behaviors and social factors leading to teenage pregnancies

Health risk behaviors

In contrast to older mothers, who often obtain prepregnancy consultation, teenagers rarely seek advice prior to getting pregnant. Therefore, abusive habits such as alcohol, cigarette, and drug abuse are not addressed and resolved prior to conception. Although younger teenagers less than 15 years of age

Table 54.2 Facts about teenage pregnancies.^{7,9,15,16}*Pessimistic facts about teenage pregnancies*

Approximately one million teenage pregnancies occur each year in the United States

75–95% are unplanned or unwanted

Approximately 50% give birth

13% of all US births are to teenagers

Teenage birthrate in 2002 was 28.5/1000 aged 15–19 years among whites, 68.3/1000 aged 15–19 years among blacks, and 83.4/1000 aged 15–19 years among Hispanics

Approximately 1 in 16 teenage girls has a baby each year

Birth rate is rising the fastest among girls aged 15–17 years

Approximately one-third to one-half are aborted

18% of teenage girls are sexually active before age 15 years

66% of teenage girls are sexually active by age 19 years

35% do not use contraception at first intercourse

Adolescent girls tend to delay using contraception until 1 year after initiation of sexual intercourse

The illegitimacy rate is 29.7 per 1000 teenagers

Optimistic facts about teenage pregnancies

Teenage birth rate has declined by 30% over past decade

Black teenage births are down by 40% over past decade

The younger 15- to 17-year-old black teenage births are down by 50% in 2002

Between 1990 and 1999, there was a 22% drop in the abortion rate

Sexual activity among teenage girls decreased by 16% from 1990 to 2001

Prevalence of multiple partners decreased by 24%

have inadequate prenatal care, it is the older teenagers, between the ages of 15 and 17 years, who have a higher incidence of drug and cigarette use as well as a higher incidence of sexually transmitted disease.^{19,20} Twenty-five percent of teenagers report cigarette smoking of more than half a pack per day,²¹ and there was a higher correlation between cigarette smoking and sexual activity. Youths who began using alcohol and drugs were also more likely to initiate sexual activity within a year.²²

As illegal drug use is prevalent among adolescents and may account for some adverse outcomes, this relationship was evaluated in an Australian study of 456 teenage antenatal patients. Comparisons were made between a control group, a marijuana-only group, and a multidrug group. After controlling for significant covariates, and in the setting of good antenatal care, the only difference in outcome was a significant linear trend toward an increased incidence of threatened preterm labor ($P = 0.02$) in those using illegal drugs.²³ There was no increase in preterm deliveries, preterm rupture of membranes, or poor neonatal outcomes. It is reassuring that, although illegal drug use and associated behaviors may increase the likelihood of teenage pregnancies, once pregnant, those individuals appear not to have significant adverse outcomes when provided with good antenatal care.

Figure 54.3 Birth rate for teenagers aged 15–19 years by race and Hispanic origin, United States, 1980–2002. Note: data for 2001 are preliminary. Rates are plotted on a log scale.

Low socioeconomic status

There is no doubt that low socioeconomic status promotes adolescent pregnancies because it is a vicious cycle. Poverty leads to a loss of opportunities, which promotes a lack of upward social mobility, leading to higher crime and adverse behaviors such as drug and alcohol abuse. Poverty also promotes poor self-esteem. All this leads to a lack of incentive to avoid parenthood. Adolescents surrounded by other pregnant adolescents will consider pregnancy to be the norm, further promoting adolescent childbearing.⁷

Poor support from parents or the father of the baby

Many teenagers do not obtain psychological support at home. The needs of teenagers are often not addressed at school and are inadequately addressed at home. With a national divorce rate of 50%, it is no surprise that teenagers are not getting the support they need. Others have shown that those teenagers with significant support from families through adult role models, family communication, religion, community involvement, good health practices, some aspirations for the future, and an ability to make responsible choices had an overall lower incidence of sexual intercourse or delayed first intercourse, and had used birth control measures at last sexual intercourse. Clearly, a strong and meaningful social structure

could have an impact on the timing of teenage behaviors that lead to pregnancy. Teenagers with strong parental and community support are less likely to become teenage parents, whereas those whose parents do not openly discuss contraception and sexual behavior with their children tend not to use contraception and are more likely to be teenage parents.²⁴

Poor self-esteem/low achievement in school

It is difficult to determine why some teenagers have low self-esteem but, when present, it fosters psychosocial behaviors resulting in teenage pregnancies. Women with low self-esteem also tend to be poor achievers or underachievers at school. They also tend to have a higher rate of drug, alcohol, and tobacco use.^{25,26} Such individuals are more likely to be influenced by their surroundings and engage in destructive behaviors. In today's society, there are many forces influencing young, moldable individuals. Most of it comes through the commercial mass media, movies, TV shows, and magazines. The perceived accepted norm of sexual freedom is rampant. It is not surprising that many teenagers believe that premarital sexual intercourse is the social norm. This type of peer pressure pervades, and it is difficult for unguided teenagers to sort out what is important for them as an individual. By the age of 19 years, 80% of young women and 87% of young men have had sexual intercourse.²⁷ Women with low self-esteem are also less likely to use contraception.

Many girls with poor self-esteem have had a prior history

of sexual or physical abuse, as high as 33%.^{28–31} This history, combined with depression, probably increases their willingness to engage in childbearing, perhaps as a means to overcome their past history and negative feelings. Healthcare providers should routinely inquire about a history of abuse when taking care of pregnant adolescents.

Racial factors

Half of all teenage births are to non-Hispanic whites, but blacks and Hispanic teenagers have almost twice the pregnancy rates of whites.³² Blacks have a higher proportion of preterm and low birthweight births than whites or Hispanics. At the same time, however, blacks also have a higher mortality rate among term, post-term, normal birthweight, and macrosomic infants.³³ Hispanics have the lowest risks of neonatal mortality at term (Table 54.3). Efforts to address the teenage pregnancy rate, however, should recognize that there are major differences between racial groups within the United States, and there needs to be some understanding of the cultural differences that contribute to perinatal and neonatal adverse outcomes.

In the final analysis, there are several basic facts as to why teenagers become pregnant: (1) poverty; (2) lack of education, both higher education and sex education; (3) lack of stable home environments and caring parents who discuss contraception and sexual behavior with teenagers; (4) health risk behaviors; (5) poor self-esteem; and (6) race.

Table 54.3 Odds ratios (ORs) and 99% confidence intervals (CIs) for pregnancy outcomes of non-Hispanic white, Hispanic, African-American (AA), and Asian women compared with white women aged 20–29 years.¹⁸

Adverse outcomes of teenage pregnancies

In the medical literature, the incidence and types of adverse outcomes resulting from teenage pregnancies vary and remain inconsistent (Table 54.4). Older literature may not apply to current practice. The primary reason is that the populations studied tended to be heterogeneous and, unless there is proper control of factors such as race, socioeconomic status, and type of healthcare system, the findings and conditions will likely be variable. Unlike older patients, adverse outcomes in teenage pregnancies are not the result of maternal medical illness, as the majority are young and healthy. Instead, the current literature supports the understanding that adverse outcomes in teenagers result from poor psychosocial environments rather than biologic risks inherent to the adolescent. In other words, adverse outcomes are more a reflection of a social problem than a medical problem.

Teenage mortality

Mortality to a teenager secondary to pregnancy is extremely low. In the past, one of the major causes of maternal mortality was eclampsia. However, with better recognition of hypertension and early intervention, these cases of maternal mortality are drastically reduced. The mortality ratio (pregnancy-related deaths per 100 000 live births) for preeclampsia and eclampsia for all women <20 years of age from 1979 to 1992 was 1.6 compared with 1.5 for all age groups, 3.3 for women aged 35–39 years, and 6.0 for women aged 40–49 years.³⁴

Table 54.4 Adverse pregnancy outcomes for adolescents.

OR, odds ratio; RR, relative risk; *significant difference.

Perinatal mortality

In California, USA, teenagers had a higher rate of infant and neonatal deaths than an older control group of white women irrespective of race, except that Asians had a similar rate to the control group.¹⁸ However, in another study, the perinatal mortality rate was not increased in adolescents compared with older women and, in some reports, the data were inconsistent.^{20,35,36} In a large retrospective review of 21 610 873 single births between 1995 and 2000, the overall fetal death rate after 24 weeks' gestation was 2.7 per 1000 total births and was not increased in younger aged women.³⁷

Preterm labor

The incidence of preterm labor in a teenage population is variable. There was no difference between young or older adolescents compared with women over 20 years of age³⁶ in one controlled study from Texas, whereas others reported a higher incidence.^{38,39}

Preterm birth

In a large inner city hospital on the east coast of the USA, younger adolescents and older adolescents were also found to have a high risk of preterm delivery compared with older control subjects.⁴⁰ A slightly lower rate of preterm birth (14.5% vs. 17.4%) was seen when black adolescents were compared with black women in general.¹⁹ In a Californian study that controlled for parity, race, and healthcare systems, adolescents also demonstrated greater risks for preterm delivery at less than 37 weeks' gestation than an older control group.¹⁸ Younger adolescents had a higher rate of preterm delivery than older adolescents.^{41,42} In contrast, in a military population in which there was equal access to a tertiary care center, young maternal age was not an independent risk factor for prematurity.⁴³ This was also the case in an ultraorthodox Jewish population with social support and medical care.⁴⁴ In another controlled study, there was no difference in preterm labor in those aged 16–17 years compared with those aged 20–22 years.³⁶ Thus, it appears that the data for preterm delivery risk are mixed, although there is a trend toward an increased risk, most likely reflecting a lack of control in some studies for factors that influence the access to, or quality of, medical care.

Preterm rupture of membranes

Despite being high-risk pregnancies, teenage pregnancies do not appear to have an increased incidence of preterm premature rupture of membranes.^{36,45}

Low birthweight

Most studies, but not all, reported a higher risk of low birthweight and very low birthweight infants from teenage

Table 54.5 Adverse neonatal outcomes for adolescents.

Event	Risk	Reference
Low birthweight	OR 0.93 (0.55–1.57)	20
	RR 1.47 (1.31–1.64)*	40
	OR 1.25 (1.00–1.56)*	46
	OR 2.0 (1.2–3.1)*	42
Very low birthweight	RR 1.25 (1.01–1.56)*	40
Perinatal mortality	OR 1.83 (0.73–4.60)	20

OR, odds ratio; RR, relative risk; *significant difference.

women.^{18,40,42,46} There is a U-shaped distribution of small babies, with the highest percentages for teenagers and women over 40 years.⁴⁷ Other studies, however, do not show an increased rate of low birthweight infants in populations in which there was a commitment to prenatal care.^{19,36,43,44} There was only a modest difference between blacks and whites (16% vs. 9% respectively)⁴⁷ (Table 54.5).

Preeclampsia/eclampsia

Gestational hypertension has not been definitively shown to be increased among adolescents when variables such as access to healthcare are controlled.^{36,45} However, one serious concern is the high incidence of preeclampsia. When eclampsia is also involved, the mortality rate is significantly increased to 1.5 per 100 000 live births. Rates of preeclampsia (6.3%) were higher in teenagers than in adult black (2.5%) and white women (2.2%) in an inner city, black population on the east coast.¹⁹ This was also true for an Atlanta inner city population.⁴⁰ It was not true, however, on the west coast, primarily in California, where there was more standardized healthcare and a higher standard of living than in inner city Baltimore or Atlanta.¹⁸ Clearly, the environment is an important issue, but it appears that adolescents, if given proper care, may not be at increased risk of hypertensive disorders of pregnancy compared with older women of similar race.³⁸ Until the etiology of preeclampsia is identified, we may not be able to assess risks unique to the age of a population because of many confounding variables.

Cesarean section

It would appear that the Cesarean section rate in teenagers should be higher because of their immature pelvises. However, this has not been proven. Although it has been reported by Moerman⁴⁸ that the pelvises of girls at menarche had room to grow, it is not certain that this leads to an obstructed pelvis. In Moerman's study, measurements were taken in an antero-posterior (AP) direction and only three planes at the sacrum, inlet, and interspinous diameter. These measurements could not accurately determine differences in the AP diameter or the

curvature of the iliac wings, thus negating their conclusion.⁴⁸ In another study, bone age was determined by radiographs of the hand and wrist in adolescents during the puerperium, and found not to correlate with adverse perinatal or neonatal outcomes. Therefore, there are no anatomic risks associated with adolescent childbearing.⁴⁹

When girls of < 15 years of age were compared with those between 20 and 22 years, the incidence of Cesarean delivery was not higher; in fact, it was lower.^{18,36} The lower rates in this population would suggest that dystocia or cephalopelvic disproportion that could result from these less mature pelvises does not happen often and that these pelvises are not "abnormal" with regard to the ability to deliver a fetus vaginally. Cesarean delivery, if performed, appears to result from other causes but not an immature pelvis.

In Nigeria, where there is a very high incidence of adolescent pregnancies, the incidence of symphysiotomies for an immature, dystotic pelvis is not high. Out of a total of 1013 symphysiotomy procedures performed in Nigeria (3.7%), the rate was not higher among adolescents, but was actually higher among older women. In 87.7%, the primary reason for performing a symphysiotomy was for cephalopelvic disproportion. This suggests that symphysiotomy was not indicated in a higher percentage of adolescents because of an immature pelvis.⁵⁰ Therefore, the concern for an increased risk of dystocia or cephalopelvic disproportion among adolescents may need to be revisited, perhaps with imaging studies.

Risk factors contributing to adverse pregnancy outcomes among teenagers

Anemia

Social pressures have influenced outcomes related to weight gain and nutrition. Anemia among adolescents is rampant, most likely secondary to poor nutrition. Many studies have demonstrated a significant incidence of anemia among African-American adolescents.⁵¹ However, adverse pregnancy outcomes have been inconsistently demonstrated. One study did find fewer adverse outcomes among those with mild to moderate anemia, but much more among those with severe anemia.^{36,52} There is an equal amount of negative impact from either low hemoglobin or high hemoglobin levels, i.e., there is a U-shaped distribution correlating low birthweight neonates with low and high degrees of anemia compared with those with normal blood count levels.⁵¹ In these cases, the lack of normal plasma volume expansion, which leads to the higher hemoglobin levels, causes poor uteroplacental perfusion, resulting in the low birthweights.⁵²

Poor nutrition

Nutritional intake is clearly a significant problem among teenagers. Across the nation, there is a serious problem with eating disorders. The incidence of anorexia among females is

15 per 100 000 person-years compared with 1.5 per 100 000 among males. It tends to be higher among younger females.⁵³ It is more common among white adolescents than blacks or Hispanics. This may explain why there is a higher risk of excessive weight gain among non-Hispanic white adolescents,⁵⁴ and that there are more girls below ideal body weight at the start of pregnancy. Because this disorder is often associated with the individual's poor body image and low self-esteem, provision of psychological care is also important in antenatal clinics. Excess weight gain may induce further hazards to the fetus if macrosomia is present and there is an increased risk of long-term health problems and obesity for the mothers.

In contrast, obesity is an extremely prevalent health issue in the United States that may be seen with poor weight gain. It is extremely important for our healthcare system to recognize the need for skilled providers who can recognize disorders in the pregnant teenager, provide the appropriate immediate intervention, and initiate a lifelong educational process.

Late prenatal care

As many as 55% of pregnant adolescents in the United States do not receive early prenatal care. Factors influencing late entry to care include unemployment (1.9; 95% CI 1.1–3.5) lower educational level (1.2; 95% CI 1.04–1.4), and race, blacks compared with whites or Hispanics (1.9; 95% CI 1.2–3.2).⁵⁵ There is a clear racial difference, with white women usually reporting more prenatal visits than black women.⁵⁶ Unplanned pregnancy is also a risk factor for late prenatal care.⁵⁷ Finally, in a study from South Carolina, prenatal care sought by adolescents correlated with the school term, with a diminished seeking of care when school was not in session.⁵⁸ Understanding and accepting these risk factors will enable the medical and social community to better design clinics that would successfully encourage adolescents to seek prenatal care.

Drug use

Cigarettes, alcohol, and illegal drug use among teenagers contribute to adverse pregnancy outcomes for a variety of reasons, including bleeding in pregnancy, fetal alcohol syndrome, and the socioeconomic issues related to the drug scene. Although use has declined since the 1970s,⁵⁹ a large number of teenagers still admit to partaking, 17% by questionnaire self-report and 11% by urine screen⁶⁰ (Fig. 54.4). Binge drinking and heavy drinking are particularly high among white teenagers. Black teenagers do not have a significantly higher rate of drug abuse than white teenagers.⁶¹ Healthcare providers need to question pregnant teenagers regarding drug abuse and be able to provide treatment and psychosocial support if needed.

Infection

Infectious complications are higher in teenage pregnancies for all ethnic groups except for Asians.¹⁸ One of the more common complications is pyelonephritis, highlighting the need for increased surveillance for subclinical urinary tract bacterial colonization. No difference in chorioamnionitis was observed between adolescents and older patients.³⁶

Teenagers have a high rate of sexually transmitted diseases. At the first prenatal visit, as many as 23.5% tested positive for *Neisseria gonorrhoeae* (1.2%), *Chlamydia trachomatis* (13%), *Trichomonas vaginalis* (8.9%), or *Treponema pallidum* (1.2%).⁶² Other investigators found a comparably high incidence of gonorrhea and chlamydia.^{63–66} Risk-taking behaviors such as inconsistent condom use, concomitant alcohol abuse, multiple sexual partners, sex with older partners, nationality, and foreigner status place them at high risk, particularly for human immunodeficiency virus (HIV) infection.^{62,67} Healthcare providers for pregnant teenagers should routinely screen for sexually transmitted disease, screen care-

Figure 54.4 Percentage of students reporting lifetime use of substances (solid bars) and use during the past 30 days (hatched bars) (from ref. 32 with permission).

fully for high-risk behavior, be able to provide counseling, and encourage condom use. Commitment to condom use among these adolescents would clearly be increased if they had a good understanding that lack of use could lead to adverse effects on their own health.⁶⁸ Subsequent evaluation of teenagers with abnormal Pap smears showing human papillomavirus infection is important because of the possibility of developing cervical dysplasia.

One very sobering reason to work toward educating adolescents against unplanned childbearing is the very real issue that HIV-positive adolescents are becoming pregnant. This will be an increasing concern as the number of parentless adolescents continues to increase (estimated that there will be 20 million orphans in Africa by the year 2010) and as they reach childbearing age. Currently, 33.5 million people globally are HIV infected. If pregnancies are planned and wanted, women will continue their HIV treatments and decrease the risks of transmission. One recent study of Puerto Rican adolescents reported that all five liveborns from HIV-infected mothers were HIV negative because the mothers had been on antiviral agents.⁶⁹ It is uncertain how successful worldwide attempts will be to curb this spread.

What can be done about reducing the incidence of teenage pregnancies?

Sex education

Although unpopular among certain groups in the USA, school sex education is one of the best means of preventing teenage pregnancies and their recurrence. Sex education is usually required in schools. However, to be fully effective, sex education in schools should include coverage of the topics of reproductive biology, sexual development, birth control, and other means of prevention such as abortion.⁷⁰ Perhaps one of the reasons for failure is the timing of this education. Marsiglio and Mott⁷¹ reported that 52% of 15-year-old girls have already initiated coitus before taking sex education classes.

Educational interventions during pregnancy and postpartum may be effective in reducing future teenage pregnancies for this population. In general, efforts to prevent repeat pregnancies have been disappointing, because educational programs have not targeted these high-risk populations well.⁷² A study evaluating five structured postnatal home visits by nurse-midwives in Australia found a reduced incidence in adverse neonatal outcomes and a significant increase in contraception knowledge.⁷³ As an educational approach is assumed to be longlasting, it may perhaps be more effective in the long term in preventing repeat teenage pregnancy. Although it may be difficult to implement in a large and diverse society, such programs may be more successful because we know that, without any intervention, the subsequent pregnancy would likely occur within 2 years in approximately half of those studied.⁷²

School-based clinics

The school environment is one of the best locations in which to establish classes to educate teenagers about responsibilities related to sexual freedom.⁷⁴ It is an environment that reaches those in the neediest age groups, students will be learning among their peers, both female and male students can be reached, and it resides within an atmosphere of learning and training. Finally, within that environment, interventions may be undertaken in the form of additional education, counseling, or introduction to prevention programs. Even more successful are those programs in which the community is actively engaged and contributes.²⁷ Although such programs have been criticized as a means of encouraging teenagers to take advantage of the welfare system, recent legislation in many areas of the USA, such as the mandated 2-year return to work program in Wisconsin, is curtailing and discouraging such behavior. In time, this will become an ineffective criticism.

Another tested concept is providing care in a specialized teenage pregnancy clinic where nutritional and social issues are more carefully addressed, where infection is more often screened for, and where patients are seen with their peers. One study reported a decreased incidence of preterm labor, preterm delivery, and preterm premature rupture of the membranes among those provided with prenatal care at a teenage pregnancy clinic. In addition, there was a higher incidence of breastfeeding and a higher rate of discharge on effective contraception. Although not a randomized trial, this effort again highlights the positive success through close, direct educational efforts with adolescents.⁷⁵ A teenage mother is also less likely to finish her secondary school education and, without that education, teenagers are likely to continue the vicious cycle of poverty, social isolation, and repeat teenage pregnancies. Therefore, school-based prenatal care, which has been shown to reduce the absenteeism and dropout rates (adjusted OR 0.39; 95% CI 0.15–0.99, $P = 0.048$), is also a positive thing.⁷⁶ It is only through education that teenage pregnancies can be reduced. Knowledge imparted from school-based clinics should be fully supported to further decrease the current teenage pregnancy rate.

Emergency contraception

Although it is debated whether access to emergency contraception promotes unprotected intercourse, it has been shown that this is not the case as there is no decrease in the age at first intercourse, nor is there an increase in the incidence of sexually transmitted diseases. The provision of emergency contraception may actually encourage young teenagers to seek pelvic examinations and Pap smear screening.⁷⁷

Emergency contraception may be taken in the form of combination pills, in two doses 12 hours apart, or progestin-only pills, in one dose or in two doses 12 hours apart. They are most effective when taken within 72 hours of unprotected

Table 54.6 Emergency contraception.

sexual intercourse but may be taken up to 120 hours after intercourse. They reduce the risk of pregnancy by 75–89%. Another form of emergency contraception includes intrauterine device (IUD) insertion, usually with a Copper T 380A IUD (Paragard), which is left in place until the patient is certain she is not pregnant (Table 54.6).

Abortion

Abortion has been practiced as a very effective means of contraception for teenagers. Abortion rates increased dramatically from the mid-1970s to the mid-1980s, from 29% to 42%.⁷ The proportion of black and white adolescents who obtain abortions is similar but, because there is a higher pregnancy rate among blacks, the rate of abortion is higher among blacks than among whites. Adolescents who obtain abortions tend to be better students from higher socioeconomic backgrounds with a lower dropout rate and higher education goals.⁷

Factors that influence abortions include perceptions that there is a lack of continued involvement from the father of the baby, a lack of a satisfying relationship with the father of the baby, a lack of parental involvement, and an existing child.¹³ Recognizing those teenagers who perceive their pregnancies as unplanned and unwanted may enable programs to provide better support for them. Adoption remains a viable

option for teenagers, and information should be given (Table 54.7).

Contraception

In order to achieve postpartum and continued health for these teenage mothers, one important issue to address is the contraceptive needs of these patients. These teenagers should be educated regarding their reproductive options and childbearing options. Older studies support the fact that adolescents are capable of using contraception effectively provided there is a supportive environment from their mothers and the babies' fathers. In those cases, subsequent pregnancies were planned because there was a closer relationship with their boyfriends, who provided sufficient support.⁷⁸

Taking care of pregnant adolescents

When an adolescent is first seen for a pregnancy, it is important to screen for sexually transmitted diseases, a history of any physical or sexual abuse, and a history of substance abuse. The social environment should be investigated when possible to determine appropriateness for the future newborn. A good dietary history is also important and should be an opportunity to address nutritional issues, particularly common ones such as iron and vitamin deficiency. They should be encouraged to gain the higher acceptable amount of weight gain if they are starting at below ideal body weight. Although medically less complex than an older patient, teenagers are still at risk for pregnancy complications, primarily preterm labor and intrauterine growth restriction. These should be monitored closely and carefully. In the postpartum period, close attention should be provided to insure that the new adolescent mother has proper support for herself and her fetus, in terms of both financial and nutritional support as well as psychosocial support. Effective contraception should be encouraged and education provided to help those with histories of drug abuse to stay clean for as long as possible. Proper referrals to support groups will be particularly important for these teenagers.

Pregnancy in older women aged > 35 years

Advanced maternal age is defined as greater than age 35 years based on higher perinatal morbidity and mortality after that age. That consensus derives from older studies from the 1980s. Within the past decade, there has been a rise in the number of births to women over 35 years, and it is now not uncommon to see women over the age of 40 years having pregnancies. There is even an increasing number of pregnant women over the age of 50 years (Fig. 54.5). Perhaps advanced maternal age should be redefined as greater than 40 years based on maternal morbidity and mortality, both of which continue to drop. Many studies have focused on such an age group, but few studies, if any, have compared the differences between women over 35 years and those over 40 years. For women interested in future childbearing, they should be informed that their pregnancy risks and fertility do start to decline after the age of 35 years and, hence, it would be prudent to keep the definition of advanced maternal age as age greater than 35 years in order to initiate awareness for this older population without an undue false sense of security.

In a study using a database of 94 346 deliveries in Montreal, the average maternal age at delivery increased from

Figure 54.5 Birth rates by age of mother: United States, 1980–2002. Note: rates are plotted on a log scale. Denominations for population-based ratios for 1991–2002 are inter- and postcensal estimates that incorporate the 2000 results. Rates for 1991–2001 have been revised and may differ from those previously published.

27 years in the 1960s to 30 years from 1990 through 1993. The proportion of pregnant women 40 years of age or older was 2.5% in the 1960s and doubled from the 1970s to the 1990s.⁷⁹ Women are either delaying their childbearing or extending their childbearing in order to account for the increasing numbers of elderly gravid women. The primary reasons are social changes that have taken place over the past four decades, including the acceptance of oral contraceptive technologies, the legalization of abortions, the availability of prenatal diagnosis, and the improvements in medical care overall such that women with diabetes or hypertension are now well controlled and able to consider pregnancy options.

Risks to older women having pregnancies

There are some unique risks to pregnancy at an older age, issues that a woman should know before embarking on a pregnancy and physicians should discuss with them in anticipation. Physicians should recognize that these older women will enter pregnancy with more medical complications than the younger patient.⁸⁰ Women greater than 35 years of age have a higher incidence of hypertension (2.7%), pre-existing diabetes (0.7%), and obesity (6.9%) at the beginning of pregnancy.⁸¹ Gestational diabetes was also identified in 6.9% of older women.

Although some older literature suggests that women of advanced age have more complications, the more recent literature refutes this. In a study in which women had access to good medical care within an urban setting and where there was a higher educational level, adverse pregnancy outcomes including small for gestational age, perinatal death, and preterm delivery were not increased compared with younger women.⁸²

Declining fertility

One of the most important facts that older women should know, particularly the older nulliparous women, is that fertility is expected to decline (Fig. 54.6) dramatically after the age of 35 years.⁸⁴ Oocyte numbers in a woman's ovary decline from several million before birth to only 200 000–300 000 at birth, but this decline and its link to infertility are not well understood. Today, the options for a woman desiring fertility have increased through assisted reproductive technologies and include *in vitro* fertilization (IVF), intracytoplasmic sperm injection (ICSI), gamete intrafallopian transfer (GIFT), zygote intrafallopian transfer (ZIFT), oocyte donation, embryo donation, and surrogacy, each with a varied but optimistic success rate.

Figure 54.6 Fertility and miscarriage rates as a function of maternal age (from ref. 83 with permission).

Risks for aneuploidy

It is well known that, with advancing age, a woman's risk of nondysjunction within the chromatids in her oocytes increases, leading to trisomies. Other forms of aneuploidy such as deletions and translocations also increase. In part, this explains the higher incidence of spontaneous abortions to women over the age of 35 years.^{84,85} Several options for prenatal diagnosis are available, and proper counseling, from either subspecialists or genetic counselors, is mandatory (Tables 54.8 and 54.9).

Multiple gestation

Dizygotic multiples are increased among gestations from older women (Fig. 54.7). This is influenced by a higher incidence undergoing assisted reproductive technologies. Among women aged 50–54 years, the rates of low and very low birthweight, preterm and very preterm delivery, small for gestational age, and mortality were higher, but the risks were lower than for single pregnancies, perhaps because of the higher levels of healthcare and socioeconomic status in these older women.⁸⁷

Mortality

Maternal mortality for women over 40 years was 50 per 100 000 in 1954, 10 per 100 000 in 1985,⁸⁸ and 8.9 per 100 000 live births in the year 2002.⁸⁹ Recent medical advances in the past few decades have decreased maternal mortality significantly. The most common causes of mortality

now are hypertensive disorders, hemorrhage, and infection. Pulmonary embolism is also a major cause. The fact that older women have higher mortality is not surprising because, as they age, women will have a higher incidence and a prolonged duration of hypertensive diseases and diabetes and, hence, a higher likelihood of complications such as hemorrhage and infection. Some of the mortality risks may also be influenced by women who have complications after corrected congenital heart disease, a problem not encountered previously in past decades.

Maternal mortality clearly rises with increasing maternal age: 1.4/100 000 deliveries for age 20–29 years; 22.1/100 000 deliveries for age group 40–44 years, OR 16.2 (95% CI

6.38–41.2); and 166/100 000 deliveries for age group ≥ 45 years, OR 121 (95% CI 27–542).⁹⁰ Mortality is also influenced by race. Black women over 40 years of age have the highest pregnancy-related mortality risk ratio, 5.6, compared with white 40+-year-old women, 2.4 (Table 54.1).⁹¹ For older black women, the most common cause of death was hypertensive disorders of pregnancy followed by hemorrhage and embolism.^{2,34}

Maternal obstetric complications due to advanced age

Cesarean sections

Cesarean sections are increased among women over 40 years;^{82,92–94} in one study, by a factor of 2, 24.3% vs. 11.7%.⁹⁵ In another study addressing older women aged 40 years and beyond in 24 032 cases, the Cesarean section rate was also higher among these women than among the control population aged 20–29 years (47% vs. 30%). The reasons for the increased rate of Cesarean sections are not fully understood. There are other increased findings in study groups such as birth asphyxia, fetal growth restriction, malpresentation, and gestational diabetes that may explain the higher rates for surgical delivery.⁹⁶ Mean gestational age were also

Table 54.8 Risk of Down syndrome in relation to maternal age (live births).⁸⁶

significantly lower. Other reasons could include higher rates of hypertensive diseases, fetal growth restriction leading to a higher incidence of fetal distress, or more dysfunctional labor due to higher parity. Indeed, a retrospective study reported that risks for emergency Cesarean sections and a need for oxytocin utilization were higher in nulliparous women age 35 years or older than in a younger group of women aged between 25 and 29 years, suggesting that there was more fetal distress and dysfunctional labor.^{81,97} In addition, there may be a higher incidence of infertility and perhaps a higher incidence of Cesarean deliveries because of these assumed “premium” pregnancies and a higher unwillingness to take riskier approaches such as forceps deliveries. It is less likely to be related to differences in the maternal pelvis, but other factors such as dysfunctional labor from multiparity and more macrosomic babies could contribute. The rate of Cesarean sections will need to be monitored as more older women become pregnant, and counseling regarding this higher rate should be provided to women in advance of pregnancy (Table 54.10).

Increased operative vaginal deliveries

Operative vaginal deliveries are higher in older women of > 35 years of age than in younger women.^{94,97} In older women, the need for oxytocin utilization is also higher.⁸¹ The causes of these findings are uncertain, but may be due to

a higher rate of dysfunctional labor, as with the higher Cesarean section rates, or they may be related to a higher chance of maternal exhaustion, but that variable is difficult to quantify.

Preeclampsia/eclampsia

Older women tend to have a higher incidence of preeclampsia and eclampsia. In a Swedish study, women aged 40 years and older had higher risks of severe preeclampsia.⁹⁰ Other retrospective studies also found a higher incidence in women aged over 40 years.^{81,97,98} In 1997, the National Center for Health Statistics started recording vital data on pregnant women aged 50–54 years. Their results indicate that women over 50 years, compared with women aged 20–29 years, 30–39 years, and 40–49 years, have a higher incidence of chronic hypertension and eclampsia.⁸⁷ Clearly, hypertensive diseases, which are more prevalent among older women, contribute to the incidence of preeclampsia and eclampsia, most likely from the underlying vasculopathy associated with chronic hypertension.

Postpartum hemorrhage

In a study from London, with a database containing more than 80% of all deliveries in a region with > 3.5 million population, increasing maternal age grouped from 18–34 years, 35–40 years, and > 40 years was studied, and odds ratios for postpartum hemorrhage were higher for women aged 35 years and older.⁹⁷

Dysfunctional labor

An association between advanced maternal age and dysfunctional labor is not well established. In a retrospective cohort study of women over the age of 40 years, maternal morbidities included a higher incidence of abnormal labor patterns.⁹⁸ However, others reported no increased risk for prolonged labor or arrest in the second stage secondary to advanced maternal age.^{82,99}

Induction of labor

The odds for induction of labor are higher for older women than for younger women.^{80,97,100} In a study from Ireland, induction of labor was 28% for women over the age of 40 years, double the rate for the younger women (12.5%).⁹⁵ In a retrospective cohort study of women over the age of 40 years, maternal morbidities included a higher incidence of labor induction. There were also more abnormal labor patterns, suggesting that older women had more pregnancy complications near term and labor was more dysfunctional, requiring more oxytocin.⁹⁸ The causes of this higher incidence could not be defined within their clinical setting, as it is not clear that dysfunctional labor is increased in this age group.

Table 54.10 Adverse pregnancy outcomes for women aged > 35 years.

It may be influenced by the physicians' desire to deliver older women by their due date because of concerns over the higher rates of adverse outcomes in older women.

Preterm labor/preterm delivery

Adverse perinatal outcomes for older women were studied and reported from a Swedish Medical Birth Register in a population-based cohort study. Although taken from a Scandinavian country where 95% or more of pregnant women receive antenatal care, confounding factors related to medical and socioeconomic factors were controlled. Preterm delivery was found to be increased among older women.¹⁰¹ In another Swedish study, women aged 40 years and older had higher risks of preterm labor and preterm birth.⁹⁰ In retrospective cohort studies of women over the ages of 35 or 40 years, preterm premature rupture of membranes and preterm labor were identified more frequently compared with younger women.^{80,81,96,97} Some of this may be attributable to assisted reproductive technologies, which are more commonly utilized among older women, as well as the higher rates of multiple gestations resulting from this utilization. However, one study of well-educated women with higher socioeconomic status did not identify an increased risk of delivery prior to 33 weeks' gestation.⁸²

Placenta previa

The incidence of placenta previa is increased for women over the age of 40 years, 3% vs. 0.92%.⁹⁵ This accounts for a higher incidence of antepartum hemorrhage. In another Swedish study, women aged 40 years and older had a higher risk of placenta previa.⁹⁰ In a study from London, higher odds ratios were noted for placenta previa and postpartum hemorrhage in older women.⁹⁷ Data from the National Center for Health Statistics on pregnant women aged 50–54 years also reported a higher incidence of placenta previa.⁸⁷ These findings reflect a higher incidence of multiparity,⁹⁸ uterine myomas, or uterine scarring from prior surgeries, which could explain the higher incidence of placenta previa.^{99,101}

Antepartum bleeding

Antepartum bleeding is more frequent for women over 40 years (8.23% vs. 2.8%).⁹⁵ This was also reported in other retrospective cohort studies.^{81,98,102} Because abruptions are more frequent among women aged over 40 years than among younger patients, 2.03% vs. 0.13%,⁹⁵ and placenta previa is more common, they could contribute to this higher rate of bleeding. Older women also have higher risks for vasculopathy, and recognized bleeding from abruptions and placenta previa may occur more frequently.¹⁰⁰

Adverse perinatal outcomes due to advanced maternal age

Early and late fetal loss

Early pregnancy loss is more common among older women because of the increased risk of aneuploidy (Fig. 54.6). As many as 50% of first-trimester spontaneous abortions are the result of chromosomal abnormalities.¹⁰³ Although first-trimester loss is approximately 15% after recognized pregnancy in younger women, it may be as high as 25% in women aged over 40 years.¹⁰⁴

Although the fetal death rate decreased from the 1960s to the 1990s, the fetal death rate increased with increasing maternal age. Women aged 40 years or older had twice the fetal death rate compared with women younger than 30 years, even after controlling for recognized coexisting conditions that contribute to fetal death.⁷⁹ This death rate included congenital malformations. Factors contributing to fetal death are influenced by maternal age because those factors include multiple gestation, hypertension, diabetes mellitus, placenta previa, placenta abruption, previous abortion, and previous fetal death. The cause of these fetal deaths is uncertain, but it is very possibly related to increasing maternal vascular disease with increasing age.

Low birthweight

Low birthweight is another adverse perinatal outcome for older women studied and reported from the Swedish Medical Birth Register in a population-based cohort study. As stated earlier, although taken from a Scandinavian country where 95% or more of pregnant women receive antenatal care, confounding factors related to medical and socioeconomic factors were controlled. Adverse outcomes included very low birthweight and very preterm delivery.^{97,101} Others have reported a rate of 10.15% for low birthweight infants in older women versus 5.92% for those less than 40 years of age.⁹⁵ Women over 50 years, compared with women aged 20–29 years, 30–39 years, and 40–49 years, had an increasing incidence of low birthweight infants. The rates of very preterm and small for gestational age neonates as well as fetal mortality were significantly higher for women aged over 50 years, possibly related to assisted reproductive technologies.⁸⁷ In another retrospective study of nulliparous women aged 35 years or older and a younger group of women between the ages of 25 and 29 years, the older aged women had higher incidences of neonatal complications, including lower birthweight and neonatal intensive care unit (NICU) admissions.⁸¹ This is not surprising because older women tend to have a higher incidence of medical complications. Whether this is enhanced by age itself is still somewhat controversial, although there are several studies suggesting that age, in and of itself, is a predisposing factor, perhaps resulting from suboptimal uteroplacental blood flow from underlying maternal vascular

disease.¹⁰¹ In most of these studies, smoking was a controlled variable. One other complication is placenta previa, which may be increased in multiparous women related to increased parity, uterine myomas, and uterine scarring from prior surgeries, and may be responsible for low birthweight infants (Fig. 54.8, Table 54.11).

Fetal death

Perinatal mortality rate (500 g and over in the first week of life) was 28.6 per 1000 live births for older women compared with 10.8/1000 for younger women. This persisted even when corrected for congenital malformations (18.7 vs. 7.5%).⁹⁵ Others have confirmed higher adjusted odds ratios for perinatal mortality, perinatal death, and intrauterine fetal death

with increasing maternal age.^{37,90,97} Suboptimal uteroplacental blood flow from underlying maternal vascular disease may be responsible for the increase in perinatal mortality¹⁰¹ as well as the increase in chromosomally abnormal fetuses.

Other adverse outcomes

Other more common adverse outcomes include admission to the intensive care unit in 16.2% of neonates from women over 40 years compared with 12.5% of neonates born to women aged less than 40 years.^{81,98} Low Apgar scores and meconium were also found among these neonates from older women.⁹⁸ Intrapartum late decelerations or scalp pH of less than 7.2 are more frequent among women aged over 40 years (16.1% vs. 8.6%).⁹⁵

Taking care of older patients

The elderly gravida deserves special attention. First of all, genetic counseling should be provided to all gravidas over 35 years of age at delivery. Options for prenatal diagnosis should be discussed in detail and offered in a timely manner. A detailed history and physical examination should be performed to determine the presence of other medical disorders and family history that may place the patient at increased risk of complications, i.e., cardiovascular disease, autoimmune disease. Any medical illness or chronic disease should be evaluated and followed closely, e.g., elevated blood pressure. Appropriate consultation with medical specialists should be

Table 54.11 Adverse neonatal outcomes for women aged > 35 years.

OR, odds ratio; RR, relative risk; *significant difference.

Figure 54.8 Crude rates for fetal morbidity and mortality among singletons by maternal age in the United States, 1997–1999 (from ref. 87 with permission).

obtained when necessary and in conjunction with a maternal–fetal medicine subspecialist. There should be a low threshold to screen for disorders such as diabetes and thyroid disease. Carers should be knowledgeable about their patients' medications and impact on the fetus and pregnancy. Fortunately, most older patients have more normal balanced diets, and the more educated patient will be easily convinced to abandon bad habits such as cigarette smoking. It should not be forgotten that psychosocial support is as important for the older gravida as it is for the adolescent patient. Perhaps it is

even more important as there is a tendency to believe that older women have planned pregnancies and therefore do not require additional psychosocial support. However, fear of an abnormal fetus, concerns about raising a child at an older age, and anxiety over the integration of a child into an established career path may be encountered more often in today's times. Finally, preparation for the birth and subsequent childrearing issues should not be forgotten when taking care of the elderly gravida.

Key points

- 1 Pregnancy at the extremes of reproductive age is more hazardous than that not at extreme ages.
- 2 Adverse outcomes from pregnancies at the extremes of maternal age are influenced by a multitude of variables that must be controlled in order to determine the real risks from younger or older maternal age.
- 3 Over one million teenagers become pregnant in the USA each year.
- 4 The teenage pregnancy rate in the USA far exceeds that in most developed countries.
- 5 The teenage birth rate decreased to 43/1000 women in 2002.
- 6 The highest rise in teenage pregnancies is among Hispanics.
- 7 Adverse pregnancy outcomes among adolescents are not due to biologic risks secondary to their age, but to poor psychosocial environments.
- 8 Risk factors that contribute to teenage pregnancies include black and Hispanic race, substance abuse, low socioeconomic status, lack of support from parents or the father of the baby, poor self-esteem, and poor school performance.
- 9 The major risk to adolescents from pregnancy is preeclampsia.
- 10 Adverse outcomes not clearly shown to be increased in adolescents include maternal mortality, perinatal mortality, preterm labor, preterm birth, preterm rupture of membranes, low birthweight, and Cesarean section.
- 11 Risk factors contributing to adverse pregnancy outcomes in teenagers include anemia, poor nutrition, late prenatal care, drug use, and infection.
- 12 Teenage pregnancies may be reduced through sex education, school-based clinics, emergency contraception, regular contraception, and abortion.
- 13 Delayed childbearing is more acceptable today because women have better access to contraception, abortion is a realistic option, prenatal diagnosis minimizes the risks of having an abnormal child, and improvements in medical care enable older women to consider pregnancy.
- 14 Risks to older gravidas result primarily from underlying medical illnesses such as hypertension and diabetes.
- 15 Access to good healthcare will minimize an older woman's pregnancy risks.
- 16 Older women have a clear and well-documented decline in fertility, whereas their risk of aneuploidy rises.
- 17 Older gravidas need to be counseled that they have an increased risk of multiple gestation, mortality, Cesarean section delivery, operative vaginal delivery, preeclampsia, eclampsia, postpartum hemorrhage, dysfunctional labor, induction of labor, preterm delivery, placenta previa, and antepartum bleeding.
- 18 The increased risk to older women of Cesarean section delivery is not clear, but could be related to higher rates of fetal growth restriction, maternal medical illness complications, failed inductions, and possibly a lower threshold for operative delivery from a perceived concern for the older pregnant woman.
- 19 Older gravidas need to be informed that they have increased neonatal risks, including early fetal loss, low birthweight, fetal death, admission to the intensive care nursery, low Apgar scores, meconium, and fetal distress in labor.
- 20 Older pregnant women would benefit from care from a team of physicians, including maternal–fetal subspecialists, internal medicine subspecialists, and social workers.

Essentials in biostatistics and perinatal epidemiology

Paula K. Roberson and Benjamin P. Sachs

The ability to evaluate the medical literature and to incorporate findings into clinical practice has become a cornerstone of medical education. Increasingly, practice guidelines are based on reliable evidence of clinical efficacy and cost-effectiveness. Evidence-based medicine is the process of systematically finding, appraising, and using contemporaneous research findings as the basis for clinical practice.¹ The purpose of this chapter is to review the epidemiologic and statistical tools needed to evaluate medical literature. Clinicians can then recommend practice patterns based on the strength of the evidence.

Epidemiology

Understanding the strengths and weaknesses of study design and the quality of evidence provided is critical in evaluating a research article. Epidemiology is concerned with the assessment of exposure and outcome. Exposure may be to a drug, treatment, therapy, surgical procedure, or genetic factor and the related outcome may be disease, morbidity, mortality, or side-effects. The basic design strategies used in epidemiologic research can be broadly characterized according to whether the investigation focuses on describing the distributions of disease (descriptive epidemiology) or on elucidating the determinants of disease (analytic epidemiology).

Descriptive epidemiology describes the general characteristics of exposure and outcome, particularly in relation to person, place, and time. Indices of person include basic demographic factors such as age, race, sex, marital status, or occupation as well as lifestyle factors such as diet or use of medication. Characteristics of place refer to the geographic distribution of an outcome such as variations among or within countries or between urban and rural areas. Descriptive studies may examine seasonal patterns or compare outcomes from different time periods. Data for descriptive studies come from diverse sources such as census records, vital statistics records, and hospital charts and office records (clinical data). Because information about many of the characteristics of

person, place, and time is readily available, descriptive studies can be performed relatively quickly and inexpensively. There are three main types of descriptive study: correlational studies, case reports (or case series), and cross-sectional studies.

Correlational studies use data from entire populations to compare exposures and outcomes among different groups during the same period of time or in the same population at different times. An example is the evaluation of folic acid intake and incidence of neural tube defects. Although correlational studies are useful for the formulation of hypotheses, they cannot be used to test hypotheses because of a number of limitations inherent in their design. Correlational studies refer to whole populations rather than individuals, so it is impossible to link an exposure to an outcome in an individual person. To test a hypothesis, it is necessary to carry out analytic studies of individuals.

A *case study* is the most basic type of descriptive study of an individual, consisting of a careful, detailed report of an intervention and outcome in a single patient. The simple case report can be expanded into a case series, describing the characteristics of a number of patients with a given exposure and outcome. Although case studies and series may suggest a correlation between exposure and outcome, it is impossible to distinguish among alternative explanations without studying an adequate sample of individuals using an appropriate comparison group.

Cross-sectional surveys simultaneously assess the status of individuals with respect to the presence or absence of exposure and outcome. Because exposure and outcome are assessed simultaneously, cross-sectional surveys cannot always identify the time sequence of exposure and outcome. As with the other types of descriptive studies, cross-sectional surveys are useful for raising the possibility of an association rather than for testing a hypothesis.

Analytic epidemiology explicitly compares exposure and outcome. The investigator assembles a group of individuals for the express purpose of systematically determining whether the outcome is different in individuals who are exposed or not exposed to a factor of interest. The use of an appropriate

comparison group allows the testing of epidemiologic hypotheses in analytic study designs. Analytic epidemiology can be further divided into two strategies: observational and interventional. The major difference lies in the investigator's role. In *observational studies*, the investigator merely observes the natural course of events, recording the exposure and outcome status of each individual. In *interventional studies*, the investigator allocates the exposure and then follows the subjects for the development of the outcome. Observational studies can be further divided into case-control and cohort studies.

In a case-control study, the levels of exposure of a case group or series of patients who have a particular outcome of interest are compared with those of a control group who do not have the outcome. Cohort studies classify subjects based on their exposure to a particular factor, and then study each group for the development of a particular outcome. An example of a cohort study is the examination of a potential relationship between diabetic control in the first trimester of pregnancy and the incidence of congenital anomalies. The risk factor is an abnormal glucose level in the first trimester, and the disease outcome is the presence or absence of a congenital anomaly. A relationship between blood sugar control in the first trimester and birth defects can also be examined using the case-control method. The cases are women with diabetes who had babies with congenital anomalies; control subjects are

diabetic women who deliver normal infants. The exposure (outcome measure) to be compared in the two groups is blood sugar control in the first trimester, which can be determined by measuring hemoglobin A_{1c} levels, for example. In this example, although the hemoglobin A_{1c} levels are collected prospectively, the study is still analyzed as a case-control (retrospective) study.

Table 55.1 gives the basic design details of cohort and case-control studies, and Table 55.2 summarizes their relative strengths and weaknesses. Although often maligned, the case-control method has many advantages. There is a potential for bias in a case-control study but, if it is well constructed and executed, it has a great potential for economically yielding valid conclusions.

Interventional studies, often referred to as clinical trials, are studies in which the investigator assigns exposure and then follows the subjects for outcome. A comparison group is used, which may involve subjects under another treatment, test, or placebo.

Randomized controlled clinical trials, considered to be most reliable in terms of the evidence they provide, involve an investigator assigning subjects at random into an experimental group and a control (placebo or standard therapy) group. If an alternative experimental treatment is given to the comparison group, the study is called a (*randomized*) *comparative clinical trial*. Randomization minimizes any potential con-

Table 55.1 Study design.

	Cohort study				Case-control study	
	Disease	No disease	Total		Disease	No disease
Risk factors	A	B	A + B	Risk factors	a	b
No risk factors	C	D	C + D	No risk factors	c	d
	Total				a + c	b + d
Cohort studies compare	A/(A + B) vs. C/(C + D)			Case-control studies compare	a/(a + c) vs. b/(b + d)	

By convention, A, B, C, and D represent the total population; a, b, c, and d represent samples of the population.

Table 55.2 Relative strengths and weaknesses of observational study design.

	Cohort studies	Case-control studies
Strengths	Enable direct estimation of disease rates Less subject to recall bias	More economical Can be completed in shorter time-frame
Weaknesses	More likely to be biased in determining disease frequency Require large sample size, particularly if disease is rare More expensive May require very long time if induction time for disease development is long May pose ethical dilemmas if exposure could be removed Subject to losing subjects in follow-up	Greater risk of recall bias Identification of appropriate control group may be more difficult

founding factors and ensures that participants are as similar as possible with respect to all variables except for the intervention of interest.

Evaluation of epidemiological studies

Precision, validity, and bias

Both precision and validity are important concepts in a critical literature review of study design. *Validity* refers to the extent that the outcome variable actually measures the effect of interest. High validity implies a lack of systematic error or *bias*. *Precision* refers to the consistency or closeness of repeated measurements of outcome to each other. Note that it is possible to have high precision and poor validity or vice versa. Kleinbaum and colleagues² helped to clarify the concepts of precision and validity with a target-shooting analogy: “Validity is concerned with whether or not one is aiming at the correct bull’s-eye; precision is concerned with individual variation from shot to shot, given the actual bull’s-eye that is being considered.”

Assessments of validity often refer to indicators of internal and external validity. *Internal validity* generally refers to validity within the study group itself and the larger group from which it is drawn. It is influenced by aspects of study design that include the subject selection, quality and appropriateness of exposure and outcome measures, and the presence of confounding factors. Limitations in internal validity most often result from selection, information, or confounding biases. *External validity* refers to the extent to which findings can be generalized to a wider population. External validity is most influenced by the comparability of the pool of potential study participants with the population for whom the generalization is intended. For example, the findings of a study conducted in an academic medical center may not apply to other clinical settings. Some investigators view external validity as nonexistent, believing that little justification exists for generalizing study results beyond the study population.

There are a seemingly infinite number of potential sources of bias that can arise in epidemiological studies. Much of an epidemiologist’s effort is spent in attempting to identify and overcome sources of bias. Sackett³ discusses a number of the most frequently encountered causes of bias.

Confounding

A *confounding factor* (or *confounder*) can be defined as a risk factor for disease, other than the exposure under study, that is unequally distributed between the cases and the comparison or control groups. Confounding is a form of bias that can occur in both case–control and cohort studies and can lead the unwary investigator to inaccurate conclusions. Table 55.3 gives four characteristics of a potential confounding variable, as described by Rothman.⁴ Many factors, including age, race, and socioeconomic status, are risk factors for prematurity.

Table 55.3 Rothman’s four characteristics of a potential confounding variable.⁴

A risk factor for disease but not necessarily an actual cause of the disease
Linked to the exposure under study
Cannot be an intermediate step in the chain of events between the exposure and the disease outcome
Must be associated with both the disease and the exposure under study

Table 55.4 Techniques to reduce confounding effects.

<i>Restriction</i> limits the admission criteria into the study with respect to known potential confounding factors
<i>Matching</i> involves comparison (control) groups that are identical to cases with respect to the matched variables (this approach may be very costly and requires a specialized matched analysis)
<i>Randomization</i> involves assigning subjects to different study groups on a random basis, in an effort to distribute known and unknown confounding factors equally among groups

When these risk factors are linked with the exposure of interest they may be confounding factors. For example, in a study of the efficacy of home uterine contraction monitoring in preventing prematurity, women who have insurance may be more likely to use such a device and, therefore, without careful development of eligibility criteria, the control group might include more women of a lower socioeconomic status. Because socioeconomic status is an index of risk for prematurity and, in this study, is linked with the exposure of interest (home monitoring), such a study would be confounded by the distribution of socioeconomic status. Table 55.4 lists techniques that can be used in the design or analysis stages of a study to reduce the effects of confounding.

Screening tests

Screening tests are the basic tools of the clinician. The fundamental concepts of screening tests are the same regardless of the test, e.g., an analysis of a hematocrit or the identification of patients at risk for premature labor. In any population, some people have a certain disease and others do not; the challenge is to identify the diseased individuals at the earliest opportunity.

Sensitivity is the probability of correctly identifying a sick individual. *Specificity* is the probability of correctly identifying a healthy individual. For example, if a normal hematocrit is defined as being above 40%, the specificity of the test is poor because many healthy people would be missed. Conversely, if an abnormal hematocrit is defined as being less than

Table 55.5 Relationship of sensitivity, specificity, and predictive values.

Risk factors	Disease	No disease
Yes	a	b
No	c	d

Predictive value negative = $d/(c + d)$; predictive value positive = $a/(a + b)$; sensitivity = $a/(a + c)$; specificity = $d/(d + b)$.

30%, the sensitivity is poor because many anemic people would be excluded. Defining the normal cutoff value affects both the sensitivity and specificity of a screening test but in opposite directions.

The *positive predictive value* is defined as the proportion of individuals with a specific risk factor who have the disease. The *negative predicative value* is the converse, i.e., the proportion of those without the risk factor who are disease free. The relationship between sensitivity, specificity, and predictive values is shown in Table 55.5. The predictive value of a screening test depends on the sensitivity and specificity of the test as well as the prevalence of the disease in question. Thus, the predictive value is not a measure of the test's accuracy. The positive predictive value may be low because the test results do not adequately reflect the true disease status *or* because the disease prevalence is low. The same statistical measures are used to evaluate diagnostic tests, although the numeric values for a given test will differ in the two settings because the applicable population will be different. For a full discussion of the statistical principles of screening and diagnostic tests, including the design of studies to evaluate them, see Pepe.⁵

Null hypothesis: type I and type II errors

The null hypothesis is the focus of statistical testing in biomedical research. In two-group comparisons, this hypothesis generally stipulates that there is no difference between the two groups with respect to the mean of a variable of interest. Thus, rejection of the null hypothesis implies an identifiable difference in the group means beyond what might be reasonably attributed to chance.

The common decision-making tool for evaluating the null hypothesis is the *P*-value, i.e., the probability that a difference at least as great as that observed would occur by chance if the null hypothesis were true. Although other criteria may be used, the most frequently applied convention is that a *P*-value of less than 0.05 leads to rejection of the null hypothesis. If the *P*-value is greater than 0.05, and therefore not significant, the null hypothesis is not rejected. The maximum *P*-value that will be declared significant is called the *alpha level* of the hypothesis test. Table 55.6 defines the possible errors in decision-making that can occur. Type I and type II

Table 55.6 Possible types of error associated with hypothesis testing.

Statistical testing decision	Truth (null hypothesis true)	Truth (null hypothesis false)
Do not reject null hypothesis	No error	Type II error (β)
Reject null hypothesis	Type I error (α)	No error ($1 - \beta$ = power)

Table 55.7 Factors relating to power and required sample size of a specific statistical test.

Alpha level (type I error)
Power ($1 -$ type II error)
Difference to detect at specified power
Standard deviation
Sample size

errors have a clear relationship. The level of either error depends on the cutoff value chosen to define significance. Thus, the type II error is larger if the type I error is reduced and vice versa.

Power and sample size

The *power* of a test is its ability to detect a difference between the groups being tested at a given level of statistical significance. In other words, it is the probability of rejecting the null hypothesis given that the alternative is true. For a given statistical probability distribution, the five factors listed in Table 55.7 are related such that, given four of the five, one can solve for the fifth. This implies that the power is not an absolute value but, for fixed alpha, standard deviation and detectable difference is a (non-linear) function of sample size (and vice versa).

The major factor under the control of the cohort study investigator is generally the sample size. As the sample size is increased, it is possible to detect smaller differences with a given power. In a case-control study, both increasing the sample size and improving the ratio of control subjects to case subjects enhance study power.⁶⁻⁸ In some settings, the measurement procedures can be modified in ways that reduce the variance.

The failure to consider statistical power is one of the most frequent errors in study design.^{9,10} Freiman and colleagues¹¹ reported an analysis of 71 “negative” randomized controlled clinical trials published in peer review journals and found that 50 (70%) of the trials used had insufficient power to detect a 50% improvement in outcome with the treatment. Similarly, DerSimonian and colleagues¹² reported the results of a survey

of methods in 67 clinical trials published in four prestigious journals; the statistical power of the trial for detecting treatment effect was discussed in only 12% of the articles. For practical purposes, sample size and power calculations are most often derived from commercial computer software programs or existing references.^{7,8,13–16} These calculations should always be based on the same statistical methods that the investigator plans to use for data analysis at the conclusion of the study.

Comparative measures of effect

In epidemiology, common comparative measures of effect include the absolute risk difference, the risk ratio (relative risk), the odds ratio, and the attributable proportion. These might be used, for example, to assess the effect of maternal smoking (exposure) on the risk of premature birth.

The *risk difference* is the proportion of diseased individuals among the exposed subjects minus the proportion of diseased individuals among the unexposed subjects.

The *risk ratio* is the proportion of diseased individuals among the exposed subjects divided by the proportion of diseased individuals among the unexposed subjects.

The *odds ratio* (OR), or relative odds, is the ratio of the odds of disease in exposed individuals relative to the unexposed, or, equivalently, the ratio of the odds of exposure among diseased individuals relative to healthy individuals. The OR is often used as an approximation of the risk ratio for case-control studies, in which the risk ratio cannot be measured directly. This approximation is a good one when the prevalence of the disease is low (the “rare disease assumption”). For further details, see Cornfield’s landmark publication¹⁷ or most epidemiologic texts.

The *attributable proportion* (or *etiologic fraction*) is an expression of the proportion of the cases of disease resulting

from exposure. It combines risk factor prevalence with the risk ratio to better assess the public health impact of the association. A full discussion may be found in Benichou.¹⁸

The null value for the risk difference and attributable risk is 0, whereas the null value for the risk ratio and OR is 1. When a confidence interval crosses these values, the null hypothesis is not rejected at the given level of significance. For example, a relative risk of 3.2 (95% confidence limits from 0.8 to 4.0) is not statistically significant at a *P*-value of less than 0.05.

Statistical testing and confidence intervals

A number of factors must be taken into account in selecting the best statistical test or group of tests. All statistical test procedures are founded in probability theory, and the validity of each test is intimately linked to assumptions about how the data relate to the probability underlying the test. Features of the study design and data are also important in statistical testing, including the nature of the exposure and outcome variables, the distribution of values of the variables under study, whether matching was included in the study design, whether measures are independent or repeated for a particular individual, and the potential confounding factors for each association tested.

For the purposes of critical literature review, Table 55.8 outlines categories of statistical tests that are used in examining various combinations of exposure (explanatory) and outcome (response) data or variables. A categorical or discrete variable is able to assume only a finite or countable number of outcomes. One example is marital status, where the outcome can be single, married, divorced, or widowed. A continuous variable such as weight, height, or gestational age can take on any value within a specified interval or continuum. Although Table 55.8 helps to narrow the choice of statistical tests to the appropriate group, the process of selecting the best test requires a

Table 55.8 Alternative univariate and multivariate statistical methods used in hypothesis testing of continuous and/or categorical data.

Exposure (explanatory) variables	Outcome (response) variables	
	Categorical	Continuous
Single		
Categorical	Contingency table (chi-squared or Fisher’s exact test) or normal approximation (Z-statistic)	Z-statistic, Student’s <i>t</i> -test, ANOVA, or nonparametric analogs
Continuous	Z-statistic, Student’s <i>t</i> -test, ANOVA, or nonparametric	Linear regression, correlation coefficient

broader knowledge of the principles of study design and biostatistical testing.

To choose the optimal statistical test, the investigator must consider the question being asked, the study design, the nature of the variables, and the assumptions of the different statistical test procedures. Because the appropriate use of statistical tests is not a trivial task, we recommend that statistical testing be performed by an individual with expertise in biostatistics and that investigators actively cultivate a collaboration with such an individual. A number of excellent general texts cogently discuss the principles of biostatistics that are relevant to clinical research.^{19–24} The take-home message concerning epidemiologic analyses was stated well by Schoolman et al:²⁵ “Good answers come from good questions, not from esoteric analyses.”

Some authors argue that confidence intervals should be reported to the exclusion of hypothesis testing and *P*-values. However, there is a one-to-one relationship between confidence intervals and hypothesis testing, and the choice of which to report should be tailored to the context of the study. Measures of effect and 95% confidence intervals (consistent with $P = 0.05$) offer the advantage of being more informative than *P*-values alone but, given the point estimate and standard error, it is possible to calculate confidence intervals of whatever confidence limit is desired. A more extensive discussion is provided by van Belle et al.²⁴

Multiple comparisons

Some investigators appear to approach each epidemiologic study as a series of statistical tests in the quest for a *P*-value less than 0.05. These “fishing expeditions” are often characterized by indiscriminate statistical comparisons that are frequently unfounded in prior hypotheses or biological plausibility. The criticism of this approach is based on the increasing probability that a “statistically significant” *P*-value is likely to be obtained by chance alone (i.e., in the absence of biological significance) if repetitive statistical tests are performed. This phenomenon is called an alpha (type I) error. If the significance level is set at 5% ($P < 0.05$), the expected frequency of this event is 1 in 20 tests performed. Incomplete reporting of statistical methods further complicates the interpretation of “significant” *P*-values; there is an apparent publication bias favoring positive results and leading to a reluctance to report the multiple “insignificant” comparisons that may accompany a single statistically significant association.

The multiple comparison criticism is best avoided by limiting statistical testing to factors about which a hypothesis has been formulated a priori and for which a biologically plausible explanation exists. Investigators are also encouraged: (1) to include detailed descriptions of the statistical methods and negative results as part of manuscripts that might otherwise focus only on a positive association,²⁶ and/or (2) to make more stringent requirements for significance or adjustments to the *P*-value obtained through multiple comparisons.²³

Some epidemiologists view these comparisons as instrumental in the generation of new hypotheses. Feinstein and Horwitz²⁷ state: “Although agreement has not been reached on when and how to adjust the statistical levels of significance in a study in which multiple agents have been investigated without preceding hypotheses about them, the results of such studies should be viewed not as conclusions but as tentative hypotheses to be confirmed by further research.”

Suggestions by Pocock and colleagues²⁸ for hypothesis testing in the clinical trial may be useful in avoiding the issue of multiple comparisons and other statistical considerations. All the preceding recommendations imply that investigators must define a priori a coordinated policy for the statistical aspects of a clinical trial; this should reflect a consistency of intent throughout the trial (beginning with trial design) on issues such as the primary study question and endpoint definitions, and throughout its conduct, analysis, interpretation, and reporting.

Multivariate analysis

Stratification is one of the major approaches used in controlling confounding factors in categorical data analysis. This approach offers the dual advantages of straightforward calculable results and ease of visual inspection of the data. Stratified data may be analyzed by standardization (standardized mortality–morbidity ratios) or summary (Mantel–Haenszel test) methods. Limitations of stratified analyses include their dependence on categorical delineation of the confounders and (given a finite number of subjects) their difficulty in accommodating more than a few factors simultaneously without the data becoming too sparse. For example, if one wished to stratify an analysis of birthweight by the mother’s socioeconomic status (SES), insurance type, and a dichotomous indicator of whether or not she received regular prenatal care, the stratum representing low SES, no health insurance, and regular prenatal care might have very few infants whose data would then unduly influence the results of the analysis.

Multivariate analyses, most appropriately used as complements to stratified analysis, offer a number of potential benefits. They can control for a greater number of variables simultaneously, facilitate the exploration of interrelationships between covariates, and provide a model that enables the calculation of the odds of disease for a particular individual.

Advances in computing technology in the past three decades have led to advances in the statistical methodology and accessibility of multivariate procedures. Among the methods encountered frequently in the clinical and epidemiologic literature are multiple linear regression, logistic regression, loglinear analysis, mixed-effects models and generalized estimating equations (GEE) for longitudinal data, and the (Cox) proportional hazards model for censored time-to-event data. General information about the appropriate application and interpretation of each of these procedures is discussed in van Belle and

colleagues.²⁴ Care is needed when assessing the adequacy of data to meet the assumptions underlying the various methods, as well as when evaluating model fit and interpreting the results. It is strongly recommended that investigators requiring analysis using these methods engage the collaboration of a statistician who is well versed in the procedures.

Causal inference

A widely accepted principle of epidemiology is that “the most one can hope to show, even with several studies, is that an apparent association cannot be explained either by design bias or by confounding effects of other known risk factors.”³⁰ Investigators are often cautioned with the maxim: “associa-

tion does not imply causation.” Nevertheless, criteria for assessing the likelihood that a given association is causal are often helpful.

Most students of medicine first become familiar with the concept of assessing causality when they are exposed to Koch's postulates. Hill proposed the epidemiologic criteria for causality shown in Table 55.9,³¹ partially in response to a discussion of Koch's work. The merits of these criteria have been subject to considerable academic debate, but Hill's guidelines provide a reasonable starting point when considering causal inference.

Breslow and Day's text³⁰ discusses the derivation of Hill's criteria that are thought to be most relevant to clinical studies, i.e., dose-response, specificity of risk to disease subgroups, specificity of risk to exposure subcategories, strength of association, temporal relation of risk to exposure, lack of alternative explanations, and considerations external to the study.

A brief introduction to the causal criteria relevant to clinical studies cannot begin to address the many thought-provoking historic and contemporary discussions on the subject of causality and causal inference. Some theorists have proposed alternative criteria, whereas others believe that no role exists for causal criteria. Rothman³² has provided a stimulating debate on causality by contemporary thinkers who refer to Popperian (deductivist), Bayesian (subjective probabilist), and frequentist (statistical) viewpoints. Additional discussion is presented in a recent paper by Rothman and Greenland.³³

Key points

- 1 Understanding a study's strengths and weaknesses of design and the quality of evidence that it provides is critical in evaluating a research article.
- 2 The basic design strategies used in epidemiologic research can be broadly divided into descriptive epidemiology or analytic epidemiology.
- 3 *Descriptive epidemiology* describes the general characteristics of exposure and outcome, particularly in relation to person, place, and time.
- 4 *Analytic epidemiology* explicitly compares exposure and outcome.
- 5 Analytic epidemiology can be further divided into two strategies: observational and interventional.
- 6 Observational studies can be further divided into case-control and cohort studies.
- 7 *Interventional studies*, often referred to as clinical trials, are studies in which the investigator assigns exposure and then follows the subjects for outcome.
- 8 Randomization minimizes potential confounding factors and ensures that participants are as similar as possible with respect to all variables except for the intervention of interest.
- 9 *Validity* refers to the extent that the outcome variable actually measures the effect of interest.
- 10 *Precision* refers to the consistency or closeness of repeated measurements of outcome to each other.
- 11 A *confounding factor* (or *confounder*) can be defined as a risk factor for disease, other than the exposure under study, that is unequally distributed between the cases and the comparison or control groups. The effects of confounding can sometimes be reduced by careful study design and analytic methods.
- 12 The predictive value of a screening test (or diagnostic test) depends on the sensitivity and specificity of the test as well as the prevalence of the disease in question.
- 13 The *P*-value associated with a test of hypothesis is the probability that a result at least as great as that observed would occur by chance if the null hypothesis were true.
- 14 The *power* of a test is its ability to detect a difference between the groups being compared at a given level of

statistical significance. In other words, it is the probability of rejecting the null hypothesis given that the alternative is true. The failure to consider statistical power is one of the most frequent errors in study design.

- 15 The odds ratio is often used as an approximation of the risk ratio for case-control studies, in which the risk ratio cannot be measured directly. This approximation is a good one when the prevalence of the disease is low (the "rare disease assumption").
- 16 The process of selecting the best statistical test requires a broader knowledge of the principles of study design and biostatistical testing. Because the appropriate use of statistical tests is not a trivial task, it is recommended that statistical testing be performed by an individual with expertise in biostatistics and that investigators actively cultivate a collaboration with such an individual.
- 17 There is a one-to-one relationship between confidence intervals and hypothesis tests; the context should

provide a guide as to which is appropriate to report in a given situation. The former emphasizes the estimation of effect size, whereas the latter is a decision-making tool.

- 18 Investigators should define a coordinated policy for the statistical aspects of a clinical trial that reflects a consistency of intent from the design of a trial through its conduct, analysis, interpretation, and reporting.
- 19 Multivariate modeling is complex. Care is needed when assessing the adequacy of data to meet the assumptions underlying the various methods, as well as when evaluating model fit and interpreting the results. It is strongly recommended that investigators requiring analysis using these methods engage the collaboration of a statistician well versed in the procedures.
- 20 Although investigators are cautioned to always keep in mind the maxim "association does not imply causation," criteria exist for evaluating the likelihood that a relationship between a risk factor and a disease is causal.

Sexuality in pregnancy and the postpartum period

Kirsten von Sydow

Sexual relations of expectant and new parents are of great medical and psychological significance. Sexual activity during pregnancy might harm the fetus, and pregnancy, birth, and breastfeeding might impair maternal sexual health. Sexuality can be a problem for (expectant) parents, but becoming a mother or a father can also improve sexual health and relationships.

This chapter presents information from several recent reviews^{1–7} and new publications.

Sexual development during pregnancy and the first year postpartum

Genital physiology and sexual responsiveness

In the first trimester of pregnancy, breasts are very sensitive and may hurt easily. In the first and second trimesters, genital vasocongestion increases during sexual excitement and leakage of urine with orgasm is not unusual. In the third trimester, vasocongestion is generally increased and influenced little by sexual excitement. Lubrication and orgasm are intensified in pregnancy, but climax may sometimes be accompanied by cramps. In the third trimester, vaginal contractions are weaker and sometimes tonic muscle spasms occur. Postorgasmic contractions usually stop after about 15 min.^{1,4}

In the first 6–8 weeks postpartum and during breastfeeding, the sexual arousability of mothers is physiologically reduced, the walls of the vagina are thinner, and orgasm is less intense. Breastfeeding women may ejaculate milk during climax. After about 3 months, or on cessation of breastfeeding, these changes regress; some women then experience orgasm more intensely than before. On resumption of intercourse, women mostly perceive their vaginal tension to be unchanged or tighter; at 3–4 months postpartum, vaginal tension is mostly unchanged but is reduced in about 20% of women. About 6–12 months after birth, sexual responsiveness is reduced in 40–50% of mothers and in about 20% of fathers.^{1,6}

Sexual interest and initiative

Generally, female sexual interest remains unchanged or decreases slightly in the first trimester of pregnancy, and decreases sharply at the end of the third trimester; however, it is remarkably variable, especially in the second trimester.⁵ Male sexual interest mostly remains unchanged until the end of the second trimester, when it decreases sharply. Female interest in tenderness remains unchanged or increases in pregnancy. The preferred erotic and sexual activities tend to remain unchanged during pregnancy and after birth, but vaginal stimulation becomes less important in the second and third trimesters.¹ At 3–4 months postpartum, female sexual interest is reduced in most cases compared with the time before pregnancy, but is subsequently very variable. Men appear to be sexually uninterested postpartum more often than women.¹

With most couples, men show more sexual initiative before, during, and after pregnancy than women.¹ Female coital activity during pregnancy and postpartum is sometimes motivated by a concern about the partner's sexual satisfaction and faithfulness.¹

Sexual activity

Coital activity in pregnancy declines slightly in the first trimester, is variable in the second trimester, and declines sharply in the third trimester. Most couples practice intercourse up to the seventh month, with coital activity occurring in about one-half to three-quarters in the eighth month, and around one-third in the ninth month. On average, the last coitus occurs 1 month before delivery. About 10% of women abstain from coitus once pregnancy is confirmed. The use of the male superior position declines during pregnancy, and other positions are practiced more often (side-by-side; rear entry; female superior, but only in the second trimester). In the second trimester of pregnancy, sexual intercourse occurs about 4–5 times per month.^{1,8,9}

On average, intercourse is resumed 6–8 weeks after the birth in Europe and the USA (16.5 weeks in Nigeria). In the third month postpartum, 88–95% of couples practice intercourse, and, by the 13th month, coital activity occurs in 97% of couples. Coital activity postpartum is highly variable. Compared with the prepregnancy period, coital frequency is reduced during the first year after the birth. About 84–90% of couples use contraceptives postpartum, mostly the oral contraceptive pill or condoms.^{1,8–10}

Nongenital physical tenderness is first unchanged and then decreases continuously from the sixth month of pregnancy until 3 years postpartum. On average, noncoital sexual contact is resumed 3 weeks after the birth, usually before intercourse is resumed. Anal intercourse is practiced by only a minority during pregnancy. The course of most heterosexual activity (e.g., coital activity, French kissing, manual genital stimulation) and female masturbation mostly follows a “standard pattern” characterized by a decrease during pregnancy (especially during the third trimester) and no or very low activity in the first 3 months postpartum; this is then followed by a slight increase. During late pregnancy and the first weeks postpartum, fellatio is practiced more often than cunnilingus. Male masturbation activity is stable throughout pregnancy and the postpartum period.^{1,8,9}

Sexual enjoyment and orgasm

Before pregnancy, 76–79% of women enjoy intercourse (7–21% do not enjoy intercourse at all). In the first trimester of pregnancy, this decreases to 59%; in the second trimester, it increases to 75–84%; and in the last trimester, it decreases again to 40–41%. More than one-half of women enjoy sexual intimacy with their partner in the first year after giving birth, with 18–20% partially enjoying it and 24–30% not enjoying it at all. Father reports the same data.¹

Before pregnancy, or in women aged under 30 years, the cumulative incidence of orgasm varies from 51% to 87%, with 10–26% of all women remaining nonorgasmic during their entire lives. Results describing female orgasm in pregnancy are contradictory. In the third trimester, 54% of sexually active women report having an orgasm with the last coitus.¹ On average, the first orgasm postpartum occurs after 7 weeks. Only 20% of women have a climax during the first coitus postpartum, rising to 75% (about the same as before pregnancy) 3–6 months after the birth. The preferred methods for reaching orgasm mostly remain unchanged. Both genders prefer manual stimulation, oral stimulation, intercourse, and masturbation.^{1,11}

Erotic aspects of the parent–infant relationship

Touching is necessary for the baby and, for both baby and mother, mostly pleasurable (data regarding fathers are not available). The physical contact with the baby can be accom-

panied by erotic feelings, especially during breastfeeding. One-third to one-half of breastfeeding mothers describe it as an erotic experience. One-quarter have guilt feelings resulting from their sexual excitement, and some even stop nursing because they are afraid of the sexual stimulation.¹

Risks and benefits of sexual activity during pregnancy

Large representative studies have observed no overall association between birth complications (perinatal mortality, preterm birth, premature rupture of the membranes, low birthweight) and either coital activity or orgasmic frequency. However, intercourse using the male superior position and intercourse in women with certain genital infections are associated with an elevated risk of preterm delivery.^{1,4,12–18} In healthy women, there is no significant relationship between the frequency of intercourse and genital infections. Pregnant women whose partners have a sexually transmitted disease (STD), have extramarital relationships, or inject drugs should use condoms; unfortunately, however, they usually do not.⁴ Few studies^{4,6,19,20} associate cunnilingus during pregnancy with the very rare complication of venous air embolism, which can occur if air is blown into the vagina.

The benefits of sexual activity during pregnancy have only occasionally been researched, but at least one study¹ has found that sexual activity and enjoyment in pregnancy is associated with higher subsequent evaluations of relationship stability, tenderness, and communication at 4 months and 3 years postpartum.

Sexual problems and dysfunctions

Epidemiology

During pregnancy, one-third to one-half of all expectant parents fear harming their baby. Men also fear harming their partner, and women worry about the sexual satisfaction of their partner or about orgasmic uterine contractions (only during the third trimester). Less frequently, expectant mothers suffer from dyspareunia (painful intercourse) or men report difficulty in ejaculating during intercourse.^{1,6,21,22}

Only 12–14% of both partners report having no sexual problems postpartum. Many mothers and fathers are afraid to resume intercourse. More than 50% of all women experience pain during their first intercourse after birth, with 41% still suffering from dyspareunia at 3 months postpartum. This is reduced to 22% at 6 months postpartum, and remains at this level until 13 months postpartum. About 57% of women are worried about the sexual satisfaction of their partners, and around one-fifth of couples have problems with contraception or milk leakage from breastfeeding mothers. Long term, the sexual relationship of at least one-third of all couples

Table 56.1 Factors associated with decreased sexual interest, activity, and enjoyment and increased sexual problems during pregnancy.

<i>Biomedical factors</i>
Tiredness
Worry that the fetus could be hurt during intercourse
Dyspareunia
Backache
Woman's low physical attractiveness (self and partner evaluation)
<i>Psychosocial factors</i>
Mental symptoms (depressed mood, emotional lability)
Prepregnancy sexual history and sexual symptoms (e.g., dyspareunia)
Negative or ambivalent feelings about the pregnancy
<i>Couple/relationship factors</i>
Low relationship satisfaction

worsens, although it improves for one-quarter of new mothers.²³

About 4–28% of fathers have extramarital relationships during pregnancy and in the first months postpartum, whereas women do so only rarely. In West Africa, postnatal marital coital abstinence is associated with an increased risk of male extramarital affairs and unprotected extramarital sex.^{1,23–25}

Etiology of sexual problems and dysfunctions

It would appear that female sexual problems and decreases in sexual activity, interest, and enjoyment during pregnancy and the postpartum period are related to the physical processes of pregnancy, delivery, and breastfeeding. However, only some of the observable changes can be attributed to physiological processes. Sexual behavior and problems during the transition to parenthood are influenced by a complex interplay of biomedical, psychological, and social–marital factors, similar to the situation in other phases of the life cycle (Tables 56.1 and 56.2^{1,7,10,23,25–28}).

The degree of perineal trauma is strongly related to postnatal dyspareunia in a dose-dependent manner (no perineal damage, 11% coital pain; unstitched tears, 15% pain; stitched tears, 21% pain; episiotomy, 40% pain) and is also associated with sexual behavior postpartum. The risk of postbirth dyspareunia is highest for women who undergo assisted vaginal deliveries (vacuum extractor, forceps), intermediate for women with spontaneous vaginal deliveries, and lowest following Cesarean sections. Women who undergo a Cesarean section resume intercourse somewhat earlier than women who deliver vaginally.^{1,2,8,10,23,29–32}

Breastfeeding (at months 1–4 postpartum) is accompanied by reduced coital activity, sexual desire, and sexual satisfaction in women and their male partners. Mothers who breastfeed long term resume intercourse at a later time, are slightly

Table 56.2 Factors associated with decreased sexual interest, activity, and enjoyment and increased sexual problems during the postpartum period.

<i>Biomedical factors</i>
Degree of perineal birth trauma (tears, episiotomy)
Assisted vaginal delivery
Tiredness
Kegel exercises not performed
No reliable method of contraception
<i>Psychosocial factors</i>
Mental symptoms (depressed mood, emotional lability)
Prepregnancy sexual history and sexual symptoms (e.g., dyspareunia)
Poor childhood relationship with father (e.g., good relationship only with mother)
<i>Couple/relationship factors</i>
Low relationship satisfaction (in women and men)
<i>Attributes of the baby and the mother–child relationship</i>
Male babies: mothers of boys are perceived by their partners as being less tender during the postpartum months than mothers of girls
Mothers with a rigid and overprotective relationship to their baby
Breastfeeding

less sexually interested, suffer from coital pain more often, and enjoy intercourse to a lesser degree. The cessation of breastfeeding has a positive effect on sexual activity, but no effect on sexual responsiveness or orgasm. The negative impact of breastfeeding on maternal (and paternal) sexuality results from changes in the hormonal status of the mother, which influences desire and lubrication, and from the changed “meaning” of the breasts (nutritional versus sexual) for both partners.^{1,8,10,23,33}

It should be borne in mind that sexual activity, tenderness, and sexual satisfaction generally decline with increasing relationship duration, in childless couples as well as in parents.¹

Diagnosis of sexual problems and dysfunctions, their prevention and treatment

Gynecological and obstetrical intervention and advice

The use of an episiotomy is strongly related to postbirth dyspareunia, even more so than spontaneous perineal tears, and its use should be reduced and restricted as far as possible to specified indications.^{1,31}

Although the majority of gynecologists believe that they spontaneously discuss sexuality with their pregnant patients, two-thirds of all women questioned in various industrialized countries do not remember discussing sexuality in pregnancy

with their gynecologist. About 76% of expectant mothers feel that sexuality should be discussed, with 45% finding that the information given by medical staff about sex during pregnancy was insufficient. Approximately 49% of women who talked to their doctor about sexuality in pregnancy raised the issue first, with 34% feeling uncomfortable in bringing up the topic themselves. Women who do not ask their gynecologists sexual questions during pregnancy more often experience an intensification of their sexual feelings than women who do ask because doctors often give restrictive advice. Alternative coital positions or alternatives to intercourse (e.g., mutual hand stimulation) are only very rarely mentioned by doctors. No doctor mentioned that sex could improve during pregnancy, and only 8–10% of women abstained from intercourse because of medical advice.^{1,4,11,21}

Intercourse and/or orgasm should be avoided by expectant mothers who have certain pregnancy complications (Table 56.3). If a woman's partner may be infected with an STD, including HIV, a condom should always be used. STD infection in the mother can lead to miscarriage or stillbirth, or can be harmful to the embryo/fetus. However, for the majority of healthy pregnant women and their partners, there is no reason to “forbid” sex, even in the last weeks before birth.^{1,4,6}

Many gynecologists are uncertain about what sexual advice to give when problems occur in pregnancy. Nearly all agree that intercourse should be avoided during and after bleeding, but there is no agreement as to how long the period of abstinence should be and when the ban on intercourse can be reversed, e.g., after vaginal bleeding has stopped. Similarly, recommendations vary with regard to the sexual consequences of premature contractions, and some doctors fail to give restrictive advice when it is necessary, e.g., in cases of incompetent cervix or vaginal infection. There is a lack of medical knowledge concerning sexuality and the management of pregnancy complications, and medical textbooks rarely contain information on this subject.^{4,21} Uncertainty and a lack of training in couple/sexual counseling might be reasons why doctors neglect this topic. Discussions about sexual problems are not included in routine antenatal care and, if they do occur, the male partner is usually not included.^{1,4}

Post birth, maternal and child health services in Europe and the USA focus more on the child than on the mother. Health

professionals do not always have the awareness, knowledge, and skills to deal with postnatal sexual problems.²⁹ Postbirth medical advice about sexuality usually focuses only on contraception, which is discussed at 76% of 6-week postnatal visits; topics such as intercourse, perineal problems, pain, and sexual interest are not mentioned and these problems are not recognized in the great majority of women.²⁹ About 22% of new mothers desire medical advice because of perineal or coital problems; three-quarters who need help actively seek it, whereas 8% feel that they have not received adequate help.¹⁰ Many couples wish to receive more information about bodily changes and sexuality postpartum, and 30% say that sexual counseling might have been helpful.¹

Practical recommendations for giving medical advice about sexuality during pregnancy and postpartum are summarized in Table 56.4.^{1,4}

Healthcare policy and prevention

At the final 6- to 8-week postnatal visit, only about one-half of all new mothers have resumed sexual intercourse. Women's sexual health problems extend well into the first postnatal year

Table 56.4 Recommendations for taking a sexual history and giving the patient sexual information.

If possible, include the partner

Put open questions and listen to the answers

Pregnancy: the current emotional, marital, and sexual situation, and the information needs of the woman and her partner
Postpartum: sexual interest, behavior, coital pain, or incontinence

Give information about normal changes during the transition to parenthood

Pregnancy: some women (and men) have no sexual interest, whereas, in others, sexual interest is intensified
Postpartum: some mothers experience erotic feelings during breastfeeding and some fathers are jealous about breastfeeding.
Vaginal dryness may be associated with breastfeeding

Acknowledge patients' and partners' fears and uncertainties and respect their inner limitations

The aim is a sexual life that both partners and, from the medical and parental point of view, the baby are contented with. This also includes the option of sexual abstinence

Give technical advice about the range of sexual options

Tenderness, noncoital sexual activities (e.g., manual and oral stimulation, masturbation) and, during pregnancy, alternative coital positions (female superior, rear entry/“spoon,” use of pillows)

Instruct the patient in self-help

Post birth: self-inspection of the vulva with a hand mirror and insertion of a finger to test for healing; vaginal muscle-toning (Kegel) exercises

Be sensitive for sexual and nonsexual domestic violence

Table 56.3 Indications for coital and orgasmic abstinence during pregnancy.

Vaginal bleeding
Abdominal pains
Rupture of the membranes
Premature dilation of the cervix
History of premature delivery, heightened risk of premature labor
Placenta previa
Placental insufficiency
Incompetent cervix
Multiple pregnancy

and sometimes even longer.^{1,29,30} Consequently, a 6-month postbirth checkup that includes questions about sexuality, for example “Have you already resumed intercourse?,” “How did it feel?,” “Do you have any perineal problems?,” and other taboo topics such as incontinence would be more helpful in identifying the full range of problems women may experience after childbirth.

A new prenatal program designed to decrease the potentially negative effects of parenthood on the quality of marital relationships had positive effects on postpartum satisfaction and the sexual aspects of marriage compared with a traditional prenatal education program.³⁴

Counseling, psychotherapy, and intervention

Perineal pain may be decreased by the resolution of inflammatory processes using therapeutic ultrasound.³⁵ If sexual problems persist after gynecological treatment has been successfully completed (e.g., coital pain from episiotomy scars) and the woman has terminated breastfeeding, a closer look at the psychological situation and the relationship of both partners is necessary. It is also helpful if the doctor or midwife is able to assess the psychosocial and sexual situation of patients

and, if necessary, refer them to mental health professionals for marital counseling or psychotherapy. This is in the interests not only of the parents but also of the newborn baby, whose life may be affected if his/her parents live in an unhappy relationship or get divorced.

Research implications can be found in two extensive reviews.^{1,7}

Conclusion

In summary, sex is of little relevance for most new breastfeeding mothers during the first 3 months postpartum because adaptation to motherhood requires all of their energy, involves profound psychosocial and hormonal changes, and results in a lack of sleep. Male sexual activity is also reduced during this phase of life but to a lesser degree. There is remarkable variation in female and male sexual behavior during pregnancy and the later postpartum stages (months 4–12). On average, all heterosexual activities tend to decline during pregnancy; they reach a point near zero in the immediate postpartum period and then slowly start to increase again.

Key points

- 1 During the last weeks of pregnancy and the first 2 or 3 months postpartum, female sexual activity is universally very low or nonexistent.
- 2 In every other phase of the transition to parenthood, female sexual activity is very variable depending on the physical and mental health of the (expectant) mother, her sexual and nonsexual biography, the relationship of the couple, and her life circumstances.
- 3 Healthy women and their partners can stay sexually active during the entire pregnancy; however, sexual activity in pregnancy should be discouraged if certain problems occur (e.g., vaginal bleeding).
- 4 Intercourse is resumed on average about 6–8 weeks post birth, but it can be many months later.
- 5 Sexual problems (e.g., dyspareunia) are very common during the first year postpartum but are often not recognized by doctors, nurses, and midwives.
- 6 Postbirth sexual problems are often related to perineal trauma (assisted deliveries, episiotomy, tears), breastfeeding, marital problems, and prebirth sexual problems of the couple.
- 7 Patients feel that doctors rarely discuss sexual issues during pregnancy and the postpartum period, although most gynecologists believe that they have done so.

Psychiatric problems during pregnancy and the puerperium

Linda L.M. Worley and Jennifer L. Melville

Psychiatric disorders are common in pregnant and postpartum women yet they often go undiagnosed and untreated. Approximately one-quarter of pregnant and postpartum women may have a psychiatric disorder, but the majority of these patients do not receive adequate treatment as part of their obstetric care. In addition to the distress associated with mental illness, pregnant women with psychiatric disorders report more somatic symptoms and are at an increased risk for poor obstetrical and neonatal outcomes. Women suffering from a severe depressive illness or psychosis are also at risk for suicide, the leading cause of maternal death through the first postpartum year.

All women should be asked early in pregnancy about any history of psychiatric disorders and use of psychiatric medications, and screened for current psychiatric disorders. If present, management plans should be initiated to decrease both complications from the illness and the high risk of recurrence following delivery. Management of psychiatric disorders is complicated by pregnancy and the potential risk to the fetus, but collaboration between obstetric providers and psychiatrists can provide effective treatments.

This chapter will provide obstetricians and perinatologists with a clinically relevant overview of psychiatric issues that may be confronted in caring for pregnant and postpartum women. It covers depressive disorders, anxiety disorders, psychiatric emergencies, and special treatment challenges including bipolar disorder, somatization, denial of pregnancy, capacity to parent, and pregnancy after loss.

Depressive disorders

Epidemiology

Depressive disorders are common in pregnancy, affecting 9–23% of antepartum women^{1–6} and 12–16% of postpartum women.^{7,8} Of these, an estimated 3–11% suffer from the most serious form of depression, major depressive disorder.^{5,6} Although these prevalence rates are similar to those seen in nonpregnant women of childbearing age, pregnant women are

more likely to be seen by a physician, increasing the opportunity for diagnosis and treatment. Table 57.1 lists the depressive disorders that an obstetrician is likely to encounter.

There are common risk factors for the development of antenatal and postpartum depression (see Table 57.2), with additional risks for postpartum depression based on prior depressive episodes. Women with a history of depression have a 25% risk of developing postpartum depression,⁵ whereas those with a history of postpartum depression have a 50% chance of it recurring and should be monitored closely throughout pregnancy and the postpartum period.

Untreated antenatal and postpartum depression have been shown to have a detrimental effect on both maternal and fetal outcomes (Table 57.3). Direct and indirect mechanisms of association have been hypothesized. Maternal psychosocial factors have been shown to affect neuroendocrine activity^{9,10} and uterine blood flow,¹¹ both of which may play a direct role in adverse outcomes such as low birthweight, prematurity, and preeclampsia. Both maternal depression and anxiety have been linked to adverse health behaviors (e.g., poor nutrition and smoking),¹² which in turn contribute to adverse pregnancy outcomes. In one study,¹³ depressed pregnant women were 4.1 times more likely to be smokers than nondepressed pregnant women. Attempts to quit smoking during pregnancy may be thwarted in the presence of comorbid depression,^{13,14} and cessation attempts may increase the risk for relapse of depression in individuals with a previous history.¹⁵

Clinical presentation

Table 57.1 lists the typical course and features of the disorders outlined below.

Antenatal depression

Antenatal depression is characterized by classic depressive symptoms (Fig. 57.1, DSM-IV¹⁶); however, it may be overlooked because many of the symptoms of depression (e.g., sleep and appetite disturbance and low energy) are also normal symptoms of pregnancy. Clinical features that are not symptoms of normal pregnancy and which support the

Table 57.1 Depressive disorders.

Syndrome	Onset/course	Possible features	Management
<i>Antenatal depression:</i> 9–23% of pregnant women	Before conception or during pregnancy May progress to postpartum depression	Must have depressed mood or anhedonia lasting at least 2 weeks Loss of interest and pleasure, sleep disturbance, appetite change, guilt, decreased concentration, suicidal ideation	For mild to moderate depression with minimal role impairment, refer for counseling or bright light therapy For depression with significant role impairment, add treatment with an antidepressant
<i>Postpartum blues:</i> 50–70% of postpartum women	Peaks 3–5 days after delivery Resolves <2 weeks	Crying spells, emotional lability, irritability, anxiety, ¹⁴¹ hypochondriasis ¹⁴¹	Reassure and educate Monitor for resolution ¹⁴¹ Encourage family to offer emotional and social support
<i>Postpartum depression:</i> 12–16% of postpartum women ^{7,8}	Within 6 months of delivery Insidious onset	Classic depression symptoms lasting at least 2 weeks (same as antenatal depression above) May also include intrusive thoughts or fears of harming infant	For mild to moderate depression with minimal role impairment, refer for counseling or bright light therapy For depression with significant role impairment, add treatment with an antidepressant Hospitalization when warranted
<i>Postpartum psychosis:</i> * 0.5% of postpartum women	Within 3 weeks of childbirth Abrupt onset Women with bipolar disorder are at high risk	Delusions, confusion, hallucinations, agitation, insomnia, disorganized thinking	Emergency referral to psychiatrist Medical workup to rule out underlying etiology

*See section on psychiatric emergencies.

Table 57.2 Risk factors for developing antenatal and postpartum depression.¹⁸

Family or personal history of depression, anxiety disorder, or bipolar disorder
Limited social support
History of physical, emotional, or sexual abuse
Cigarette smoking or alcohol or substance use
Current financial, occupational, health, or relationship stressors
Abrupt discontinuation of an antidepressant before completing a full course of treatment

diagnosis of depression include depressed mood, anhedonia, guilt, hopelessness, and suicidal thoughts.

Postpartum depression

Postpartum depression is also characterized by classic depressive symptoms (Fig. 57.1, DSM-IV) and often has an insidious onset in the 6 months following delivery. Patients may be ashamed to reveal how badly they are feeling to their doctor as the postpartum period is expected to be a joyful time for the new mother. Postpartum depression is a serious form of

Table 57.3 Risks of untreated depression

Antepartum risks

Increased physical pain and discomfort¹¹⁵
Increased use of cigarettes, alcohol, and other drugs^{124,125}
Inadequate self-care and poor compliance with prenatal care²⁸

Peripartum risks

Low birthweight (< 2500 g)^{126,127} and SGA infants¹²⁷
Preeclampsia¹²⁸
Preterm delivery (< 37 weeks)¹²⁷
Operative delivery¹²⁹

Postpartum risks

Difficulty breastfeeding¹³⁰
Poor growth and failure to thrive^{131,132}
Decreased IQ in infants and children⁴²
Missed pediatric outpatient appointments and increased emergency room visits¹³³
Marital and relationship difficulties¹³⁴
Depression in children⁴³

SGA, small for gestational age.

A Five (or more) of the following symptoms have been present during the same 2-week period and represent a change from previous functioning. At least one of the symptoms is either (1) *depressed mood* or (2) *loss of interest or pleasure (anhedonia)*

Note: do not include symptoms that are clearly due to a general medical condition (or pregnancy)

- (1) *Depressed mood nearly every day for most of the day*, as indicated by either subjective report (e.g., feels sad or empty) or observation made by others (e.g., appears tearful). Note: in children and adolescents, can present as irritable mood
- (2) *Markedly diminished interest or pleasure in all, or almost all, activities nearly every day for most of the day* (as indicated by either subjective account or observation made by others)
- (3) Significant weight loss when not dieting or weight gain (e.g., a change of more than 5% of body weight in a month), or decrease or increase in appetite nearly every day. Note: in children (and pregnancy), consider failure to make expected weight gain
- (4) *Insomnia or hypersomnia nearly every day*
- (5) *Psychomotor agitation or retardation nearly every day* (observable by others, not merely subjective feelings of restlessness or being slowed down)
- (6) *Fatigue or loss of energy nearly every day*
- (7) *Feelings of worthlessness or excessive or inappropriate guilt (which may be delusional) nearly every day* (not merely self-reproach or guilt about being sick)
- (8) *Diminished ability to think or concentrate, or indecisiveness nearly every day* (either by subjective account or as observed by others)
- (9) *Recurrent thoughts of death (not just fear of dying), recurrent suicidal ideation without a specific plan, or attempted suicide or a specific plan for committing suicide*

In addition:

- B The symptoms do not meet criteria for a mixed episode (of bipolar disorder with simultaneous mania and depression)
- C The symptoms cause clinically significant distress or impairment in social, occupational, or other important areas of functioning
- D The symptoms do not result from the direct physiological effects of a substance (e.g., a drug of abuse, medication) or a general medical condition (hypothyroidism)
- E The symptoms are not better accounted for by bereavement, i.e., after the loss of a loved one, the symptoms persist for longer than 2 months or are characterized by marked functional impairment, morbid preoccupation with worthlessness, suicidal ideation, psychotic symptoms, or psychomotor retardation

Figure 57.1 DSM-IVR diagnostic criteria for a major depressive episode.¹⁶

depressive illness that requires management and should not be confused with the “baby blues.”

Postpartum blues

Postpartum blues, or “baby blues,” are a common phenomenon, affecting 50–70% of postpartum women. Characteristic symptoms include crying spells, emotional lability, and irritability, peaking 3–5 days post delivery. These symptoms are usually mild and self-limited, usually resolving within 2 weeks.

Management

The high prevalence of depressive disorders warrants screening of all pregnant and postpartum women. Self-report screening instruments, such as the PRIME-MD Patient Health Questionnaire 9-item (PHQ-9; Fig. 57.2A), can easily be incorporated into obstetric care to facilitate diagnosis and treatment or referral. When establishing a diagnosis, potential underlying etiologies such as hypothyroidism, nicotine withdrawal, substance use, and current abuse must be considered.

Management of depression during pregnancy depends on both the severity of symptoms and degree of impairment (Fig. 57.2A and B). The optimal treatment for antenatal and postpartum depression minimizes the risk to the fetus and neonate while limiting morbidity from untreated psychiatric illness in the mother.¹⁷ Support groups and interpersonal psychotherapy [with a counselor such as a licensed clinical social worker (LCSW) or a PhD psychologist] have been found to be effective in cases of mild depression with minimal impairment.^{8,18–20} Additionally, a trial of light therapy (e.g., sitting in front of a broad-spectrum light each morning for approximately

15–60 min) may be warranted.^{21–23} The duration of exposure should be decreased if side-effects of hypomania or nausea emerge. Social support for the patient is also very important, with the involvement of family and friends if possible.

Antidepressant treatment may be necessary in cases of major depression with impaired role functioning. Carefully conducted observational studies of human fetal and neonatal exposure to therapeutic doses of many psychotropic medications in pregnancy and lactation have been largely reassuring,^{24–28} although no randomized trials of antidepressants in pregnancy have been conducted. For many antidepressants that have been studied^{29,30} there has been no reported increase in the frequency of major malformations over the baseline rate of 2–4% found in the general population. However, first-trimester exposure to the most anticholinergic selective serotonin reuptake inhibitor (SSRI), paroxetine (Paxil), may be associated with a mildly increased risk for major congenital malformations, particularly cardiovascular malformations.³¹ SSRIs are widely used in pregnancy; prescribing information for commonly used SSRIs for which antenatal exposure data are available are listed in Table 57.4. Tricyclic antidepressants (TCAs) have also been widely used in pregnancy. Certain TCAs have been labeled as pregnancy category D by the Food and Drug Administration (FDA), but pooled available data suggest that these drugs are likely to be safe for use during pregnancy.^{25,26} Among the TCAs, desipramine and nortriptyline are preferred because they are less anticholinergic and the least likely to exacerbate the orthostatic hypotension that may occur during pregnancy. Avoid using TCAs in patients prone to taking impulsive overdoses or in patients with cardiac conduction delays. Prospective data on the use of mirtazapine,

Figure 57.2 (A) PHQ-9: depression screen; (B) role impairment screen.

nefazodone, and trazodone are not currently available.²⁸ Monoamine oxidase inhibitors (MAOIs) are generally avoided during pregnancy because of their potential to precipitate a hypertensive crisis in the event that tocolytic medications are necessary.²⁸ Severely depressed patients with acute suicidality or psychosis, or women who wish to avoid extended exposure to psychotropic medications during pregnancy, may also be effectively treated with electroconvulsive therapy (ECT).^{32,33}

A transient neonatal discontinuation syndrome has been reported in babies born to women taking antidepressants at term.³⁴ Although this syndrome is rare, it is recommended that newborns with recent *in utero* antidepressant exposure be monitored for symptoms of tachypnea, respiratory distress, desaturation upon feeding, hypoglycemia, poor tone, and weak or absent cry for at least 48 h after birth,^{34,35} and that supportive care be appropriately administered. If the risk of maternal illness does not outweigh the risk of neonatal withdrawal, a tapering of the maternal antidepressant dose in the days or weeks before birth may help minimize the risk of symptoms from neonatal discontinuation syndrome. If this is done, the normal antidepressant dose should be resumed immediately following delivery. Neonates of smokers are at an additional risk for withdrawal from nicotine.^{36,37}

The decision whether to breastfeed while taking antidepressants should be discussed with the patient before delivery. The American Academy of Pediatrics endorses breast milk as the ideal form of nutrition for the newborn, citing both physical and emotional benefits.³⁸ Significant data exist document-

ing the low excretion of SSRI and TCA³⁹ antidepressants in breast milk (see Table 57.4).⁴⁰ Minimal concentrations of sertraline, paroxetine, and nortriptyline in breast milk make them the preferred antidepressants in breastfeeding.⁴⁰ If women take an antidepressant in pregnancy, it is recommended that the same antidepressant be continued during lactation to limit the infant's exposure to a single medication.⁴¹

Antidepressant medication may be initiated and monitored by the obstetrical provider or the consulting psychiatrist (see antidepressant treatment tips, Table 57.5). Treatment choices must balance the risks associated with untreated depression^{42,43} against the potential risks from treatment with antidepressants. It is the treating physician's responsibility to give accurate and up-to-date information on the reproductive safety of pharmacological treatment and to help the patient make an informed decision regarding treatment.²⁸ A resource list at the end of this chapter includes registries that maintain up-to-date information on antidepressant use in pregnancy. If medication is initiated, depressive symptoms should be reassessed at each appointment (with the PHQ-9) and the dose adjusted accordingly (see Table 57.4). Once the depression is in remission (a score < 5 on the PHQ-9), treatment should be continued for a full 6–9 months.^{44,45} After a full course of treatment, medication should be gradually tapered and discontinued over 2–4 weeks with careful observation for reemergence of symptoms. A patient who has experienced more than two major depressive episodes may require maintenance antidepressant treatment to remain depression free.^{46,47}

Table 57.4 Administration schedule for selected SSRI antidepressants.

Antidepressants	Dose range (mg/day)	Initial suggested dose	Characteristics and administration schedule
<i>Fluoxetine (Prozac)</i> : pregnancy class C	10–40	10–20 mg every morning with food (10 mg if ↑ anxiety)	Activating; not first choice in patients with ↑ anxiety, but can be beneficial for patients with fatigue Increase in 10-mg increments at intervals of 7 days Maintain 20 mg for 4–6 weeks before dose increase Monitor maternal and neonatal weight gain; decrease dose in week before delivery to aid in neonatal clearance
<i>Sertraline (Zoloft)</i> : pregnancy class C	50–150	25–50 mg q.d. with food (25 mg if ↑ anxiety)	Increase in 25–50 mg increments at intervals of 7 days as tolerated Maintain 100 mg for 4–6 weeks before dose increase Extensively studied for use in breastfeeding; minimal amounts transfer into breast milk, and milk can be discarded 8–9 h after dose to further minimize exposure ¹⁴²
<i>Paroxetine (Paxil)</i> : pregnancy class D*	10–50	10–20 mg q.d. with food (10 mg if ↑ anxiety, every morning)	The most anticholinergic of the SSRIs Avoid first-trimester exposure when possible* Sedating; good choice for patients with ↑ anxiety Increase in 10-mg increments at intervals of 7 days up to a maximum of 40 mg/day Maintain 20 mg for 4–6 weeks before dose increase Monitor the newborn for transient neonatal discontinuation syndrome ^{143,144} Of the SSRIs, this passes least into breast milk and is virtually undetectable ¹⁴⁵
<i>Citalopram (Celexa)</i> : pregnancy class C	10–40	10–20 mg every morning with food (10 mg if ↑ anxiety)	Increase in 10-mg increments every 7 days as tolerated Maintain 20 mg for 4–6 weeks before dose increase This medication has been widely prescribed in Europe during pregnancy and lactation

*Preliminary results of two recent studies indicate that paroxetine increases the risk of congenital malformations, particularly cardiovascular malformations. Patients taking paroxetine who become pregnant or who are currently in the first trimester of pregnancy should be alerted to the potential risk to the fetus. Discontinuing paroxetine therapy or switching to another antidepressant should be considered for these patients. For individual patients, however, the benefits of continuing paroxetine may outweigh the potential risk to the fetus. Paroxetine should generally not be initiated in women who are in the first trimester of pregnancy or in women who plan to become pregnant.³¹

Table 57.5 Antidepressant treatment tips.

Rule out bipolar disorder (e.g., episodes of high energy, little need for sleep, excessive spending); if present, refer to psychiatry for management
For <i>anxious</i> patients, begin with lowest possible dose and increase <i>very</i> slowly
Resume a medication that worked previously (<i>if safe in pregnancy</i>)
Use a <i>single</i> antidepressant medication ⁴¹
Use the same medication in pregnancy and lactation ²⁴

Low birthweight ¹³⁶
Preeclampsia ¹²⁸
Premature rupture of membranes ¹³⁷
Preterm delivery ¹³⁸
Operative delivery ^{137,139}
Increased risk for behavioral/emotional problems in children ¹⁴⁰

Anxiety disorders

The most common psychiatric disorder in women is anxiety disorder; approximately one in three women suffer from an anxiety disorder at some time in their life.⁴⁸ Anxiety disorders include generalized anxiety disorder, panic disorder, obsessive–compulsive disorder, social and other phobias, and post-traumatic stress disorder. Although the evidence shows that

untreated anxiety disorders are associated with poor obstetrical outcomes⁴⁹ (see Table 57.6), limited data exist that examine the impact of pregnancy and the postpartum period on the course of many of these disorders. It does appear that the postpartum period is a time of elevated risk for an exacerbation of anxiety-related symptoms.⁵⁰ Obstetricians need to recognize these disorders and understand their management.⁴⁹ The anxiety disorders for which data exist are discussed below.

Panic disorder in pregnancy

Epidemiology

The prevalence of panic disorder in women is approximately 1–3% in community samples and 3–8% in primary care samples.⁵¹ Pregnancy does not appear to be protective; panic symptoms often continue throughout pregnancy and worsen postpartum without treatment.^{49,52–54} Approximately 50% of patients with panic disorder have comorbid major depression. In some cases, the first symptoms of panic disorder begin following birth.⁵⁵ In a prospective study⁵⁶ of pregnant women with pre-existing panic disorder, 7 out of 10 continued to have symptoms throughout pregnancy. In this study, treatment with an SSRI during the third trimester and postpartum was effective in preventing postpartum exacerbation of the disorder.⁵⁷

Clinical presentation

A panic attack is characterized by “out of the blue” episodes of terror and may be indistinguishable from symptoms of a heart attack with a pounding heart, chest pain, shortness of breath, sweating, and nausea.¹⁶ Classically, panic attacks occur without warning and often wake an individual from sleep. The location where an attack occurs may become associated with precipitating the episode, and phobias and avoidance may ensue in an effort to avert further attacks.

Management

The obstetrician generally refers a patient with panic disorder for treatment. Treatment with medication during pregnancy generally consists of an SSRI, beginning with a very low dose. When initiating SSRI treatment, some psychiatrists will also provide benzodiazepines for breakthrough panic attacks. In addition, cognitive behavioral therapy has been shown to be as effective as medication (SSRIs, high-potency benzodiazepines, and tricyclic antidepressants) and more effective than placebo in multiple randomized controlled trials.

Obsessive–compulsive disorder

Epidemiology

Obsessive–compulsive disorder (OCD) has a lifetime prevalence of approximately 2.5% for both women and men,⁵⁸ but prospective studies identifying the prevalence in pregnant and postpartum women are lacking.⁵⁹ A connection between pregnancy, childbirth, and obsessional states has long been recognized,^{60,61} and women are more vulnerable to the onset of OCD during pregnancy and following childbirth.^{62–65} In addition, women with pre-existing OCD who miscarry are at a significant risk for an exacerbation of symptoms.⁶⁶

Clinical presentation

OCD is characterized by the presence of obsessions (e.g., excessive concern with dirt or germs)⁵⁹ and compulsions (e.g., checking locks and windows, repetitive handwashing, or other ritualistic behaviors).¹⁶ In the postpartum state, the obsessions

can include unwanted aggressive thoughts toward the infant. To relieve the distress caused by the obsessions, the patient feels compelled to perform ritual behaviors to prevent bad things from happening.

Management

Patients with OCD should be referred for psychiatric treatment. Treatment will usually include higher doses of SSRIs and behavioral therapy to help the patient decrease her compulsions.⁶⁷

Post-traumatic stress disorder

Epidemiology

Lifetime rates of post-traumatic stress disorder (PTSD) in women range from 10.4% to 13.8%.^{49,51,68} The exact rates in pregnancy are unknown, but one study⁶⁹ found a 7.7% prevalence of PTSD in economically disadvantaged pregnant women. PTSD in pregnancy has been associated with an increased incidence of miscarriage, hyperemesis, and preterm labor.⁷⁰ PTSD often occurs alongside generalized anxiety disorder,⁶⁹ depression, and substance abuse.⁴⁹ PTSD in women is most often a sequela of sexual assault,^{51,68} and women with a history of sexual assault may attempt to avoid reminders of the trauma such as intrusive procedures in prenatal care.⁶⁹

Clinical presentation

Women with PTSD suffer from intrusive recollections of an experienced or witnessed life-threatening traumatic event. Recollections can present as flashbacks, nightmares, sympathetic nervous system arousal, emotional numbing, or global hyperarousal, and patients will make great efforts to avoid stimuli that trigger reminders of the trauma.¹⁶ In pregnancy, labor pains may induce flashbacks and dissociative exacerbations.⁷¹

Management

Evidence-based treatment for PTSD includes SSRIs, which have been shown to be more effective than placebo. Cognitive behavioral therapy (CBT) and eye movement desensitization have also been shown in randomized controlled trials to be effective. The obstetrician should avoid precipitating trauma by intrusive medical procedures whenever possible,⁶⁹ and should provide the patient with verbal information before the initiation of any procedure or touch.

Psychiatric emergencies

Psychiatric emergencies are most likely to occur in the first month postpartum,^{72,73} but may arise at any point in the course of obstetric care. Four major conditions should be regarded as emergencies requiring immediate psychiatric consultation: psychosis, delirium, suicidal ideation, and homicidal ideation.

Psychosis and psychotic disorders

The term psychosis refers to a gross impairment in reality testing characterized by the presence of auditory or visual hallucinations or a false fixed belief system.¹⁶ Psychosis may occur as a result of an organic precipitant or a major mental illness (e.g., schizophrenia, schizoaffective disorder, bipolar disorder, major depression, and delusional disorders). The evaluation for a primary episode of psychosis must rule out any underlying medical illness (e.g., metastatic brain tumor, endocrine or metabolic disorder, electrolyte disturbance, medication- or substance-induced effect).

Epidemiology

Psychotic psychiatric disorders occur in less than 2% of women aged from 18 to 44,⁷⁴ and the prevalence is similar in pregnant and nonpregnant women of childbearing age.⁷⁵ The annual incidence in pregnancy is 7.1 cases per 100 000 pregnancies.⁷⁶ Because newer antipsychotic medications induce less hyperprolactinemia, more women taking antipsychotics are now becoming pregnant. Schizophrenia has been associated with preterm delivery, low birthweight, and small for gestational age (SGA) infants.^{77–79} In addition, there is an increased risk of stillbirth⁸⁰ and neonatal death.^{78,79,81} Offspring of women with schizophrenia have an 8- to 10-fold higher risk of developing the disorder than the general population.⁸²

Postpartum psychosis affects 2 out of 1000 new mothers⁷² and most often has an abrupt onset within the first 2 weeks after birth. Women with bipolar affective disorder have a 100-fold greater risk of developing a postpartum psychosis than women with no previous psychiatric history.^{83–86} In addition, women with bipolar disorder are at a higher risk for postpartum depression than women with a history of unipolar depression. Postpartum psychotic exacerbations occur in 25% of women with a prior history of schizophrenia,⁸⁷ and for women with a prior episode of postpartum psychosis the estimates of recurrence in subsequent pregnancies range from 20% to 90%.^{88,89}

Clinical presentation

The essential features of a psychosis are hallucinations or delusions. Psychotic individuals may behave bizarrely and have disorganized thoughts and speech but generally remain cognitively oriented to person, place, time, and situation. The majority of postpartum psychoses are affective (i.e., manic or depressive psychoses) and may present with perplexity, confusion, and prominent delusions and hallucinations.^{90–94} Family members may report waxing and waning episodes (generally more characteristic of delirium), with the patient appearing well one moment and psychotic the next.⁸⁸ The patient may also experience somatic psychotic symptoms (e.g., tactile, olfactory, and visual hallucinations) that are generally more characteristic of a psychosis precipitated by a brain tumor or withdrawal from a substance.⁹³ Mothers with postpartum psychosis rarely express hostility toward the newborn

but may harbor potentially dangerous delusional thoughts (e.g., believing that the infant is “evil” or “would be better off dead”).

Management

Regardless of the underlying etiology, the presence of psychosis constitutes a psychiatric emergency. Judgment is so seriously impaired in the presence of delusions or hallucinations that the obstetrician should be concerned about the risk for suicide or homicide. Command auditory hallucinations, in which a patient hears a voice directing her actions, are particularly worrying. In addition to requesting an immediate psychiatric evaluation to assess the current risk for suicide or homicide, the obstetrician should contact a concerned family member who can assist with a history and disposition. The patient must not be left unsupervised while awaiting psychiatric evaluation and appropriate disposition. A thorough medical workup including vital signs, electrolytes, urine drug screen, and physical and neurological examinations is necessary. Obtaining an accurate past psychiatric and substance use history is also critical in guiding the appropriate intervention and treatment. Tables 57.7 and 57.8 list the pharmacological treatment considerations in psychosis.

Ideally, a woman with a past history of psychotic disorder will obtain a preconception consultation with both an obstetrician and a psychiatrist to evaluate whether she should remain on antipsychotic medication throughout the pregnancy or discontinue it during gestational periods of highest risk.⁹⁵ Typical antipsychotics, including chlorpromazine and thioridazine, have the longest history of use in pregnancy; there are fewer safety data available for the newer atypical antipsychotics, including olanzapine and clozapine, and these drugs have been associated with an increased risk of glucose intol-

Table 57.7 Treatment considerations in psychosis.⁹⁴

Infants born to psychotic women (on no medication) have twice the normal rate of malformations ²⁵
No treatment regimen is completely safe ¹⁴⁶
The risks of harm associated with exposure to antipsychotics <i>in utero</i> or through breastfeeding are unknown ^{146,147}
Discontinuing antipsychotic treatment during pregnancy is associated with a 65% relapse rate ¹⁴⁸
The risk of avoiding medication may outweigh any treatment-associated danger
Avoid neuroleptics during the first trimester when possible ^{149,150}
Avoid low-potency antipsychotics (chlorpromazine) with orthostatic hypotension and sedation ¹⁴⁶
Use high-potency traditional antipsychotics (haloperidol or flupenazine) at the lowest effective dose
Use a single antipsychotic medication
Monitor newborn for perinatal syndrome; motor restlessness, tremor, hypertonicity, abnormal movements, and difficulty with feeding ¹⁵¹

Table 57.8 Specific pharmacological treatment considerations in psychosis.⁹⁴

Exposure data	
Conventional (typical) antipsychotics¹⁵²	
<i>Phenothiazines</i>	
Thorazine (chlorpromazine)	Long history of use in pregnancy for hyperemesis gravidarum Use between weeks 4 and 10 increases risk of anomalies to 4 in 1000 ^{153,154}
Thioridazine (Mellaril)	Not associated with a higher rate of malformations ¹⁵⁴
Fluphenazine (Prolixin)	Not associated with a higher rate of malformations ¹⁵⁴
Trifluoperazine (Stelazine)	Not associated with a higher rate of malformations ¹⁵⁴
Perphenazine (Trilafon)	Not associated with a higher rate of malformations ¹⁵⁴
<i>Buterophenone</i>	
Haloperidol (Haldol)	Low dose used in hyperemesis not associated with malformations ^{155,156} Elevates prolactin
New (atypical) antipsychotics: limited data available	
Clozapine (Clozaril), ¹⁵⁷ used in treatment of refractory schizophrenia	Does not appear to increase teratogenic risk ⁹⁴ Risks for agranulocytosis in fetus are unknown Contraindicated in breastfeeding; may cause sedation, decreased suckling, restlessness or irritability, seizures, and cardiovascular instability ^{157,158} Monitor for hyperglycemia and excessive weight gain Accumulates in fetal serum and breast milk more than maternal serum ¹⁵⁹
Olanzapine (Zyprexa)	Does not appear to increase teratogenic risk ⁹⁴ Lower prolactin levels than with other antipsychotics; increases fertility Monitor for hyperglycemia and excessive weight gain
Risperidone (Risperdal)	Elevates prolactin Limited data available
Quetiapine (Seroquel)	Limited data available
Aripiprazole (Abilify)	Limited data available
Ziprasidone (Geodon)	Limited data available

erance and weight gain during gestation. All antipsychotics have been placed in pregnancy category C by the FDA. At present, the newer atypical agents do not demonstrate any evident safety advantages in pregnancy and lactation compared with older, more typical neuroleptic agents.⁹⁴

If an acutely psychotic patient conceives, her mental state may deteriorate resulting from the stress of pregnancy. She is at risk for incorporating her bodily changes into her delusional thinking such as believing that fetal movement is caused by “snakes growing in her belly.” In circumstances of acute psychosis, the risk of deterioration and noncompliance with prenatal care must be weighed against the risk of exposure of the fetus to medication. Generally, symptoms are rapidly controlled with antipsychotic medication, keeping the patient and fetus safe. Once stable, the medication dose can be gradually reduced.⁹⁶ For patients with treatment-resistant psychosis during pregnancy or those who do not wish to expose the fetus to medication, ECT has been used and appears safe if both the mother and fetus are carefully monitored.⁹⁷ Women with postpartum psychosis who are at risk of harm to themselves or others require immediate psychiatric hospitalization. Ideally, they should be admitted with their infants whenever possible.

Delirium

Delirium refers to a state of acute cerebral insufficiency resulting from an underlying medical emergency and is associated with high morbidity and mortality. Delirium is rare in obstetrics but may be seen in cases of sepsis, severe anemia, hypoxia, and electrolyte disturbance. Alcohol and benzodiazepine withdrawal may also precipitate a potentially life-threatening delirium with elevated vital signs. The classic symptoms of delirium are a waxing and waning course of disorientation, bizarre perceptual disturbances, and psychomotor agitation or retardation. Patients with delirium will often be unable to draw the hands on the face of a clock.

Suicidal ideation

Suicide is the leading cause of maternal death in the first postpartum year.^{98,99} Patients with delirium, psychosis, bipolar disorder, and severe depressive illness are at a heightened risk for suicide.⁹⁸ Delirium and psychosis pose a serious risk of suicide as the patient may act swiftly with little or no warning. In one study, nearly one-half of mothers who committed suicide had been admitted to a psychiatric hospital following a previous

childbirth, but healthcare providers caring for them in subsequent pregnancies were frequently unaware of their histories. Suicidal ideation may be expressed passively (“I’d be better off dead”) or actively (“I would like to drive my car off the bridge”). It is important to inquire as to whether the patient has envisioned a method by which to take her own life, whether she has the means to do so, what has prevented her from acting on her feelings, and whether she feels safe not to act on them now. The obstetrician should request an emergency psychiatric consultation to evaluate the need for medication and/or hospitalization.

Homicidal ideation

As with suicide, homicide is a serious risk in delirium and other psychotic states because the patient may act suddenly and without warning, often in response to command hallucinations. In general, the expression of homicidal thoughts should be taken at face value as a plea for immediate help. The obstetrician should request an emergency psychiatric consultation as to the need for hospitalization and the application of the mandatory duty to warn potential adult victims and protect potential child victims.¹⁰⁰

Miscellaneous treatment challenges

Bipolar disorder (manic depressive disorder)

Epidemiology

Bipolar disorder is a serious, recurrent psychiatric illness with a lifetime prevalence of above 1% for women and men.⁴⁸ Studies examining the specific prevalence of this disorder in pregnancy do not exist. The postpartum period represents the time of highest risk for symptom exacerbation and 40% of women with bipolar disorder experience postpartum mania or depression.^{85,101} A history of postpartum exacerbation increases the risk of postpartum episodes in subsequent pregnancies. Recent studies have shown that puerperal prophylaxis with a mood stabilizer reduces the rate of recurrence to 10%.^{102–104} Given the risks associated with a postpartum bipolar episode for both mother and newborn, the use of prophylactic mood stabilizers is advised.⁸⁵ Suicide is also a grave concern, with actual suicide carried out by 10–15% of individuals with the most severe form of bipolar disorder.⁹⁹

Clinical presentation

Bipolar disorder is characterized by alternating episodes of depression and mania. Symptoms of mania may include an elated or irritable mood, having high energy and requiring little sleep, grandiose ideas of self-importance, rapid and pressured speech, spending excessive amounts of money, a high libido, and poor impulse control.¹⁶

Management

The management of bipolar disorder during pregnancy and postpartum is challenging and should be undertaken by a psychiatrist with expertise in women’s mental health, in close collaboration with the patient’s obstetrician. Mood stabilizers such as valproic acid (Depakote) and carbamazepine (Tegretol), which are routinely prescribed to manage bipolar disorder, are neurotoxic (see Table 57.9) and associated with significant rates of malformation (e.g., neural tube defects, craniofacial anomalies, growth retardation, microcephaly, and heart defects).^{105,106} Lithium, although less teratogenic than once thought, is associated with a 0.1–0.2% risk for Ebstein’s anomaly when taken during the first trimester. To date, lamotrigine (Lamictal) appears to be the safest mood stabilizer in pregnancy but data are limited. Antipsychotics are safer than most other mood stabilizers. Mood stabilizers are frequently discontinued during conception and early pregnancy in an attempt to avoid the windows of greatest risk to the developing fetus (see Table 57.10); the mother should be closely monitored during this time. For women who wish to breastfeed, proactive planning should be undertaken by the patient, psychiatrist, and pediatrician, who will review the latest evidence regarding the potential risks and benefits. The cautious approach⁸⁵ for a bipolar woman who wishes to breastfeed (on a mood stabilizer during the final weeks of pregnancy) is to pump and discard her breast milk for the first 2 days following delivery. This allows a “washout” period for the infant’s immature system before initiating breastfeeding. After these first 2 days, lactation consultants and supportive pediatricians are instrumental in assisting the newborn to take the breast rather than a bottle. The breastfeeding mother must be knowledgeable about the signs and management of potential toxicity in her newborn.

Eating disorders

Anorexia nervosa and bulimia complicate approximately 1% of pregnancies;¹⁰⁷ they affect 4.5 million American women overall¹⁰⁸ and are a risk factor for hyperemesis gravidarum. Most women attempt to hide their eating disorder and may not spontaneously reveal their behavior to the obstetrician. Detection is important, however, as eating disorders are associated with miscarriage, low birthweight, intrauterine growth retardation (IUGR), preterm delivery, Cesarean birth, low Apgar scores,¹⁰⁸ and a higher frequency of postpartum depression.¹⁰⁹ Anorexia is also associated with a high mortality rate, which is frequently attributed to cardiac failure and severe electrolyte abnormalities.¹⁰⁸ All women with hyperemesis gravidarum should be screened for comorbid eating disorders.

Clinical presentation

The prevalence of anorexia nervosa in women between the ages of 15 and 29 is approximately 0.1%¹¹⁰ and appears to be increasing. It is characterized by a 15% reduction in weight below the normal range, an intense fear of gaining weight, and

Table 57.9 Pharmacological treatment considerations in bipolar disorder.

Medication	Organ dysgenesis	Clinical management	Breastfeeding ⁸⁵
<i>Lithium</i> : considered first-line treatment option in pregnancy ^{101,160}	Ebstein's anomaly occurs in 1 in 20000 of the general population, and 1 or 2 in 1000 offspring of lithium users, although the absolute risk remains small ^{161,162}	High-resolution ultrasound with fetal echocardiography at 16–18 weeks to aid in decision-making ¹⁶³ Increase dose in second trimester Decrease dose in labor Maintain adequate hydration Observe the neonate for signs of toxicity, ¹⁶³ and “floppy baby” syndrome, and manage supportively	Expert opinion ranges from strong statements against breastfeeding while taking lithium to supporting a mother's informed choice ¹²² Many have breast fed without complication with careful monitoring of infant's and mother's blood levels, complete blood count (CBC) and thyroid status, and a rapid reduction in dose exposure when infant has fever, dehydration, or diarrhea ¹⁶⁴
<i>Valproate</i> : avoid in pregnancy if possible	First-trimester exposure associated with neural tube defect (5–9%) Effect occurs 17–30 days post conception Risk is dose related	4 mg of folic acid per day before and during pregnancy ¹⁰⁵ Measure B12 level before folate supplementation ¹⁰¹ Observe neonate for heart rate decelerations; ¹⁶⁵ withdrawal symptoms of irritability, jitteriness, feeding difficulties, abnormal tone; ¹⁶⁶ liver toxicity, ¹⁶⁷ hypoglycemia, ¹⁶⁸ and low fibrinogen levels ¹⁶⁹	Usually compatible with breastfeeding ^{164,170} Infant serum levels range from undetectable to 40% of maternal serum levels Half-life in neonates is 47 h; in infants from 10 days to 2 months, half-life is 9–22 h ¹⁷¹
<i>Carbamazepine</i> : avoid in pregnancy if possible	Neural tube defect (0.5–1%), ^{172,173} craniofacial defects (11%), fingernail hypoplasia (26%), and developmental delay (20%) ¹⁷² Risk worse when co-administered with valproate ¹⁷³	20 mg of oral vitamin K per day in the last month of pregnancy ¹⁷⁴ Can cause fetal vitamin K deficiency; administer 1 mg i.m. of vitamin K to exposed neonates ¹⁰¹	Usually compatible with breastfeeding ^{164,170} Infant serum levels range from 6% to 65% of maternal serum concentrations ⁸⁵ Monitor for hepatic dysfunction ^{164,175,176}
<i>Lamotrigine</i> : approved as a maintenance therapy for bipolar disorder	Risk for major malformation appears to be similar to the general population rate (about 2%)	Increase dose in second trimester Decrease dose in labor ¹⁷⁷ Observe neonate for hepatotoxicity and skin rash	Infant serum levels range from 23% to 33% of maternal serum concentrations
<i>Gabapentin</i>	More research is needed before safety in pregnancy and breastfeeding can be clarified ¹⁷⁸		
<i>Oxcarbazepine</i>	More research is needed before safety in pregnancy and breastfeeding can be clarified ¹⁷⁸		

Table 57.10 Associated risks in bipolar disorder.¹⁰¹

<i>Potential risks of pharmacotherapy in pregnancy</i>
Neural tube defects (window of risk: 17–30 days after conception)
Heart defects (window of risk: 21–56 days after conception)
Lip/palate defects (window of risk: 8–11 weeks after conception)
Craniofacial defects (window of risk: 8–20 weeks after conception)
Neurobehavioral teratogenicity from exposure after the first trimester
<i>Pregnancy and recurrence risks</i>
Abrupt discontinuation of a mood stabilizer (1–14 days) led to a 100% relapse of illness
Slow taper over more than 2 weeks (15–30 days) led to a 62% risk for relapse

a distorted body image. In nonpregnant women, one criterion for diagnosis is the lack of menses for 3 months.¹⁶ Binging, purging, and laxative use are often present and increase the risk for cardiac irregularities. Women may attempt to conceal their weight loss from healthcare providers and may try to wear shoes or have heavy items in their clothing when being weighed.

The prevalence of bulimia in women ranges from 1% to 3.8%^{111,112} and consists of recurrent episodes (at least two times per week for 3 months) of uncontrollable binge eating with inappropriate compensatory behavior to prevent weight gain. These compensatory behaviors include self-induced vomiting; misuse of laxatives, diuretics, enemas, or other medications; and excessive exercise.¹⁶ Women with bulimia may be of normal weight, underweight, or slightly overweight.

An atypical eating disorder occurs in women with diabetes who withhold their insulin to lose weight. Clinical signs include disparate hemoglobin A_{1c} levels and dramatic weight fluctuations over time. Recognition of this maladaptive pattern of weight control is of critical importance as it is associated with extremely high rates of diabetic complications.¹⁰⁸

Management

Obstetricians should routinely calculate prepregnancy body mass index (BMI)¹¹³ and ask patients about any current or past history of eating disorders. Women with a BMI below 18 kg/m² before pregnancy will need to gain extra weight in the early part of pregnancy to prevent fetal growth restriction.¹¹⁴ For pregnant women with an eating disorder, it is important to screen for comorbid depression.¹⁰⁹ It is also helpful to query the patient about her preferences for weight measurements (e.g., allowing the patient to face away from the scale or not informing her of the result unless it is significantly low).¹¹³ The patient should be comanaged with a team of eating disorder specialists in dietetics and mental health.

Somatization

Patients with multiple physical complaints who lack organic findings are challenging to the physician. Pregnant women with current depressive and anxiety disorders have significantly more somatic symptoms such as nausea, headaches, shortness of breath, and discomfort with intercourse than pregnant women without these disorders.¹¹⁵ In addition, depression and anxiety are associated with a general amplification of the normal physical symptoms of pregnancy (both pregnancy-related and other physical symptoms).¹¹⁵

When a patient complains of multiple unexplained physical symptoms and she does not have depression or an anxiety disorder, she may have somatization disorder. The DSM-IV criteria for somatization disorder include a history of many physical complaints beginning before the age of 30 and occurring over a period of several years, resulting in the seeking of treatment or significant impairment in social, occupational, or other important areas of functioning. The symptoms must include: (1) pain in at least four different parts of the body; (2) at least two gastrointestinal symptoms; (3) at least one sexual symptom; and (4) one neurological symptom. The physical symptoms cannot be fully explained by a known medical condition or substance, or are in excess of what would be expected.¹⁶ Management should include avoiding unnecessary medical tests, offering reassurance, and scheduling additional time for patient visits to allow time to address her physical complaints through physical examination. Healthcare providers should avoid prescribing analgesic and anxiolytic substances. In addition, the healthcare provider may offer nonjudgmental education that the patient's body may be exquisitely sensitive and "oversignaling" the normal physical changes associated with pregnancy. Some patients benefit from CBT where they relearn how to interpret bodily cues.

Denial of pregnancy

Denial of pregnancy¹¹⁶ is a heterogeneous condition called an "adjustment disorder with a maladaptive denial of a physical condition."¹¹⁷ It can be associated with continued menstruation-like bleeding (use of oral contraceptives may contribute) throughout the pregnancy, causing the woman to believe she cannot be pregnant. Denial, an unconscious defense mechanism, can appear when a woman is confronted with an unwanted or unintended pregnancy. This defense mechanism is common in children and immature adults during times of severe external stress and internal conflict.

When a woman beyond 20 weeks' gestation is informed of a pregnancy for which she has been completely unaware, she may feel embarrassment and guilt.¹¹⁸ The patient may feel that she has put her fetus at risk by not seeking prenatal care and by failing to alter her lifestyle appropriately. Immediately following the diagnosis, the care team should address the psychosocial stressors associated with the denial. Psychiatric assessment and counseling are indicated to evaluate the patient's parenting skills and support network, and whether she is prepared and capable of caring for her child.

Capacity to parent

When it is feared that a newborn will be at risk if a parent is allowed to take the child home and/or a previous history of child abuse or neglect exists, a maternal competency evaluation in the immediate postpartum period may be warranted. Risk factors involve both maternal and newborn features (see Tables 57.11–57.13). A comprehensive assessment including evaluations by psychiatry,¹¹⁹ nursing, neonatology, and social work departments will provide a better understanding of the mother's capacity to parent and will guide appropriate interventions for the future.¹²⁰

Pregnancy after loss

Carrying a pregnancy following a previous pregnancy or neonatal loss is associated with significant distress and anxiety for the woman and her partner.^{55,66,121} Table 57.14 lists recommendations for managing a pregnancy following a previous loss.

Key points

- 1 Women suffering from a severe depressive illness or psychosis are at risk for suicide, the leading cause of maternal death through the first postpartum year.⁹⁸
- 2 About 9–23% of antepartum women suffer from depression characterized by feelings of anhedonia, guilt, hopelessness, and possible suicidal thoughts.
- 3 Antepartum depression is associated with increased physical pain and discomfort,¹¹⁵ smoking, alcohol and other drug use,^{124,125} and poor participation in prenatal care.²⁸
- 4 Antepartum depression is associated with low birthweight,^{126,127} SGA infants,¹²⁷ preeclampsia,¹²⁸ preterm delivery,¹²⁷ and operative delivery.¹²⁹
- 5 During the postpartum period, 50–70% of women experience transient postpartum blues.
- 6 During the postpartum period, 12–16% of women suffer from postpartum depression.
- 7 Women with a previous history of depression have a 25% risk for developing postpartum depression.
- 8 The abrupt discontinuation of an antidepressant before a full course of treatment is associated with a significant risk for the relapse of depression.
- 9 Women with a history of postpartum depression have a 50% chance of it recurring and should be monitored closely throughout pregnancy.
- 10 Postpartum depression is associated with difficulty in breastfeeding,¹³⁰ poor growth of the infant as well as failure to thrive,^{131,132} decreased IQ in infants and children,⁴² missed pediatric outpatient appointments and increased emergency room visits,¹³³ marital and relationship difficulties,¹³⁴ depression,⁴³ and violence in children.¹³⁵
- 11 Minimal concentrations of sertraline, paroxetine, and nortriptyline in breastmilk make them preferred antidepressants in breastfeeding.⁴⁰

- 12 Anxiety disorders are common in women and are associated with low birthweight,¹³⁶ preeclampsia,¹²⁸ premature rupture of membranes,¹³⁷ preterm delivery,¹³⁸ operative delivery,^{137,139} and increased risk for behavioral/emotional problems in children.¹⁴⁰
- 13 Women with bipolar disorder have a significant risk for postpartum psychosis, depression, and mania.
- 14 Puerperal prophylaxis with a mood stabilizer decreases the rates of postpartum bipolar exacerbations to 10%.
- 15 Prescribing an antidepressant medication to a woman with bipolar disorder who is not on an antimanic agent can precipitate mania.
- 16 Eating disorders are associated with miscarriage, low birthweight, IUGR, preterm delivery, Cesarean birth, low Apgar scores, and postpartum depression.
- 17 An atypical eating disorder in diabetics who withhold their insulin for weight control is associated with widely fluctuating weight and hemoglobin A_{1c} levels, and significant morbidity and mortality.
- 18 The onset of OCD often occurs in the postpartum period.
- 19 Women with post-traumatic stress disorder may experience flashbacks and dissociative episodes during obstetrical procedures and labor.
- 20 Schizophrenia is associated with preterm delivery, low birthweight, SGA infants, stillbirth, and neonatal death.

Ethical and legal dimensions of medicine of the pregnant woman and fetus

Judith L. Chervenak, Frank A. Chervenak, and Laurence B. McCullough

Ethics is an essential dimension of maternal–fetal medicine.^{1–3} In this chapter, we develop a framework for physicians’ clinical judgment and decision-making regarding the ethical dimensions of the medical care of pregnant women and fetuses. We explain the ethical concept of the fetus as a patient and identify its implications for maternal–fetal medicine in a preventive ethics approach. This approach appreciates the potential for ethical conflict and adopts ethically justified strategies to prevent those conflicts from occurring. Because the professional liability crisis has become the dominant legal concern for obstetrician–gynecologists, our discussion of legal issues focuses on medical malpractice.

Medical ethics and law

Ethics is the disciplined study of morality. Medical ethics is the disciplined study of morality in medicine and concerns the ethical obligations of physicians and healthcare organizations to patients as well as the obligations of patients themselves.⁴ The approach to medical ethics has been secular since the eighteenth-century European and American Enlightenments;⁵ it makes no reference to God or revealed tradition, but focuses on what rational discourse requires and produces. Therefore, medical ethical principles (Figs 58.1–58.3) should be understood to apply to all physicians, regardless of their personal religious and spiritual beliefs.⁶ Medical ethics and law have been closely related since Thomas Percival’s *Medical Ethics* appeared in 1803.⁷ Percival’s early version of this text was entitled *Medical Jurisprudence*.⁸ Criminal law sets the boundaries of acceptable behavior, whereas civil law plays a large role in regulating drugs and devices, licensing physicians and healthcare organizations, regulating insurance companies and employer-provided health plans, and regulating medical practice.

The informed consent process

The close relationship of ethics and law is illustrated by informed consent. This process involves three sequential

autonomy-based behaviors on the part of the patient: (1) absorbing and retaining information about her condition and the alternative diagnostic and therapeutic responses to it; (2) understanding the information (i.e., evaluating and rank-ordering those responses, and appreciating that there could be benefits and risks of treatment); and (3) expressing a value-based preference. The physician has a role to play in each of these three behaviors. They are respectively: (1) to recognize the capacity of each patient to deal with medical information (and not underestimate that capacity), provide information (disclose and explain all medically reasonable alternatives, i.e., supported in beneficence-based clinical judgment), and recognize the validity of the values and beliefs of the patient; (2) to not interfere with but, when necessary, assist the patient in her evaluation and ranking of diagnostic and therapeutic alternatives for managing her condition; and (3) to elicit and implement the patient’s value-based preference.⁴

The legal obligations of the physician regarding informed consent were established in a series of cases during the twentieth century. In 1914, *Schloendorff v. The Society of The New York Hospital* established the concept of simple consent, i.e., whether the patient says “yes” or “no” to medical intervention.^{9,10} This decision is still quoted today in the medical and bioethics literature: “Every human being of adult years and sound mind has the right to determine what shall be done with his body, and a surgeon who performs an operation without his patient’s consent commits an assault for which he is liable in damages.”⁹ The legal requirement of consent further evolved to include disclosure of sufficient information to enable patients to make informed decisions about whether to say “yes” or “no” to medical intervention.^{9,10}

There are two legal standards for such disclosure. The professional community standard defines adequate disclosure in the context of what the relevantly trained and experienced physician tells patients. The reasonable person standard, which has been adopted by most states, goes further and requires the physician to disclose “material” information, i.e., what any patient with that particular condition needs to know and what the lay person of average sophistication should not be expected to know.¹⁰ The reasonable person standard has

The principle of beneficence

The principle of beneficence requires one to act in a way that is expected reliably to produce the greater balance of benefits over harms in the lives of others. To put this principle into clinical practice requires a reliable account of the benefits and harms relevant to the care of the patient and of how those goods and harms should be reasonably balanced against each other when not all of them can be achieved in a particular clinical situation, such as a request for an elective Cesarean delivery. In medicine, the principle of beneficence requires the physician to act in a way that is reliably expected to produce the greater balance of clinical benefits over harms for the patient.

Figure 58.1 The principle of beneficence.

Nonmaleficence

Nonmaleficence means that the physician should prevent causing harm and is best understood as expressing the limits of beneficence. This is also known as “*primum non nocere*” or “first do no harm.” This commonly invoked dogma is really a latinized misinterpretation of the Hippocratic texts that emphasized beneficence while avoiding harm when approaching the limits of medicine.

Figure 58.2 Nonmaleficence.

The principle of respect for autonomy

The principle of respect for autonomy requires one always to acknowledge and carry out the value-based preferences of the competent adult patient, unless there is compelling ethical justification for not doing so, e.g., prescribing antibiotics for viral respiratory infections. The female or pregnant patient increasingly brings to her medical care her own perspective on what is in her interest. The principle of respect for autonomy translates this fact into autonomy-based clinical judgment. Because each patient’s perspective on her interests is a function of her values and beliefs, it is impossible to specify the benefits and harms of autonomy-based clinical judgment in advance. Indeed, it would be inappropriate for the physician to do so, because the definition of her benefits and harms, and their balancing, are the prerogative of the patient. Not surprisingly, autonomy-based clinical judgment is strongly antipaternalistic in nature.

Figure 58.3 The principle of respect for autonomy.

emerged as the ethical standard, and specialists in maternal–fetal medicine are urged to adopt it.⁴ Using this standard, the physician should disclose to the patient: (1) her diagnosis or that of the fetus (including differential diagnosis when only that is known); (2) the medically reasonable alternatives to diagnose and manage the condition; and (3) the short-term and long-term benefits and risks of each alternative.

As a rule, the result of the informed consent process should be implemented. When the patient refuses to accept any of the

alternatives supported in beneficence-based clinical judgment, the physician is ethically and legally obligated to engage in what is known as “informed refusal.” This legal and ethical obligation arose from the 1980 case of *Truman v. Thomas* in California.^{10,11} Dr. Thomas had delivered several of Mrs Truman’s babies and, on the delivery of her last child, recommended that she have a Pap smear. She refused to have this test until she could pay for it and did not accept Dr. Thomas’s offer to perform it without charge. Mrs Truman subsequently

presented to Dr. Thomas with advanced cervical cancer from which she died. In the malpractice action brought by her survivors, Dr. Thomas stated that he did not tell Mrs Truman about detectable presymptomatic changes in her cervix indicative of cervical cancer or that he was concerned that she could die from such disease. The California Supreme Court ruled that, because the risks were of clinical salience to Dr. Thomas (they were the motivation for his offering the Pap smear), he should have informed Mrs Truman about these risks so that her refusal would be informed. This case changed practice and introduced the concept of informed refusal into medical law and ethics.

The ethical and legal obligation of the physician in the matter of informed refusal is very clear and not difficult to fulfill. The law requires that the patient be informed about the medical risks he or she is taking by the refusal of treatment. The risks that should be disclosed are those that are salient in clinical judgment: if they are important to the physician, i.e., they motivate the physician to offer or recommend a diagnostic test or therapy, they are salient. Any discussion, especially regarding the risks of refusal, should be thoroughly documented in the patient's chart. Preventive ethics requires that disclosure of risks be followed by a strong recommendation that the patient reconsider his or her refusal. This preventive ethics approach avoids the need to abandon the patient, keeps lines of communication open, and sends a powerful signal of concern to the patient from the physician about the medical folly of refusal.

The fetus as a patient

The ethical principles of beneficence and respect for autonomy play a complex role in maternal-fetal medicine. There are obviously beneficence- and autonomy-based obligations to the pregnant patient: the physician's perspective on the pregnant woman's health-related interests provides the basis for the physician's beneficence-based obligations to her, whereas her own perspective on those interests provides the basis for the physician's autonomy-based obligations to her. The fetus cannot meaningfully be said to possess values and beliefs because of an insufficiently developed central nervous system. Thus, there is no basis for saying that a fetus has a perspective on its interests and there can be no autonomy-based obligations to the fetus. Hence, the language of fetal rights has no meaning and therefore no application to the fetus in obstetric clinical judgment and practice despite its popularity in public and political discourse in the USA and other countries.⁴ Obviously, the physician has a perspective on the fetus's health-related interests and can have beneficence-based obligations to the fetus, *but only when the fetus is a patient*.

One prominent approach for establishing if the fetus is a patient has involved attempts to show whether the fetus has independent moral status; this is the first sense of the concept of the fetus as a patient. For the fetus to have independent

moral status, one or more characteristics that the fetus possesses, in and of itself and therefore independently of the pregnant woman or any other factor, must generate and therefore ground obligations to the fetus on the part of the pregnant woman and the physician. Many fetal characteristics have been nominated for this role, including the moment of conception, implantation, central nervous system development, quickening, and birth. There is considerable variation among ethical arguments about when the fetus acquires independent moral status. Some take the view that the fetus has independent moral status from the moment of conception or implantation.¹² Others believe that independent moral status is acquired in degrees, resulting in "graded" moral status,¹³ or that the fetus never has independent moral status while it is *in utero*.¹⁴

Despite the ever-expanding theological and philosophical literature on this subject, there is no single authoritative account of the independent moral status of the fetus. This is not surprising because there is no single method that would be authoritative for all of the markedly diverse theological and philosophical schools of thought involved in this endless debate; debates about such a final authority within and between theological and philosophical traditions would have to be resolved in a way satisfactory to all, an inconceivable intellectual and cultural event. Therefore, there is no stable or clinically applicable meaning of the fetus as a patient in terms of its independent moral status. As a result, we abandon these futile attempts to understand the fetus as a patient in terms of its independent moral status and turn to an alternative approach that makes it possible to identify ethically distinct senses of the fetus as a patient and their clinical implications for directive and nondirective counseling.

Analysis of this second sense of the concept of the fetus as a patient begins with the recognition that it is not necessary to possess independent moral status to be a patient. Rather, being a patient means that one can benefit from the applications of the clinical skills of the physician. Put more precisely, a human being without independent moral status is properly regarded as a patient when two conditions are met: (1) that human being is presented to the physician, and (2) clinical interventions exist that are reliably expected to be efficacious, i.e., they are expected to result in a greater balance of clinical benefits over harm for the human being in question.¹⁵ This second sense of the concept of the fetus as a patient is called the dependent moral status of the fetus.

The authors have argued elsewhere⁴ that beneficence-based obligations to the fetus exist when the fetus is reliably expected to later achieve independent moral status as a child and person. In other words, the fetus is a patient when the fetus is presented for medical interventions, whether diagnostic or therapeutic, that can be reasonably expected to result in a greater balance of good over harm for the child and person the fetus can become during early childhood. The ethical significance of the concept of the fetus as a patient, therefore,

depends on links that can be established between the fetus and it later achieving independent moral status.

The viable fetal patient

Viability is one such link between the fetus and it later achieving independent moral status. However, it must be understood in terms of both biological and technological factors; it is only by virtue of both factors that a viable fetus can exist *ex utero* and thus achieve independent moral status. The fetus is a patient when it is viable, i.e., when it is of sufficient maturity that it can survive into the neonatal period and achieve independent moral status with the requisite technological support and when it is presented to the physician.

Viability exists as a function of biomedical and technological capacities, which are different in different parts of the world. Consequently, there is no worldwide uniform gestational age to define viability at the present time. In the USA, we believe viability presently occurs at approximately 24 weeks' gestation.¹⁶

When the fetus is a patient, directive counseling for fetal benefit is ethically justified. In clinical practice, this involves one or more of the following: recommending against the termination of pregnancy; recommending against nonaggressive management; or recommending aggressive management. Aggressive obstetric management includes interventions such as fetal surveillance, tocolysis, Cesarean delivery, or delivery in a tertiary care center when indicated. Nonaggressive obstetric management excludes such interventions. Directive counseling for fetal benefit, however, must also take into account the presence and severity of fetal anomalies, extreme prematurity, and obligations to the pregnant woman.

It is crucial to appreciate that, in obstetric clinical judgment and practice, the strength of directive counseling for fetal benefit varies according to the presence and severity of anomalies. As a rule, the more severe the fetal anomaly, the less directive counseling should be for fetal benefit. In particular, when lethal anomalies such as anencephaly can be diagnosed with certainty, there are no beneficence-based obligations to provide aggressive management. Such fetuses are dying patients; counseling should be nondirective in recommending between nonaggressive management and termination of pregnancy, but directive in recommending against aggressive management for the sake of maternal benefit.¹⁷ By contrast, third-trimester abortion for Down syndrome or achondroplasia is not ethically justifiable because there is a high probability that the future child will have the capacity to grow and develop as a human being.^{18,19}

Any directive counseling for fetal benefit must occur in the context of balancing beneficence-based obligations to the fetus against beneficence- and autonomy-based obligations to the pregnant woman. Any such balancing must recognize that a pregnant woman is obligated only to take reasonable risks of medical interventions that are reliably expected to benefit the

viable fetus or later child. A unique feature of obstetric ethics is that the pregnant woman's autonomy influences whether, in a particular case, the viable fetus ought to be regarded as being presented to the physician.

Obviously, any strategy for directive counseling for fetal benefit that takes into account obligations to the pregnant woman must be open to the possibility of conflict between the physician's recommendation and a pregnant woman's autonomous decision to the contrary. Such conflict is best managed preventively through the informed consent process as an ongoing dialogue throughout a woman's pregnancy, augmented as necessary by negotiation and respectful persuasion.^{4,20}

The previable fetal patient

As technological factors cannot result in the previable fetus becoming a child, the only possible link between the previable fetus and the child it can become is the pregnant woman's autonomy. The previable fetus has no claim to the status of being a patient independently of the pregnant woman's autonomy; the link between the previable fetus and the child it can become can only be established by the pregnant woman's decision to confer the status of being a patient on her previable fetus. The pregnant woman is free to withhold, confer, or, having once conferred, withdraw the status of being a patient on or from her previable fetus according to her own values and beliefs. The previable fetus is presented to the physician as a function of the pregnant woman's autonomy.⁴

If a pregnant woman refuses to confer the status of being a patient on her previable fetus, counseling regarding the management of her pregnancy should be nondirective in terms of continuing the pregnancy or having an abortion. If she does confer such status in a settled way, beneficence-based obligations to her fetus come into existence and directive counseling for fetal benefit becomes appropriate. Just as for viable fetuses, counseling must take into account the presence and severity of fetal anomalies, extreme prematurity, and obligations owed to the pregnant woman.

For pregnancies in which the woman is uncertain about whether to confer such status, the authors propose that the fetus be provisionally regarded as a patient. This justifies directive counseling against behavior that can harm a fetus in significant and irreversible ways, for example substance abuse, especially of alcohol, until the woman decides whether to confer the status of being a patient on the fetus.

In particular, nondirective counseling is appropriate in cases of what we term near-viable fetuses, i.e., those that are 22–23 weeks of gestational age, for which there are anecdotal reports of survival. In our view, aggressive obstetric and neonatal management should be regarded as clinical investigation (i.e., a form of medical experimentation) and not a standard of care. There is no obligation on the part of a pregnant woman to confer the status of being a patient on a near-viable fetus

because the efficacy of aggressive obstetric and neonatal management has yet to be proven.

Legal considerations

Black's Law Dictionary defines malpractice as "an instance of negligence on the part of a professional."²¹ Negligence is a tort or civil wrong whose elements are: (1) a duty recognized by the law; (2) a failure on the part of the person to conform to the standard required; (3) a reasonably close connection between the conduct and the resulting injury, known as the "proximate or legal cause;" and (4) actual loss or damage to the interests of another.²² The court provides a remedy for this civil wrong in the form of equity or money damages.

The duty to the patient arises from the physician-patient relationship and is generally considered to be a contractual duty implied from the actions of the parties rather than one expressed in written form.²² This relationship ends with the consent of both parties, dismissal of the physician, or when the services of the physician are no longer needed.²²

Good Samaritan legislation has been enacted in 49 US states and the District of Columbia to encourage physicians to render aid in emergency situations.²³ In general, these statutes were designed to safeguard the physician by "protecting them from liability for any injury they cause or enhance." These statutes generally do not apply to doctors who provide emergency services in the ordinary course of their activities or to doctors who have a pre-existing duty to the injured party. Often, these laws also do not protect an obstetrician who attends the emergency delivery of a woman with whom the physician has no physician-patient relationship if that delivery occurs in a hospital setting.²⁴

Standard of care

In a medical malpractice action, the standard of conduct for the physician is usually expressed as "the minimum knowledge, skill and care ordinarily possessed and employed by members of the profession in good standing."²² For those who are specialists, the standard is modified accordingly.²² Therefore, a physician who has met the applicable legal standard will not be liable for an honest mistake in judgment even if the clinical outcome is poor.

The standard of care in a medical malpractice action is usually established by expert testimony of other physicians who are limited by the state of medical knowledge at the time of the incident.²⁵ In contrast, after-acquired knowledge is admissible when assessing causation of the injury.²⁶ In the early 1960s, courts recognized that, because of the wide dissemination of medical information by journals and at specialty conferences, the practice of medicine was similar throughout the country.²⁶

Most medical malpractice cases require the testimony of an expert to establish the standard of care. Expert testimony is very different from that given by a lay witness; lay witnesses are allowed to testify only to that which they actually perceived through their own senses. This allows jurors to use their own life experiences to better assess whether witnesses' testimonies are credible. Experts, however, are allowed to testify about events that they have not witnessed and about matters that are outside the general knowledge of most jurors.²⁷ Therefore, courts have sought to prevent abuses by establishing criteria for the reliability of medical testimony.

The Supreme Court's decision in the case of *Daubert v. Merrill Dow* established what have become known as the *Daubert* factors for the admissibility of medical testimony in federal courts.²⁸ These are: (1) whether the expert's technique or theory can be or has been tested; (2) whether the technique or theory has been subject to peer review and publication; (3) the known or potential rate of error of the technique or theory when applied; (4) the existence and maintenance of standards and controls; and (5) whether the technique or theory has been generally accepted in the scientific community.²⁸ Before *Daubert*, which was based on the federal rules of evidence, courts used what was known as the Frye standard, under which expert testimony was admissible only if it was based upon techniques or procedures that were "generally accepted in the medical community."²⁹ In the case of *Daubert*, the plaintiffs offered the testimony of eight expert witnesses regarding the teratogenicity of Bendectin (an antinausea drug), whereas the medical literature was overwhelmingly adverse to the plaintiff's position.²⁸ The Supreme Court opined that courts should act as gatekeepers to exclude expert testimony that is unreliable. *Daubert* challenges can take two forms.²⁸ The first is a challenge made to the expert in a motion for summary judgment (a motion to dismiss the case because there are no triable issues of fact). In this motion, the defense asks the court to dismiss the case by arguing that the plaintiff's case has no merit because it is based on an expert's opinion or theory that is not scientifically reliable. The second form is a pretrial motion (motion *in limine*) to preclude the expert from testifying.²⁸ In either case, the court can decide to hold a separate hearing either before or even during a trial before deciding whether to allow the expert to testify before the jury.²⁸

In cases in which the jury is considered capable of determining whether negligence occurred without the benefit of an expert opinion, the doctrine of *res ipsa loquitur* applies.³⁰ In such cases, the harm to the patient could not ordinarily have occurred without the negligent conduct of the defendant, and the thing or things that caused the harm must have been in the exclusive control of the defendant. The burden in such cases then shifts to the defendant to prove that he or she did not commit the negligent act.³⁰ An example of this type of case would be an instrument left in an abdomen during a surgical procedure.

Causation

There must also be a causal link between the conduct and the harm that results. The proximate or legal cause in a medical malpractice action is usually expressed as a “reasonable medical probability” that the conduct was a “substantial factor” in bringing about the harm.³¹ Most jurisdictions require that there is more than a 50% probability that the alleged conduct caused the harm,³¹ e.g., in a typical cerebral palsy case, plaintiffs will allege that, despite other potential causes, the damage to the infant was most likely the result of hypoxia at birth. The requirement is often not met when the plaintiff has a pre-existing condition and alleges a lost opportunity for cure, such as an obstetrician’s failure to recognize premature labor or failure to treat a woman who suffered from an amniotic fluid embolism. In *Falcon v. Memorial Hospital*, a Michigan court held that a woman who suffered an amniotic fluid embolism could recover for negligent treatment even though there was testimony that, had she been given the proper treatment, she would have had only a 33% chance of survival.³²

Other birth-based causes of action are wrongful pregnancy, wrongful birth, and wrongful life. In a wrongful pregnancy action, one or both parents of a child born following a negligently performed sterilization procedure can bring suit on their own behalf for the costs of having an unplanned child. Most US jurisdictions recognize this cause of action.³³ In a wrongful birth action, the parents of an unhealthy child born following negligent genetic counseling or negligent failure to diagnose a fetal defect or disease bring suit for the costs of having to raise and care for an impaired child, arguing that they were wrongfully deprived of the ability to avoid or terminate a pregnancy to prevent the birth of a child with the defect or disease.³⁴ Most states allow recovery for the “extraordinary expenses of raising a child with a birth defect.”³⁴ In a wrongful life action, an unhealthy child born following either a negligently performed sterilization of one of his or her parents, or negligent genetic counseling or testing, argues that he or she has been damaged by being born at all.³⁴ To date, most courts have rejected this cause of action.

New York has recently recognized a separate cause of action for emotional distress on behalf of the mother in the absence of an independent injury to her. In *Broadnax*,³⁵ the Court of Appeals (the highest New York state court) held that medical malpractice resulting in miscarriage or stillbirth entitled the mother to damages for emotional harm. In *Sheppard-Mobley v. King*, the Supreme Court, Second Department, Appellate Division, held that malpractice resulting in the birth of a severely impaired child was a violation of the duty of care to the mother and also entitled her to damages for emotional harm.³⁶ The Court of Appeals later rejected this cause of action.³⁷

Damages

The monetary damages awarded in an obstetrical malpractice suit involving a child with cerebral palsy can be enormous. In New York, recent jury verdicts of \$90 million and \$112 million in brain-damaged baby cases have made headlines and are frequently cited as evidence of a crisis.³⁸ It should be recognized that many, if not all, of these large verdicts are reduced on appeal.³⁸ Many trial lawyers also enter into what is known as a “high-low” agreement whereby the parties agree on a high settlement value in the event of a plaintiff’s verdict and a low value for a defendant’s verdict.³⁸ Such agreements protect plaintiffs from a lengthy appeals process and are typically set close to the limits of the insurance policy available for that case. In the case of the \$112 million jury verdict noted above, the plaintiffs actually received \$6 million because such an agreement was made just prior to jury deliberations.³⁸

Impact of obstetrical malpractice on physicians

In 2003, a professional liability survey by the American College of Obstetricians and Gynecologists (ACOG) found that 76.3% of obstetricians had a least one claim filed against them during their career. The average number of claims against all respondents was 2.64, and 29.6% had at least one claim filed during their residency.³⁹ In the same survey, 14% of respondents said that they no longer practice obstetrics, and 12.3% had decreased the level of high-risk obstetrical cases that they take because of liability concerns.³⁹

Tort reform

Tort reform in the medical malpractice context has primarily focused on enacting legislation designed to discourage lawsuits by placing a cap on pain and suffering or by making it more difficult to file a claim, as well as by replacing litigation with another system of compensation for injured parties such as a no-fault system.⁴⁰ In California, the use of a \$250,000 cap has resulted in insurance premium increases that are less than one-third of those in states not using caps.⁴¹ In Florida, a no-fault system for compensation reduced the number of tort claims for premature labor and delivery, injury, and death by 16–32%, but the total claims frequency rose by 11–38% when no-fault claims were added to tort claims.⁴² It should be noted that because of the narrow statutory definition for “birth-related neurological injury,” many children, including many premature infants, did not qualify for coverage.

As most medical malpractice lawsuits are brought in state rather than federal courts because of jurisdictional issues, procedural reforms enacted in the different states and influenced heavily by political support from various interest groups will undoubtedly influence obstetrical malpractice insurance premiums in the future.

Conclusion

In this chapter we have provided a general ethical and legal framework for maternal–fetal medicine. Implementing this framework on a daily basis is essential for creating and sus-

taining the physician–patient relationship in obstetrics and gynecology. This framework emphasizes preventive ethics, i.e., an appreciation that the potential for ethical conflict is built into clinical practice, and the use of such clinical tools as informed consent and negotiation to prevent such conflict from occurring.

Key points

- 1 Medical ethics and law have been closely related since at least the early nineteenth century.
- 2 The informed consent process implements the ethical principle of respect for autonomy in the decision-making process between physicians and patients.
- 3 Simple consent concerns whether the patient accepts or refuses treatment.
- 4 Informed consent concerns whether the patient's decision about treatment is adequately informed and is voluntary.
- 5 The professional community standard requires the physician to provide information to the patient that any adequately trained and experienced physician would provide.
- 6 The reasonable person standard requires the physician to provide information that any patient with that particular diagnosis needs in order to make an informed decision.
- 7 The previable fetus is a patient solely as a function of the pregnant woman's autonomy and has no independent claim to this moral status.
- 8 The viable fetus is a patient when it is able to exist *ex utero*, with full technological support, and when it is presented to the physician.
- 9 When the fetus is not a patient, counseling about the management of pregnancy should be nondirective.
- 10 When the fetus is a patient, counseling about the management of pregnancy should be directive with the weight of recommendations a function of both the fetal patient's and the pregnant woman's interests.
- 11 Malpractice is an instance of negligence on the part of a professional. The elements of malpractice are duty, breach, causation, and damages.
- 12 The duty to the patient arises from the physician–patient relationship and is generally considered to be a contractual duty implied from the actions of the parties rather than one expressed in written form.
- 13 Good Samaritan legislation may not protect an obstetrician who attends the emergency delivery of a woman in a hospital setting.
- 14 In a medical malpractice action, the standard of conduct for the physician is usually expressed as “the minimum knowledge, skill and care ordinarily possessed and employed by members of the profession in good standing.”
- 15 For those who are specialists, the standard is modified accordingly.
- 16 Most medical malpractice cases require the testimony of an expert to establish the standard of care.
- 17 In the case of *Daubert v. Merrill Dow*, the Supreme Court established what have become known as the *Daubert* factors for the admissibility of medical testimony in federal courts.
- 18 *Daubert* challenges can take two forms: (1) a motion for summary judgment, or (2) a pretrial motion to prevent the expert from testifying.
- 19 The proximate or legal cause in a medical malpractice action is usually expressed as a “reasonable medical probability” that the conduct was a “substantial factor” in bringing about the harm.
- 20 Wrongful pregnancy is an action brought on behalf of one or both parents for the costs of raising an unplanned child and is often brought after a negligent sterilization procedure.
- 21 Wrongful birth actions are brought on behalf of the parents of a child who is unhealthy and who claim that they were wrongfully denied the chance to terminate the pregnancy. Most states allow recovery for the extraordinary expenses associated with raising such a child.
- 22 Most states have rejected wrongful life actions where an unhealthy child argues that he or she has been damaged by being born at all.

Obstetric and Peripartal Events

Bleeding in the third trimester

Lawrence W. Oppenheimer and the late Carl A. Nimrod

Bleeding in the third trimester is common. The most important cause is placental abruption (also called *abruptio placentae*), which has an incidence of approximately 0.6% in the USA and an associated risk of stillbirth of 12%. Placenta previa, which can also cause bleeding in the third trimester, occurs with a frequency of 0.3%. There is a significant association of Cesarean section with placenta previa and placenta accreta. Vasa previa is a rare but important cause of vaginal bleeding and occurs in 1 in 3000 to 5000 pregnancies. However, in approximately 50% of cases of vaginal bleeding, the etiology is either unexplained or assumed to result from local lesions.

Placenta previa

Introduction

Placenta previa is defined as a placenta implanted in the lower segment of the uterus presenting ahead of the leading pole of the fetus. It occurs in 2.8 to 4.0 out of 1000 singleton pregnancies^{1,2} and 3.9 out of 1000 twin pregnancies¹ and represents a significant clinical problem in terms of the need for hospitalization, potential need for blood transfusion, and risk of premature delivery. The incidence of hysterectomy in women who have undergone a Cesarean section because of placenta previa is 5.3%, which represents a relative risk of 33 compared with women undergoing Cesarean section without placenta previa.³ Perinatal mortality rates are 3–4 times higher than in normal pregnancies.⁴ This is principally because of the association of placenta previa with preterm birth;⁵ however, even after 37 weeks' gestation, the risk of neonatal mortality from placenta previa is still double that of babies born without previa.⁶ The risk factors for placenta previa^{2,7,8} are listed in Table 59.1. Placenta previa does not appear to be associated with significant fetal growth restriction^{4,8} and has a negative association with pregnancy-induced hypertension.⁸

Diagnosis

Placenta previa classically presents with painless vaginal bleeding. The traditional classification of placenta previa describes the degree to which the placenta encroaches upon the cervix. This categorization into low-lying, marginal, partial, or complete placenta previa⁹ was originally based on digital palpitation through the cervix. In modern practice, the diagnosis of placenta previa is usually made in asymptomatic women found to have a low-lying placenta on routine ultrasonography, and digital vaginal examination may be completely avoided.⁹ The superior accuracy of transvaginal sonography (TVS), which can measure the actual distance between the placental edge and the internal cervical os, has rendered the traditional classification obsolete,¹⁰ and the “sonic” finger obviates the need for the “double-setup” examination except in very rare circumstances.¹¹ Transvaginal sonography enables reclassification of placental position in up to 60% of cases compared with transabdominal sonography (TAS).^{12–15} The inherent inaccuracies of TAS include poor visualization of the posterior placenta,¹⁶ interference of the fetal head with visualization of the lower segment,¹⁷ obesity,¹⁸ and under- or overfilling of the bladder.^{19,20} For these reasons, the diagnosis of placenta previa by TAS is associated with a false-positive rate of up to 25%²¹ (Figs 59.1 and 59.2). Accuracy rates for TVS are high (sensitivity 87.5%, specificity 98.8%, positive predictive value 93.3%, negative predictive value 97.6%), establishing it as the “gold standard” for the diagnosis of placenta previa.²² A small randomized trial²³ has confirmed the benefit of TVS compared with TAS. TVS has also been shown to be safe in the presence of placenta previa,^{22,24} even when there is established vaginal bleeding. It is also possible to accurately image the placenta using magnetic resonance imaging (MRI), a superior technique to TAS,²⁵ but MRI may not provide any benefit over TVS.

Prediction of placenta previa at delivery

The occurrence of placenta previa is common in the first half of pregnancy (Fig. 59.3) and its persistence to term will depend

Table 59.1 Selected risk factors for placenta previa.

Risk factor	Typical odds ratio (OR)
Maternal age ≥ 40 (vs. < 20)	9.1
Illicit drugs	2.8
≥ 1 previous Cesarean section	2.7
Parity ≥ 5 (vs. para 0)	2.3
Parity 2–4 (vs. para 0)	1.9
Prior abortion	1.9
Smoking	1.6
Congenital anomalies	1.7
Male fetus (vs. female)	1.1
Pregnancy-induced hypertension	0.4

on the gestational age at diagnosis and the definition employed for the exact relationship of the internal cervical os to the placental edge on TVS.^{20,26–31} The results of these studies are summarized in Table 59.2. The data suggest that a placental edge that overlaps the internal os by less than 10 mm on TVS at any time before 24 weeks is highly unlikely to be associated with a placenta previa at term. The process of placental “migration,” or relative upward shift of the placenta as a result of differential growth of the lower segment, is continuous into the late third trimester.^{20,23,32} (Fig 59.4). For this reason, it is reasonable to carry out repeated imaging every 4 weeks until delivery. Vaginal delivery is possible when, at any gestational age, the distance from the placental edge to the internal os is greater than 20 mm.^{10,32} Transperineal or

Table 59.2 Persistence of placenta previa at delivery based on various gestational ages at TVS and overlap distances of the placental edge.

Reference no.	Number of patients	Gestational age (weeks)	Overlap (mm)	Incidence [<i>n</i> (%)]	Previa at delivery (%)

			11–24	–	63
			≥ 25	–	100

Figure 59.1 Transabdominal scan of placenta covering cervical os at 28 weeks’ gestation. Note the full bladder at top right.

Figure 59.2 Transvaginal scan of the above case with an empty bladder. The placental edge no longer covers the os. At follow-up, the placental edge moved further away and resulted in vaginal delivery.

Figure 59.3 Transvaginal scan at 16 weeks showing a 20-mm overlap of the placental edge. By 25 weeks, the placenta was no longer low lying.

translabial ultrasound can provide a higher diagnostic accuracy than TAS and may be a useful alternative when TVS is not available.³³

The need for Cesarean section at term is predicated by the distance from the os to the placental edge, and by clinical features (e.g., presence of unstable lie and/or bleeding). Four studies have examined the likelihood of Cesarean section in

cases of placenta previa based on the distance from the os to the placental edge on the last ultrasound before delivery.^{10,33-35}

The last scan was performed at a mean of 35–36 weeks' gestation, and a distance of > 20mm was associated with a high likelihood of vaginal delivery (range 63–100%). It has been suggested that below this cutoff distance of 20mm, the placenta should be defined as “low-lying” rather than as a previa;

Figure 59.4 Transvaginal scan of placental edge 7 mm from the internal os posteriorly at 30 weeks’ gestation in a woman presenting with vaginal bleeding. The fetal head is on the left. Migration continued and vaginal delivery occurred at 39 weeks.

this is to avoid the bias of physicians performing an elective Cesarean section based on the report of a previa,³⁴ and to enable these cases to be managed in the high expectation of a vaginal delivery.

A distance of between 20 and 0 mm from the os to the placental edge on the last scan results in a higher likelihood of Cesarean section. This distance may be further subdivided: from 10 to 0 mm, a Cesarean section is required in most cases but vaginal delivery is possible depending on clinical features; and from 20 to 11 mm, the likelihood of significant hemorrhage is reduced, and delivery by Cesarean section varies and may be driven by the physician’s prior knowledge of the ultrasound finding.^{34,35} In this latter group, trial of labor may be appropriate in the absence of an unstable lie or bleeding,³⁴ although more data in the form of prospective studies are required. In all cases where the placenta overlaps the os by any amount (greater than 0 mm) on the last scan before delivery, delivery by Cesarean section is necessary.^{32–35} This group may be defined as “complete placenta previa.” A classification of placenta previa is given in Table 59.3, describing the likelihood of Cesarean section according to the distance from the placental edge to the internal os near term.

Management

A policy of expectant management, pioneered by MacAfee,³⁶ continues to be the standard with the focus on bedrest and avoiding preterm birth. This approach has reduced preterm birth and perinatal mortality;³⁷ however, preterm delivery remains a problem with 46% of women diagnosed with pla-

Table 59.3 Likelihood of Cesarean section based on placental-edge to internal-os distance on last scan prior to delivery performed at an average of 35 weeks’ gestation.

Distance	Cesarean section
Overlapping	100%
< 10 mm	84%
> 10 mm and < 20 mm	40%
> 20 mm	16%

centa previa delivering preterm.⁴ The requirement for prolonged bedrest in hospital associated with this conservative approach is very stressful for women³⁸ and is increasingly being questioned. The difficulty lies in predicting the likelihood of bleeding in the individual patient.³⁹ Almost three-quarters of all women with placenta previa experience at least one episode of bleeding, at a median gestational age of 29 weeks, but the majority remain stable for a prolonged period and will not deliver until a median of 36 weeks.⁴⁰ However, the clinical outcomes of placenta previa are highly variable and cannot be predicted confidently from antenatal events.⁴¹ A number of retrospective studies⁴⁰ have provided evidence for the safety and cost-effectiveness of outpatient management of placenta previa^{41,42,43} culminating in a randomized controlled trial of inpatient versus outpatient management of placenta previa.⁴⁴ The evidence suggests that outpatient management is an acceptable alternative for selected patients.

Figure 59.5 Transabdominal scan of placenta accreta. There is loss of the hypolucent zone between the placenta and myometrium, multiple lacunae (Swiss cheese appearance), and abnormal vasculature extending into the bladder wall. The case was managed by classical Cesarean section; the placenta was left *in situ* and resorbed spontaneously.

Tocolytic therapy has been shown to prolong pregnancy in symptomatic women.^{45,46} However, in a small study using home uterine monitoring, uterine contractions did not appear to be a major factor in the onset of bleeding, and tocolytic therapy did not alter the clinical course.⁴⁷ Further studies into the potential benefits of prolonging pregnancy using cervical cerclage are required.^{48–50}

When carrying out a Cesarean section, a low transverse uterine incision is usually possible. If available immediately prior to incision, an examination by ultrasound will allow the operator to avoid cutting through the placenta, which can then be peeled aside and the nearest window of membranes located and entered. The frequency of blood transfusion, either antenatally or peripartum, is fairly low, and autologous blood donation is not feasible for most patients.⁵¹ Two retrospective studies have concluded that regional anesthesia is safe for Cesarean section,^{52,53} and one small randomized trial has suggested that epidural anesthesia is superior to general anesthesia with regard to maternal hemodynamics.⁵⁴

Placenta previa/accreta

The association between a previous Cesarean section and placenta previa and placenta accreta/percreta (pathological adherence of the placenta) is well recognized. The incidence of placenta previa increases with the number of previous deliveries by Cesarean section,^{55,56} and there is a suggestion that the incidence of previa is rising because of the increasing Cesarean section rate.⁵⁷ The mechanism of causation of previa by a previous scar is poorly understood but may be the result

of reduced differential growth of the lower segment, resulting in less upward shift in placental position as pregnancy advances.⁵⁸ Certainly, the increasing Cesarean section rate has resulted in an increased incidence of placenta accreta which, in a 1997 study,⁵⁷ occurred in 1 in 2500 deliveries. The relative risk of placenta accreta in the presence of placenta previa is 2065-fold higher than in women who have a normally situated placenta.⁵⁷ The risk of placenta accreta in the presence of placenta previa increases dramatically with the number of previous Cesarean sections, with a 25% risk for one prior Cesarean section and more than a 40% risk for two prior Cesarean sections.⁵⁶ Placenta accreta is a significant condition with a high potential risk for hysterectomy and a maternal death rate reported at 7%. Prenatal diagnosis may be beneficial in preparing for delivery.^{59–61} A number of imaging techniques including ultrasonography^{61–63} and color Doppler^{64–67} (Fig. 59.5) are helpful in making a prenatal diagnosis of placenta accreta. Dynamic contrast MRI can differentiate chorionic villi and decidua basalis, and can provide excellent contrast between the placenta and myometrium anywhere within the uterus^{68–70} (Fig. 59.6).

The key diagnostic imaging features described in placenta accreta are summarized in Table 59.4. Conservative treatment, leaving the placenta *in situ*, may be a useful management option⁷¹ (Table 59.5).

Vasa previa

In vasa previa, the fetal vessels cross within the membranes between the internal os and the presenting part, usually the

Figure 59.6 MRI of anterior placenta with loss of the retroplacental space and invasion of the placenta into the myometrium superior to the bladder.

Table 59.4 Ultrasound features of placenta accreta.

Hypoechoic zone between myometrium and placenta less than 2 mm
Disruption of the hyperechoic uterine serosa–bladder interface
Lacunar spaces (Swiss cheese) in placental parenchyma
Prominent vessels extending from placental base to uterine wall
Dilated blood vessels and turbulent blood flow in lacunae
Abnormal blood vessels linking the placenta and bladder with diastolic flow
Focal extension of placental tissue beyond the uterine serosa

Table 59.5 Management options in placenta accreta/percreta.

<i>Hysterectomy</i>
Avoid incision of placenta or attempted removal
Use of cell saver
Deliberate cystotomy to assist bladder mobilization
Placement of ureteral stents
Hypogastric artery ligation or embolization/balloon occlusion
<i>Uterine conservation</i>
Classical Cesarean section avoiding placenta
Leave placenta <i>in situ</i> if no hemorrhage
Prophylactic radiological hypogastric artery embolization/balloon occlusion
Attempt placental removal if bleeding occurs
Control bleeding by: circumferential sutures over placental site, prostoglandin F2-alpha myometrial injection, ligating uterine pedicles and/or ovarian vessels, uterine packing

fetal head. It is an uncommon form of placental anatomy, occurring in 1 out of 3000–5000 pregnancies.⁷² It primarily occurs in two settings: a velamentous cord insertion or a succenturiate lobe on the opposite side of the internal os from the main placental structure. Because fetal vessels within the membranes are unprotected by Wharton’s jelly, they are prone to compression during labor and may tear when the membranes rupture, resulting in severe fetal heart rate abnormalities accompanied by slight or moderate vaginal bleeding leading to fetal exsanguination.

Vasa previa is strongly associated with a low-lying placenta,⁷³ even when a second-trimester placental location subsequently converts to normal.⁷⁴ Ultrasound imaging including Doppler, color Doppler, and power Doppler technology with TVS, now offers the possibility of predicting vasa previa well before the onset of labor although, at present, screening for vasa previa would not be considered to be part of routine care. In two large case series, the specificity and sensitivity of a prenatal diagnosis was excellent.^{72,75} The survival rates of infants with a prenatal diagnosis was 97% compared with 44% in those not diagnosed before delivery.⁷⁶ The protocol for ultrasound identification and management of vasa previa is shown in Table 59.6.

Placental abruption

Placental abruption is defined as a complete or partial separation of the placenta prior to delivery and is accompanied by hemorrhage into the decidua basalis. The incidence of placental abruption is approximately 0.6% in singleton preg-

Figure 59.7 Sites of periplacental hemorrhage that have been described sonographically. Subchorionic hemorrhage may be remote from the placenta but is thought to arise from marginal abruptions. The term *preplacental hemorrhage* has been chosen to describe both subamniotic hematoma and massive subchorial thrombosis. Intraplacental hemorrhages (intervillous thrombi) may also be identified but are difficult to distinguish from placental lakes or other intraplacental sonolucencies.

Table 59.6 Protocol for diagnosis of vasa previa.⁵²

Attempt to visualize cord insertion in all cases
High index of suspicion with low-lying placenta or succenturiate lobe
Sweep across the lower uterine segment to look for velamentous vessels
Color or power Doppler with TVS to further investigate suspicious cases
Ascertain whether pulse rate maternal or fetal on Doppler
Follow-up sonograms if vessels identified over or near the cervix
Cesarean delivery if vasa previa confirmed in later pregnancy

nancies and 1% in twin pregnancies,⁷⁷ although quoted rates vary widely from 0.1% to 2.7%.⁷⁸ The wide range of reported incidences may be explained by the different criteria used for diagnosing placental abruption as well as the increased recognition of milder forms, for example complete, partial, or marginal placental detachment (Fig. 59.7). Perinatal mortality occurs in 11.9% of cases of abruption compared with 0.8% of all other births.⁷⁹ Older case series report a perinatal mortality rate of up to 21%.⁸⁰ Abruption is associated with a nearly ninefold increase in the risk of stillbirth;⁸¹ the case fatality rate, expressed as the number of abruption-stillbirth cases per 100 total placental abruption cases, is reported to be 5.3%⁸⁰ to 7%.⁸² Abruption accounts for more than 8% of all cases of perinatal mortality.⁷⁹ The high mortality rate results, in part, from its strong association with preterm delivery; in a large population study, 55% of the excess perinatal deaths with abruption resulted from early delivery.⁷⁹ Placental abruption appears to be occurring more frequently probably because of increased ascertainment and reporting.⁸²⁻⁸⁴ The risk of preterm birth in women with abruption ranges from 39.6%⁸⁰ to 50%⁷⁹ compared with 9.1% for women without abruption. Abruption is also significantly associated with fetal growth restriction, which occurs in 14.3% of cases of placental abruption and 8.1% of cases without abruption;⁸⁰ this association is stronger for term than for preterm babies. At each gestational age, the relative risk of abruption is highest among babies in the lowest weight percentile and progressively

Figure 59.8 Gestational age-specific perinatal mortality rate (plotted on a logarithmic scale) in pregnancies with and without abruption, in the USA, in 1995 and 1996 (reproduced from ref. 79, with permission).

declines with increasing weight. This effect is slightly greater for term babies than for preterm babies, thus, at about 36 weeks' gestation, a baby weighing less than those within the first percentile for weight had a relative risk of abruption of 9.8 compared with a baby weighing more than those in the 90th percentile.⁷⁹ The excess in perinatal mortality rate in cases of abruption increases toward term both in relation to gestational age⁷⁹ (Fig. 59.8) and to birthweight⁷⁹ (Fig. 59.9) compared with pregnancies without abruption. Even in babies weighing around 4000g, who have the best chance of

Figure 59.9 Birthweight-specific perinatal mortality rates (plotted on a logarithmic scale) in term pregnancies (≥ 37 weeks) with and without placental abruption, in the USA, in 1995 and 1996 (reproduced from ref. 79, with permission).

survival, the excess perinatal mortality rate due to abruption is increased 25-fold.

Risk factors

Table 59.7 shows the etiological fractions for a number of factors that are significantly associated with the occurrence of abruption.⁸⁵ The factor in this study with the highest etiological fraction is the presence of a male fetus, which has an associated risk of 16.3%. The next most important determinant is severe growth restriction. The association between placental abruption and advanced maternal age is inconsistent and may be more a factor of parity.⁸⁶ Smoking is an important preventable cause of abruption;^{77,87–89} a meta-analysis of a large number of studies on smoking in pregnancy⁹⁰ showed that there was a strong concordance in the finding of a twofold increased risk of abruption in women who smoke. The results suggest that between 15% and 25% of placental abruption episodes could be prevented if women stopped smoking cigarettes during pregnancy. The analysis included five studies where dose–response relationships showed a two- to threefold increase in the incidence of abruption in women who smoked more than 20 cigarettes per day (Table 59.8).

Table 59.7 Etiological fractions for significant determinants of abruption.

Determinant	Etiological fraction
Male fetus	0.163
Severely small for gestational age	0.064
Unmarried	0.054
Age > 35 years	0.053
Smoking > 10 cigarettes per day	0.042
Preeclampsia	0.038
Rupture of membranes > 24 h	0.032
Chorioamnionitis	0.026
Prepregnancy hypertension	0.015
Pregnancy-induced hypertension without albuminuria	0.010

From ref. 85, with permission.

Table 59.8 Meta-analysis of the joint effects of cigarette smoking and hypertensive disorders on the risk of placental abruption.

Hypertensive disorder	Nonsmokers	Smokers
None	1.0 (referent)	1.4 (1.2, 1.5)
Chronic hypertension	2.8 (2.5, 3.2)	5.2 (2.7, 10.0)
Mild preeclampsia	0.9 (0.6, 1.2)	2.3 (1.6, 3.3)
Severe preeclampsia	4.1 (2.8, 6.0)	5.9 (3.4, 10.3)
Chronic hypertension with preeclampsia	2.0 (0.7, 5.4)	7.8 (2.4, 25.9)

From ref. 90, with permission.

Data are given as odds ratio (95% confidence interval).

Maternal hypertension is a major risk factor for placental abruption,^{77,78,85,91,92} and women with preeclampsia are twice as likely to develop placental abruption as normotensive women.⁷⁸ At least two studies^{91,92} did not find an increased risk of abruption in chronically hypertensive women, although they did confirm the important effect of severe preeclampsia and superimposed preeclampsia. An interaction between smoking and hypertensive disorders is also well known. Overall, the incidence of placental abruption in women with hypertensive disorders in pregnancy is 10%.⁹³ In severe preeclampsia or eclampsia, quantitative proteinuria and degree of blood pressure elevation are not predictive of placental abruption.⁹⁴ A paradoxical effect of smoking is also well known in that the risk of mild and severe preeclampsia is reduced by one-half in smokers.⁹⁵ However, women who smoked and were hypertensive had an almost eightfold increased risk of abruption compared to women who had neither condition.^{90,91,95} Cocaine is a potent cause of placental abruption and may have a high prevalence in some areas.⁹⁶ Up to 10% of women using cocaine may experience abruption,⁹⁷

Table 59.9 Factors significantly associated with placental abruption.

Factor	Typical odds ratios
Severely small for gestational age	3.99
Cocaine use	3.92
Chorioamnionitis	2.61
Premature rupture of membranes	2.44
Alcohol	2.29
Chronic hypertension	2.21
Oligohydramnios	2.09
Twins	2.06
Smoking	2.00
Preeclampsia	1.9
Parity > 3	1.6
Maternal age > 35	1.37
Unmarried	1.27

and its effect appears to be related to vasoconstriction in the placental bed.⁹⁸ Rupture of the membranes,^{77,99} and associated chorioamnionitis, and birthweight discordance in twins also have a significant impact on the likelihood of abruption.¹⁰⁰ The typical odds ratios (ORs) for factors associated with abruption are given in Table 59.9. Overall, however, an etiological factor is present in less than one-half of cases⁸⁵ and the majority of placental abruption occurs in women with no established risk factors. Placental abruption remains, therefore, difficult to predict and is largely unpreventable. A combination of risk factors may allow the identification of a group of women at high risk of abruption in whom increased surveillance may be appropriate.¹⁰¹

Pathogenesis

The association of abruption with poor fetal growth suggests that the origins of abruption may extend back to the earliest stages of pregnancy. The chronic process underlying abruption may also contribute to the risk of preterm delivery.³ Pathological studies suggest that abruption is associated with abnormal placental vasculature, thrombosis, and reduced placental perfusion.¹⁰² A high incidence of inherited thrombophilias is noted in patients with abruption, and in particular there is an increased prevalence of mutations in the genes coding for Factor V Leiden, homocysteine, activated protein C resistance, and antiphospholipid antibodies.^{103,104} Postpartum women who have experienced placental abruption should be considered for screening for the presence of these factors.¹⁰⁵

For women who have experienced placental abruption, the risk of recurrence in subsequent pregnancies is observed to be 10–15% (i.e., 30-fold increased risk),⁷⁸ although in one study the risk was found to be increased 100-fold.¹⁰⁶ In cases with two previous abruptions, the OR of a third abruption was 36.5.¹⁰⁷

Table 59.10 Clinical presentation in 59 cases of moderate to severe abruption.

Vaginal bleeding	78%
Fetal distress	50%
Uterine tenderness/back pain	66%
High-frequency contractions	17%
Uterine hypertonus	17%
Unexplained preterm labor	22%
Dead fetus at admission	15%
Perinatal death of fetus alive at admission	18% (9 out of 50)

Adapted from ref. 108.

Management of moderate to severe abruption

Approximately 30% of women presenting with bleeding in the third trimester are diagnosed with definitive placental abruption.¹⁰⁸ Hurd and co-workers¹⁰⁸ reported the outcome of 59 cases of abruption prospectively managed in a selective manner; the clinical features are described in Table 59.10. The mean diagnosis to delivery time in patients with a clinical presentation consistent with abruption was 2 h and 54 min, and the Cesarean section rate was 52%.¹⁰⁹ Clinical management decisions in cases of moderate to severe placental abruption must be individualized and aggressive plans for delivery made if there is evidence of fetal distress or maternal hemodynamic instability or coagulation disorders. Minimizing the interval between presentation and delivery may be important.¹¹⁰ Knab¹¹¹ found that almost 70% of all cases of perinatal mortality occurred in infants who were delivered more than 2 h from the time of diagnosis. In one series of 33 women with clinically overt placental abruption associated with fetal bradycardia, death or cerebral palsy occurred in 33% of the cases; a diagnosis to delivery interval of 20 min or less was associated with substantially reduced neonatal morbidity and mortality compared with delivery at 30 min (OR of 0.44).¹⁰⁸ There is some evidence that women diagnosed with concealed abruption, with an absence of vaginal bleeding, have a higher stillbirth rate, perhaps because of a delay in diagnosis.¹¹¹ In most cases, blood eventually escapes from behind the membranes or past an impacted fetal head and bleeding occurs. Fetal heart rate abnormalities are common in abruption, occurring in 58% of cases.¹¹² Cesarean section rates in this study were 71%, and undergoing a Cesarean section significantly reduced the odds of perinatal death to 0.1. Abruption may also present as backache associated with a nontender uterus.¹¹³ Although being a very subjective clinical measure, the estimation of degree of placental separation can be used to assess the risk of stillbirth and preterm delivery⁸⁰ (Fig. 59.10). Women with severe hemorrhage are more likely to be classified as having over 50% placental separation. The presence of severe hemorrhage may serve as a reliable marker for the severity of placental abruption.⁸⁰ Management principles for severe abruption are given in Table 59.11.

Figure 59.10 Adjusted relative risks with 95% confidence intervals of the association between extent of placental separation and stillbirth and preterm delivery, Mount Sinai Hospital, NY, 1989–1996 (reproduced from ref. 80, with permission).

Table 59.11 Management principles for severe abruption.

Fetal assessment for viability, welfare, and size (growth restriction is common)
Estimate severity of abruption (uterine tone, hardness, pain, amount of vaginal bleeding)
Maternal assessment for hypovolemia and coagulation status
Early aggressive treatment of suspected disseminated intravascular coagulation ¹¹⁴
Kleihauer–Betke test and Rhesus status should be checked as fetal–maternal hemorrhage is present in up to 30% of cases, particularly in traumatic abruption ¹¹⁵
Expedite delivery of a live fetus with a low threshold for Cesarean section

Mild abruption

A rapid Cesarean section appears to be beneficial for acute cases of placental abruption; however, less severe cases, particularly those presenting well before term, may be managed more conservatively.^{109,116} In women presenting preterm, either with vaginal bleeding in the absence of uterine tenderness, or fetal distress, or in whom there was a retrospective diagnosis of abruption, 26% delivered on the day of admission, 50% delivered within 3 days and, of the remainder, about one-half delivered 15 or more days after admission. Some were treated with tocolytics although this practice is controversial and no benefit was seen in an uncontrolled study of 95 preterm women.¹¹⁷ Bond and co-workers¹¹⁸ expectantly managed 43 cases of abruption at less than 35 weeks' gestation and achieved a mean prolongation of pregnancy of 12 days, but the Cesarean section rate was still high at 75%.

Where vaginal delivery is pursued, amniotomy may be beneficial in hastening delivery. Oxytocin may likewise be helpful and there is no evidence that the latter increases complica-

tions.^{118,119} Many cases of unexplained vaginal bleeding, which occur in up to 6% of the obstetric population, may result from marginal placental separation.⁸⁸ Vaginal and cervical lesions should also be excluded. The prognosis is generally good although patients should be followed in case of recurrence. Unlike abruption, the lack of association with smoking suggests the possibility of a distinct pathological process in these cases.⁸⁸

Ultrasound diagnosis

Negative findings on ultrasound do not exclude the possibility of significant placental abruption. Scholl¹¹⁶ reported ultrasound visualization of a clot in only 25% of placental abruption cases and found that ultrasound was unhelpful in management. In a series of 110 women who underwent ultrasonic examination for suspected abruption after 22 weeks' gestation, umbilical artery resistance indices on Doppler were in the normal range in 79% of cases and direct visualization of abruption was only possible in 20%.¹²⁰

Glantz and Purnell¹²¹ found a sonographic detection rate of only 11% for abruption but, in general, abnormal ultrasound findings were predictive of a more adverse outcome. Abruption may appear as a sonolucent area of blood (Fig. 59.11) or as a more echogenic picture of an organized blood clot (Figs 59.12 and 59.13). Fetal mortality may be as high as 75% when a retroplacental hemorrhage of greater than 60mL is present.¹²²

Trauma

Fetal death occurring as a result of injury during pregnancy is often preceded by placental abruption.¹²³ Abruption was diagnosed in 6.8% of injured pregnant women and fetal death occurred in 3.4% of trauma victims.¹²⁴ However, the injury

Figure 59.11 Sonolucent, retroplacental portion of the placenta identified by the markers '+' and 'x', indicative of an area of abruption at least 2 weeks after the occurrence.

Figure 59.12 A large organizing hematoma in the placenta anteriorly at 29 weeks' gestation. The fetal head is in the lower right of the picture. Emergency Cesarean section was performed shortly after this picture was taken because of spontaneous fetal heart rate decelerations and a healthy fetus was delivered.

Figure 59.13 Placenta and 225 mL of retroplacental blood clot from the same case as in Fig. 59.11.

severity score in pregnant trauma victims is poorly predictive of placental abruption and fetal death. Even relatively minor injuries were associated with adverse pregnancy outcomes.¹²⁴ Traumatic abruption was more likely in car accidents occurring at speeds above 30 miles per hour.¹²⁵ The importance of

correct seatbelt restraints for pregnant women should be emphasized.^{126,127} Placental abruption following trauma may be asymptomatic and a high index of suspicion should be maintained;¹²⁸ it is recommended to carry out fetal monitoring for a minimum of 4 h.¹¹⁵

Key points

- 1 The most important cause of bleeding in the third trimester is placental abruption (with an incidence of approximately 0.6%), followed by placenta previa (with an incidence of 0.3%).
- 2 Major risk factors for placenta previa include: maternal age with an odds ratio (OR) of 9.1, prior Cesarean section (OR 2.7), multiparity (OR 2.3), and smoking (OR 1.6).
- 3 Transvaginal sonography (TVS) obviates the need for the “double-setup” examination and has become the “gold standard” for the diagnosis of placenta previa.
- 4 Vaginal delivery is possible when the distance from the placental edge to internal os is greater than 20 mm on TVS at any gestational age.
- 5 A Cesarean section is necessary when the placenta overlaps the internal os by any amount after approximately 35 weeks’ gestation.
- 6 A placental edge lying within 20 mm of the os but not overlapping requires individualized management but vaginal delivery is possible.
- 7 The risk of placenta previa in any pregnancy increases with the number of previous deliveries by Cesarean section.
- 8 In any pregnancy, the risk of placenta accreta in the presence of placenta previa increases dramatically with the number of previous deliveries by Cesarean section with a 25% risk for one Cesarean section and more than a 40% risk for two.
- 9 Prenatal diagnosis of placenta accreta by ultrasound or magnetic resonance imaging (MRI) may be beneficial in preparing for delivery.
- 10 Vasa previa is strongly associated with a low-lying placenta, and color Doppler with TVS now offers the possibility of prediction of vasa previa well before the onset of delivery.
- 11 Placental abruption is associated with a nearly nine-fold increase in the risk of stillbirth compared with pregnancies without abruption.
- 12 Major risk factors for placental abruption include: cocaine use (OR 3.9), chorioamnionitis (OR 2.6),

- chronic hypertension (OR 2.8), severe preeclampsia (OR 4.1), twins (OR 2.1), and smoking (OR 2).
- 13 Between 15% and 25% of placental abruption episodes could be prevented if women stopped smoking cigarettes during pregnancy.
 - 14 The majority of placental abruption occurs in women with no established risk factors.
 - 15 A high incidence of inherited thrombophilias, in particular Factor V Leiden, homocysteine, activated protein C resistance, and antiphospholipid antibodies are found in patients with abruption.
 - 16 In subsequent pregnancies, the risk of recurrence of placental abruption is observed to be 10–15% (i.e., 30-fold increase in risk).
 - 17 70% of all perinatal mortality occurred in infants who delivered more than 2 h from the time of diagnosis of abruption.
 - 18 Negative findings on ultrasound do not exclude the possibility of significant placental abruption.
 - 19 The injury severity score in pregnant trauma victims is poorly predictive of placental abruption and fetal death.
 - 20 Kleihauer–Betke test and Rhesus status should be checked as fetal–maternal hemorrhage is present in up to 30% of cases, particularly in traumatic abruption.

Normal and abnormal labor

Wayne R. Cohen

All approaches to the systematic assessment of labor are grounded in the concept that it is possible to evaluate the progress of labor by analyzing the relationships among cervical dilation, fetal descent, and elapsed hours in labor.¹⁻⁷ This kind of graphic analysis forms the basis for clinical decision-making in dysfunctional labor but it must be used in conjunction with other obstetric data. Thus, information about pelvic architecture, uterine contractility, fetal size, position, and attitude, and the state of fetal oxygenation must be integrated with labor curve data if the obstetrician is to make the most informed and appropriate clinical judgments.

To a large extent, intrapartum decision-making is a process of estimating *seriatim* the probability of a safe vaginal delivery as updated information is obtained during the course of labor. All of the clinical data used in reaching decisions about obstetric interventions (especially the use of oxytocin, conduction anesthesia, Cesarean section, and instrumental delivery) should be viewed from this perspective.

Normal cervical dilation

The relationship between cervical dilation and the time elapsed in labor is described by a sigmoid-shaped curve (Fig. 60.1).¹⁻³ Dilation is traditionally divided into a latent phase and an active phase. The latent phase extends from the onset of labor until the upward inflection in the curve and is associated with little incremental change in dilation. Enhancement in the rate of dilation begins at the onset of the active phase, during which most cervical dilation occurs. A gradual increase in dilation (the acceleration phase) initiates the active phase and leads, usually in about an hour, to a period of more rapid and linear dilation (the phase of maximum slope). During the terminal part of the active phase, the deceleration phase, dilation appears to slow. In fact, the cervix continues to open at a constant rate but, as it retracts around the head (which has begun to descend) to achieve complete dilation, its movement is directed cephalolaterally. This change cannot be appreciated

readily by examination with the fingers, because only radial changes in distance can be determined.

By convention, full cervical dilation is considered to be 10 cm. This is a clinically useful approximation; however, because the cervix does not generally dilate to more than the largest diameter of the object passing through it, full dilation for most term babies is somewhat less, whereas for exceptionally large babies it may be more. This issue is of particular importance when interpreting the labor curves of very premature fetuses whose head diameter may be considerably less than 10 cm; in these cases, the curve of dilation is necessarily foreshortened.

In general, the labors of multiparas are shorter than those of nulliparas, with a shorter latent phase and more rapid rates of dilation and descent in the active phase and second stage.³ Criteria for all multiparas are the same, irrespective of how many babies they have had.¹⁻³ Multiparas who have had all previous babies by Cesarean section should be judged by nulliparous criteria during labor.⁸

Latent phase

During the latent phase, the cervix is prepared for the more rapid dilation that will occur later.^{3,9,10} Physical changes take place that can be appreciated clinically; these constitute what has been referred to as ripening or maturation of the cervix and, in some patients (particularly nulliparas), occur largely or completely before the onset of labor. The duration of the latent phase is inversely proportional to the degree of prelabor cervical maturation. The palpable softening, effacement, and anterior rotation of the cervix in the pelvic axis that occur during the latent phase are prerequisites for entering active phase dilation.

Measurement of the duration of the latent phase requires knowledge of the time of onset of labor, which cannot always be determined with certainty. It is reasonable to use the time at which the patient began to perceive regular uterine contractions as an approximation. The latent phase tends to be shorter in multiparas than in nulliparas, a consequence, at

Figure 60.1 Composite of normal cervical dilation and fetal descent curves showing their interrelations and components. From Cohen WR, Friedman EA, eds. *Management of labor*. Rockville, MD: Aspen Publishers, 1983.

least in part, of the fact that multiparas tend to begin labor with more cervical dilation. For the same reason, the latent phase is often shorter in multiple gestations, hydramnios, or after removal of a cervical cerclage.

During the latent phase, the cervix dilates slowly (maximally 0.5 cm/h) or not at all. The shift to active phase often occurs at approximately 5 cm of cervical dilation,¹¹ but it can be misleading to identify this transition by the absolute degree of dilation. For example, the conversion from latent to active phase may occur at 3 cm of dilation, especially for patients who began labor with the cervix closed. The transition to active phase may not occur until about 6 or 7 cm of dilation in multiparas who began labor with the cervix dilated 4 or 5 cm.

Active phase

Except for the usually brief acceleration and deceleration periods, cervical dilation during the active phase is linear and much more rapid than in the latent phase. To determine normality, clinical assessment of labor requires measuring the speed at which the cervix dilates during the active phase. When two observations of cervical dilation have been made during this period of linear change, the slope of the dilation line can be calculated. Once established, this rate tends to be constant for each individual (i.e., if the labor is normal, dilation continues at the same rate until the deceleration phase is reached). Abnormalities of active phase are defined by deviations from this projected rate of dilation. These deviations can be readily identified if serial observations of cervical dilation and fetal station are plotted on square-ruled graph paper. Observation and calculation of slopes are relatively simple.¹ Paradigms exist in order to use the graphic system without the

need for calculations;⁴⁻⁶ some electronic medical records automate these calculations.

Full cervical dilation occurs when the cervix retracts to the widest diameter of the presenting part. Usually the cervix retracts symmetrically but sometimes a segment lingers, particularly anteriorly, in the presence of deflexed attitudes of the head. Full dilation should not be diagnosed until the entire cervix has retracted spontaneously to or beyond the widest diameter of the leading part of the fetus.

As indicated previously, during the phase of maximum slope of dilation, descent of the fetus normally begins; during the terminal period of dilation, descent of the fetus tends to accelerate as the widely dilated cervix retracts around the presenting part.

Normal fetal descent

As the cervix dilates in late active phase, resistance to fetal descent decreases and the force of uterine contractions, coupled after complete dilation with active maternal bearing-down efforts, begins the expulsion of the fetus. By the time of complete cervical dilation, descent has usually become linear and, during the second stage, normally proceeds in this way until the presenting part encounters the pelvic floor. The efficiency and normality of the descent mechanism can be judged from the rate of descent. If the relationship between fetal descent and elapsed time in labor is plotted graphically, it is apparent that descent also has a latent phase during which little in the way of descent occurs under most circumstances (Fig. 60.1). The degree of descent that has occurred before the onset of labor has prognostic importance for the probability of vaginal delivery. In fact, an unengaged head at the onset of

labor is associated with a considerably increased risk for Cesarean delivery.¹²

Considerable descent may sometimes occur during the latent phase. Multiparas often commence labor with the presenting part at a relatively high station, and appreciable descent takes place in the latent phase. Of utmost importance in this regard is that lack of fetal descent before active phase labor is not evidence of a labor aberration or of fetopelvic disproportion.

Uterine activity in labor

Initially, contractions are often mild and somewhat irregular; they become progressively more intense, frequent, and regular as the latent phase progresses. However, this is not always the case and a broad range of contraction patterns may be observed in the normal latent phase, including very intense and frequent contractions. It is usually impossible to identify the transition from latent phase to active phase labor solely on the basis of uterine activity.

During the active phase, contractions are generally more frequent and of greater amplitude and duration than in the latent phase. However, a large spectrum of contractile patterns exists during normal labor¹³ and there is no reliable or predictive means to identify dysfunctional dilation or descent by observing uterine activity. Consequently, the clinical identification of dysfunctional labor should be based primarily on aberrations in the graphic patterns of labor. This approach allows a continuous assessment of and provides an unequivocal language for communicating labor progress.¹⁴

Abnormal labor

Latent phase dysfunction

A prolonged latent phase (Figs 60.2 and 60.3; Table 60.1) is diagnosed when the latent phase exceeds 20 h in nulliparas or 14 h in multiparas.^{3,10,15} It is most likely to occur when labor

begins with the cervix minimally effaced and dilated. The latent phase is particularly susceptible to the inhibitory effects of narcotics and anesthetics, which may predispose to prolongation of this period of labor.

The diagnosis of a prolonged latent phase may lack precision because of the difficulty in ascertaining the exact time of labor onset. It is important to recognize that the latent phase may normally be quite long. A prolonged latent phase is not a predictor of active phase disorders, nor does it have a strong association with cephalopelvic disproportion. It may sometimes occur as a result of a contractile abnormality that could become apparent later. Ignorance about the normal course of the latent phase may lead to unnecessary Cesarean section under the erroneous assumption that continuous progress should be expected in all phases of labor or that very long labors are always abnormal.

Treatment of prolonged latent phase consists of maternal sedation or active efforts to stimulate uterine contractility (Fig. 60.3). Stimulation with oxytocin effectively converts a prolonged latent phase to an active phase in 85% of cases and this response generally occurs within 3 h. A similar proportion of patients respond favorably to narcotic sedation ("therapeutic rest"). After a dose of morphine sulfate, the patient

Figure 60.2 Schematic showing various disorders of dilation (broken lines) compared to a normal pattern of dilation (solid line). (A) prolonged latent phase; (B) protracted active phase; (C) arrest of dilation; (D) prolonged deceleration phase.

Table 60.1 Dysfunctional labor patterns.

Dysfunction	Nulliparas	Multiparas
<i>Disorders of dilation</i>		
Prolonged latent phase	> 20 h duration	> 14 h duration
Protracted active phase	Dilation at < 1.2 cm/h	Dilation at < 1.5 cm/h
Arrest of dilation	2 h without progress in active phase	2 h without progress in active phase
Prolonged deceleration phase	> 3 h duration	> 1 h duration
<i>Disorders of descent</i>		
Protracted descent	Descent at < 1 cm/h	Descent at < 2 cm/h
Arrest of descent	1 h without progress after active descent has begun	1 h without progress after active descent has begun
Failure of descent	No descent by deceleration phase or second stage onset	No descent by deceleration phase or second stage onset

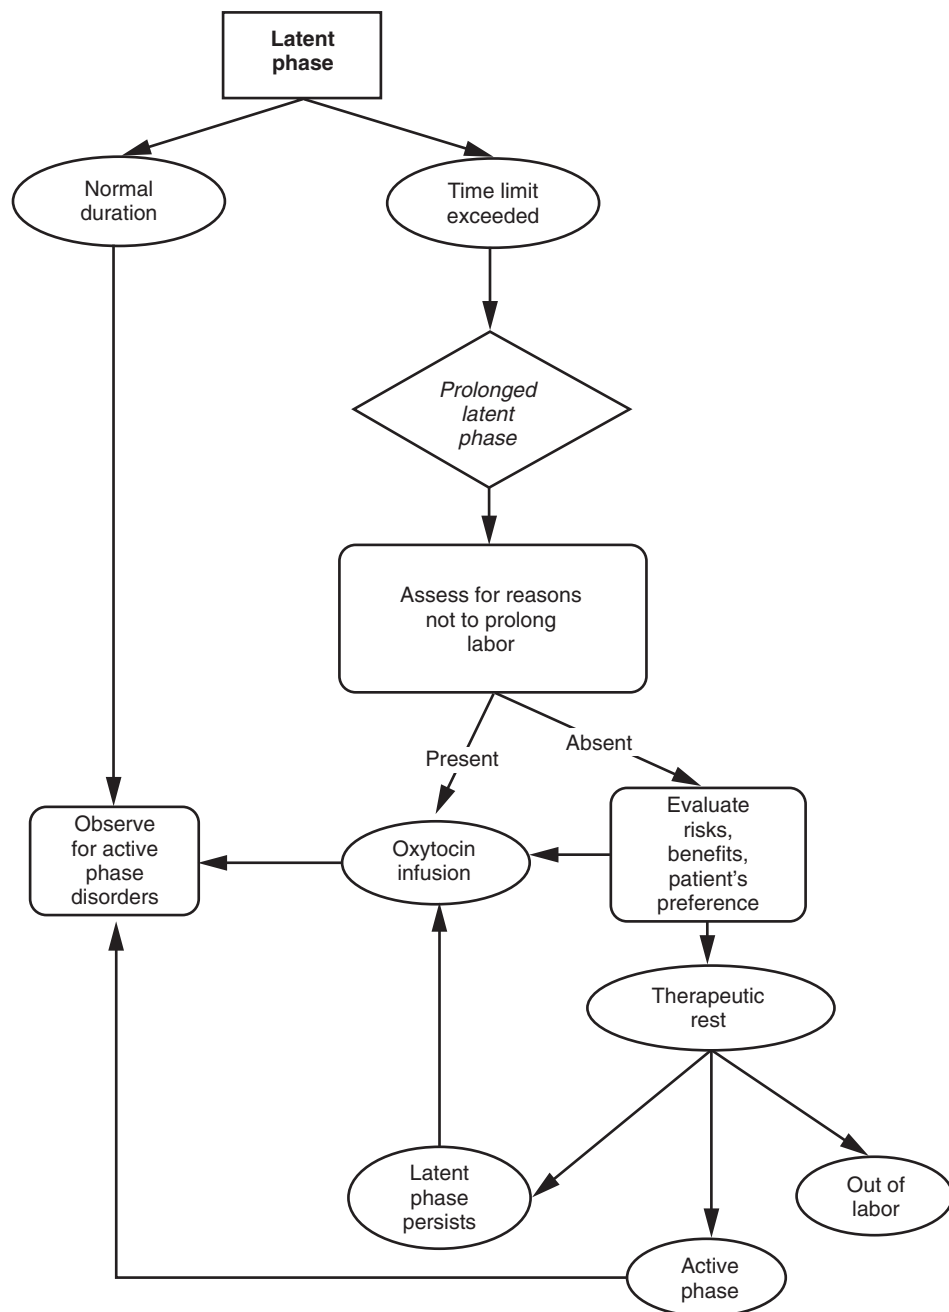

Figure 60.3 Paradigm for management of prolonged latent phase, diagnosed when the latent phase exceeds 20 h in a nullipara and 14 h in a multipara. Oxytocin stimulation and narcotic sedation are equally effective. Choice depends on the patient's preference and the presence of risks that would accrue if the labor were prolonged.

often sleeps for several hours and awakens in active phase labor. Having had a respite from many hours of painful contractions, she may be more eager and better prepared to cope with the physical and emotional demands of the active phase. Approximately 10% of women persist in a desultory latent phase after the effects of the narcotic have abated; in these cases oxytocin stimulation is still necessary. Another advantage of therapeutic rest is that it allows the identification of the approximately 5% of women diagnosed with prolonged latent phase who are in false labor;^{3,15} their contractions abate completely after narcotic treatment.

The choice between uterine stimulation and therapeutic rest depends on the clinical situation. There are concerns that fetal deoxygenation may occur after treatment with some narcotic drugs;^{16,17} however, no adverse outcomes have been reported after treatment of prolonged latent phase with narcotics, and the approach does not seem to be associated with an increased rate of neonatal depression. Active intervention with oxytocin should be used whenever a fetal or maternal condition exists that could be jeopardized by prolonging the labor, unless there is a clear contraindication to its administration. Similarly, when there is a reason to minimize the duration of labor, it is reasonable to intervene during the latent phase, even before the normal endpoint. The presence of prolonged rupture of membranes, preeclampsia, early intrauterine infection, or certain acute maternal illnesses favors an approach of active stimulation of labor. Finally, the mother's wishes should be taken into consideration; some women prefer oxytocin stimulation, whereas others prefer the interposition of some rest into the arduous and stressful experience of birth.

Active phase dysfunction

Two abnormalities of active phase dilation have been identified (Figs 60.2, 60.4, and 60.5; Table 60.1). A protracted active phase is diagnosed when cervical dilation progresses linearly after commencement of the active phase but at a rate below the established limits of normal.¹⁸ Arrest of dilation occurs when cervical dilation ceases for 2 h during the active phase¹⁹ (although this is the standard definition, there is evidence that even an hour of well-documented arrest may be of clinical importance and should prompt evaluation²⁰). The term prolonged deceleration phase may be used to describe protracted or arrested labor during the terminal period of cervical dilation.³ The time limits for the duration of the deceleration phase are 3 h in nulliparas and 1 h in multiparas. The obstetric conditions associated with protraction and arrest disorders are similar, but the therapeutic approaches differ (Figs 60.3 and 60.4). All active phase disorders commonly occur in association with cephalopelvic disproportion, malpositions (especially persistent occiput posterior or transverse), excessive sedation or anesthesia, chorioamnionitis, or deciduitis. Myometrial dysfunction, which may be primary or a consequence of the preceding factors, also contributes.

In the evaluation of any active phase dysfunction, a thor-

ough examination of the patient is necessary to identify any associated or predisposing conditions. Clinical cephalopelvimetry is useful in ascertaining the likelihood of disproportion. An experienced clinician can accurately evaluate the dynamic as well as the static aspects of fetopelvic fit. In addition to determining the architectural characteristics of the pelvis, this examination should confirm the fetal position and attitude, along with the degree of cranial bone molding and caput succedaneum formation. Use of the Müller–Hillis maneuver (vaginal examination during the peak of a contraction, in advanced cervical dilation, with gentle fundal pressure applied) provides a useful assessment of the degree of descent, rotational tendencies, and attitudinal changes that are likely to occur with subsequent contractions.²¹ If disproportion seems unlikely and fetal head position is normal, it is necessary to carry out an assessment of uterine contractility and search for infection and possible pharmacological inhibition of labor. The risk of dysfunctional active phase labor may be increased in older mothers²² but diagnosis and therapy should not be influenced by maternal age.

Available evidence suggests that when protraction disorders arise *de novo*, they are not amenable to correction by stimulating uterine contractions.³ If, however, the protraction disorder has resulted from some inhibitory influence, oxytocin may prove beneficial. For example, if the protraction disorder was provoked by conduction anesthesia or by other drugs that have the potential to inhibit contractility, oxytocin infusion may override these inhibitory influences and restore normal dilation. By contrast, a protraction disorder that has arisen in the absence of these inhibitory factors probably would not benefit from uterine stimulation, irrespective of the degree of contractility present.

Protraction disorders are sensitive to many inhibitory factors and may be exacerbated or even converted to arrest disorders under some circumstances, for example after an excessively large dose of analgesia or conduction anesthesia. Deliberate rupture of the fetal membranes (amniotomy) as a treatment for protraction disorders has not been proven to be beneficial, and it may sometimes worsen the situation by precipitating an arrest of dilation.^{3,23}

Arrest of dilation may evolve during a protracted or a previously normal active phase. This dysfunction requires the same kind of evaluation as for protraction disorders, with the understanding that an arrest of labor is more commonly associated (at least 40%) with cephalopelvic disproportion.^{3,19} Therapy also differs because arrest disorders may respond to oxytocin augmentation of uterine activity. In the presence of an arrest, cephalopelvic relationships must be evaluated carefully and a judgment made about the probability of disproportion. If the evidence for fetopelvic disproportion is considerable, especially if uterine activity is normal, it may be appropriate to deliver by Cesarean section. If the pelvis is deemed probably adequate, stimulation of uterine activity with close maternal and fetal surveillance is reasonable.

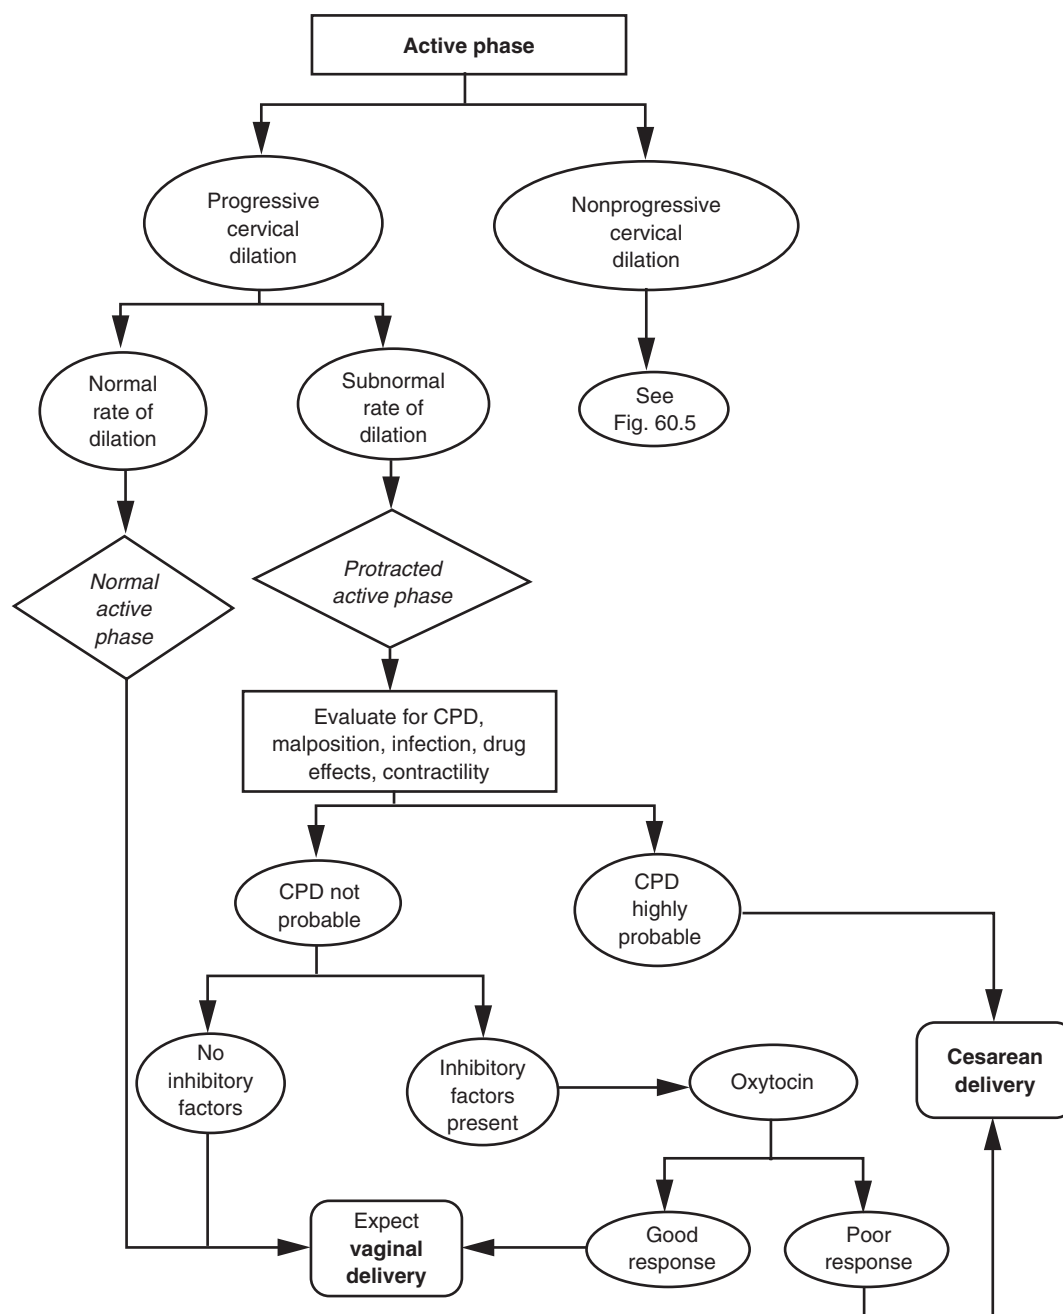

Figure 60.4 Paradigm for management of protracted active phase, diagnosed when dilation is progressive but occurs at < 1.2 cm/h in nulliparas and < 1.5 cm/h in multiparas. A good response to oxytocin is defined as one in which dilation is maintained at the same or improved rate. Oxytocin is useful in this disorder when the slow progress is related to the presence of factors that may inhibit contractility (e.g., infection, drug effects). CPD, cephalopelvic disproportion.

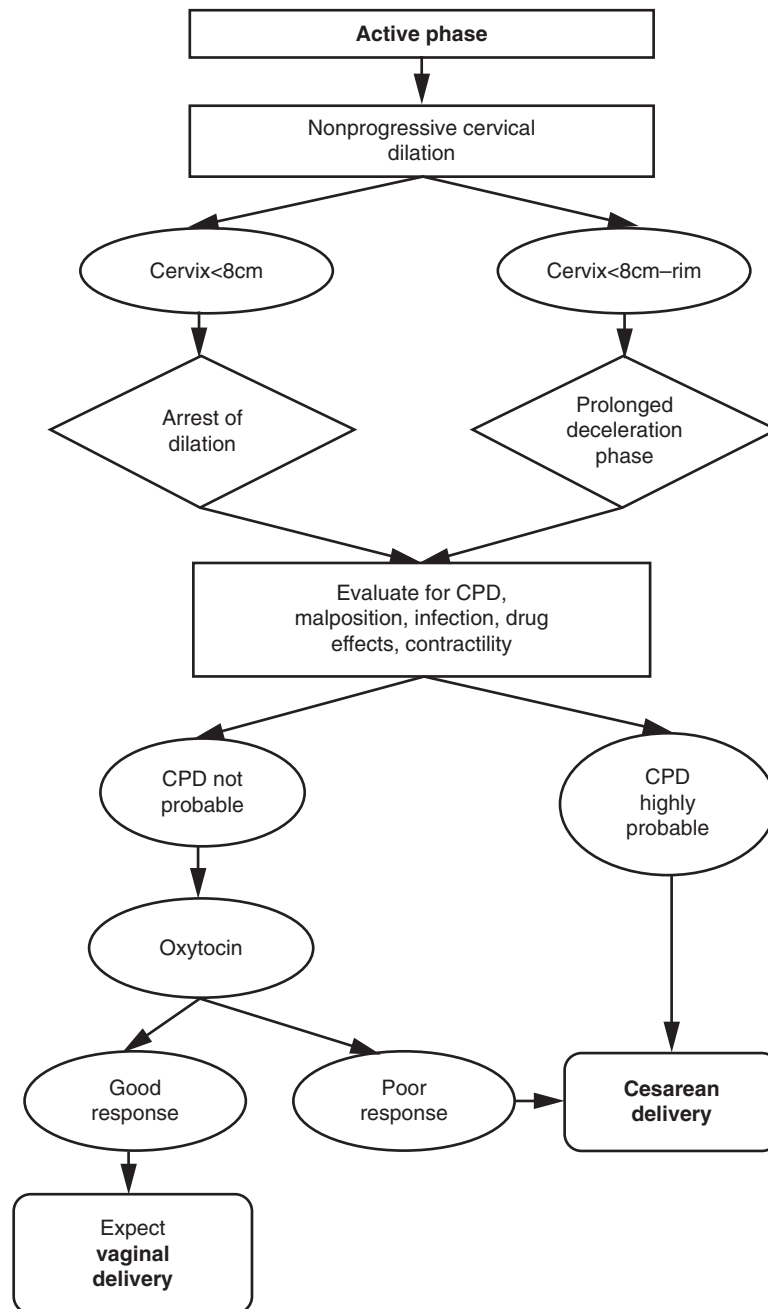

Figure 60.5 Paradigm for management of arrest of dilation, defined as an absence of progress in dilation for 2h once the active phase has begun. When progress is abnormally slow or ceases at the end of the active phase, prolonged deceleration phase is diagnosed (> 3h in nulliparas; > 1h in multiparas). There is a strong association with cephalopelvic disproportion (CPD). A good response to oxytocin is defined as a postarrest slope that is equal to or greater than the prearrest slope. A poor response usually requires Cesarean delivery.

Sometimes arrest disorders resolve without the need for oxytocin or operative intervention. This may occur spontaneously or as the result of an abatement of inhibitory factors. The use of maternal ambulation, warm baths, anxiolytic drugs, or psychoprophylactic techniques has advocates, but the efficacy of these techniques has not been proven.

There are three possible outcomes of oxytocin infusion for an arrest disorder: absence of any further change in dilation or descent, progress that is as good as or better than that before the arrest, or progress at a rate that is lower than the prearrest rate. About 85% of the patients who respond to oxytocin do so within 3 h of treatment.^{3,24} If there has been no return to the prearrest slope after this interval, delivery by Cesarean section is usually necessary.

If oxytocin results in cervical dilation that is at least as rapid as before the arrest, the likelihood of eventual vaginal delivery is high. If dilation resumes at a rate slower than before the arrest, it is likely that disproportion or an insurmountable problem with uterine contractility is present. The use of an intrauterine pressure catheter is often desirable to document the change in uterine activity in response to oxytocin and to warn when excessive stimulation is occurring. The goal of any treatment must be individualized but, in general, firm contractions (approximately 50 mmHg at peak intensity) that occur every 2–3 min indicate sufficient contractility. Quantitative measures of contractility, such as Montevideo units, are thought by some to be helpful in guiding oxytocin therapy, but the relationship between these assessments of contractility and the likelihood of a change in cervical dilation or fetal descent is not reliably predictable. Whatever approach to the assessment of contractility is used, it is important to remember that the use of oxytocin may increase the likelihood of fetal hypoxemia. Therefore, continuous fetal heart rate monitoring and close observation of uterine contractility are required when uterotonic drugs are used. It also appears that dysfunctional labor may precipitate abnormal fetal heart rate patterns.²⁵

The potential benefit of artificial rupture of membranes in labor is controversial. Although rupture of membranes can induce labor in many individuals, its influence on labor that is already established is less certain. Some studies have shown a modest shortening of active phase labor in response to rupture of membranes.^{23,26} Although amniotomy may increase uterine work,²⁷ a beneficial effect on dysfunctional labor has not been proven. Many clinicians believe that rupture of the membranes is effective in terminating arrest disorders but objective data have failed to verify this.²⁸ It is, nevertheless, reasonable to rupture membranes when an arrest disorder has been identified. The few patients who respond do so promptly; it is therefore generally inappropriate to wait longer than approximately 60 min to determine whether rupture of membranes has been successful in altering the pattern of labor progress.

When conduction anesthesia is employed, it should generally begin during the active phase of dilation. To have a

minimal effect on labor progress and provide pain relief when most required, an epidural anesthetic should be given during the acceleration phase of labor. When it is properly administered, it has little or no inhibitory effect on the progress of normal cervical dilation or fetal descent. Anesthesia is more likely to slow labor progress if administered during the latent phase or in the presence of a protraction or arrest disorder. This does not mean that conduction anesthesia is contraindicated in such circumstances; it may be beneficial for pain relief but it should also be recognized that it might prolong the latent phase or create an active phase abnormality requiring the administration of oxytocin.

Although there is evidence that the use of epidural analgesia is associated with an enhanced likelihood of Cesarean section, this has not been a universal finding.^{29,30} Epidural anesthetics do have the potential to prolong labor or even to induce abnormalities in dilation or descent but these effects depend to a large extent on the anesthetic technique. The type of drug used, the dose given, and the time and method of administration all determine the influence on labor. Furthermore, the outcome is determined largely by the clinical attitude of the obstetrician. For example, if the physician believes that the second stage of labor must always be terminated after 2 h, operative delivery would be more common in patients whose second stage is prolonged by epidural analgesia. However, a physician who understands that such prolongations are usually innocuous would not feel compelled to intervene. Therefore, epidural analgesia administered with a proper regard for the clinical situation will generally have no significant adverse impact on labor progress or mode of delivery.

The second stage of labor

The first stage of labor, which extends from the onset of labor to complete cervical dilation, serves to ready the parturient for expulsion of the fetus from the uterus. Having been prepared by the physical and biochemical changes that result in cervical ripening, uterine contractions produce rapid cervical dilation. The cervix retracts around the presenting part in order to dilate maximally and descent begins. Thus, during the second stage of labor (from complete dilation to delivery), the focus of interest changes from cervical dilation to descent of the fetus. The process of fetal expulsion is evaluated from the characteristics of the descent curve. The rate at which active descent occurs is influenced by several factors including: uterine contractile force; voluntary maternal expulsive efforts; fetal size, position, and attitude; deformability of the fetal head; pelvic architecture; and the characteristics of the pelvic floor.

Three descent disorders have been identified: protracted descent, arrest of descent, and failure of descent^{3,7,31,32} (Fig. 60.7; Table 60.1). All are associated with similar obstetric conditions and are, in many respects, analogous to the protraction and arrest disorders of dilation. Ascertainment of the

Figure 60.6 Schematic showing possible disorders of descent. (A) failure of descent; (B) protracted descent; (C) arrest of descent.

significance of descent abnormalities requires considerable clinical insight and experience because assessment must include determination of fetal position and attitude, molding, and the evolving mechanism of labor in relation to the patient's pelvic form. Identification of the station of the presenting part may be difficult if considerable scalp edema or molding of the head is present. Suprapubic palpation of the head, as well as vaginal examination, may be necessary to determine whether true descent of the head has occurred as opposed to molding with advancement to the leading edge but no descent of the biparietal diameter.

Thorough cephalopelvimetry and an evaluation for other associated obstetric problems are both necessary when descent disorders are diagnosed. Analogous to disorders of active phase dilation, the best evidence suggests that oxytocin stimulation of uterine activity is generally not beneficial in the presence of protracted descent, but an arrest or failure of descent may respond.

Cephalopelvimetry

Clinically astute obstetricians and midwives take pride in their knowledge of pelvic architecture and its influence on labor. Although radiographic pelvimetry is now used infrequently, accurate clinical pelvimetry is still required to make proper judgments about labor.

The knowledge of pelvic architecture and its relationship to labor should be used as a complementary technique to the analysis of labor curves. This approach makes it possible to explain the observed mechanism of labor, to judge the effects of labor on the fetal skull, and helps to make a reasonable and informed judgment concerning the advisability of uterine stimulation or operative intervention.

The value of an interpretation of cephalopelvic relationships and an evaluation of the labor curves cannot be overestimated as a means of providing a safe outcome of dysfunctional labor. For an optimal assessment of labor, both cephalopelvic rela-

tionships and labor curves must be considered together rather than individually. For example, a narrowed midpelvis with a molded head impinging on the inlet in the presence of a failure of descent makes the probability of safe vaginal delivery remote. Similarly, an arrest of descent with a posterior position in a midpelvis with prominent ischial spines (making internal rotation difficult) and a forward lower sacrum (resisting further descent without rotation) also suggests an insurmountable problem. The use of oxytocin would not be recommended in either case. If these disorders of labor occurred in the presence of a more favorable pelvic structure, spontaneous delivery would be more likely and uterine stimulation safer.

Duration

The question of whether the length of the second stage should be a consideration in the timing of delivery has been a persistent theme in obstetrics. Although some data appear to show a direct relationship between duration and morbidity, several lines of evidence suggest that it is not appropriate to terminate labor merely because an arbitrary period of time has passed in the second stage, as long as the labor progress and fetal heart rate patterns are normal.³³⁻³⁵ This does not imply that long second stages are always innocuous; they are more commonly associated with dysfunctional descent patterns that often require prompt evaluation and treatment. Decisions about management in the second stage must be based on a careful evaluation of the maternal and fetal condition and of the progress of descent.

The possible influence of epidural analgesia on the progress of descent during the second stage is of particular importance. Epidural anesthetics can potentially delay descent in three ways: by inhibiting perineal sensation and the mother's reflexive urge to bear down; by reducing uterine contractility; or by compromising motor function and reducing the effectiveness of the mother's voluntary pushing efforts. Any potential delay of descent will depend on several factors including the dose and nature of the anesthetic agent and the mode of administration. When the minimum effective dose of epidural anesthetic is used (with an appropriate consideration of the clinical situation), few significant inhibitory effects on labor should be anticipated except for a modest lengthening of the second stage in some cases. As long as fetal oxygenation remains adequate, there is no danger in allowing such prolongation.

Concerns about the long-term health of the pelvic floor have also led some obstetricians to minimize second stage duration. There is conflicting evidence as to whether there is a relationship between the length of the second stage and the likelihood of pelvic floor problems later in life.^{36,37} Alternatives to a long second stage instrumental vaginal delivery (or Cesarean section) confer other risks to the mother and fetus, and the optimal approach to prevent the development of pelvic floor problems later in life is yet unclear.

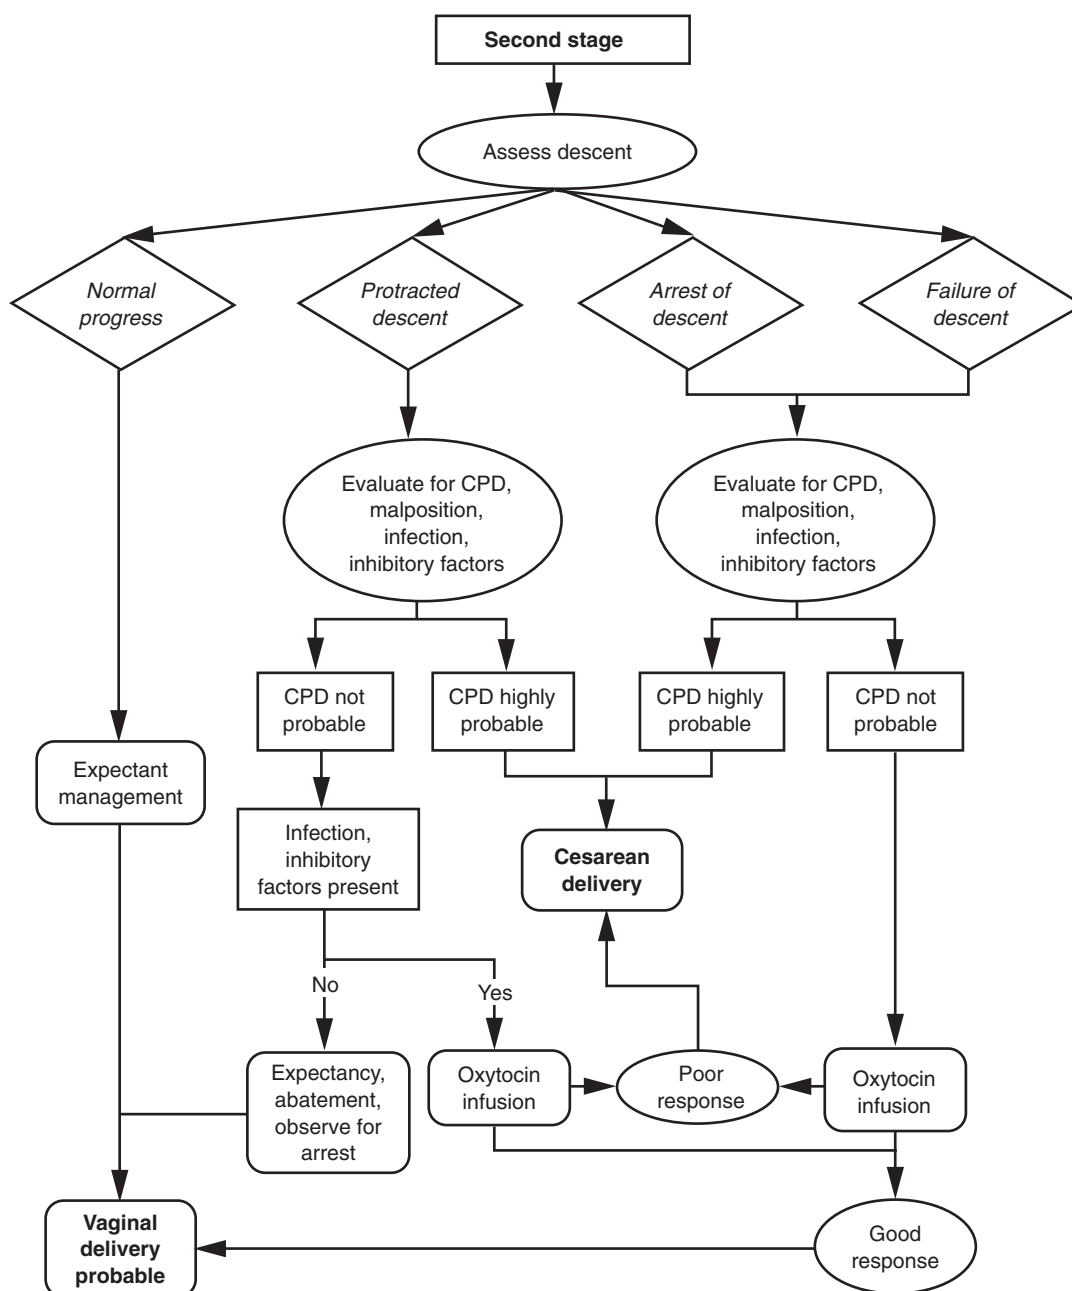

Figure 60.7 Paradigm for management of the second stage. Progress is assessed by the rate of descent rather than elapsed time. Fetal position, station, attitude, and molding should be determined at each examination. A good response to oxytocin given for arrest of descent is defined as a postarrest slope equal to or greater than the prearrest slope. CPD, cephalopelvic disproportion.

Conclusions

The disciplined approach to the management of labor advocated in this chapter emphasizes the need to use objective clinical information to optimize decision-making.³⁸ It is evident, nevertheless, that the process of assisting women with childbirth requires the practitioner to integrate such objective data with the spectrum of psychosocial features unique to each individual's labor. A woman's attitudes and expectations concerning pregnancy are conditioned by her social and cultural background and by her experiences during gestation. Consequently, no universal formula exists for the provision of emo-

tional support; rather, the practitioner must respond to the patient's needs, encouraging her to express her questions, fears, or concerns and discussing them in an honest and reassuring way.

The obstetrician cannot guarantee a good outcome for every childbirth but, through the application of the principles expressed in this chapter, can promise to seek the best outcome possible for the mother and fetus in the safest possible way. This should occur in the context of a birth experience that is emotionally enriching for the parturient and her family and that treats the laboring mother with the requisite gentleness, dignity, and compassion demanded by the process of giving birth.

Key points

- 1 A graphic analysis of dilation and descent is required to determine whether or not labor progress is normal.
- 2 Intrapartum decision-making is a process of continuously reassessing the probability of safe vaginal delivery.
- 3 Factors involved in estimating the feasibility of safe delivery include: the pattern of dilation and descent; uterine contractility; fetal size, position, and attitude; and the state of fetal oxygenation.
- 4 The first stage of labor includes the latent phase and the active phase.
- 5 The latent phase extends from labor onset to the beginning of the active phase, which is marked by an increase in the rate of cervical dilation.
- 6 The active phase ends with complete cervical dilation. This signals the start of the second stage of labor, which ends with delivery of the fetus.
- 7 In a normal labor, dilation will be linear through most of the active phase.
- 8 A prolonged latent phase is one that is longer than 20 h in a nullipara or 14 h in a multipara.
- 9 A prolonged latent phase is treated by stimulation with oxytocin or by maternal sedation.
- 10 A protracted active phase is one in which dilation is progressive and linear, but at a rate below normal.
- 11 A protracted descent is one in which active descent is progressive and linear, but at a rate below normal.
- 12 Protraction disorders do not respond to oxytocin except when they have been caused by some inhibitory factor such as anesthesia or infection.
- 13 A prolonged deceleration phase is one that is longer than 3 h in nulliparas and 1 h in multiparas.
- 14 Cephalopelvic disproportion, second stage disorders, and shoulder dystocia should be considered in cases of prolonged deceleration.
- 15 A failure of descent occurs when no descent is observed from early labor to the onset of the deceleration phase or the second stage. It is the labor disorder that has the strongest association with cephalopelvic disproportion.
- 16 The normality of dilation and descent cannot be ascertained from the pattern of uterine contractility.
- 17 All protraction and arrest disorders may be associated with cephalopelvic disproportion, malposition, intrauterine infection, excess analgesia or anesthesia, or deficient uterine contractility.
- 18 Most patients with arrest disorders who respond to oxytocin will do so within 3 h of treatment.
- 19 Artificial rupture of membranes can induce labor; however, it is not certain whether it can reliably enhance an established labor dysfunction.
- 20 Properly administered epidural anesthesia should have little effect on the course of labor except for some lengthening of the second stage.
- 21 It is not appropriate to terminate labor simply because an arbitrary period of time has elapsed in the second stage.
- 22 Upright or squatting postures may enhance descent in some labors.

Operative vaginal delivery

Edward R. Yeomans

Operative vaginal delivery (OVD) is an endangered species. In the animal kingdom, the label of “endangered species” implies that, unless special measures are adopted, extinction may result. Metaphorically, OVD may become extinct if current statistical trends continue unabated. Proper training in OVD techniques during residency is necessary but not sufficient. Those techniques, once learned, must be practiced to maintain this vitally important skill. The purpose of this chapter is to present the current status of both forceps delivery and vacuum extraction as options intermediate between spontaneous vaginal and Cesarean delivery. Recommendations regarding how to interdict the progression toward extinction of OVD will be made at the close of the chapter, but a return to the “halcyon days” (of even a decade ago) is unlikely.

History

It is instructive, in view of the above-stated purpose of examining the current status of OVD, to briefly review the past. The use of forceps dates back some 400+ years, whereas the use of the vacuum extractor (VE) began only in the 1950s (although James Young Simpson, after whom Simpson forceps are named, experimented with a VE device in the mid-1800s). A glance at the crude design (Fig. 61.1) of the original Chamberlen forceps can give the modern practitioner some perspective on the improvements introduced over four centuries. During the 1700s, Levret and Smellie contributed the pelvic curve, and Tarnier elucidated the principle of axis traction in the 1800s. Kielland, Barton, and Piper designed and “field tested” their special instruments in the 1900s. More subtle design changes such as the pseudofenestrated blades developed by Luikart¹ and the divergent forceps proposed and used by Laufe also occurred in the last century. In the mid-1950s, Malmstrom invented a practical VE device, which included rigid steel cups of various sizes. In 1973, Kobayashi introduced a soft-cup product made of silicone rubber. Subtle refinements in cup design and construction as well as vacuum-generating equipment took place over the next three decades. Importantly, the commercialization and marketing of VE

devices vastly exceeded anything that ever characterized the development of a new forceps. It is interesting to consider whether business interests affected the reversal of the ratio of forceps to vacuum operations between 1980 and 2000, or whether this was based solely on scientific or clinical grounds. In 1980, the rates of forceps to VE procedures in the United States was 18 to 1.² By 1990, it was 3 to 2 and, in 2000, it was 1 to 2, and will likely swing further to the VE side. In 1952, more than half of all the babies in the United States were delivered by forceps. By 2002, that proportion had fallen to 2.3%! In fact, even combining forceps and VE accounted for only 5.9% of all deliveries in 2002,³ and it is this datum that prompted the “endangered species” analogy. The steady, even precipitous, decline in OVD paralleled an unprecedented increase in Cesarean deliveries worldwide, but especially in the United States. However, it is naïve to attribute the former to the latter without examining the problem more closely.

In the first half of the twentieth century, Cesarean delivery was dangerous for mothers. Refinements in blood banking, anesthesia, antibiotic availability, and hospital-based childbirth all made possible a 1950 report⁴ of 1000 consecutive Cesarean deliveries without a maternal death. By 1980,⁵ that number had grown to 10 000 consecutive Cesareans with no maternal mortality. The focus of care shifted from maternal outcome to perinatal outcome, and difficult instrumental vaginal deliveries came under scrutiny. Even by 1950, Cesarean delivery was an option that only minimally increased maternal risk, but reduced the neonatal risk associated with difficult vaginal delivery. In the 1970s and 1980s, the Cesarean rate escalated by far more than could be accounted for by the small number of difficult vaginal deliveries. The threat of litigation began to influence capable, well-trained practitioners to consider their own risk in addition to those of mother and baby in choosing a route of delivery when it appeared that spontaneous delivery was not an option. Studies conducted in the last 10–15 years called attention to pelvic floor damage with OVD,⁶ to risk associated with vaginal breech delivery⁷ and vaginal birth after Cesarean section (VBAC),⁸ and to infant birth trauma associated with OVD.⁹ The contribution of other factors, such as regional anesthesia and the presence

Figure 61.1 Chamberlen forceps.

of family members in the delivery room, to the declining frequency of OVD is difficult to evaluate. Pediatricians and neonatologists focus on only one of the two patients whose interests must be considered in selecting the route of delivery, so they may favor Cesarean delivery to improve the outcome for the neonate. More recently, women themselves have requested elective repeat and even elective primary Cesarean delivery. All of these factors, and more that have not been cited, account for the shrinking percentage of OVD performed in 2005. Are these few procedures sufficient to train residents, and later to maintain proficiency?

Training

The written word (this chapter, for example) can impact on an operator’s skill to only a limited degree. In the foreword to his renowned textbook on forceps,¹⁰ Dr Edward Dennen advised that the trainee be given a series of “painstaking lectures” on the subject of forceps delivery, then “drilled extensively” on the manikin. Then the intern is allowed to do an easy case under direct supervision. After that, the volume of work would increase according to the individual’s ability and interest. In Dennen’s practice lifetime, the “volume of work” was enormous. He reported on over 13 000 forceps deliveries. The problem now is obvious: there is no volume of work. Residents in training perform few procedures. Then, when they graduate, most perform even fewer. The median number of OVD procedures in 1 year reported by candidates preparing to take their oral board examination was five!¹¹

Some opinion leaders in the field of obstetrics and gynecology¹² have written that elective forceps is no longer considered to be an indication. Others defend the practice, some when conditions for outlet forceps are met, others who sanction elective low forceps as well. This author strongly supports the performance of elective outlet forceps both in residency training and after graduation, to acquire and maintain proficiency, respectively.

Table 61.1 1988 American College of Obstetricians and Gynecologists’ classification of forceps and vacuum.

<i>Outlet forceps</i>	
Scalp is visible at introitus without separating labia	
Fetal skull has reached pelvic floor	
Sagittal suture is in anteroposterior diameter or right or left occiput anterior or posterior position	
Fetal head is at or on perineum	
Rotation does not exceed 45°	
<i>Low forceps</i>	
Leading point of fetal skull is at station ≥ +2 cm* and not on the pelvic floor	
Rotation of ≤ 45° (left or right occiput anterior to occiput anterior, or left or right occiput posterior to occiput posterior)	
Rotation of > 45°	
<i>Midforceps</i>	
Station above + 2 cm but head engaged	
<i>High forceps</i>	
Not included in classification	

*Station is measured in cm from the ischial spines to the perineum (0 to +5 cm).

Support for this procedure is predicated on adherence to the definitions outlined in Table 61.1.

It has been said that “experience is not a substitute for training; it serves only to increase confidence, not skill.”¹³ This is a thought-provoking criticism of an accreditation system that places undue emphasis on numbers of procedures of whatever type rather than the quality of training in that procedure. Admittedly, the latter is harder to evaluate.

A regimental approach to training is advocated by the author, following the recommendation of the senior Dr Dennen: lectures (e.g., those outlined in Table 61.2), manikin practice, followed by graduated degree of difficulty progressing from easy outlet forceps, then to low forceps without rota-

tion; from there, to low forceps with 45–90° rotation and, finally, to low forceps with 90–180° rotation and carefully selected midforceps procedures. Augmenting this training approach is instruction in the use of forceps at Cesarean delivery for fetuses in cephalic or breech presentation and the routine use of Piper forceps to the aftercoming head at vaginal breech delivery. Some clinicians believe that experience with both forceps and VE should be provided to residents and, if clinical volume is adequate, such an approach has merit. At the University of Texas-Houston LBJ Hospital residency program, experience with forceps is disproportionately emphasized. This stems from the author's firm belief that a graduate proficient in the use of forceps can readily master the technique of VE with only a few cases, whereas the reverse is not achievable.

Case selection and choice of instrument

These two areas are closely related, and they require a working knowledge of both the art and the science of OVD. Indications and prerequisites are readily tabulated (Tables 61.3 and 61.4), but the art demands more than running through a “pilot's checklist.”¹⁴ The course of labor, maternal and fetal status, adequacy of anesthesia, exact diagnosis of the position of the fetal head (including attitude, caput, molding, asynclitism, and station of the presenting part) and, of great importance, the maternal pelvic architecture must all be assessed and integrated to arrive at a decision to attempt OVD. It is highly recommended to document this assessment, especially the clinical pelvimetry, in the maternal medical record prior to embarking on the procedure, if time permits.¹⁵ As part of the

Table 61.4 Prerequisites for forceps application.

-
- Experienced operator in attendance
 - Engagement of the fetal head
 - Knowledge of the position of the fetal head
 - Completely dilated cervix
 - Clinically adequate pelvis
 - Adequate anesthesia
-

OVD training at the author's institution, the position of the fetal head is ascertained at every vaginal examination from 6 cm right up to the time of application of an instrument or, more commonly, just prior to spontaneous delivery of the head. Moreover, clinical pelvimetry is recorded for the majority of laboring women, but especially for those diagnosed with a labor abnormality or candidates for OVD. Dr Dennen referred to this as “constant alertness;” without it, inaccurate assessments are made and the risk of injury to either patient increases.

The art of clinical pelvimetry is vanishing from modern training programs. In all but a small percentage of cases, the inability to deliver spontaneously is followed by immediate resort to Cesarean delivery without considering an attempt at OVD. Pursuing such a course perforce renders clinical pelvimetry meaningless. In his article¹⁶ entitled “Midforceps delivery: a vanishing art” (parenthetically, if it was vanishing in 1963, it is of historical interest only in many programs today), Danforth meticulously describes the characteristics of the four pelvic types of Caldwell and Moloy, not only at the inlet but at all levels traversed by the presenting part. This article is strongly recommended for required reading in a modern OVD training program.

From the foregoing discussion, case selection can be a daunting task, literally requiring years of practice. It would be naïve to think, given the complexity of the case selection process, that a single instrument could be chosen for all clinical problems. In the randomized clinical trials comparing forceps with VE, the student of OVD is led to believe that there are only two choices. However, there are 5–10 commonly used forceps from which to select. Vacuum proponents can select from a number of different cup designs, tailored in some cases to the position of the fetal head. The choice of an instrument for OVD is different for the trainee than for the experienced operator. If the trainee is exposed to one or only a few instruments during residency, he or she is likely to rely on that instrument even when better choices are available. Trainees should be encouraged to make the instrument fit the clinical situation, not vice versa. Table 61.5 contains some elementary guidance with respect to choosing an instrument. Only after residency is it reasonable to allow experience or “comfort” to be a major factor in instrument selection. In addition to Table 61.5, the following clinical case scenario is included to illustrate the combined tasks of case selection and choice of instrument.

Table 61.5 Selection of instrument.

Outlet or low, parous woman, no molding – Tucker–McLane
Outlet or low, nullipara, molding – Simpson, Simpson–Luikart
Low or mid with asynclitism – Luikart
Low with rotation – Kielland, Barton
Aftercoming head – Piper, Laufe, Kielland
Face – Simpson, Kielland

A primigravid woman at 41 weeks' gestation is admitted to labor and delivery with a diagnosis of premature rupture of membranes at term. Oxytocin induction is begun. The active phase of labor is protracted and, after 2 h of the second stage, the fetal head is at +2 station, 60° LOA, with moderate asynclitism. Caput is present over the anterior parietal bone, but molding is insignificant. Clinical pelvimetry confirms a gynecoid pelvis with blunt ischial spines and a hollow sacrum. The estimated fetal weight is 3600 g and fetal heart tones are reassuring. After counseling, the woman states that she would like to avoid a Cesarean delivery if possible (yes, women still do say this). Her pain relief is satisfactory with an effective epidural anesthetic. She is fatigued from 2 h of voluntary expulsive effort that began immediately after complete dilation was diagnosed. Is this case appropriate for OVD? The woman is unlikely to achieve spontaneous delivery secondary to fatigue. She would like to avoid Cesarean section. Factors such as asynclitism and epidural are amenable to operative correction. A VE would be likely to fail because of the difficulty of obtaining proper cup placement and a resulting tendency to pop off. Luikart forceps represent an ideal choice. The pseudofenestrated blades are unlikely to leave forceps marks on the fetal face. The sliding lock permits correction of asynclitism. The overlapping shanks do not distend the perineum the way that parallel shanks would. The bar built into the handle of the left branch prevents undue compression of the fetal head. All these advantages were cited by Luikart in his 1940 article.¹⁷ Interestingly, several major birthing centers in the city of Houston do not even have Luikart forceps in their armamentarium!

It should be obvious that case selection and choice of instrument require sound clinical judgment and broad experience. Even under favorable circumstances, all these intricacies only set the stage for the most critical step: proper execution of the delivery.

Technique – forceps

This section can only serve as a springboard to provide both the resident and the young practitioner with the impetus to read more and practice more in an effort to develop and refine their clinical skills. Procedure-specific textbooks are available to enrich the knowledge of proper technique but, analogous to hitting a golf ball or playing the piano, there is no substitute for practice. A few pointers are suggested to guide the

beginner through narrow straits (pun intended) that have been encountered by all who claim to be experienced in OVD. To intrigue the reader with more than a modicum of experience, some of these points are not available in other sources.

As noted in a now superseded ACOG Technical Bulletin on OVD,¹⁸ the ART of forceps is an acronym that stands for application, rotation, and traction. Of these, application is the most important, for inability to apply the forceps effectively sabotages the whole procedure. A decidedly worse circumstance is to place the forceps inaccurately and fail to recognize the error prior to either rotation or traction. Three of the previously referenced “pointers” pertain to application:

1 For a head that is at 60° LOA, as in the example, the posterior, in this case left, blade should be applied first. The fingers of the protecting (right) hand should extend beyond the toe of the blade and should assist in maintaining the cephalic curve of the blade in contact with the contour of the fetal skull. Once the blade has been inserted to the appropriate depth, pressure with the index and middle fingers of the right hand on top of the blade should direct it to a position slightly inferior to the posterior (left) lambdoid suture. This is the easy blade to place! The anterior (right) blade should be held obliquely, not vertically, with the handle in the right hand extending toward the left groin of the woman. The handle should then be lowered in contact with the woman's left thigh as the thumb of the left hand advances the heel of the blade into the pelvis. Almost immediately, the right cephalic prominence of the fetal head will be encountered and this structure (not really a structure but a feature of the fetal frontal bone) will cause difficulty in rotating the blade into the anterior, right upper quadrant of the pelvis where it needs to be. The secret is to press the handle laterally and inferiorly with the right hand, thereby bringing the blade away from the forehead of the baby. Simultaneously, the index and middle fingers of the left hand positioned under the right blade should lift it into its final position just below the anterior (right) lambdoid suture. Prior to checking the application, asynclitism (if present) should be corrected using a sliding lock, a key feature of Luikart and Kielland forceps.

2 The three standard checks proposed by Dennen presuppose the use of a fenestrated blade in order to check depth of application. No more than one fingerbreadth should be able to be inserted into the posterior aspect of the fenestra (window) of the blade. This check cannot be performed with either a solid blade or a pseudofenestrated blade. Therefore, gauging depth of insertion requires assessment of the distance between the upper border of the heel of the blade and the bony head. This distance should be < 2 cm. The other two checks should be made as recommended by Dennen: the sagittal suture should bisect the plane of the shanks, and the posterior fontanelle should be one fingerbreadth above (anterior to) the plane of the shanks.

3 Not mentioned by Dennen, but readily accessible to the operator, is the relationship of the upper aspect of each blade to the lambdoid sutures. The lambdoid suture on each side should be palpable above the upper aspect of the blade for occiput ante-

rior positions. Furthermore, the distance from the upper aspect of the blade to the lambdoid sutures should be equal and symmetric. When either lambdoid suture cannot be palpated separately from the top of the blade, the possibility of an undesirable, brow–mastoid application should be considered. Traction should not be initiated until the application is corrected.

Once a proper application has been achieved, checked, and determined to be correct, rotation to the anterior (OA) can be undertaken. For conventional forceps with a pelvic curve, the handles should transcribe a wide arc, while the toes of the blades (out of view of the operator) transcribe a narrow arc. Two pointers are relevant:

- 1 The handles should not occupy the midsagittal plane prior to attempting rotation. Instead they should point to the maternal leg on the same side as the fetal occiput.
- 2 Rotation of the handles in a wide arc can be accomplished with one hand. The fingers of the other hand should be placed in the lambdoid suture adjacent to the posterior aspect of the anterior lambdoid suture to assist with and monitor the rotation.

Last but not least is traction. Modern forceps have no strain gauge attached to them, and the size and strength of modern operators vary substantially. Force can be wasted against the posterior aspect of the pubic bone, or force may be directed too far posteriorly for too long, thus putting the external anal sphincter at risk of tearing. Two very important pointers apply to traction on the forceps:

- 1 Every operator, regardless of experience, should use a Bill's axis traction handle on at least a few occasions to gain an appreciation of how descent of the fetal head affects the direction of traction. This principle is illustrated diagrammatically in the 1994 ACOG Technical Bulletin.¹⁸
- 2 The control of the delivery once the occiput is under the symphysis is the responsibility of the operator. Raising the handles too high risks vaginal sulcus as well as periurethral lacerations. Failure to raise the handles enough puts the anal sphincter at risk. Forceps add 8% to the volume of the fetal head passing through the introitus. Once the fingers of the dominant hand have secured the chin of the fetus through the maternal soft tissue, the forceps should be removed, ideally in the opposite order to the way they were placed, before completing the delivery of the head. An episiotomy of appropriate size and type can aid in decreasing traction force and protecting maternal anatomy. Maternal morbidity such as deep perineal lacerations (third- and fourth-degree extensions) can be significantly diminished by the skill of the operator. Some reports attribute morbidity to the instrument and neglect the fact that the instrument may not have been used properly to effect delivery.

Technique – vacuum extraction

Just as with forceps, proper technique with the VE can minimize maternal and neonatal morbidity. Proper cup placement over

the vertex of the fetal skull, symmetrically covering the skull both side-to-side and anteriorly to posteriorly, is a critical aspect of VE. Asymmetric cup placement may inappropriately extend the head and present a larger diameter to the maternal pelvis, thereby leading to detachment of the cup and possibly failure of the procedure. Most series in the literature report a higher failure rate for VE than for forceps delivery. Imparting torque to the cup, even the soft cup, should be avoided. Excluding maternal soft tissue from the suction cup is essential. Traction perpendicular to the plane of the biparietal diameter (BPD) of the fetal head requires practice. Total duration of the extraction as well as number of pop-offs should be monitored carefully. Traction should be intermittent, as with forceps, and coordinated with the woman's voluntary expulsive effort. Most importantly, traction should be associated with visible progress in descent of the fetal head. Despite its increasing popularity, there is the potential for serious neonatal morbidity with the use of the VE. Some of this serious morbidity is related to poor technique, and other morbidity is related to reluctance on the part of the operator to abandon the procedure when problems are encountered. The very serious subaponeurotic hemorrhage will be considered later in the chapter.

Maternal and perinatal outcome for OVD

At present, both forceps and vacuum extractors are acceptable and safe instruments for OVD.¹⁹ Better quality evidence than currently exists is needed to determine the proper place for OVD in the future. For example, there are no randomized controlled trials (RCTs) of OVD with Cesarean delivery, the logical comparison group. In contrast, there are RCTs for vacuum versus forceps, but these trials are hampered by small sample size, by the incorrect assumption that there are only two instruments being compared (vacuum and forceps, but not which vacuum or which forceps), and by the unprovable notion that operators have equal skill and experience with both instruments. There are also some studies classified as level II evidence that will be reviewed. Regrettably, much of the literature on OVD is consigned to level III evidence, and much of that is limited by small sample size. Analyses of large databases also suffer from potentially serious limitations: the reliability of the data collection, the omission in the database of an important datum such as indication for OVD, and the span of time covered by the database, which could obscure important changes in practice.

There are several additional considerations in examining outcomes of OVD:

- 1 What are the important outcomes?
- 2 What is the appropriate comparison group?
- 3 When was the study done? Does it reflect current practice?
- 4 Where was the study conducted? In a country with a comparable threat of litigations? In an institution where most OVDs are performed by residents?

Table 61.6 Maternal and neonatal morbidity from OVD.

Maternal	Neonatal	
<i>Short term</i>	<i>Short term</i>	
Deep perineal lacerations (third and fourth degree)	Low Apgar score	Skull fracture
Vaginal lacerations	Acidosis	Ocular injury
Cervical lacerations	Facial nerve palsy	Scalp trauma
Urinary retention	Brachial plexus palsy	Jaundice
Vulvovaginal hematomas	Intracranial hemorrhage	Cephalohematoma
Symphyseal separation	Subgaleal hemorrhage	Cervical spine injury
Lumbosacral plexopathies		
<i>Long term</i>	<i>Long term</i>	
Damage to pelvic floor resulting in:	Intellectual handicap	
Urinary incontinence	Cerebral palsy	
Fecal incontinence	Other permanent neurologic handicap	
Pelvic prolapse		
Cystocele		
Rectocele		
Enterocoele		
Uterine prolapse		

Note: Cesarean delivery is also associated with significant maternal and neonatal morbidity.

Clearly, there are more questions than answers, but it is still necessary to examine and critique what evidence exists. One significant restriction is imposed on this literature review: only studies reported after the 1988 ACOG classification of forceps deliveries was adopted will be considered.

Table 61.6 contains the maternal and neonatal outcomes most commonly cited as morbidity in reports on OVD. The frequency of the complications listed in the table is highly variable among reported studies, and also variable according to the method of delivery, forceps versus vacuum. Moreover, the morbidity is not only attributable to the instrument but also to the skill of the operator, maternal and fetal characteristics, and indication for delivery. Some generalizations reported in the literature regarding the morbidity of forceps and VE procedures fail to account for skill, degree of difficulty, and severity of the injury. Selected examples from recent publications serve to illustrate these points.

Maternal morbidity

A systematic review of 10 randomized trials of forceps versus vacuum concluded that VE is associated with less maternal trauma than forceps.²⁰ The largest single trial²¹ in that review confirmed that maternal injuries were more common with forceps. However, in that study, all deliveries were performed by residents supervised by maternal–fetal medicine fellows. Nineteen cases assigned to the forceps group were abandoned because of poor forceps application. Whether injuries that occurred should be attributed to the instrument or to operator skill is unclear.

In a retrospective study,²² Damron and Capeless reported

that third- and fourth-degree lacerations occurred more often with forceps (54%) than with VE (27%). In contrast, de Parades et al.²³ noted anal sphincter injury in less than 13% of forceps deliveries, but did not compare their results with VE procedures. In the latter report, all deliveries were performed by trained obstetricians. Operator skill likely contributes more to the outcome than the instrument used.

A small RCT by Fitzpatrick and colleagues²⁴ found that “altered fecal continence” was more common in the forceps group at a follow-up visit 3 months postpartum. Conversely, at 5-year follow-up, Johanson et al.²⁵ found no significant differences in either bowel or urinary dysfunction between women delivered by forceps or those delivered by VE. Thus, length of follow-up also affects the frequency of maternal morbidity. If maternal morbidity was consistently worse for forceps, which some of the above-mentioned reports refute, one would still have to weigh the neonatal morbidity prior to recommending “the instrument of first choice.”

Neonatal morbidity

A large database analysis by Towner and colleagues⁹ confirmed that the frequency of neonatal intracranial hemorrhage is nearly the same for VE as for forceps. However, most cases of subgaleal hemorrhage reported have been associated with VE. As opposed to maternal perineal trauma, subgaleal bleeding is a potentially life-threatening complication in the infant. Cephalohematomas do not cross suture lines because they are limited by the periosteum of individual cranial bones. Subgaleal bleeds involve the subaponeurotic layer of the scalp, can expand in all directions, and can even extend downward into

the neck. This space can accommodate almost the entire circulating blood volume of the infant. Most concerning is the fact that subgaleal hemorrhage can complicate VE deliveries that are described as easy with no pop-offs and involving no prolonged traction.

Shoulder dystocia is associated with brachial plexus injury. Several studies show that shoulder dystocia occurs more frequently after VE than after forceps deliveries. Once again, the explanation for this observation may not lie with the instrument itself, but rather with such variables as indication for use, starting station, or inability to successfully apply forceps.

Clearly, the selection of an instrument for OVD is more complex than balancing maternal and neonatal morbidity. The clinical situation and the training and experience of the operator should be the primary determinants of choice of instrument. Nevertheless, studies that compare the results of forceps with VE deliveries are valuable, and further investigation is needed.

OVD versus Cesarean delivery

In the author's opinion, a more important question is the comparison of OVD with Cesarean delivery. As noted previously, there has never been an RCT conducted to resolve this dilemma. The most frequent indication for OVD in the past was elective or prophylactic vaginal delivery. Now, with OVD numbers dwindling substantially, most are indicated, not elective. Drife²⁶ raised the concern that indicated OVDs are not all difficult and, further, that many easy deliveries were enrolled in clinical trials.

Only two investigations have attempted to compare difficult vaginal delivery with Cesarean delivery. The first, by Bashore et al.,²⁷ compared 358 forceps deliveries with 486 Cesarean deliveries for similar indications. Maternal febrile morbidity occurred in 25% of the Cesarean group, compared

with 4% in the forceps group, and women undergoing Cesarean were transfused more frequently. All infants in the forceps group were occiput transverse or occiput posterior at the start of the procedure and, except for two, were at +2 to +3 station (on a 5-cm scale). Thus, most were low forceps according to the ACOG classification, and easy outlet forceps were completely excluded. A more recent attempt to define "difficult" forceps is the study by Murphy and colleagues²⁸ from the UK. All women in both the vaginal and the Cesarean delivery groups were completely dilated. The study design was retrospective. Only those women whose deliveries took place "in theater" (in the operating room) were included. Thus, difficulty was not defined specifically by either station or rotation. Women in the Cesarean group ($n = 209$) experienced major hemorrhage more often than those in the OVD group ($n = 184$); within the OVD group were 58 forceps, 67 VE, and 59 combined forceps and VE deliveries. Overall neonatal morbidity was low.

Conclusions

In the introduction to this chapter, it was stated that recommendations would be made to preserve the performance of indicated OVD and prevent what clearly appears to be a pathway toward extinction. Elective instrumental delivery should continue to be offered to women who meet the requirements. This experience should be supplemented in training programs by instruction from the podium and on manikins. The graduate obstetrician should insure that hard-earned skills do not diminish over time; therefore, he or she should continue to perform both indicated and elective procedures and monitor the results. Only through training and practice can we confidently offer our patients an option intermittent between spontaneous vaginal delivery and Cesarean section.

Key points

- 1 The frequency of operative vaginal delivery has declined steadily over the last 40 years.
- 2 The use of elective outlet forceps is still justifiable today.
- 3 It is advisable to write a preoperative note that includes pelvic examination findings before performing operative vaginal delivery.
- 4 Luikart forceps are an appropriate choice to correct asynclitism.
- 5 One important prerequisite for forceps application is an exact knowledge of the fetal position.
- 6 The most important check to confirm proper forceps application is to ascertain that the sagittal suture bisects the plane of the shanks.
- 7 Use of a Bill's axis traction device is recommended for the new operator to appreciate the direction of traction.
- 8 Forceps should be removed prior to delivery of the fetal head.
- 9 The critical principle in vacuum extraction is proper cup placement.

- 10 The frequency of neonatal intracranial hemorrhage is approximately the same for both vacuum and forceps.
- 11 At 5-year follow-up, there were no significant differences in either fecal or urinary incontinence for women delivered by forceps compared with those delivered by vacuum.
- 12 Randomized trials of forceps versus vacuum did not demonstrate conclusively which should be the "instrument of first choice."
- 13 The most important variables in classifying forceps or vacuum deliveries are station and rotation.
- 14 The primary function of Kielland forceps is rotation.
- 15 Vacuum extraction is associated with a much greater risk of subgaleal bleeding than forceps.
- 16 Twice as many vacuum procedures are performed in the United States compared with forceps deliveries.
- 17 One of the hazards of OVD is damage to the pelvic floor.
- 18 Selective use of episiotomy rather than routine use is advocated for operative vaginal delivery.
- 19 Candidates for the oral board examination report minimal (< five procedures/year) experience with operative vaginal delivery.
- 20 The most important requirement for operative vaginal delivery is proper training during residency.

Epidemiology and demography

Definitions

Traditionally, pediatricians have defined prematurity as having a birthweight of 2500 g or less. Today, this is more commonly known as *low birthweight (LBW)* in a liveborn infant.¹ According to the World Health Organization, a preterm birth is any birth, regardless of birthweight, which occurs up to 37 menstrual weeks' gestation.² *Williams Obstetrics* defines preterm birth as a birth occurring before 38 menstrual weeks' gestation.³ In this chapter, preterm is used to describe a fetus or pregnancy up to 37 weeks' gestation, based on the best obstetric criteria.

The lower gestational age limit for a preterm birth, whether the baby is born alive or dead, is 20 weeks. This lower limit is based on traditional medical definitions³ and some statutory legal definitions of stillbirth,⁴ rather than on clinical utility (i.e., the neonate's ability to survive).^{5,6}

Importance of subject

Preterm birth is one of the most important issues in reproductive medicine; in 2002, the preterm delivery rate was 12%.⁷ It is directly responsible for 75–90% of all neonatal deaths that are caused by lethal congenital malformations.^{8,9} Preterm birth also accounts for the vast majority of perinatal mortality and both short- and long-term neonatal morbidity. The major diseases of the preterm infant result from organ immaturity, and the incidence and severity of disease are inversely related to gestational age.¹⁰ These conditions include respiratory distress syndrome (RDS), patent ductus arteriosus, necrotizing enterocolitis (NEC), hyperbilirubinemia, intraventricular hemorrhage (IVH), retinopathy of prematurity, and neonatal sepsis. Previously, if preterm infants survived, they faced a high risk of significant long-term handicap (blindness, deafness, cerebral palsy, or mental retardation). Today, only 7.5% of very LBW (VLBW) infants (less than 1500 g) have a condition that results in a major handicap. Neonatal survival has been reported as early as 22–23 weeks' gestation. In the

last 20 years, the break-even or 50% survival rate dropped from 25–26 weeks' gestation or a birthweight of 750 g,¹¹ to 24 weeks or 600 g;^{12,13} the mortality rate in infants weighing from 501 to 600 g was 71%, whereas it was 89% for infants weighing from 401 to 500 g¹³ (Fig. 62.1). Although the overall handicap rate of these infants was high, the severe handicap rate in survivors was about 30%.¹³

Epidemiology

LBW is a surrogate measure for the health of any community or nation. LBW is one of the strongest determinants of infant mortality and morbidity; thus, it continues to be closely monitored. The classification of LBW births is summarized in Table 62.1.¹¹ Many mildly preterm infants have birthweights of 2500 g or more (35–36 weeks); conversely, many moderately LBW infants (1500–2499 g) are actually full term. In some series, nearly one-half of LBW infants were considered term.¹⁴ The concepts of preterm birth and LBW differ in their pathogenesis but share many predisposing factors (Table 62.2)¹⁵ and, as such, these phenomena are often considered together. It is noteworthy that impaired fetal growth does not exert the same force on neonatal and infant mortality as early gestational age.

The national distributions of LBW and prematurity are markedly skewed.¹⁶ More than 60% of all LBW infants weigh 2000 g or more at birth, a time when survival is extremely high and neonatal morbidity is very low. Moreover, nearly 85% of preterm births occur at 32 weeks or more,¹⁷ a time when uncorrected gestational age-specific mortality is 4% or less. Neonatal mortality and severe morbidity tend to be most prevalent in the late second trimester and early third trimester, a period that accounts for fewer than one in six preterm births.

Despite decades of advances in reproductive medicine and large reductions in the rates of neonatal and infant mortality, the incidence of LBW and VLBW births has not decreased (Fig. 62.2).⁷ The rate of LBW births declined during the 1970s and early 1980s. From a low of 6.7% in 1984, it increased to a rate of 8% in 2002, its highest level since 1975.¹⁶ The incidence of VLBW births also increased from 1.2% to 1.5%,

Figure 62.1 Mortality before discharge by birthweight among infants born in NICHD Neonatal Research Network Centers between 1 January 1995 and 31 December 1996. Data expressed as percentage died and 95% confidence intervals for each 100-g birth weight interval. From ref. 13, with permission.

whereas the national preterm birth rate increased steadily from 10.2% to 12%.⁷

Racial disparity between black people and white people

The incidence of LBW and VLBW infants differs substantially between black people and white people.¹⁷ The incidence of preterm birth is 17.4% in black people and 11.0% in white people,¹⁷ and this racial disparity increases as gestational age at delivery decreases (Fig. 62.3).¹⁷

The reasons for these demographic differences are complex and relate to socioeconomic and biological differences between races. It had been assumed that socioeconomic disadvantages

* Black race is a risk factor for both growth retardation and premature birth. The risk is twice that for white people and remains present when confounding social and economic variables are controlled. Classification of risk for black people as cultural and biological is due to the uncertainty of the role of these variables.

were primarily responsible for the substantial difference in rates but, after controlling for some confounding socioeconomic variables, investigators found that the twofold increase in the relative risk for LBW infants remained.¹⁵ In fact, the rate of VLBW births in low-risk black women was 1.7 times higher than that of high-risk white women. According to Papiernik

and colleagues,¹⁸ these differences can be explained, in part, by biological differences in gestational length.

According to Naeye,¹⁹ urogenital infections represent the largest single category of black-white disparity in perinatal mortality. Black women have higher rates of lower urogenital tract infection than other ethnic groups. These infections include sexually transmitted infections such as syphilis, gonorrhea, chlamydia, and trichomoniasis.²⁰ Black women also have a higher incidence of nonsexually transmitted urogenital tract colonization and infections, including bacteriuria, bacterial vaginosis, group B streptococcal infections, and genital mycoplasmas;²¹ the rate of bacterial vaginosis in black women ranges from 20% to 50% compared with 7% to 30% in white women. Although these infections may account for up to 35% of the difference in perinatal mortality between black people and white people, racial differences in reported sexual behavior do not account for the difference in rates of infections.

Epidemiology and etiology

Many epidemiological risk factors are not etiological *per se*, but are simply markers identifying patients at increased risk for preterm birth. Table 62.3 lists the identifiable causes most proximate to preterm birth. Most spontaneous preterm births do not belong to the idiopathic category; only after known or suspected causes are eliminated should patients be diagnosed with idiopathic preterm labor. More recent studies have shown that clinically evident membrane rupture, medical or obstetric maternal complications, or fetal complications account for approximately 70% of preterm births.^{9,22,23}

A study by Amon and colleagues⁹ showed that most infants at highest risk (less than or equal to 1000 g) are born prematurely as a result of etiological factors that are currently not preventable. Although placental pathology was not systematically studied, 82% had a major identifiable associated finding, thus classifying only 18% as idiopathic preterm birth.⁹

Subclinical intra-amniotic infection or accelerated fetal pulmonary maturation remain undiagnosed unless an assessment is carried out by amniocentesis;²⁴⁻²⁶ the incidence of idiopathic preterm labor would be lower than the 30-50% that is often quoted if amniocentesis were performed more often. When a comprehensive evaluation, including placental pathology, immunopathology, and intrauterine infection, is combined with clinical factors, up to 96% of patients have a potentially identifiable etiology and more than 50% of patients have two or more proximate causes.²⁷ The remainder of this chapter focuses on spontaneous preterm labor with intact membranes, a small portion of which is idiopathic.

Pathophysiology

The pathophysiology of preterm labor is unknown. This is not surprising because the normal mechanisms that initiate parturition spontaneously at term are also unknown. However,

there is extensive literature available on the biomolecular processes closely involved with the phenomenon of labor. Factors produced locally within the placenta, chorioamniotic membranes, and decidua, together with biochemical messages from the fetus, act in some complex manner to initiate normal spontaneous labor.

In all mammalian species tested, prostaglandin production increases during and perhaps even before labor. In many species, the three most temporally related uterine events antecedent to the onset of spontaneous labor are cervical ripening, formation of gap junctions, and an increase in oxytocin receptors. Fundamentally, these mechanisms must bring about myometrial contraction by regulating the free intracellular cytosolic calcium concentration in myometrial cells. Myometrial cells contract when the concentration of calcium increases, and relax when the concentration decreases.²⁸

Another key regulator of myometrial contractility is the phosphorylation (causing contraction) and dephosphorylation (causing relaxation) of myosin light chains. Cellular tocolytic mechanisms include the regulation of myosin phosphorylation, cyclic adenosine monophosphate (cAMP) regulation of myosin light-chain kinase, regulation of intracellular free calcium levels, and regulation of adenylate-cyclase activity.²⁹

Organ communication

Up to 30% of preterm labor may be caused by infection. The generation of cytokines is considered to be the normal response to a variety of infectious mediators. One of the host tissues generating such responses is maternal decidua. Inflammatory cytokines are elevated in the amniotic fluid and plasma of women in preterm labor. Notably, anti-inflammatory cytokines such as interleukin 10 (IL-10) do not appear to be present in substantial quantities. Animal models have verified that bacteria, bacterial cell-wall products, and inflammatory

cytokines such as IL-1 and tumor necrosis factor can stimulate preterm labor. IL-6 is subsequently released and can mediate a systemic response. Healing of the inflammatory process may occur through the actions of IL-10, IL-4, and transforming growth factors. Dysregulation of the normal host defense inflammatory response could result in preterm labor and delivery.³⁰ Placental histology indicates that inflammation only accounts for 30–40% of cases of preterm labor. The most common noninflammatory lesion of the placenta is decidual thrombosis and acute atherosclerosis, which may lead to uteroplacental ischemia and subsequent initiation of preterm labor.³¹ This may explain the subset of patients who have complications of fetal growth restriction and placental abnormalities.

Other factors such as fetal stress and decidual hemorrhage are also important in preterm labor. Initiators such as peptide hormones (e.g., corticotropin-releasing hormone) and inflammatory mediators may promote the production of uterotonic factors (e.g., prostanooids and endothelin) that result in contractions and the release of proteases (e.g., collagenases and elastases), which in turn initiate membrane rupture and cervical change. Accordingly, extracellular matrix proteins [e.g., fetal fibronectin (fFN), also known as oncofetal fibronectin, and prolactin] in cervicovaginal secretions are elevated. Such release may lead to further cervical change and disruption of the tightly regulated maternal–fetal interface, ultimately resulting in preterm delivery.³²

Biochemistry of cervical change

The structure and function of the cervix has been well described.³³ The underlying stroma is predominantly an extracellular connective tissue matrix, mainly made up of type I and type III collagen. Other important constituents of the matrix are water, glycosaminoglycans, proteoglycans, dermatan sulfate, hyaluronic acid, and heparin sulfate. Elastin, the functional protein of elastic fibers, runs longitudinally between bundles of collagen fibers. The ratio of elastin to collagen is highest at the internal os. Smooth muscle cells make up 10–15% of cervical tissue, with the greatest number of cells located just below the internal os, and fewer found toward the external os.

Controversy exists over whether cervical ripening is primarily a biochemical rearrangement of the extracellular matrix related to biomechanical factors such as increased intrauterine pressure at the lower segment from the presenting fetal part or uterine activity, or whether it is due to an inflammatory reaction in which macrophages and polymorphonuclear cells release enzymes to degrade collagen, which then leads to proteolytic rearrangement.³⁴ It may be that both theories of initiation are correct, but one may predominate over the other, especially in view of the different biomolecular mechanisms for labor. Apoptosis is a genetically timed event; it may also be an intrinsic cause of preterm labor, explaining the many cases of preterm labor in certain families.³⁵

Therapeutic implications of pathophysiological subsets

Recognizing the etiological heterogeneity, complexity, and interactive nature of the underlying biomolecular processes of preterm labor, Keelan and colleagues³⁶ have elegantly proposed that future therapeutic trials be tailored to the specific etiological mechanism determined by a battery of preterm labor tests (Table 62.4). Preterm labor *per se* is not a disease in itself but an aberration of timing with diverse underlying heterogeneity. Consequently, in the future, a careful strategy of specific biomolecular diagnosis and treatment for preterm labor will be necessary.

Clinical antecedents to preterm labor and delivery

Many risk factors antedate the diagnosis of preterm labor, but unfortunately these factors are not very specific. This lack of specificity is further compounded by the inability to accurately diagnose preterm labor. True preterm labor, if left untreated, implies cervical progression and prompt preterm delivery. Unfortunately, the overlap with false, nonprogressive, and episodic preterm labor is considerable.

Traditional risk factor scoring and prevention programs

In general, risk scoring quantitatively screens a population for factors associated with a given outcome or disease. One of the fundamental principles underlying a screening program of any type is that there be safe and effective management plans for identified patients. If individuals can be identified before the onset of their condition or early in the course of their disease, preventive measures may be employed to eliminate, lessen, or even stabilize a condition. Unfortunately, preterm labor and delivery have been resistant to most prevention and management efforts. Methods used to prevent preterm birth are quite inconsistent and of limited clinical value.³⁷ There are limitations to screening, regionalization, eleventh-hour care, prophylactic and therapeutic antibiotics, bedrest, social and psychological support, and educational programs.³⁸ Furthermore, there are inconsistencies and a lack of effectiveness, even among well-staffed, well-funded, and well-organized comprehensive prematurity prevention programs.³⁹

Nonetheless, risk scoring can clearly identify a group of pregnant individuals who are at an increased risk for spontaneous preterm labor and birth, and these individual high-risk patients can then receive high-risk care. Various clinically based risk scoring systems have been developed to identify women who have an above-average risk for preterm birth. However, although spontaneous preterm labor with intact membranes is treatable with tocolytic agents, it is important to note that there are still many other proximate causes of

Table 62.4 Potential applications of newer therapeutic options for the treatment of preterm labor.

Cause of preterm labor	Diagnostic indicators	Treatment options
Clinical chorioamnionitis	↑ fFN, IL-6, and ECM proteases Normal free CRH Positive clinical indicators	Deliver if maternal or fetal condition compromised Antibiotics, glucocorticoids
Subclinical chorioamnionitis	↑ fFN, IL-6, and ECM proteases Bacterial vaginosis Normal free CRH	Antibiotics, PGHS inhibitors/β-mimetics Glucocorticoids Deliver if maternal or fetal condition compromised
Lower genital tract infection	↑ Vaginal fFN, IL-6, and ECM proteases Bacterial vaginosis Normal free CRH	Antibiotics with regular review
Idiopathic endocrinopathies	↑ Free CRH, ?↑ fFN ?↑ Salivary E ₃ Normal cytokines	Prophylactic progesterone/glucocorticoids Oxytocin antagonists if presenting with PTL ?No donor therapy
High risk for PTL (i.e., previous PTL)	History/social factors ↑ Free CRH at 26 wks ?↑ fFN/salivary E ₃	Prophylactic progesterone Prophylactic glucocorticoids If presenting with PTL: OT antagonist/NO/β-mimetics
Decidual hemorrhage	Clinical indicators Normal free CRH/salivary E ₃ ↑ ECM proteases	Glucocorticoids If in PTL: glucocorticoids, tocolysis (β-mimetics/PGHS inhibitors) unless otherwise contraindicated
Fetal hypoxia/stress	↑ Free CRH ↑ Salivary E ₃	Glucocorticoids OT antagonist/(β-mimetics/PGHS inhibitors)
Cervical incompetence	↓ fFN, IL-6, and ECM proteases Normal free CRH	Cervical cerclage

preterm birth for which short- and long-term tocolysis is contraindicated (e.g., antepartum stillbirth, significant maternal hemorrhage, chorioamnionitis, lethal congenital abnormalities, and eclampsia).

In the USA, Creasy and colleagues⁴⁰ first popularized a scoring system of risk factors to predict spontaneous preterm birth. More than 30 items are divided into four categories: socioeconomic, prior medical history, daily habits, and current pregnancy problems. Screening is performed at the initial prenatal visit and repeated near the end of the second trimester. Patients with a score of 10 points or more are considered to be at high risk.

This system (modified from that of Papiernik⁴¹) identified 9% of the study population as high risk at the initial screening and 13% at the second screening. The prevalence of preterm birth in this population was 6.1%. The sensitivity of the high-risk score was 64%, with a positive predictive value of 30%. This system relies heavily on past obstetric history; consequently, it is more effective in the multiparous than the nulliparous patient. The Creasy score was later used in a hospital obstetric population in San Francisco as one part of a comprehensive preterm birth prevention program with

impressive results although they acknowledged the limitations of historical controls and the potential for major population differences.⁴²

Holbrook and colleagues⁴³ reduced the number of items in their simplified risk scoring system for the prediction of preterm labor (not preterm birth) from 37 to 18 without any significant statistical loss of identification, prevalence, sensitivity, or positive predictive value (Table 62.5). Some 14% of patients were identified as high risk; the sensitivity was 41% and the positive predictive value 25%. The modified system does not require the calculation of a risk score. Twelve factors are defined as major (any one indicating high risk) and six as minor (two or more indicating high risk).

Main and colleagues²³ performed a similar combined risk scoring and intervention study. In their prospective study, 132 of 380 patients (35%) were classified as high risk. In the study population the prevalence of preterm birth was 16.3%. In the low-risk control subjects the preterm delivery rate was 12.9%, of whom 78% had preterm labor or premature rupture of membranes. The sensitivity of the high-risk score was 48%; the positive predictive value of the high-risk score was 27%. Of note, of preterm deliveries due to preterm labor in women

Table 62.5 Major and minor risk factors of the modified scoring system for spontaneous preterm labor.

<i>Major factors*</i>
Multiple gestation
Previous preterm delivery
Previous preterm labor, term delivery
Abdominal surgery during pregnancy
Diethylstilbestrol exposure
Hydramnios
Uterine anomaly
History of cone biopsy
Uterine irritability (admission to rule out preterm labor)
More than one second-trimester abortion
Cervical dilation (> 1 cm) at 32 weeks
Cervical effacement (< 1 cm) at 32 weeks
<i>Minor factors†</i>
Febrile illness during pregnancy
Bleeding after 12 weeks
History of pyelonephritis
Cigarette smoking (>10 per day)
One second-trimester abortion
More than two first-trimester abortions

*Presence of one or more indicates high risk.

†Presence of two or more indicates high risk.

with candidacy for tocolysis, more than 50% were classified as low risk.

In the same report, high-risk patients were randomly assigned to a comprehensive preterm birth prevention program or standard high-risk care.²³ Unfortunately, the extensive intervention program *failed* to lower the incidence of preterm birth. Preterm delivery occurred in 25% of the patients in the preterm birth prevention program, compared with 21% of the high-risk control patients. The authors attributed these unfavorable results to the high incidence (70%) of proximate causes of preterm birth not amenable to tocolytic therapy.

After evaluating 31 studies describing preterm birth prevention programs, Hueston and colleagues⁴⁴ found that only six studies had controlled for scientific bias. A meta-analysis on these studies did not find any benefit for preterm birth education programs in preventing neonatal mortality or preterm birth. However, there was an increase in the diagnosis of preterm labor.

In a more complex screening process that also includes race, low prepregnant body mass index (BMI; underweight), and a poor work environment, the positive predictive value for spontaneous preterm birth for nulliparous patients was 28% and for multiparous patients was 33%.⁴⁵

Despite the limitations for prevention of spontaneous preterm labor and birth, risk scoring is an inexpensive index that can be used readily to identify individual pregnant women at risk in clinical practice. After identification these women

Table 62.6 Risk for recurrent preterm labor.

deserve a more intense workup and ongoing individualized medical attention. Such women may actually modify their behavior (e.g., stop smoking and illicit drug use) and decrease somewhat their risk status. Moreover, such women are motivated to learn how to effectively access health care as and when their symptoms arise.

Recurrence risk for preterm labor and preterm birth

In a middle-class population, a second-trimester abortion was associated with an increased risk of preterm labor (14%) in subsequent pregnancies.⁴³ In an indigent population, if the second-trimester loss occurred between 19 and 24 weeks, the subsequent preterm delivery rate was approximately 50%.⁴⁶ One or two first-trimester abortions are not associated with subsequent preterm labor, but three first-trimester abortions are associated with an increased risk of preterm labor (12%).⁴³

The recurrence risk for preterm birth varies from 15% to 40% after one previous premature delivery.^{14,47–50} An intervening term pregnancy markedly decreases the risk of a subsequent preterm birth. The recurrence risk significantly increases with two or more previous preterm births (Table 62.6).⁵¹ The more premature the delivery, the less likely the subsequent pregnancy is to deliver at term.⁵²

Digital cervical examination

Asymptomatic cervical dilation may represent silent preterm labor, cervical incompetence, or a normal anatomic variation. In the general obstetric population, the frequency of preterm asymptomatic cervical dilation increases as gestation advances. The risk of preterm birth by gestational age at cervical dilation was studied by Papiernik and colleagues (Table 62.7).⁵³ In two other studies,^{54,55} cervical dilation was found to be associated with preterm birth, with a positive predictive value of 27–28%. In a low-risk population, Stubbs and colleagues⁵⁶ found an association between preterm birth and cervical dilation at 28–32 weeks' gestation (positive predictive value 12%). The relative risk for preterm birth with asymptomatic cervical dilation was two- to fourfold higher than the

risk for preterm birth with an undilated cervix. Conversely, at least three previous reports have emphasized that such dilation is a normal anatomic variant, particularly in the multiparous patient.⁵⁷⁻⁵⁹ These studies showed no significant increase in the rate of preterm birth with cervical dilation.

A large multicenter randomized controlled trial in seven European countries compared the use of “routine” cervical examination at every prenatal visit with a clinically “indicated” examination in a general obstetric population of more than 5600 patients.⁶⁰ There were no significant differences in the rates of preterm birth, LBW, premature rupture of membranes, admission to neonatal intensive care units, or perinatal mortality between the two groups. Although routine cervical examinations and associated interventions appear logical to the clinician, this powerful clinical study does not support routine digital cervical evaluation.

Sonographic cervical evaluation

Digital examination is prone to subjectivity and variation between examiners. If the cervix is closed, funneling at the internal os cannot be evaluated digitally. If the cervix is dilated, placement of the examining finger next to the fetal membranes may increase the risk of infection or membrane rupture. Transvaginal sonography appears to provide a relatively noninvasive, more reproducible, accurate, and quanti-

tative description of cervical anatomy. Cervical sonography is also a better predictor of preterm birth resulting from preterm labor.⁶¹ Transvaginal scanning is preferred to transabdominal or translabial scanning because of cervical proximity, lack of obscurity, and increased accuracy; the technique is well described by Sonek and colleagues.⁶² The biological variation in the endocervical length of the cervix resembles a normal bell-shaped curve. A length of approximately 35 mm represents the 50th percentile, whereas lengths of 25 and 45 mm represent the 10th and 90th percentiles respectively. The relative risk of spontaneous preterm delivery before 35 weeks is inversely related to transvaginal sonographic cervical length.⁶³ A more thorough ultrasound description of the cervix includes the parameters shown in Fig. 62.4.⁶⁴

In a group of expectantly managed patients with funneling diagnosed at less than 25 weeks’ gestation, a sonographic funneling percentage of more than 50% had a sensitivity, specificity, and positive and negative predictive values of 80–85% for the development of preterm birth. In patients with 25–50% funneling, only 30% delivered preterm.⁶⁵ In this group, clinical interventions did occur and so the natural history of funneling was unknown; however, treatment, when effective, decreases the magnitude of the positive predictive value.

In practice, it is rare to see a clinically significant funnel if the functional (residual) cervical length is 30 mm or more.⁶⁶ Thus, measurement of the degree of funneling becomes more important as the sonographically apposed endocervical length shortens. The technique of cervical sonography is comprehensively reviewed by Iams⁶⁶ and Doyle and Monga.⁶⁷

Table 62.7 Percentage of general obstetric patients with cervical dilatation of the internal os > 1 cm.

Home uterine activity monitoring

Home uterine activity monitoring (HUAM) allows the patient at risk to be physically monitored at home with external tocodynamometers. The data are transmitted by telephone to a central viewing station, where the pattern of uterine activity is assessed by a nursing service. The nursing service contacts the patient once or twice daily and prepares a detailed history on the patient’s current status. Should the service detect abnormalities, the physician is notified immediately.

Figure 62.4 Cervical length with and without funneling (from ref. 64 with permission).

The principal variable that is monitored is the frequency of uterine activity. Studies have shown that the mean frequency of uterine contractions per hour rises with increasing time of gestation.^{68,69} Some believe that there is a further increase in frequency from 24 h to 48 h before the onset of true labor.⁶⁹ However, in a prospective evaluation, Iams and colleagues⁷⁰ found that the “window of opportunity” for early tocolysis does not extend beyond 12–24 h before overtly symptomatic preterm labor occurs. The mean contraction frequency for women destined to have preterm labor is higher than for those who deliver at the normal time, but the overlap between these two groups is high, limiting its positive predictive value.⁶⁹

Some monitoring devices are extremely sensitive, and mothers cannot always perceive the measured uterine activity. In one study,⁷¹ only 10% of women correctly perceived their contractions more than half of the time, whereas in another study⁷² that used a different monitor, 54% of high-risk patients perceived more than 75% of their contractions.

Initially, a few randomized and nonrandomized trials indicated that preterm birth might be prevented by twice-daily monitoring of high-risk women together with daily nursing support and high-quality obstetric care.^{69,73–75} These studies demonstrated that the use of HUAM decreased the preterm birth rate over traditional outpatient care. However, Iams and colleagues⁷⁶ and Porto and colleagues⁷⁷ found that provider-initiated nursing education and clinical support was the primary beneficial component of the HUAM program.

The results of some more recent randomized controlled studies^{78,79} have shown a benefit of HUAM, whereas others have shown no benefit.^{76,80–82} A critical review of the literature^{83,84} suggests multiple study design problems including: the accuracy and reliability of the HUAM device; management of the control group; the use of intermediate endpoints rather than preterm delivery or neonatal morbidity or mortality; double counting of twins; and limiting analysis to subgroups who developed preterm labor. Accordingly, Corwin and colleagues⁸⁵ reanalyzed all of the patients who were enrolled in their earlier trial and addressed some of the study design problems. They found that HUAM resulted in improved pregnancy outcome, decreased preterm birth and a decreased need for neonatal intensive care.⁸⁵

A powerful and meaningful study by Dyson and colleagues⁸⁶ of a large number of high-risk pregnant women ($n = 2422$) investigated whether: (1) adding the HUAM device to daily nursing contact could reduce the rate of spontaneous preterm delivery at less than 35 weeks' gestation; and (2) daily nursing contact, irrespective of monitor use, would be more effective than weekly nursing contact. The authors found that adding the HUAM device to daily contact with the nurse did not improve either the early detection of preterm labor or the pregnancy outcome. Moreover, daily nursing contact did not improve any measure of outcome compared with weekly nursing contact. The authors concluded that the similarity in outcome among the three groups was a result of three factors: (1) the patients received thorough training and a checklist was

used for consistency; (2) women were asked to palpate their uteri twice daily and to keep a daily log of the number of contractions and symptoms of labor; and (3) each woman was scheduled for weekly contact with a designated nurse who reviewed her daily logs and encouraged her to seek assistance as and when needed.

In conclusion, the bulk of the scientific evidence available does not suggest that HUAM be considered as the standard of care, and the American College of Obstetricians and Gynecologists do not recommend this system.⁸⁷ However, controversy exists as to whether HUAM has an important role to play in outpatient management.⁸⁸ Incorporating the time of day and diurnal pattern of uterine activity into a HUAM program may provide more accurate and predictive information in addition to an assessment of contraction frequency.⁸⁹ There may be patient subsets that could benefit from HUAM programs, such as those with advanced dilation and those in rural settings, who may not have quick access to a perinatal center.

Fetal fibronectin

Fibronectins are a group of proteins found in plasma, extracellular tissue, and amniotic fluid. Plasma fibronectin helps regulate oncotic pressure, coagulation, and bacterial opsonization. fFN is a unique fibronectin found in the basement membrane near the choriodecidual interface. It is produced by fetal membranes and is likely to function as an adhesive binding the placenta and membranes to the decidua. Fibronectin found in the cervical stroma is distinct from fFN.

fFN is commonly found in cervicovaginal secretions before 20 weeks' gestation and at term. Its clinical detection at 22–34 weeks at concentrations greater than 50 mg/mL is considered abnormal and indicates choriodecidual disruption. Because fFN is also found in amniotic fluid, its presence in the vagina may indicate the presence of amniotic fluid in cervicovaginal secretions. fFN may leak into the vagina by at least three other possible mechanisms. First, during the early process of uteroplacental membrane development, fFN is found in the vagina before completion of the choriodecidual interface. Second, cervical ripening during preterm and term labor, as a result of biomechanical stress caused by uterine contractions, promotes the loss of fFN from the interface. Third, inflammation at the interface may occur during preterm and term labor resulting in fFN expression in the cervicovaginal fluid.

There is a relationship between the presence of fFN in cervicovaginal secretions and spontaneous preterm birth. Three categories of patients have been evaluated: symptomatic patients hospitalized for evaluation of preterm labor, high-risk asymptomatic patients, and asymptomatic patients taken from the general obstetric population.^{90–93}

In a large study of patients ($n = 763$) presenting with symptoms of preterm labor, almost 20% tested positive for fFN.⁹⁴ In these circumstances, the most pressing concern for the physician is the likelihood of imminent preterm birth;

therefore, delivery within 1 week is an appropriate measure of preterm birth in symptomatic patients. Rapid testing has increased the usefulness of fFN measurements, with similar positive and negative predictive values.⁹³ The clinical implications of this test are summarized in Fig. 62.5. It is important to note the differences between the pretest positive and negative predictive values and the post-test positive and negative predictive values. From a clinical viewpoint, it remains unclear as to how clinical management should be affected. With a negative result or with no test at all, the odds of delivering within a week are extremely low. Correspondingly, 1% of the fFN-negative group (6 out of 613) delivered a VLBW infant, which is similar to the expected incidence (1.5%) of VLBW births from all causes in the total US obstetric population.

Testing for fFN produces numerous false-positive results. Lukes and colleagues⁹⁴ found that cervical dilation or manipulation can explain some of the false-positive results, specifically: cervical dilation, recent sexual intercourse, vaginal bleeding, recent cervical examination, and uterine contractions. To improve the accuracy of positive results, specimens

	fFN+	fFN–	
Delivery ≤ 7 days	19	3	22
Delivery > 7 days	131	610	741
	150	613	763

	Predictive value	
Test	+	–
Without test	2.9%	97.1%
fFN negative	0.5%	99.5%
fFN positive	12.7%	88.3%

Figure 62.5 The predictive value within 1 week of fFN. The primary endpoint delivery is less than or equal to 7 days. (Modified from data in ref. 91.)

should be obtained before any cervical manipulation and before advanced dilation or increased uterine activity has occurred. Faron and colleagues⁹⁵ noted that test results were more frequently positive among multiparous than nulliparous women. The collection technique is illustrated in Fig. 62.6.

The overall rate of fFN positivity in low-risk populations was found to be 3–4%.⁹⁶ More than one-half of spontaneous preterm births before 28 weeks were associated with a positive fFN test result at 24 weeks.⁹⁶ This isolated finding appeared to be promising for the prevention of extremely LBW births. However, there was also an extremely high false-positive rate in that 83% of fFN-positive subjects delivered after 28 weeks, and 75% of fFN-positive patients delivered after 34 weeks.⁹⁶ The association of a positive fFN test result at the 24-week visit with spontaneous preterm birth before 34 weeks was as follows: sensitivity, 23%; specificity, 97%; positive predictive value, 25%; and negative predictive value 96%.⁹⁶

fFN has also been proposed as a marker for upper genital tract infections. In women who delivered very preterm infants, a positive fFN test result was highly associated with clinical chorioamnionitis, histological chorioamnionitis, and neonatal sepsis, all of which were increased further in the presence of bacterial vaginosis.⁹⁷ Subsequently, a randomized multicenter trial with antibiotics was carried out. Unfortunately, of the asymptomatic women with a positive cervical or vaginal fFN test between 21 and 25 weeks' gestation, treatment with metronidazole plus erythromycin did not decrease the risk of spontaneous delivery or result in improved neonatal outcomes.⁹⁸

Urogenital tract infections

There is increasing evidence that urogenital tract infection, inflammation, or both are associated with and causative of many cases of preterm labor.⁹⁹ The association between asymptomatic bacteriuria and preterm birth is clear;¹⁰⁰ untreated asymptomatic bacteriuria may lead to pyelonephritis during pregnancy. In one study,¹⁰¹ treatment of group B

Figure 62.6 Specimen collection for fFN testing. Lightly rotate swab across either the posterior fornix of the vagina or the ectocervical region of the external cervical os for 10 seconds. This must be done prior to digital examination; alternatively, wait another 24h.

streptococcal bacteria, which indicate heavy colonization of the lower urogenital tract, resulted in a decreased incidence of preterm birth. However, in a separate study,¹⁰² prenatal treatment of group B streptococci with erythromycin was ineffective in preventing preterm birth.

Histological chorioamnionitis is more often seen in cases of preterm birth. Intra-amniotic positive culture results are also associated with preterm labor and birth and, in many cases, the same organism is also cultured from the vagina. Therefore, ascending cervicovaginal bacteria seem to cause deciduitis and upper genital tract infections.⁹⁹

The association between bacterial vaginosis and preterm birth has been clearly demonstrated.¹⁰³ The relative risk of preterm delivery is 1.5–3 times higher in patients with bacterial vaginosis than in patients without. Studies have demonstrated that bacterial vaginosis may be a marker for a treatable and preventable cause of spontaneous preterm labor. Hauth and colleagues¹⁰⁴ evaluated 624 women at high risk for spontaneous preterm labor as defined by one of two clinical characteristics: a previous spontaneous preterm birth and a weight of less than 50 kg before pregnancy. Out of these high-risk women, more than 40% had bacterial vaginosis. In this double-blind placebo-controlled randomized trial, patients were treated with a 7-day course of oral metronidazole (500 mg, twice daily) and enteric coated erythromycin (300 mg, twice daily). Bacterial vaginosis was associated with a significantly higher rate of preterm delivery at less than 37, 34, or 32 weeks' gestation, regardless of treatment assignment. Antibiotic therapy was only associated with a lower rate of spontaneous preterm birth at less than 37 weeks and only in women with bacterial vaginosis. Thus, there appears to be no benefit in treating women without bacterial vaginosis and who have a very preterm birth (i.e., < 32 weeks).

These findings were similar to those of Morales and colleagues¹⁰⁵ who studied women with both bacterial vaginosis and a previous preterm birth, treated with either oral metronidazole or placebo. In these two randomized studies, the beneficial effects were demonstrated in asymptomatic women. Symptomatic patients were not treated within these protocols.

However, contrary to these conclusions and other meta-analyses, a recent systematic review of *all* of the literature found no evidence to support the use of antibiotic treatment for bacterial vaginosis or *Trichomonas vaginalis* in reducing the risk of preterm birth or its associated morbidities in low- or high-risk women. In fact, for women with *T. vaginalis*, the use of metronidazole reduced the risk of persistent infection but increased the incidence of preterm birth.¹⁰⁶

Major symptoms of preterm labor

A host of complaints may herald preterm labor (Table 62.8) but many of these symptoms are common in normal pregnancy and are often dismissed by prenatal care providers; however, a study comparing the symptoms of women in preterm labor with the normal symptoms of pregnant women

Table 62.8 Chief symptoms of preterm labor.

Abdominal pain
Back pain
Pelvic pain
“Gas pain”
Menstrual-like cramps
Vaginal bleeding
Pinkish staining
Increased vaginal discharge
Pelvic pressure
Urinary frequency
Diarrhea

indicated that there was significant overlap.¹⁰⁷ Contractions or menstrual-like cramps are often the most conspicuous complaint, with only 13% of preterm labor patients giving a negative response to all questions about these symptoms. Approximately 10% of normal pregnant women complained of painful contractions.

A common set of complaints relates to painless uterine activity, described as “balling up” and tightening of the uterus. Some complaints are misinterpreted and consequently misreported by the patient, thus misleading both physician and patient. These include “gas pains,” intestinal cramps, constipation, and an increase in fetal movements, any of which may represent undiagnosed actual preterm labor.

In a study of outpatients at increased risk for preterm labor being monitored by a HUAM program ($n = 51$), Iams and colleagues¹⁰⁸ found that only 67% of those who developed preterm labor were symptomatic. Uterine activity recordings *per se* without patient symptoms prompted diagnosis in 24%. A further subgroup (9%) were asymptomatic and were discovered only when silent cervical dilation was found during routine cervical examination. However, the numbers in this study were small and further research is needed.

Vague constitutional symptoms relating to the abdomen and pelvis may also indicate preterm labor, and it is generally a good idea to inform patients, especially those at increased risk, about these vague signs. In addition, a bloody vaginal discharge (bright red, pink, brown, or other discoloration) may well be the signal of a cervical change. Patients experiencing any of these preceding symptoms should be encouraged to contact the physician as soon as possible.

Diagnosis

An accurate diagnosis of preterm labor is difficult until labor has obviously advanced beyond the point of successful tocolysis. With this caveat in mind, preterm labor can be classified as threatened or actual. The basis for such a classification is the difference in prognosis. Approximately 85% of patients with threatened preterm labor deliver at term, whereas

40–50% of all patients in actual preterm labor deliver at term.

The hallmark of threatened preterm labor is uterine activity. Threatened preterm labor is diagnosed when the patient has uterine activity but no evidence of cervical changes. Previously, many of these patients may have been diagnosed as having painful Braxton Hicks contractions. The change in terminology is clinically important because it raises an index of suspicion. The recurrence rate of threatened preterm labor in a pregnancy is approximately 30%; of these women, approximately one-half deliver preterm.¹⁰⁹

Usually, patients with threatened preterm labor respond to simple conservative measures (bedrest, hydration, sedation, or limited doses of subcutaneous terbutaline or nifedipine). Less commonly, continuous infusion of a tocolytic agent may be required for unrelenting, significant uterine activity. The prognosis of a term delivery appears to be improved if preterm labor begins in the third trimester rather than in the second trimester.

During actual preterm labor (as diagnosed by Ingemarsson's criteria¹¹⁰ – Table 62.9), approximately 20% (3 out of 15) of placebo-treated patients delivered at term, compared with 80% (12 out of 15) of terbutaline-treated patients.¹¹⁰ Patients with bleeding, uterine malformations, fever, multiple gestation, and other known causes of preterm labor were excluded. All patients were given 10 mg of diazepam intramuscularly; if this had no obvious effect on contractions, treatment was continued with either terbutaline or placebo.

Creasy¹¹¹ has modified the Ingemarsson criteria (Table 62.10); these diagnostic criteria are well accepted for nulliparous women; however, although there is general agreement that the same diagnostic criteria can be used for multiparous women, their prognostic value may be less.

Documenting cervical change requires serial documentation of cervical status, ideally by the same examiner and under similar circumstances (e.g., during a contraction). One method

of determining cervical change is by noting changes in the Bishop score.¹¹² Dilation of the internal cervical os or effacement of cervical length are most significant; other measures of change, such as consistency and position, seem to be clinically inadequate for an accurate diagnosis.

Although not part of the diagnostic criteria for actual preterm labor, fetal station has a prognostic value: the lower the station, the greater the risk of spontaneous preterm delivery. A patient who has a lower frequency of documented uterine contractions with a higher degree of cervical compliance based on the Bishop scoring criteria or transvaginal cervical sonography is at an increased risk for premature delivery.

To be most successful, many practitioners believe that tocolytic therapy should be started before serial cervical change is documented. However, a report by Utter and colleagues¹¹³ disputes this idea of early tocolysis. The authors compared the preterm delivery rates before tocolysis in 98 patients without serial cervical changes in dilation or effacement (group 1) and 75 patients with serial cervical changes (group 2). In both groups, the mean dilation before ritodrine therapy, as well as other risk factors, were the same. The outcomes of each group were not statistically different, with 50% of group 2 patients and 40% of group 1 patients delivering at term. The authors concluded that, even with significant cervical dilation (up to 3 cm), observation was a reasonable alternative until subsequent uterine activity and cervical change could be determined to indicate ritodrine therapy.

The use of cervical sonography and fFN measurements may further define who could benefit from tocolysis as the combination of both a positive fFN and a short cervix was strongly associated with preterm delivery (Fig. 62.7).¹¹⁴

Managing preterm labor

After a diagnosis of preterm labor is made, appropriate evaluations and initial management plans are instituted. The evaluation phase has two major parts: first, the need for tocolytic therapy is assessed, focusing on the specific nature of the agents to be used and, second, an etiological diagnostic workup is carried out.

During evaluation, the physician seeks contraindications to substantially prolonging the pregnancy (Table 62.11). Temporary efforts to inhibit uterine activity (so that antenatal corticosteroids can be given, the mother can be transported to a tertiary care center, and conditions for maternal and fetal well-being can be optimized) must be weighed against the relative urgency and necessity of delivery.

Ideally, tocolysis should not be given to patients with threatened preterm labor who resolve their uterine activity with conservative therapy. In these patients, testing for fFN and evaluating the cervix for anatomical changes by digital and sonographic examination may help prevent patients from undergoing prolonged surveillance and tocolysis. The fundamental issue involved in withholding tocolytic agents because

Table 62.9 Ingemarsson's criteria for diagnosing preterm labor.

Gestation of 28–36 weeks
Painful, regular, uterine contractions occurring at intervals of less than 10 min, for at least 30 min, by external tocography
Intact membranes
Cervix effaced or almost effaced and dilated between 1 and 4 cm

Adapted from information in ref 110.

Table 62.10 Creasy criteria for diagnosing preterm labor.

Gestation of 20–37 weeks
Documented uterine contractions (4 in 20 min or 8 in 60 min)
Documented cervical change or cervical effacement of 80% or cervical dilation of 2 cm (or more)
Intact membranes

Adapted from information in ref. 111.

Figure 62.7 Frequency of spontaneous preterm delivery according to cervical length (CL), categorized as < 15 mm, 15–29 mm, and ≥ 30 mm, and vaginal fFN measurement. (From ref. 113.)

Table 62.11 Contraindications to tocolysis.

Absolute contraindications	Relative contraindications
Fetal demise	Fetal heart rate abnormalities
Lethal fetal anomaly	Fetal growth restriction
Severe preeclampsia or eclampsia requiring immediate delivery	Preeclampsia not requiring immediate delivery
Chorioamnionitis	Stable late second or third trimester vaginal bleeding
Severe hemorrhage	Significant maternal disease
	Cervical dilation ≥ 5.0 cm
	Progressive structural but nonlethal fetal anomalies

of contraindications to therapy is whether the odds of delivery and its attendant maternal and perinatal risks outweigh the odds of prolonging the pregnancy with medical interventions and its attendant maternal and perinatal risks.

The lower limit for initiating tocolysis in a favorable candidate is approximately 17–20 weeks' gestation. Different opinions exist as to what are the upper limits of fetal age and weight for appropriate tocolytic therapy. In "uncomplicated" patients, some physicians initiate tocolytic therapy at 36 weeks' gestation.¹¹⁵ Based on changes in the vascular intracranial anatomy and nursery performance of cardiovascular, pul-

monary, and gastrointestinal systems, few data support an overly aggressive tocolytic approach at tertiary care centers beyond the beginning of the 35th week, or an estimated fetal weight of 2000 g, particularly if fetal lung maturity is present. Once the appropriateness of therapy has been determined, the physician must take a number of factors into account before deciding which tocolytic agent to give (Table 62.12).

During the initial evaluation period, some authors recommend performing microbiological cultures (including amniotic fluid), urine toxicology, and baseline maternal cardiac, hematological, and electrolyte evaluations. While these test results are pending and the mother and fetus are deemed stable, a thorough ultrasound examination is done to complete the etiological and prognostic evaluation. Table 62.13 lists the factors to be assessed by ultrasonography; many of these factors have a tremendous influence on clinical management.

Fetal age, weight, and growth status

Gestational age is one of the most important determinations that must be made. Of course, gestational age is not one number but rather a range of numbers based on the best obstetric estimate. At best, sonographic fetal age, based on biometry, is an estimate determined by the mean for a population of normally grown and uncomplicated fetuses.

Routine fetal biometric measurements should be performed including the biparietal diameter (BPD), head circumference,

occipitofrontal diameter (OFD), cephalic index, abdominal circumference (AC), and femur length (FL). After the gestational age has been assigned, the estimated fetal weight (EFW) should be calculated; it is recommended to use the formulae of Shepard and colleagues¹¹⁶ or Hadlock and colleagues¹¹⁷ to calculate the EFW. In cases of dolichocephaly, fetal age and weight are underestimated and this finding should be included in any decision-making.

The determination of EFW also becomes important at the lower limits of viability. As with gestational age, estimating fetal weight by sonography carries an inherent error. At the lower limits of viability, a 10% error in predicted birthweight usually corresponds to less than 75 g. Assuming a fetal weight gain of 15 g per day at 24–25 weeks' gestation, this is equivalent to ± 5 days of average fetal growth. Although some patients have marked fetal growth restriction, birthweight is still the cornerstone of immediate neonatal prognosis, particularly for infants who weigh less than 1000 g.⁵ Accordingly, a determination of fetal weight is useful for predelivery counseling regarding prognosis and is superior, at times, to standard determinations of gestational age at predicting survival.¹¹⁸ In the same study,¹¹⁸ BPD was even more reliable than

EFW in determining neonatal prognosis, and performed as well as actual birthweight.

After age and weight have been assigned, intrauterine growth status should be assessed. Several investigators have suggested that fetal growth restriction is more common than expected in the setting of preterm labor.^{119,120} Westgren and colleagues¹²¹ studied the relationship of idiopathic preterm labor to fetal growth retardation by assessing the ratio of femur length to abdominal circumference (FL/AC). Previously, two groups had found that, between 21 and 42 weeks' gestation, the FL/AC was constant ($22 \pm 2\%$) and independent of gestational age.^{122,123} Westgren and colleagues¹²¹ found that 41% of infants who were delivered prematurely after failed tocolysis had an FL/AC above 23.5 (indicating asymmetric fetal growth restriction) compared with 5% of patients in preterm labor who responded well to tocolytic therapy.

A finding of fetal growth restriction is of great clinical relevance and importance in management at the lower limits of fetal viability (i.e., 22–25 weeks). In these situations, sonographic measurements may underestimate fetal age secondary to suboptimal growth, and the infant may be erroneously declared previable. In cases of fetal growth restriction at the

other end of the prematurity spectrum (32 to 36 weeks), it is not uncommon to find fetal pulmonary maturity when performing transabdominal amniocentesis.

Fetal number

Preterm labor is at least 12 times more common in multiple pregnancies than in singleton pregnancies.⁸ In the USA, there is a 50% chance that a multiple gestation will be delivered before 37 weeks.⁷ More than 50% of all twins and 90% of all triplets are delivered with LBWs compared with 6% of all singletons.⁷

Assisted reproductive technology has led to an increase in the numbers of twins and higher order multiple gestations. Twins resulting from selective reduction of higher order multifetal gestations are born earlier and weigh less than twins who began their pregnancy as twins. It is not clear why this occurs but reduced pregnancies have a higher incidence of placental abruption and spontaneous preterm labor.^{124,125}

Multiple gestations also have a higher incidence of many other maternal and fetal complications that strongly influence the management of preterm labor and delivery. These include complications such as preeclampsia (incidence of 20–33%), severe polyhydramnios, fetal growth restriction, fetal malformation, nonimmune hydrops, and twin–twin transfusion syndrome. Therefore, a complete sonographic evaluation is required for appropriate decision-making and choice of drug therapy in multiple gestations that are complicated by preterm labor. When using tocolysis combined with fluid therapy, the risk of pulmonary edema is higher in multiple gestation than in singleton pregnancies. To prevent pulmonary edema, total fluid intake should be restricted to 3000 mL of salt-free or salt-poor solutions per 24 h.

Malpresentation

Fetal malpresentation is common in patients with preterm labor and delivery; the incidence of malpresentation is inversely related to gestational age. Using sonography, it is possible to detect an associated uterine malformation, placental abnormality, polyhydramnios, oligohydramnios, or fetal abnormality. Suspicion of a fetal malformation or genetic syndrome is warranted in cases of malpresentation as there is a higher incidence of fetal malformation in the preterm breech infant; Nisell and colleagues¹²⁶ reported an incidence of fetal malformation of 13.6% in all breech infants born after 28 weeks' gestation and weighing less than 2500 g at birth. Additionally, Braun and colleagues¹²⁷ reported a higher incidence of breech-presenting fetuses in a variety of cases of fetal malformation or neuromuscular dysfunction. These included hydrocephalus, neural tube defects, trisomy syndromes 18, 13, and 21, myotonic dystrophy, and other uncommon syndromes.

When faced with preterm delivery (from 25 to 34 weeks) of a breech-presenting fetus in the absence of other clinically

pertinent maternal or fetal complications, most specialists in maternal–fetal medicine usually perform a Cesarean section, despite the fact that there is little scientific proof to justify this approach.^{128,129} It is appropriate to consider performing a Cesarean section for singleton breech-presenting fetuses estimated to weigh between 600 and 1500 g with a gestational age of 24–32 weeks. At less than 600 g or less than 24 weeks' gestation, inherent fetal biology is thought to be a better predictor of survival or intraventricular hemorrhage (IVH) than delivery mode.

Individualization of care is necessary regarding the delivery mode of extremely LBW preterm breech infants. Head entrapment, which has a reported incidence of 5–10%, may occur in both vaginal and Cesarean deliveries.¹³⁰ However, management of this complication is thought to be easier at Cesarean section than at vaginal delivery.

Fetal well-being

Fetal well-being during the course of preterm labor is most commonly assessed using the nonstress test. A classically reactive test is most widely defined as at least two accelerations of fetal heart rate of 15 beats per minute (b.p.m.) for 15 s during a 20-min monitoring period. If the criteria for reactivity are not met, the test is considered nonreactive; this is usually as a result of fetal sleep cycles, medication, or prematurity, especially at less than 32 weeks' gestation. Once sleep cycles or drugs are eliminated then a further assessment of well-being is indicated.

Because the contraction stress test is strongly contraindicated in the presence of preterm labor, the test of choice for further fetal evaluation is the biophysical profile. Fetal tone, fetal movement, amniotic fluid volume, and fetal breathing movements (FBMs) are all usually manifested weeks before classic fetal heart reactivity.¹³¹ According to the criteria of Manning and colleagues,¹³² fetal oxygenation is sufficient if these four parameters are present, regardless of reactivity.

In the setting of preterm labor, modifications of classical criteria for a reactive nonstress test have been described by Castillo and colleagues.¹³³ By defining reactivity as three accelerations of 10 b.p.m., all fetuses tested at 26 weeks were reactive at the end of the 60-min monitoring period, and approximately 90% of the 24-week fetuses were reactive.

Umbilical artery reverse diastolic flow can be ominous and indicates little time for conservative management. Other non-invasive data are prone to high false-positive rates. Accordingly, if noninvasive data are contradictory with regard to oxygenation status, particularly in fetuses at high risk for acidosis yet remote from term, funicentesis (percutaneous umbilical cord sampling) can be helpful in the optimal management of preterm labor. This technique has been well described by Amon and colleagues.¹³⁴ If the results of fetal acid–base status are within the normal range, a few days of expectant management may be helpful to enable antenatal glucocorticoid administration.¹³⁵

Fetal breathing movements

There seems to be a significant decrease in FBM during true labor. Several investigators have observed that the presence or absence of FBMs may identify the patients in preterm labor destined to deliver within 2–7 days of diagnosis.^{136–138} This prediction is most accurate in uncomplicated preterm labor without membrane rupture, antepartum hemorrhage, or multiple gestation, and before the initiation of tocolytic therapy.

In a comparison with fFN testing, measurements of FBMs were a less reliable indicator of preterm labor than a negative fFN result or a Bishop score of less than 2.¹³⁹ The use of indomethacin for tocolysis is clearly associated with an increase in FBMs,¹⁴⁰ whereas magnesium sulfate may be associated with a decrease in FBMs.

In patients who delivered at less than 32 weeks and within 24 h of a FBM test, Sherer and colleagues¹⁴¹ found that severe umbilical vasculitis was less frequent in cases in which FBMs were present compared with cases in which FBMs were absent [8 out of 55 (15%) versus 18 out of 56 (32%)]. They concluded that histological evidence of fetal inflammation is associated with an absence of fetal breathing but not chorioamnionitis, even in cases with intact membranes.

Fetal malformation

There is an increased incidence of fetal malformations in patients with preterm labor.¹⁴² Often, these patients have advanced preterm labor, spontaneous rupture of membranes, or vaginal bleeding. In a study of more than 30 000 women who had experienced three singleton births,⁴⁹ fetal malformation was most common in infants born prematurely. It was not uncommon to find multiple congenital anomalies, and the rate of central nervous system malformations was as high as 8 per 1000 pregnancies. Overall, the relative risk that an infant with a congenital malformation would be born preterm was 2.0.

Therefore, it is important to perform a complete fetal malformation screen during preterm labor. If sonographic evidence suggests aneuploidy, a rapid fetal karyotype may be useful for optimal medical and obstetric management of labor, mode of delivery, place of delivery, and neonatal resuscitation.¹⁴³ If a lethal karyotype is found, tocolysis should be discontinued.

Polyhydramnios

Polyhydramnios is an uncommon but important cause of preterm labor. It occurs as a result of uterine overdistention and has been defined as an amniotic fluid volume of more than 2000 mL. It is usually diagnosed when uterine enlargement is greater than expected for gestational age and there is an inability to palpate fetal parts. Massive uterine overdistention may result in maternal respiratory compromise and postrenal

obstruction. As many as 40% of patients with polyhydramnios experience preterm labor and delivery.¹⁴⁴ Sonography is used to confirm the diagnosis, to help determine the proximate cause, and to guide therapeutic mechanical relief via reduction amniocentesis.

Polyhydramnios may be caused by maternal, fetal, or placental factors, or by a combination of factors. In one study,¹⁴⁵ approximately 60% of cases were idiopathic. Maternal causes include diabetes mellitus and red cell alloimmunization (anti-D, anti-Kell, etc.); these conditions can be readily excluded using laboratory tests. Fetal etiologies include a complicated multiple gestation, nonimmune hydrops, and structural congenital malformations. Fetal malformations were found in 75% of cases with severe polyhydramnios compared with 29% of mild cases.¹⁴⁵ Central nervous system defects account for approximately 45–50% of all fetal malformations, upper gastrointestinal defects represent approximately 30%, and circulatory abnormalities account for approximately 7%. A placental cause of polyhydramnios is a large chorioangioma, a benign vascular malformation that acts like an arteriovenous shunt. Tumors that are large enough to produce polyhydramnios and cause preterm labor are rare and associated with fetal hydrops.

The rate of preterm labor and delivery is related to the underlying cause rather than to the degree of polyhydramnios: fetuses with congenital abnormalities [16 out of 41 (39%)] and those of diabetic mothers [10 out of 45 (22%)] had a significantly higher incidence of preterm birth than those with idiopathic polyhydramnios. In contrast, for mild cases of polyhydramnios, preterm delivery occurred in 37 of 199 (19%), in moderate cases, 12 out of 55 (22%), and in severe cases, 3 of 21 (14%), thus indicating no significant differences in prematurity for varying degrees of polyhydramnios.¹⁴⁶

Oligohydramnios

Oligohydramnios is caused by a significant reduction in amniotic fluid volume and is easily diagnosed with ultrasound. In the setting of preterm labor, it may occur as a result of premature rupture of the membranes, maternal intake of nonsteroidal anti-inflammatory agents, severe intrauterine growth retardation, or a genitourinary malformation in which fetal urination into the amniotic cavity is absent. Serial sonography and invasive procedures can differentiate between these causes.

The diagnosis of lethal renal diseases is important because many of these cases may present with fetal distress or malpresentation during preterm labor; these are the two most common fetal indications for Cesarean section. Approximately 60% of patients with Potter's syndrome develop preterm labor, and 40–60% are in breech presentation.¹⁴⁷ In these situations, Cesarean section is performed solely for maternal indications. Tocolysis is not indicated except for possible diagnostic evaluation and maternal transfer.

Fetal gender

A curiosity of preterm birth is an excess of male fetuses, which has been demonstrated in multiple studies. A more recent analysis¹⁴⁸ found a 7.2% excess of male fetuses among singleton preterm births of white women with an increased effect in married women. Male excess was also found in twins born prematurely to white women but to a lesser degree than singletons. Out of 14 948 low-risk singleton pregnancies included in the RADIUS study, male fetuses accounted for a 13.6% population-attributable risk for spontaneous preterm labor, an even stronger effect than a positive urine culture.¹⁴⁹ These data suggest the existence of a mechanism of preterm birth that is influenced by fetal gender.

Fetal gender has important prognostic significance; female infants weighing less than 1000 g have a significant survival advantage.⁵ By regression analysis, Fleisher and colleagues¹⁵⁰ found that the lecithin–sphingomyelin (L/S) ratio in female fetuses reached 2:1 at 33.7 weeks, 1.4 weeks earlier than in male fetuses. Phosphatidylglycerol first appeared at 34 weeks in female and at 35 weeks in male fetuses.

Amniocentesis and neonatal outcome

In experienced hands, amniocentesis carries a minimal risk in the late second trimester or third trimester, and there is no scientific evidence that it stimulates labor. Leigh and Garite²⁶ used amniocentesis during preterm labor to detect subclinical infection and fetal pulmonary maturity and found that 12% had positive culture results. These patients presented at earlier gestational ages and were more likely to have ruptured membranes and to deliver within 48 h of admission than those with negative culture results. One-third of the patients at 31–32 weeks' and 50% of those at 33 weeks' gestation or more had mature L/S ratios.

The amniotic cavity is normally sterile; thus, isolation of any organism indicates microbial invasion. Microorganisms can gain access to the cavity by ascending from the lower genital tract, maternal hematogenous spread, retrograde fallopian tube spread, and iatrogenic introduction during invasive prenatal diagnostic and therapeutic procedures. The most common organisms found in the amniotic fluid are *Ureaplasma urealyticum*, *Mycoplasma hominis*, and *Fusobacterium* species.

In a review of 11 studies of transabdominal amniocentesis in patients with preterm labor and intact membranes, Romero and Mazor²⁵ found a positive culture rate of 16%. In the patients with positive culture results, 58% had clinical chorioamnionitis, 65% were refractory to tocolysis, and 40% had membrane rupture. The respective rates of these complications in patients with negative culture results were 7%, 16%, and 4%. Although a large percentage of the microbes recovered were anaerobic, neonates rarely developed significant anaerobic infections. A review of preterm labor patients with intact membranes found that amniotic fluid infection

occurred at a rate of approximately 13%.¹⁴⁹ Approximately 10–15% of neonates in the positive culture group developed sepsis compared with approximately 2% in the negative culture group.¹⁵¹

Rapid amniotic fluid tests for infection have been studied. The most common tests in order of descending sensitivity are measurements of IL-6 levels, a glucose concentration of less than or equal to 15 mg/dL, a white blood cell count greater than or equal to 50 cells/ μ L, and Gram's stain.¹⁵² Leukocyte esterase and catalase tests have also been performed.¹⁵³ The false-positive rates for glucose concentration and white blood cell counts are high.

The appropriate management of patients with positive intra-amniotic culture results remains controversial. Some regimens include antibiotics and immediate delivery but, in others, the fetus is delivered only when there is clear clinical evidence of infection, particularly in fetuses of 25–26 weeks or less. For fetuses of 34 weeks' gestation or more, delivery in the setting of a positive amniotic fluid culture result appears reasonable.

In 1990, we analyzed neonatal morbidity in preterm infants born with mature amniotic fluid tests (Table 62.14).¹⁵⁴ The mothers presented with spontaneous preterm labor and were potential candidates for tocolytic therapy. We found that despite pulmonary maturity, RDS and other morbidities still occurred as an inverse function of gestational age. Hence, prolongation of pregnancy should still be attempted even in the presence of mature amniotic fluid indices for selected patients at less than 34 weeks' gestation. It should be noted that none of the infants had significant RDS at 34 weeks or more. In 1993, Wigton and colleagues¹⁵⁵ confirmed our findings regarding the high false maturity rate of pulmonary maturity tests in the preterm infant with resultant neonatal morbidity.

Konte and colleagues¹⁵⁶ found a similar inverse relationship between neonatal morbidity and gestational age (Table 62.15). In a more indigent population, Lewis and colleagues¹⁵⁷ found a lower rate of RDS of approximately 15% at 34 weeks, with a negligible incidence at 35 weeks or beyond. They recommended that delivery be delayed through the 34th week. At 34–36 weeks, Myers and colleagues¹⁵⁸ found that fetal lung maturity testing was a cost-effective procedure. Testing of fetal lung maturity is biochemically similar between twin and singleton pregnancies and has the same neonatal prognostic value for a given gestational age.¹⁵⁹

Uterine malformations

A review of pregnancy outcome in 182 women with uterine anomalies found that preterm labor occurred in approximately 25% of 265 pregnancies.¹⁶⁰ Patients with complete bicornuate uteri had the highest incidence of preterm labor (66%), but the number of such patients studied was small ($n = 6$). Didelphia and all varieties of bicornuate uteri were associated with a greater than 20% incidence of preterm labor, whereas preterm labor occurred in up to 37.5% of patients

with unicornuate uteri.¹⁶¹ The best fetal survival rate was found in women with complete septate uteri (86%), whereas the worst rates were found in women with complete bicornuate (50%) and unicornuate uteri (40%). Uterine anomalies may be associated with cervical incompetence, malpresentation, and maternal genitourinary malformations.

Management decisions at the lower end of viability

Managing preterm delivery at the lower limits of viability (currently 22–24 weeks' gestation) is a vexing problem. The biological and clinical variables associated with obstetric and neonatal management that favorably influence neonatal outcome have been reviewed.^{5,11,12,118,162–164} It is optimal for delivery in such cases to occur in immediate proximity to a neonatal intensive care center.¹⁶⁵ When conditions permit, decisions regarding delivery of a severely preterm fetus (i.e., 22–26 weeks' gestation by best obstetric estimate) are ideally

made after the mother has been transported to a tertiary care center. Highly coordinated predelivery family counseling by obstetricians and neonatal physicians is recommended to discuss the prognosis and plan management, thereby minimizing anxiety, confusion, and fear.

Survival rates increase as a function of gestational age and birthweight. Gestational age-specific survival rates and management recommendations have been reviewed.^{166,167} The survival rate is 50% at 24 weeks' gestation, between 60% and 70% at 25 weeks, and between 70% and 80% at 26 weeks.^{13,167–169} Improvements in birthweight-specific survival from 1983 to 1996 are shown in Table 62.16. Literature reviews have found that subsequent severe handicap rates in extremely preterm survivors are about 30%.^{167,170,171} Of all extremely LBW nonsurvivors, 70–80% die in the first week of postnatal life, most in the first few days.^{11,172}

Consideration of Cesarean section for fetal distress should begin at an estimated gestational age of 24 weeks, an estimated weight of 600g, or both. In infants weighing less than 1000g, survival based on birthweight has tighter confidence

Table 62.16 Improvements in neonatal survival with increasing birthweight in extremely low birthweight infants.

intervals than that based on gestational age.¹⁶⁸ Accordingly, intervention based on EFW is a reasonable approach at the borderline of viability. Outcome based on BPD assessment is even more superior to EFW and is in line with birthweight.¹¹⁸

An obstetric willingness to perform Cesarean delivery for fetal indications is associated with an increased rate of survival and a virtual absence of intrapartum stillbirth.¹⁷³ This willingness was an even better predictor of survival than either the obstetrician's opinion of viability or actual Cesarean section;^{174,175} it results in both a greater likelihood of intact survival and survival with serious morbidity.

Because of inherent inaccuracies in estimating fetal age and weight, survival considerations on behalf of the fetus should begin at between 22 and 23 weeks' gestation and 450–500 g. The likelihood for survival in these instances is very low (i.e., less than 10–20%); therefore, Cesarean section for fetal indications is best avoided. Survival, if it occurs, generally occurs regardless of the delivery mode. To protect the mother from an undue risk of Cesarean section, which has little potential benefit for the newborn, the mother should be offered all other available options including transfer to a tertiary care center, family counseling, standard hydration, fetal monitoring, maternal positioning, maternal oxygenation, controlled sterile delivery, and the presence of one or two neonatologists at delivery. Additional measures include transcervical amnioinfusion and acute tocolysis for uterine relaxation.^{176,177}

Tocolytic agents

In the last five decades, a host of drugs have been used in the attempt to inhibit preterm labor. These include relaxin, beta-

sympathomimetic agents, ethanol, prostaglandin synthetase inhibitors, organic calcium-channel blockers, magnesium sulfate, diazoxide, aminophylline, progestogens, and, more recently, oxytocin analogs that block oxytocin receptors and nitric oxide donors. Many of the older agents had high success rates initially, but subsequent reports have shown a reduced and somewhat limited efficacy.

Beta-sympathomimetic agents

Beta-adrenergic receptors have been described by Lands and colleagues.¹⁷⁸ Beta-1 receptors are predominately found in the heart, small intestine, and adipose tissue, whereas beta-2 receptors are predominately found in the uterus, blood vessels, bronchioles, and liver. Some agents (e.g., ritodrine) have been promoted as having selective beta-2 activity.¹⁷⁹ Beta-2 selective sympathomimetic amines are structurally related to catecholamines and stimulate all beta receptors throughout the entire body.¹⁸⁰ Tachyphylaxis is seen with continued use,^{181,182} however, a short course of intermittent therapy may provide a sustained myometrial response.

The side-effects of these agents represent an exaggeration of their physiological effects. The following complications of the cardiovascular system are found: peripheral vasodilation with a decrease in diastolic blood pressure, a positive chronotropic effect with decreased ventricular filling time, a positive inotropic effect, and a tendency toward arrhythmogenesis.¹⁸³ Supraventricular tachycardia, nonspecific T-wave changes, and transient ST-segment depression all resolve with discontinuation of drug therapy. It is not uncommon to find chest pain with parenteral administration. These drugs increase oxygen demand and decrease coronary artery perfusion. They may

cause myocardial ischemia; however, levels of cardiac isoenzymes are not increased. These clinical and electrocardiographic findings may relate directly to drug therapy or indirectly to electrolyte disturbance *per se*, rather than to ischemia.¹⁸⁴ Maternal cardiac death has also been reported.^{185–187}

Pulmonary edema may occur in a small percentage of patients treated with parenteral beta-sympathomimetic agents.¹⁸³ This life-threatening complication has several predisposing factors: multiple gestation, a positive fluid balance, blood transfusion, anemia, infection, associated hypertension, polyhydramnios, and underlying cardiac disease. Ritodrine causes the retention of salt and water at the level of the kidney;¹⁸⁰ plasma volume expands and the hematocrit level drops by 10–15%.¹⁸⁸ These findings highlight the importance of refraining from using isotonic fluids throughout ritodrine therapy, restricting total fluids to less than 3000 mL/day, and maintaining a meticulous fluid intake and output record. Because betamethasone and dexamethasone are almost devoid of mineralocorticoid activity, they may be used safely with beta-mimetics.¹⁸⁹

Metabolic complications, such as hypokalemia resulting from increases in glucose and insulin, hyperglycemia resulting from glucagon stimulation and glycogenolysis, and an increase in free fatty acids as a result of lipolysis, are common with intravenous therapy.^{190,191} Less common is lactic acidosis and ketosis,¹⁹² and occasionally there have been cases of diabetic ketoacidosis.¹⁹³ Ritodrine has less effect on glucose intolerance than does oral terbutaline.^{194–196}

The effects on uteroplacental perfusion are controversial; some studies have shown an increase, whereas others have shown a decrease.^{197,198} Placental transfer does occur and it is not uncommon for the fetus to develop a mild tachycardia. Common effects on the neonate have been limited primarily to hypoglycemia, occasional ileus, hypocalcemia, and hyperbilirubinemia.¹⁹⁹ Apgar scores are not significantly affected,²⁰⁰ and long-term follow-up studies have revealed no significant problems in child development.^{201–205}

Controversy exists as to whether there is an association between beta-agonist tocolysis and neonatal IVH.^{206–208} However, a large and very well-designed prospective randomized placebo-controlled Canadian study of ritodrine tocolysis could not demonstrate any increased risk of IVH in the group given ritodrine.²⁰⁹ Sinclair²¹⁰ noted no difference in the treatment arms of this study with regard to corticosteroid usage, supporting the view that beta-agonist tocolysis with and without corticosteroid therapy does not increase the risk of IVH.

Ritodrine

Favorable reports in 1980 by Barden and colleagues¹⁸⁵ and Merkatz and colleagues²¹¹ promulgated the clinical use of ritodrine in the USA. Ritodrine became the first drug approved by the Food and Drug Administration (FDA) for the inhibition of preterm labor. It was reported to have a similar efficacy but fewer side-effects than previously used tocolytic agents and, generally, the side-effects were thought to be acceptable. There

was evidence that it prolonged pregnancy and, when compared with control subjects, there was a significant reduction in the incidence of neonatal death and RDS.²¹¹

A subsequent meta-analysis of ritodrine efficacy was performed on 890 women who participated in 16 scientifically acceptable controlled trials.²¹² There were significantly fewer deliveries in the beta-mimetic group during the first 24 and 48 h of therapy, and there was a slight reduction in the percentage of preterm deliveries in the group receiving beta-mimetic therapy. However, there was no significant reduction in the incidence of LBW infants, respiratory distress morbidity, or perinatal mortality. The Canadian trial found a statistically significant 48-h delay in labor in women receiving ritodrine as opposed to placebo, and there was a trend toward improved neonatal survival in women receiving ritodrine who were randomized at between 24 and 27 weeks.²⁰⁹

Ritodrine infusions should be given according to the guidelines in the manufacturer's package insert¹⁸⁵ or according to the method of Caritis and colleagues.²¹³ Attention should be paid to contraindications as shown in Table 62.12. Intramuscular ritodrine administration has been described²¹⁴ and consists of three injections of 5–10 mg of ritodrine at 2-h intervals. This method appears to be a safe and effective alternate route to intravenous therapy.²¹⁵

To date, beta-agonists have not been shown to be effective when given as a prophylactic agent. In fact, one meta-analysis has indicated the lack of tocolytic efficacy of standard oral beta-agonist maintenance therapy.²¹⁶

A European report of a randomized, double-blind, placebo-controlled trial of a sustained release ritodrine capsule resulting in three daily doses of 80 mg of ritodrine found significant benefits compared with the control group.²¹⁷ Recurrent preterm labor occurred much less often in the treatment group [1 out of 50 (2%) compared with 11 out of 45 (25%) patients]; and spontaneous preterm delivery occurred less often (0 out of 50 compared with 4 out of 45 patients).

Terbutaline

Terbutaline is commonly used in the initial management of preterm labor. Initially, its efficacy was thought to be quite significant but subsequent studies have found that it is limited.^{110,218,219} Terbutaline has significant, potentially life-threatening side-effects, similar to those of ritodrine, especially when given intravenously.^{183,220}

Terbutaline can also be given subcutaneously; the effect is rapid and there are fewer side-effects.^{221–223} The ease of administration and the avoidance of intravenous hydration makes the subcutaneous route a reasonable alternative. In a commonly used regimen, 0.25 mg is given subcutaneously every 20–60 min until contractions have subsided. Close attention is paid to the maternal heart rate and other symptoms, in order to prevent serious complications. Oral administration of terbutaline results in widely varying serum concentrations.²²⁴ The usual daily dose ranges from 10 to 30 mg, with a

maximum daily dose of approximately 40 mg. Cardiovascular collapse and peripartum heart failure have been rarely associated with oral terbutaline therapy.^{225,226}

A more recent development in terbutaline administration is the use of a continuous subcutaneous infusion pump, although controversy exists regarding the efficacy of this therapy.²²⁷⁻²³⁰ It should be noted that the numbers involved in most of these studies were small and the results inconclusive. This type of outpatient therapy is very expensive and invasive; nonetheless, it has unique features and does ensure round-the-clock compliance.

Prostaglandin synthetase inhibitors

Prostaglandin synthetase inhibitors are among the most effective drugs known for inhibiting preterm labor.²³¹ They are easily administered and well tolerated by the mother. However, they have only a limited window of human application because of fetal safety.

Out of all the traditional tocolytic agents available, indomethacin is likely to have the greatest efficacy. Zuckerman and colleagues²³² first reported its clinical use as a tocolytic agent in the treatment of preterm labor in 1974. Around 80% of patients responded to 100 mg of indomethacin administered rectally followed by 25 mg given orally every 6 h. Other studies showed similar results.^{233,234} When randomized placebo-controlled studies as well as comparison studies were performed, indomethacin (daily dose range from 100 to 200 mg) was found to be significantly more effective than placebo^{235,236} or beta-agonists.²³⁷⁻²³⁹ More recent trials indicate that beta-agonists²⁴⁰⁻²⁴² and magnesium sulfate²⁴³ have similar efficacy.

Maternal side-effects are minimal and primarily consist of a gastrointestinal upset, which may require the use of calcium carbonate (Maalox). Indomethacin is contraindicated in patients with hematological dysfunction, peptic ulcer disease, and known allergies; it appears to increase the bleeding time. It is relatively contraindicated in maternal renal disease. Indomethacin does not significantly affect uteroplacental perfusion²⁴⁴ or Apgar scores.²³⁶

The most significant potential complications in the fetus relate to the premature closure of the ductus arteriosus, right-sided heart failure, and fetal death.²⁴⁵ The prostaglandin E series allows the ductus arteriosus to remain patent, whereas indomethacin tends to transiently constrict the ductus;^{246,247} it is much more likely to reversibly constrict the ductus after 31 weeks.²⁴⁸ Irreversible closure of the ductus is more likely at a much later gestational age, closer to the time of physiological closure; however, there are case reports of fetal deaths resulting from complete ductal closure.²⁴⁹ Sonographic evaluation of structural fetal anatomy to rule out a ductal-dependent lesion is thus important before and during therapy of preterm labor with indomethacin. Use for more than 72 h should prompt a further evaluation of the ductus and an investigation to rule out fetal heart failure. Nonetheless, fetal echocar-

diography reports have suggested the relative cardiovascular safety of indomethacin.²⁵⁰

In the neonate, the most feared complication is persistent pulmonary hypertension.²⁵¹ Fetal and neonatal oliguria is not uncommon;²⁵²⁻²⁵⁴ in fact, idiopathic polyhydramnios may be treated effectively with indomethacin.^{255,256} Sonographic surveillance for oligohydramnios is indicated when indomethacin is used for more than 72 h. There are case reports of neonatal bowel perforation,²⁵⁷ and hyperbilirubinemia may occur because indomethacin can displace bilirubin from the binding sites of albumin.²⁵⁸ Indomethacin use may also predispose to NEC and IVH.^{254,259} However, others²⁶⁰⁻²⁶² have found no increase in neonatal complications in prenatally exposed infants delivered at less than 32 weeks' gestation. Because of the variance in fetal safety, one could consider these agents as second-line therapy, using proper precautions to minimize fetal and neonatal effects.

The 1980s database suggested that the selective use of indomethacin before 34 weeks' gestation caused no substantial and permanent side-effects to the fetus or neonate.^{263,264} However, since that time, there have been reports that suggest both short- and long-term side-effects.^{265,266} More recent findings suggest that sulindac has a more favorable safety profile than indomethacin, although both have similar degrees of efficacy.²⁶⁷⁻²⁶⁹

More data are being accumulated using cyclo-oxygenase-2-selective inhibitors (COXIBs), and there may also be a role for the newly developed prostaglandin F2 alpha-receptor antagonists.²⁷⁰

Magnesium sulfate

In 1985, magnesium sulfate was the second most commonly prescribed parenteral agent for tocolytic therapy in the USA after beta-sympathomimetic agents.²⁷¹ More recent evidence and clinical experience favor magnesium over beta-sympathomimetics with regard to safety and tocolytic efficacy.²⁷² Magnesium sulfate has become the first-line agent of choice for continuous intravenous tocolytic therapy.

Properly used, magnesium sulfate is safe for both tocolysis and seizure prophylaxis. Most clinicians monitor reflexes, respiration, urine output, and intermittent serum magnesium levels to prevent the serious complication of hypermagnesemia. A diminished glomerular filtration rate diminishes the excretion of magnesium, and continued administration of parenteral magnesium sulfate may result in toxicity as serum levels rise. Fortunately, a fast-acting and safe antidote is readily available; intravenous injection of calcium gluconate or chloride rapidly antagonizes the actions of excessive magnesium.

Pharmacology

Only 30% of the normal daily intake of oral magnesium is absorbed; this absorption occurs in the upper small bowel by an active process. The National Research Council's

recommended dietary allowance of magnesium for pregnant women is 450mg daily. Dietary sources of magnesium are meat, milk, dark-green vegetables, seafood, and chocolate. The kidney is the major regulator of the serum magnesium concentration because magnesium is principally excreted in the urine.²⁷³

The mechanism by which hypermagnesemia exerts its relaxant effects on smooth muscle differs from that of skeletal muscle. Smooth muscle undergoes pharmacomechanical coupling mediated by various agonists rather than the electro-mechanical coupling characteristic of skeletal muscle. Excess magnesium depresses the peripheral neuromuscular system by inhibiting acetylcholine release and reducing the sensitivity of the motor end plate potential. Acetylcholine is unnecessary for spontaneous contractility of smooth muscle.

The exact mechanism by which magnesium diminishes or abolishes uterine activity remains unclear. Experimental data support the view that the extracellular magnesium ion concentration affects the uptake, binding, and distribution of intracellular calcium in vascular smooth muscle.²⁷⁴ Similar mechanisms may operate in gravid uterine smooth muscle. Calcium uptake into postpartum myometrial cells appears to be inhibited by high extracellular magnesium concentrations.²⁷⁵ The extracellular excess of magnesium results in an increase of 50% in intracellular magnesium concentrations. The inhibition of calcium channel currents appears to be related to magnesium-induced tocolysis.²⁷⁶

In general, maternal magnesium sulfate-induced hypermagnesemia is associated with increased urinary excretion of both magnesium and calcium. In the study of Hoff and colleagues,²⁷⁷ three-fourths of the elemental magnesium infused was excreted during the infusion and 90% was excreted within 24 h of the end of the infusion. The urinary excretion of calcium was three times that observed in control subjects; the mean total maternal serum calcium decreased by 12% and the mean serum ionized calcium by 25%. Acutely, phosphate and calcitonin levels did not change significantly, but the mean parathyroid hormone level increased by approximately 25% from baseline to the end of the infusion.

Maternal side-effects

Tables 62.17 summarizes the major clinical side-effects of maternal hypermagnesemia, and Table 62.18 gives the critical serum levels of magnesium needed for some of these effects to occur. Clinically, respiratory depression from hypermagnesemia does not occur before the disappearance of the deep tendon reflexes. The absence of the reflex arc should therefore serve as a warning sign of impending magnesium toxicity. For patients who inadvertently receive high doses of magnesium intravenously over a short period, the initial clinical presentation may be respiratory or cardiac arrest.²⁷⁸⁻²⁸⁰

One of the most important side-effects encountered during standard tocolytic therapy with magnesium sulfate is chest pain, possibly due to myocardial ischemia. This uncommonly occurs as a result of magnesium sulfate therapy alone, but

Table 62.17 Potential maternal effects of hypermagnesemia.

<i>Common side-effects</i>	
Loss of deep tendon reflexes	
Warmth during infusion	
Mild central hypothermic effects	
Increase in skin temperature	
Cutaneous vasodilation	
Nausea, possible emesis	
<i>Not uncommon side-effects seen with moderately elevated serum levels</i>	
Somnolence, lethargy, lightheadedness	
Visual blurring, diplopia	
Dysarthria	
Nystagmus	
Constipation and dyspepsia	
<i>Uncommon side-effects</i>	
Potential of other neuromuscular blockers	
Lengthening of the P-R and QRS interval	
Controversial effect on the T wave	
Chest pain	
Pulmonary edema	
<i>Effects seen at very high serum concentrations</i>	
Respiratory depression	
Cardiac arrest	
Profound muscular paralysis	
Amnesia	
Decreased rate of impulse formation of the sinoatrial node	
<i>Rare side-effects</i>	
Profound hypotension	
Maternal tetany	
Hypersensitivity: urticarial reaction	
Paralytic ileus	

Table 62.18 Critical serum levels for magnesium sulfate.

Therapeutic range	6-8 mg/dL
Loss of deep tendon reflexes	8-12 mg/dL
Respiratory paralysis	12-15 mg/dL
Cardiac arrest	> 20 mg/dL

Based in part on information obtained from ref. 277.

more often there are additional factors. A higher incidence of cardiorespiratory side-effects occurs in patients undergoing supplemental drug therapy after failed single-agent therapy.^{281,282}

A potentially lethal side-effect encountered during magnesium sulfate tocolytic therapy is pulmonary edema. It occurs with an incidence of approximately 1%, compared with 5% in patients receiving beta-sympathomimetics.^{283,284} Generally, these cases are complicated by other factors associated with pulmonary edema including multiple gestation, polyhydramnios, preeclampsia, anemia, blood transfusion, chorioam-

Table 62.19 Potential fetal and neonatal effects of hypermagnesemia.

Controversial effects on fetal heart rate variability
Lack of significant effect on fetal umbilical Doppler studies

nionitis, positive fluid balance, operative delivery, dual-agent therapy, and prolonged therapy.²⁸⁵⁻²⁸⁷ With proper patient selection, judicious therapy, and close monitoring, the risk of pulmonary edema can be minimized.²⁰⁹

Perinatal side-effects

Neonatal and fetal side-effects of magnesium sulfate therapy are summarized in Table 62.19.²⁸⁷ None of the neonatal effects appears to be due to magnesium alone; they may be related to confounding variables such as maternal illness, fetal growth retardation, and prematurity. A decreased bone density is seen in magnesium-treated patients compared with control subjects.^{288,289}

Reports of the effect of magnesium sulfate on fetal behavior are inconsistent.²⁸⁷ Gray and colleagues²⁹⁰ found no significant decrease in FBMs after intravenous magnesium sulfate therapy. Indeed, they found no significant changes in any characteristic of the fetal biophysical profile when magnesium was used for tocolysis over a 12-h period. However, Sherer²⁹¹ demonstrated a blunted fetal response to vibroacoustic stimulation in a study of five pregnant women treated with magnesium sulfate for tocolysis.

Because of both maternal heat loss from peripheral vasodilation and a blunted shivering ability, a maternal central hypothermic effect can occur, with the temperature dropping as low as 94°F (34.4°C). The baseline fetal heart rate changes accordingly as it is very sensitive to maternal temperature, and a temporary benign fetal bradycardia occurs. Concomitant accelerations are reassuring and delivery is not indicated.

Efficacy and relative safety

In 1966, Rusu and colleagues²⁹² performed the first therapeutic trials of magnesium as a tocolytic agent. In 1977, Steer and Petrie²⁹³ were the first investigators to publish the results of a clinical trial evaluating such therapy in English. They studied 71 patients in preterm labor with intact membranes who had a painful, identifiable contraction pattern with a frequency of 5 min or less. Out of these patients, 31 received ethanol and 31 received intravenous magnesium sulfate; the remaining nine received an infusion of 5% dextrose in water. The

magnesium group were given a 4-g loading dose of a 10% solution intravenously, followed by 2 g/h. Successful treatment was defined as the absence of contractions for a 24-h interval. The success rate was higher in the magnesium group (77%) than in both the alcohol group (45%) and the control group (44%). In patients with cervical dilation of 1 cm or less, the respective success rates were 96%, 72%, and 60%. The respective frequencies of patients remaining undelivered for at least 1 week were 74%, 42%, and 33%. The authors concluded that magnesium sulfate may become an alternate method of controlling preterm labor.

In 1982, three studies were published. In a randomized trial of tocolytic therapy with magnesium sulfate versus intravenous terbutaline, Miller and colleagues²⁹⁴ found that magnesium was equally as effective as terbutaline but resulted in fewer side-effects. Spisso and colleagues²⁹⁵ reported on a large case series that used magnesium sulfate as the primary tocolytic agent and concluded that it is effective and has minimal adverse effects in patients at risk for preterm delivery. Valenzuela and Cline²⁹⁶ reported on five patients who, after failing to respond to beta-mimetic agents, were treated successfully with intravenous magnesium sulfate.

In 1983, Elliott²⁹⁷ reported on 355 patients with and without intact membranes who were treated with magnesium sulfate as the primary tocolytic agent. The author found that magnesium sulfate had a similar efficacy to ritodrine. Failure to respond to magnesium was often as a result of chorioamnionitis, advanced cervical dilation, and placental abruption. Around 7% of patients experienced side-effects but, of these, only 2% required discontinuation of medication.

In 1984, Tchilinguirian and colleagues²⁹⁸ performed a randomized trial of magnesium sulfate versus intravenous ritodrine and found a similar efficacy. Beall and colleagues²⁹⁹ performed a randomized trial of ritodrine versus terbutaline versus magnesium sulfate, using each as a primary agent. A crossover arm was used when single-agent primary therapy was unsuccessful. They concluded that, in a busy service, magnesium sulfate was the primary tocolytic agent of choice.

In 1987, Hollander and colleagues²⁷¹ carried out an excellent prospective randomized study analyzing the efficacy and safety of magnesium sulfate versus ritodrine. All patients were in preterm labor with intact membranes and associated cervical changes. Successful tocolysis was defined as cessation of uterine activity and delay in delivery for 72 h or more from the onset of treatment. The success rates of ritodrine and magnesium sulfate as primary agents were 83% and 91% respectively. When administered as either a primary or secondary agent, the success rate of ritodrine was 79% and magnesium sulfate was 88%. A delay in delivery of 1 week or more occurred in 72% of patients given ritodrine and 75% of those given magnesium sulfate. The mean serum level of magnesium required to achieve tocolysis was 6.6 mg per 100 mL. The authors concluded that magnesium sulfate was easy to administer and clinically efficacious, and that the side-effects were

less alarming than those of ritodrine. They recommended that magnesium sulfate be used as the primary agent for tocolytic therapy, with ritodrine as a back-up.

In 1990, Cox and colleagues³⁰⁰ published a randomized trial comparing magnesium sulfate therapy with no tocolytic therapy in 156 women thought to be in preterm labor. They found no significant prolongation of pregnancy in the group receiving magnesium. Cox and other authors of tocolytic efficacy studies concluded that magnesium sulfate was ineffective in preventing preterm birth. However, this was not a blind study. In the control group, only 28% delivered within 24 h. Almost two-thirds of the control patients had a delay in delivery of at least 1 week, with most remaining undelivered for more than 28 days. Because the majority of the control group did not readily deliver soon after admission, most patients in this study were not in true actual preterm labor. This finding renders the conclusions of ineffectiveness of magnesium sulfate therapy as speculative at best.

In 1992, Chau and colleagues³⁰¹ compared intravenous and oral magnesium therapy versus subcutaneous and oral terbutaline therapy. For short-term tocolysis, no significant differences were found between the groups. However, magnesium was associated with a higher rate of term delivery.

In 1995, Hales and colleagues³⁰² evaluated the efficacy and safety of magnesium sulfate therapy in twins compared with singletons. The same dosing regimen was used in both groups, and no differences were found between them in terms of efficacy. Areflexia was less common in the twin group, but other side-effects were similar. They concluded that higher dosing was not required in twin gestations. However, tocolysis in higher order multifetal gestations does appear to require higher doses.³⁰³

When moving the inpatient that responded to intravenous magnesium therapy to an outpatient situation, many practitioners slowly discontinue drug therapy. In fact, a randomized trial found that a weaning period was not necessary; retocolysis within 24 h was actually more common in the group undergoing slow weaning.³⁰⁴

Dual-agent therapy

In 1984, Ferguson and colleagues²⁸³ performed the first trial comparing dual-agent primary therapy of magnesium sulfate and intravenous ritodrine with intravenous ritodrine and noted serious side-effects. The study was randomized and the administration of magnesium versus intravenous fluids was blinded. The authors concluded that the adjunctive use of magnesium sulfate with ritodrine was associated with an unacceptable increase in serious side-effects and probably no increase in efficacy.

In 1984, Hatjis and colleagues³⁰⁵ performed a slightly different evaluation comparing primary ritodrine therapy with dual-agent ritodrine plus magnesium sulfate in those who failed primary ritodrine therapy. Treatment-related maternal-fetal complications after dual-agent secondary therapy did not differ among the groups. The authors concluded that

adding magnesium in pharmacological doses to conventional ritodrine therapy improved pregnancy outcome in those not responding to primary ritodrine therapy.

In a 1987 study, Hatjis and colleagues³⁰⁶ randomly assigned patients in preterm labor to one of two treatment groups. One group of 32 women initially received ritodrine alone, while another group of 32 received ritodrine and magnesium sulfate concurrently. The authors concluded that concurrent administration of ritodrine and magnesium sulfate was more efficacious than ritodrine alone and caused no apparent increase in adverse side-effects. However, the efficacy conclusion is debatable because the ultimate success rates of tocolysis in both groups were similar.

Diamond and colleagues²⁸⁶ reported on 11 patients who received additional magnesium therapy for preterm labor after unsuccessful therapy with ritodrine alone. One patient developed cardiovascular complications, and pulmonary edema developed in a patient with a twin pregnancy.

Ogburn and colleagues²⁸⁵ studied the effect on preterm labor of a combination of magnesium sulfate and ritodrine or terbutaline in 23 high-risk patients. Pregnancy was prolonged for at least 1 week in six of the patients (26%). Five (22%) developed pulmonary edema and, of these, three had twin gestations with intact membranes, and two had premature rupture of membranes. The authors concluded that combination therapy may be effective in prolonging some pregnancies with preterm labor, but only with an increase in maternal risk. Wilkins and colleagues²⁸¹ also found significant risks with dual-agent intravenous therapy.

Careful titration of dual-agent therapy appears to be safe in some hands.^{307,308} In one of these studies,³⁰⁷ the increased safety may have resulted from the low initial drug infusion rates of intravenous terbutaline and the elimination of the magnesium bolus.

Other empirical drug combinations containing magnesium sulfate have been used quite successfully and safely in our hands (e.g., magnesium sulfate and intermittent oral or subcutaneous terbutaline or oral nifedipine). We and others have found that the combination of magnesium sulfate and indomethacin was relatively safe and advocated its use for patients with advanced cervical dilation.^{309,310}

Long-term therapy

In 1986, Wilkins and colleagues²⁸¹ reported a normal outcome in two patients in preterm labor who had been treated continuously for 6 and 13 weeks with intravenous magnesium sulfate for tocolysis. In each case, conventional therapy with intravenous and oral ritodrine failed to abate uterine contractions and attempts to wean the patients off magnesium sulfate were unsuccessful. In 1989, Dudley and colleagues³¹¹ added 51 patients to the database, successfully supporting long-term magnesium sulfate therapy. They concluded that there need be no time limit for treatment and that magnesium sulfate tocolysis may be continued as clinically indicated. However, some reports have implicated long-term continuous infusion of mag-

nesium sulfate for tocolysis in the genesis of transient neonatal radiographic bony lesions.^{288,312}

Oral magnesium as prophylaxis for preterm delivery

Serum magnesium levels are usually lower in pregnancy than in the nonpregnant state, and during preterm labor levels appear to drop still further.^{313,314} Some authors have suggested an etiological relationship between low magnesium concentrations and preterm delivery.^{315–317} Oral tocolysis with magnesium oxide and gluconate has been used.³¹⁸ The mean serum concentration of magnesium may increase from 1.44 ± 0.22 mg per 100 mL before oral therapy to 2.16 ± 0.32 mg per 100 mL after therapy.³¹⁹

In 1987, Martin and colleagues³¹⁹ reported on 50 patients in preterm labor who had undergone successful tocolysis. One-half received magnesium sulfate followed by oral magnesium gluconate, and the other one-half received intravenous ritodrine followed by oral ritodrine. The number of patients who progressed to 37 weeks' gestation was similar in both groups, but more of the ritodrine patients suffered side-effects (40% versus 16% of the non-ritodrine group). The authors concluded that both oral agents were equally as effective in prolonging pregnancy to term.

A randomized trial comparing oral terbutaline with magnesium oxide for the maintenance of tocolysis revealed no significant difference in efficacy.³²⁰ The authors did find fewer side-effects and a significant cost advantage was apparent with the magnesium therapy. Another study compared tocolysis with oral ritodrine, oral magnesium, and no oral maintenance;³²¹ the investigators were unable to demonstrate any pregnancy prolongation as a result of oral therapy.

Sibai and colleagues³²² performed a double-blind randomized controlled study of 400 young primigravid normotensive patients in whom oral daily administration of 365 mg of magnesium aspartate hydrochloride was compared with an aspartic acid placebo. There were no significant differences between the two groups regarding the incidences of preterm labor, preterm delivery, placental abruption, fetal growth retardation, preeclampsia, or admissions to the neonatal intensive care unit. They concluded that magnesium supplements had no demonstrable benefit in the population tested; even with a sample size 10 times larger, no decrease in preterm labor would have been detected in the magnesium group.

Recommended clinical protocol

Most published studies have used a loading dose of 4 g of intravenous magnesium sulfate followed by doses of 2 g/h, but others^{323–326} have advocated a 6-g loading dose. The clinical protocol in Table 62.20, modified from Petrie, allows for fine-tuning of infusion rates with decreased potential for fluid overload and is well tolerated by most patients. Paying careful attention to contraindications (Table 62.12), and to fluid intake and output, diminishes the risk of pulmonary edema and magnesium toxicity.

Magnesium sulfate, cerebral palsy, and infant mortality

Can cerebral palsy be prevented by the use of magnesium sulfate? In a retrospective epidemiological study, antenatal exposure to magnesium sulfate in VLBW infants was found to reduce the incidence of cerebral palsy at 3 years of age or more.³²⁷ However, other investigators have not been able to find an association between magnesium and a reduced risk of cerebral palsy.³²⁸ Some clinical investigators have found that the cerebroprotective effect is a result of the underlying indication for treatment rather than magnesium *per se*. They reported fewer neurological impairments in infants born to magnesium-treated women with preeclampsia than infants born to magnesium-treated women with spontaneous preterm labor.³²⁹ Infection, a common underlying mechanism in patients with preterm labor, may be the real predisposing factor.^{330,331} Animal models indicate that magnesium deficiency is related to higher levels of IL-1, IL-6, tumor necrosis factor- α , endothelin, and inflammatory neuropeptides.³³²

A report from Mittendorf and colleagues³³³ found an alarming increase in total pediatric mortality in infants born to women in spontaneous preterm labor who were randomized to receive prenatal exposure to magnesium sulfate. After a preliminary analysis, nine out of 10 pediatric deaths were found to have occurred in the magnesium-exposed group. The causes of the nine deaths could be categorized as follows: post neonatal (4); severe twin transfusion syndrome in a 26-week pregnancy (2); multiple congenital anomalies (1); subepicardial hemorrhage in an 885-g infant who underwent cardiopulmonary resuscitation in labor and delivery (1); and neonatal apnea treated after discharge home (1).

The study by Mittendorf and colleagues had tremendous implications for the use of magnesium sulfate therapy for tocolysis. Importantly, the authors should have provided a clear description of all other potentially confounding variables to make sure the process of randomization actually functioned as it should in theory; however, they presented very few data regarding other potential confounders or risk factors. A barrage of criticism was unleashed from centers around the world,^{334–337} and there was general disfavor by guest editorial writers. Methodological problems of the Mittendorf study included: scientific bias because the study was not blind, the presence of deaths not easily related to magnesium, double counting as a result of an excess number of twins in the magnesium group, the inclusion of randomized patients who did not actually receive magnesium, and incomplete data on the control group. Data from other studies have shown no positive association between magnesium sulfate and neonatal mortality.^{338,339} In fact, the authors found a strong negative association and stated that magnesium actually conferred a degree of protection against neonatal death. The Australian study³³⁹ concluded that the pediatric outcome for very low birthweight infants was improved in women given magnesium sulfate for preterm labor.

Table 62.20 A clinical recipe to administer magnesium sulfate.

1. 100mL of a 50% solution of magnesium sulfate is easily obtained from readily available products. This volume contains 50g of magnesium sulfate.
2. 100mL is sterilely removed from a 500-mL bag of 5% dextrose in water. Fifty grams of magnesium sulfate is injected into the remaining 400mL of fluid for intravenous infusion. It should be noted that 10mL of this final solution equals 1g of magnesium sulfate.
3. A loading dose of 6g is infused over 30min. Perspiration and flushing are observed and occur with a feeling of warmth due to vasodilatation. These findings are usually noted early during the intravenous infusion and continue to a greater or lesser degree throughout the infusion. The face, neck, and hands are particularly affected. Nausea and emesis may occur.
4. The initial continuous maintenance rate is 2–3g/h for 60min. One or two doses of subcutaneous terbutaline 0.25mg per dose, may be used during this interval if there are no contraindications and rapid diminution in uterine activity is desired.
5. Complete and rapid uterine quiescence is unnecessary.
6. The infusion rate is increased in increments of 0.5g/h every 30min until uterine activity begins to decrease or signs and symptoms of hypermagnesemia occur. These findings include lethargy, somnolence, diplopia, dysarthria, blurred vision, dry mouth, dizziness, and nystagmus. These effects generally occur at a dose of greater than 2g/h (2.5–4.0g/h). Downward adjustments in the rate by half-gram increments are generally all that is needed; discontinuation of therapy for side-effects is rarely needed. If necessary, intravenous injection of 1g of calcium gluconate can be used in the symptomatic patient; this will be followed by rapid symptomatic relief.
7. The infusion is continued at the lowest effective rate of 2g/h, whichever is greater, for at least 12h of relative uterine quiescence.
8. Oral beta-sympathomimetic therapy is administered and the magnesium infusion is discontinued. Should uterine activity begin to increase during this interval, magnesium sulfate infusion should be increased to the effective rate.
9. If the patient cannot be successfully weaned from intravenous magnesium therapy, continuous short-term therapy (24–72h) may be safely administered, usually at rates of 2–3g/h. During this interval, another attempt at weaning may be attempted.
10. If uterine activity recurs coincident with the conversion from intravenous magnesium therapy to oral beta-sympathomimetic, attempts to use other tocolytic agents may be instituted.
11. Should discontinuation of magnesium infusion and conversion to an oral tocolytic agent fail to abate increasing uterine activity, continuous intermediate-term to long-term therapy with magnesium sulfate may be given. In general, cervical dilation will not change significantly during these therapeutic maneuvers. During long-term magnesium sulfate infusion therapy, the patient can be managed safely in a step-down unit. The healthcare team should be ready to provide emotional and moral support for patients requiring long-term hospitalization.
12. Most true failures of magnesium sulfate therapy and progressive preterm labor are due to cervical dilatation of >4cm, placental abruption, or chorioamnionitis.
13. The occasional patient continues to have increased uterine activity, yet has no associated cervical changes while on magnesium sulfate therapy. Other tocolytic agents may be tried in these cases in an attempt to quiet the uterus.
14. Patients who are refractory to treatment for preterm labor are likely to have an identifiable pathophysiologic process, most notably amniotic infection or abruptio placentae. An amniocentesis for studies of infection and pulmonary maturity are indicated.
15. Dual-agent combination therapy with intravenous magnesium sulfate and intravenous beta-sympathomimetic agents is not recommended due to a significantly increased risk of side-effects. However, dual therapy magnesium with oral or subcutaneous tocolytic agents is reasonable. Combined use of magnesium with nifedipine, indomethacin, or oxytocin analogs may be used but needs further study.
16. In the severely preterm gestation with inevitable delivery due to advanced cervical dilation (4–8cm), aggressive magnesium tocolysis alone or in combination with other tocolytic agents may be extremely useful in delaying delivery for 24–48h to improve the neonatal survival advantage by giving antenatal betamethasone.

Modified from ref. 289.

Nifedipine

A better term for calcium-channel blockers is *calcium antagonists* because they do not completely block calcium influx into the cell; such an action would be incompatible with life. Rather, calcium antagonists are used to normalize excessive pathological muscle contractility and pacemaker activity at the cardiac, vascular, and uterine tissue and organ levels.³⁴⁰

Nifedipine inhibits uterine activity and has less of an effect on the cardiac conduction system than verapamil, another calcium channel antagonist. The mechanism of action of nifedipine appears to be limited to the inhibition of the slow voltage-dependent channels regulating calcium influx. Adverse pharmacological effects include vasodilation, negative inotro-

pism, and sinoatrial or atrioventricular node conduction disturbances. Because it is a potent vasodilator, nifedipine may cause dizziness, lightheadedness, flushing, headaches, and peripheral edema.³⁴¹ Although the overall incidence of side-effects is 17%, severe effects necessitating discontinuation of therapy occur in 2–5% of patients.³⁴² The negative inotropic and dromotropic (affecting cardiac nodal conduction) effects of nifedipine are minimal. This is largely because of the heart's baroreflex response to peripheral vasodilation. Idiosyncratic reactions to nifedipine are rare.

Nifedipine is rapidly and almost completely absorbed from the gastrointestinal tract. Absorption after sublingual administration is rapid but less complete, with levels being measurable in the plasma within 5 min.³⁴³ The rate of absorption of

oral and sublingual capsules varies widely among patients. Ferguson and colleagues³⁴⁴ have shown that the mean elimination half-life of nifedipine is 81 ± 26 min (range 24–156 min) in patients with preterm labor treated with sublingual nifedipine (bitten and held between molars). Prevost and colleagues³⁴⁵ found that the elimination half-life of nifedipine is 78 ± 30 min (range 24–156 min) when it is given as oral capsules in preeclamptic patients. Within 360 min of receiving a 10-mg oral dose, plasma nifedipine concentrations were undetectable in 12 out of 15 preeclamptic patients. The lower limit of detection for nifedipine in their assay was 10 ng/mL. The mean ratio of fetal cord to maternal serum nifedipine was $0.93 \pm .20$, whereas the mean amniotic fluid concentration was 53% \pm 15% in simultaneously obtained maternal vein samples.

Clinical experience

In 1978, Andersson and Ulmsten³⁴⁶ observed that nifedipine produced significant pain relief and a decrease in uterine activity in patients with severe primary dysmenorrhea. A significant reduction in uterine activity during menses in normal women was also observed. In 1980, Ulmsten and colleagues³⁴⁷ first reported on the clinical use of nifedipine for tocolysis, with favorable results, while in 1985, Kaul and colleagues³⁴⁸ reported on the combined use of nifedipine and oral terbutaline for tocolysis. In 1986, Read and Wellby³⁴⁹ performed a small randomized trial of oral nifedipine versus intravenous ritodrine versus no treatment, with favorable results in the nifedipine group.

More recent prospective randomized studies have supported nifedipine as having a similar efficacy to more commonly used tocolytic agents. When compared with intravenous ritodrine, several authors^{350–353} found that nifedipine was equally as effective and had diminished adverse effects, namely, nausea, chest pain, tachycardia, and palpitations. In normotensive patients, nifedipine caused a statistical decrement in blood pressure, but one of unlikely clinical significance; this decrease was much less than that associated with ritodrine. However, nifedipine was associated with more flushing.

In a study comparing nifedipine with magnesium sulfate as a first-line agent, Glock and Morales³⁵⁴ found that both treatment regimens were equally as effective and associated with the same frequency of side-effects. However, patients in the magnesium group experienced chest pain more often and needed to discontinue drug therapy. More patients in the nifedipine group experienced episodes of transient hypotension, although none was clinically significant. The authors stressed the need for adequate hydration before the use of nifedipine tocolysis. Initially, a 10-mg capsule of nifedipine was given sublingually; if uterine activity persisted, this dose was repeated every 20 min, up to a maximum of 40 mg during the first hour. If tocolysis was successful, oral therapy was initiated for 48 h with a 20-mg dose every 4 h. Patients were then maintained on oral nifedipine, with a 10-mg dose every 8 h. Comparing nifedipine with intravenous ritodrine, Papatsonis and colleagues³⁵⁵ demonstrated the safety and efficacy of

nifedipine. These authors used higher dosages of nifedipine than all previous studies; short-acting nifedipine was used initially with up to 40 mg in the first hour, followed by a slow release formulation in dosages of up to 160 mg daily.

In the triage treatment of premature uterine irritability and contractions, a one-time, 30-mg dose of oral nifedipine compared favorably with a subcutaneous terbutaline injection protocol.³⁵⁶ A tendency toward fewer side-effects was noted in the nifedipine group.

Nifedipine, as well as terbutaline and ritodrine, has been associated with drug-induced hepatitis.³⁵⁷ In combination with magnesium, nifedipine has been rarely associated with neuroblockade, an effect that is reversible on administration of calcium and discontinuation of magnesium.^{358,359} Rarely, hypocalcemia can also occur;³⁶⁰ however, combined usage with magnesium is not contraindicated.

Circulatory effects

Based on animal studies, concerns about the potentially untoward effects on uteroplacental blood flow in humans initially limited the clinical application of nifedipine during pregnancy.^{361–363} However, the advent of Doppler velocity waveform analysis has enabled uteroplacental and fetal blood circulation to be evaluated. Studies of the effect of nifedipine in 21 pregnant women with preterm labor using continuous wave Doppler revealed no significant changes in the pulsatility index of the fetal middle cerebral artery, umbilical artery, and the uteroplacental vessels.^{364,365} Other studies^{366,367} found that oral nifedipine reduced blood pressure in preeclamptic patients remote from term, but this was not associated with any adverse effects on fetal or uteroplacental circulation when measured by the Doppler technique.

Clinical implications

Nifedipine has an efficacy profile that is at least as good as that of beta-agonists and magnesium sulfate. More recently, it has been reported that nifedipine has an improved efficacy over ritodrine.³⁵⁵ Its safety profile renders it quite favorable in comparison with other tocolytic agents.

Progestational agents

Progestational agents have been widely used to prolong pregnancy in women who are judged to be at an increased risk of miscarriage or preterm birth. The most commonly used agent is 17 α -hydroxyprogesterone caproate (17P). Keirse³⁶⁸ reviewed the literature and noted a significant decrease in the preterm labor and birth rate in patients given drug therapy. There was no significant effect on neonatal morbidity or mortality. This drug was primarily given weekly in doses of 250–1000 mg.

Meis and colleagues³⁶⁹ noted a significant reduction in preterm delivery with a weekly injection of 250 mg of 17P. The data are summarized in Fig. 62.8. Therapy was initiated

at 16–20 weeks’ gestation in multiparous singleton patients with a history of a spontaneous preterm delivery. Therapy was more useful for prophylaxis than for inhibiting active preterm labor. A similar study by da Fonseca and colleagues³⁷⁰ noted

Figure 62.8 Effects of 17P on preterm delivery at 32 and 37 weeks’ gestation. Patients had a previous history of spontaneous preterm delivery, and were given weekly injections of 250mg of 17P. There was a decreased incidence of preterm delivery at < 37 weeks [RR 0.66 (0.54–0.81)] and < 32 weeks [RR 0.58 (0.37–0.91)]. Decreased incidences of both LBW births and IVH (RR 0.25 (0.08–0.82) were observed. (From ref. 369.)

both decreased uterine activity and preterm birth when a 100-mg progesterone suppository was given daily to high-risk patients.

A randomized double-blind trial of 29 women by Erny and colleagues³⁷¹ compared the effect of a placebo with four capsules of 100mg each of an oral progesterone formulation. Oral micronized progesterone decreased uterine activity in 80% of the test group compared with 42% of the placebo group.

A recent meta-analysis noted that one needs to treat a minimum of eight patients with 17P to prevent one preterm birth (Table 62.21).³⁷²

Oxytocin receptor blockade

The concentration of oxytocin receptors in uterine tissue increases dramatically just before and during labor.³⁷³ Augmented uterine sensitivity to constant serum levels of oxytocin may result in an increase in uterine activity. Oxytocin receptors are also found in the decidua and stimulation at this level produces prostaglandins. Consequently, the potential role of oxytocin antagonists as tocolytic agents has been studied; theoretically, they may offer greater specificity with fewer side-effects than agents in current use.^{374–376}

In randomized placebo-controlled trials of women with threatened preterm labor, atosiban, a specific competitive inhibitor of oxytocin-binding oxytocin, reduced and abolished uterine activity more often than a placebo. Side-effects were uncommon and consisted of nausea, vomiting, headache, chest

pain, and dysgeusia.^{377–379} Additional trials to compare the effects of atosiban with beta-agonists revealed that it has a similar efficacy but produces a lower frequency of maternal side-effects.^{380,381} As it is only available in a parenteral form, maintenance therapy using a subcutaneous atosiban pump appears to be the most favorable method of administration.³⁸²

Nitroglycerin

Nitric oxide is a potent smooth muscle relaxant, and decreased synthesis of nitric oxide in the uterus is associated with initiation of labor in animal models.³⁸³ *In vitro*, cyclic guanosine monophosphate (cGMP) induces myometrial relaxation. Glyceryl trinitrate, also known as nitroglycerin, is a nitric oxide donor.³⁸⁴ Abouleish and Corn³⁸⁵ presented data on the role of nitroglycerin in labor and reviewed the literature regarding its obstetric uses. It has been used effectively in external version and breech extraction, in cases of retained placenta, in relieving entrapment of the after-coming head, and in the management of uterine inversion. The drug has a rapid onset and a very short duration of action; it has an extremely short half-life of approximately 2 min. In obstetric situations, intravenous nitroglycerin, in doses of 50–500 µg, promoted uterine relaxation within 45–75 s and without clinically significant side-effects. The drug is available in many forms, including sublingual tablets, sublingual aerosol, transdermal patch, ointment, and the intravenous route. An extended release oral capsule is also marketed. Fetal perfusion does not appear to be effected.³⁸⁶

Lees and colleagues³⁸⁷ reported on 13 consecutive patients who were treated with 10-mg transdermal patches for 24 h after 1 h of preterm labor. If uterine activity continued, an additional patch was applied. Uterine activity generally abated within 24–48 h, with no adverse effect on maternal vital signs and fetal heart rate. Headache was a relatively common side-effect.^{388,389} Nitroglycerin appears to have less serious maternal and fetal cardiovascular side-effects than intravenous ritodrine.^{390,391} Recent studies have found nitroglycerin to be less effective than either magnesium sulfate or beta-agonists, but better than placebo.^{392,393}

Antenatal glucocorticoids

An initial report by Liggins and Howie³⁹⁴ in 1972 revealed a significant decrease in RDS and neonatal death in patients receiving two doses of 12 mg of betamethasone 24 h apart. Several subsequent trials have found similar results. The optimal glucocorticoid preparation and the ideal dose are unknown, although most studies have used betamethasone or dexamethasone. These two agents are identical except for a 16-methyl group which is in the alpha position in dexamethasone and the beta position in betamethasone. Neither agent has significant mineralocorticoid activity (as opposed to hydrocortisone or methylprednisolone). Both drugs result in

elevated plasma glucocorticoid activities for approximately 60–72 h and both readily cross the placenta.

Benefits

Data from 12 controlled trials involving more than 3000 participants demonstrated that corticosteroids reduced the incidence of RDS in each subgroup examined.³⁹⁵ Reductions in respiratory morbidity were also associated with reductions in IVH, NEC, and neonatal death. Fortunately, these beneficial effects occurred in the absence of strong evidence for adverse effects of corticosteroids. Patients with premature rupture of membranes were included in the analysis.

The meta-analysis was updated in 1995, as part of the National Institutes of Health (NIH) Consensus Conference.³⁹⁶ Beneficial effects were found with a 50% reduction in RDS in the group receiving antenatal corticosteroids between 29 and 34 weeks. The most dramatic effects (i.e., a 70% reduction) were noted in infants born 24 h after but within 7 days of the last dose of corticosteroids. A lesser effect (i.e., a 30% reduction) was noted in those infants who were delivered within 24 h of the initial treatment. Neonatal mortality was substantially reduced (i.e., a 40% reduction), particularly in patients less than 28 weeks, especially when the case fatality for RDS was high, as seen pre-1980. In this meta-analysis, both male and female infants benefited and maternal race did not seem to adversely influence any beneficial response to corticosteroids; however, in the largest single randomized study carried out (the 1981 US Collaborative study³⁹⁷), there were no benefits for male or white infants. In the meta-analysis, reductions were also noted in the rates of periventricular and intraventricular hemorrhage (i.e., a 50% reduction), and NEC (i.e., a 65% reduction).

Nonrandomized trials have also supported the use of corticosteroids in preventing mortality in very preterm gestations and extremely LBW infants.^{5,396} Randomized data indicated a decrease in the severity of RDS before 28 weeks, but not a decrease in incidence.³⁹⁸

Risks

Data from more than 30 000 patients from five large observational databases in the multicenter network³⁹⁹ reveal that antenatal corticosteroid exposure was associated with a significant increase (30–50%) in neonatal sepsis and NEC, a finding at odds with the meta-analysis³⁹⁶ and two early randomized trials, one of which was in patients with membrane rupture.^{400,401} Sinclair²¹⁰ incisively critiqued Crowley's meta-analysis,³⁹⁶ indicating that many of the substantive randomized trials excluded some patients from analysis. This important critique found that 135 out of 739 infants (almost 20%) were excluded postrandomization from analysis.⁴⁰⁰

Ohlsson and Fox⁴⁰² also constructively critiqued the meta-analysis with regard to IVH; they found missing data, inaccuracies, and outcome ascertainment bias. They recommended

Table 62.22 Absolute risk of RDS (%) based on TDx-FLM (fetal lung maturity) II ratio and gestational age.*

*These risk estimates reflect the prevalence pattern of RDS across the gestational age range observed in the current study data. The overall prevalence of RDS in a clinical setting depends on both the prevalence of RDS at each gestational age and the distribution of gestational ages encountered.

that a best-evidence synthesis be used as an intelligent alternative to meta-analysis, with a detailed description of each study.⁴⁰³

Before the 1994 consensus statement,⁴⁰⁴ concern about the harmful effects of corticosteroids limited the widespread application of this therapy.⁴⁰⁴ Animal data have suggested that corticosteroids result in alterations in immune response, neurological development, and fetal growth. These harmful effects seem to be limited to studies in which large pharmacological doses of corticosteroids were used in early gestation, and they have not been replicated to any significant degree in the human database. Data from trials with long-term follow-up for up to 12 years have indicated that antenatal corticosteroids do not adversely affect physical growth or psychomotor development.⁴⁰⁴

Short-term effects of transient adrenal suppression, by feedback inhibition of adrenocorticotrophic hormone, have been demonstrated in the mother and newborn after prenatal exposure to a single course of corticosteroids.⁴⁰⁵ Maternal cortisol levels returned to normal within 48 h of the last dose, and fetal cortisol levels returned to baseline within 6 days of the last dose. Other hormones are also transiently suppressed after a single course of prenatal corticosteroids. Neonatal adrenal suppression occurs for less than a week as measured by reduced levels of dehydroepiandrosterone, hydroxyprogesterone, estrogens, and growth hormone. Nonetheless, the neonate has a normal cortisol response to stress after one course of prenatal corticosteroids. It is not known how hormone levels and the neonatal response to stress are affected after the longer periods of adrenal suppression that occur with multiple corticosteroid courses.

Clinical caveats

The benefit of antenatal corticosteroids *per se* in patients with preeclampsia and multiple gestations is unknown. In higher order multifetal gestations, antenatal corticosteroids are associated with an increase in uterine contractions.⁴⁰⁶ In patients with premature rupture of membranes, a benefit of antenatal corticosteroids has been demonstrated, but the benefit–risk ratio was controversial. In general, the benefits from corticosteroids for reducing RDS and mortality were additive to those derived from surfactant. However, it should be noted that an absence of amniocentesis-determined pulmonary maturity was not used in any of these trials as a basis for the administration of corticosteroids; rather, the basis for administration was gestational age. The risk for RDS varied greatly with gestational age even with documentation of fetal lung maturity (Table 62.22).⁴⁰⁷

The NIH consensus statement concluded that all fetuses between 24 and 34 weeks' gestation at risk for preterm delivery are candidates for antenatal corticosteroid therapy.⁴⁰³ However, to avoid the overuse of corticosteroids in the presence of risk factors for preterm delivery, some important caveats are suggested. As a general rule, neither initial nor repeat corticosteroid injections are indicated for at-risk pregnant women whose pregnancies are stable enough to be managed on an outpatient basis. Initial corticosteroids are indicated for patients who require hospitalization and have an increased risk of delivering prematurely in a relatively emergent setting, but repeat courses are generally not. This has been demonstrated in a large randomized trial.⁴⁰⁸ For patients who received their steroids in the remote past, a single rescue dose may be of benefit.⁴⁰⁹ For patients who may deliver precipitously, a benefit has been shown if steroids are given as

little as 4 h before delivery.⁴¹⁰ Patients with active peptic ulcer disease, active viral infection, active tuberculosis, and either active or suspected chorioamnionitis should probably not receive antenatal corticosteroids.

Thoughtful consideration must be exercised in gestational and pregestational diabetic women. Glucocorticoid therapy is likely to provoke insulin resistance and a deterioration in diabetic control, and the combination of beta-agonists and corticosteroids may well have an even more marked effect. As such, fetal hyperinsulinism resulting from hyperglycemia may actually block surfactant production of type 2 pneumocytes.³⁹⁶ In addition, a case of glucocorticoid-induced ketoacidosis has been reported in a patient with gestational diabetes in the setting of preterm labor.⁴¹¹ Glucose values should be closely monitored and insulin should be either added or significantly increased to cover the acute effect of antenatal corticosteroids, which lasts approximately 72 h.

Steroids can also affect fetal biophysical parameters. Changes in the fetal heart rate pattern can occur,^{412,413} and fetal movement and breathing can be temporarily affected by betamethasone.⁴¹³

Adjunctive therapy

Adjunctive therapy to optimize the perinatal outcome of impending preterm delivery is fourfold:

1 Administering antenatal corticosteroids together with thyroxine or thyrotropin-releasing hormone (TRH) has been advocated to further decrease the risk of RDS, chronic lung disease, and the number of ventilator days in the neonatal intensive care nursery.^{414,415} However, recent studies have demonstrated that a combination of TRH and corticosteroids provides no benefit beyond the use of corticosteroids alone.^{416–418}

2 Initial studies have shown that medical therapies, such as the antenatal administration of phenobarbital and vitamin K, are useful in the prevention of IVH; however, further confirmation is required before they can be accepted as clinically valuable adjunctive therapies.^{419–423}

3 Administering antenatal antibiotics to patients in preterm labor, to prolong “subclinically” infected pregnancies and to prevent neonatal sepsis, outside the accepted standard antibiotic regimen for intrapartum chemoprophylaxis for group B streptococci, is still controversial and is not established practice.^{424,425} In the NIH randomized double-blind placebo-controlled study,⁴²⁶ treatment with ampicillin and erythromycin during preterm labor with intact membranes was ineffective in prolonging pregnancy or decreasing neonatal morbidity. A meta-analysis⁴²⁷ found no statistically significant differences in neonatal morbidity or mortality, a finding at variance with the use of antibiotics in patients with premature rupture of membranes.⁴²⁸ The meta-analysis⁴²⁷ did find a favorable trend toward the reduction of neonatal pneumonia and NEC, but also a trend toward an increase in neonatal mortality. They concluded that the data do not support the routine

use of adjunctive antibiotics in patients with preterm labor. However, most of the studies compared used differing regimens of antibiotics, rendering the meta-analysis itself somewhat questionable. In a more recent randomized blind clinical trial, treatment of patients with threatened preterm labor between 26 and 34 weeks with a combination of ampicillin and metronidazole significantly prolonged gestation and decreased admission to the neonatal intensive care unit.⁴²⁹ There were no demonstrable effects on maternal and neonatal infectious morbidity. However, several large multicenter studies have failed to demonstrate a benefit of prophylactic antibiotics in the prevention of preterm labor in at-risk patients.^{430–432}

4 Operative delivery of the very preterm fetus using procedures such as episiotomy, prophylactic forceps, and prophylactic Cesarean section has been studied as a means to prevent neonatal birth trauma and IVH.^{433–437} However, prophylactic operative delivery in the vertex-presenting preterm fetus has not been scientifically proven to decrease mortality or be of any significant benefit to the neurological status of the infant, be it related to intracranial hemorrhage, seizures, or traumatic injury. Major surgical maneuvers strictly on behalf of the fetus are best reserved for established indications such as nonreassuring fetal heart rate patterns and malpresentation. Even although Cesarean section is commonly practiced for the breech preterm fetus, there are no randomized studies that have shown a benefit from operative delivery.^{128,129,438,439} As such, selective vaginal breech delivery, with uterine relaxation to prevent or treat head entrapment, is not an unreasonable option in experienced hands.

Preventing preterm birth

Most preterm births result from spontaneous but not idiopathic preterm labor. To be able to prevent preterm birth, it is crucial to be able to predict when it will occur. Predictions based on risk scoring systems, biochemical markers, and cervical examination are still of limited value; prophylaxis with bedrest, cerclage, and tocolytic and progesterational agents is also of limited value, and HUAM remains highly controversial, with the bulk of evidence not being very supportive. Programs for the prevention and early detection of preterm labor are still being developed because preterm birth remains the major problem facing modern perinatal medicine.

Advances in risk factor assessment have identified several of the strongest known predictors of spontaneous preterm birth.⁴⁴⁰ These are a previous spontaneous preterm birth, black race, low BMI (thinness), a positive fFN test, a foreshortened cervical length on sonographic evaluation, and the presence of bacterial vaginosis in women at high risk for spontaneous preterm birth. A previous spontaneous preterm birth is strongly associated with a short cervix. Bacterial vaginosis may be a causal factor or a marker for a causal factor such as upper genital tract infection. A positive fFN test and a short cervix are not simple independent antepartum markers of

Table 62.23 Preterm prelabor management matrix.

Cervical length	Symptoms of preterm cervical effacement (+1)	Increased uterine activity or funneling (+2)	Increased uterine activity and funneling (+3)
40 mm or more (−1)	0	+1	+2
30–39 mm (0)	+1	+2	+3
20–29 mm (+1)	+2	+3	+4
10–19 mm (+2)	+3	+4	+5

From ref. 445, with permission.

The preterm prelabor profile was derived by adding the number in the row heading category to the number in the appropriate column heading category. For score of 0, no action was required. For score +1, rest was advised. For score of +2, rest and oral tocolysis were prescribed. For score of +3, rest and oral tocolysis were begun, with tocolysis via subcutaneous pump if symptoms and transvaginal ultrasound findings were not stabilized. For score of +4, rest and tocolysis via subcutaneous pump were prescribed. For score of +5, hospital admission for intravenous tocolysis with magnesium sulfate was advised.

distinct causal pathology; in fact, they are intimately involved in the process of labor itself.

Factors that decrease the risk of preterm birth are also important. Measurement of cervical length using transvaginal ultrasound was carried out in 85 twin pregnancies at 24–26 weeks' gestation.⁴⁴¹ A cervical length of more than 35 mm retrospectively identified a group of 34 women with a low-risk twin pregnancy. Only one of these patients was delivered before 34 weeks, indicating a high positive predictive value of 97%. Identification of twin gestations at low risk allows physicians to be more selective in choosing interventions. More research on risk-decreasing factors is merited.

Preterm birth prevention programs

Because there is no single treatable factor that can prevent preterm birth, many investigators have developed comprehensive preterm birth prevention programs. These programs exist at the national, community, and individual physician level. Papiernik and Breart⁴⁴² were among the first to institute such a program; its fundamental components include universal preterm birth and preterm labor education of patients, families, staff, and payor sources. Critical to the program's success is 24-h access to care, provider-initiated contact, and a continued commitment to the program. Results are not achieved overnight and, in fact, may take years to develop; the French national program was gradually implemented in 1971. Educational efforts to increase the detection of uterine activity and decrease physical activity were also provided by the mass media. Temporary maternity leave with guaranteed job security supplemented with homecare assistance were integral to the success of the program.

Although most preterm birth prevention programs have been ineffective, particularly in indigent populations, a model community-wide program from West Los Angeles has had promising results.⁴⁴³ This preterm birth prevention project even targets women with mildly high-risk factors, and is reported to be cost-effective in the prevention of prematurity.⁴⁴⁴

Individualized programs, even in the private practice arena, seem to have potential value. In a nonrandomized intervention study,⁴⁴⁵ patients were assigned in rotation to one of five private practice offices for prenatal care and delivery. In four offices, standard obstetric care was provided while, in the remaining office, a prematurity prevention program was used. Features of the program included visit-by-visit screening, patient education, transvaginal cervical ultrasound as indicated, outpatient modification of physical activity, graded outpatient oral and subcutaneous tocolysis, and inpatient tocolysis for failed outpatient therapy. A preterm prelabor management matrix was designed for use in the study office (Table 62.23).⁴⁴⁵ Infants in the prematurity prevention group ($n = 374$) were compared with infants from the other four groups ($n = 1391$). Significantly fewer VLBW births [0 out of 374 (0%) versus 23 out of 1391 (1.65%), $P < 0.008$] and LBW births [11 out of 374 (2.9%) versus 89 out of 1391 (6.4%), $P < 0.008$] were reported in the study office.

Prevention strategies and policies

Prevention strategies can be viewed from either the obstetricians' or the pediatricians' viewpoint. There are three levels of prevention strategy for the mother. Primary prevention focuses on the entire reproductive-age population and seeks to eliminate known factors associated with preterm birth. Some of these are summarized in Table 62.24. In addition, it is clear that there is a benefit in limiting artificial reproductive technology to single or twin gestations.

The study by Miller and Merritt⁴⁴⁶ is a prime example of the potential impact of behavior modification on prematurity. They studied six modifiable behavioral risk factors that are significantly related to LBW: low prepregnant maternal weight for height, low maternal weight gain, lack of prenatal care, age younger than 17 or older than 35 at delivery, cigarette smoking, and the use of drugs and alcohol. Among white women, the risk of a LBW birth was 29% if three of these variables were present; 10% if two variables were

Table 62.24 Primary prevention strategies.

Delay childbearing until age 17 years
Delay interpregnancy interval
Eliminate low maternal weight for height
Smoking prevention and cessation
Prevent and detect sexually transmitted diseases, and treat to cure
Detect bacteriuria and treat to cure
Manage fertility to avoid multifetal gestation
Provide or refer for preconceptional counseling
Detect and treat iron-deficiency anemia
Provide or refer for drug abuse prevention and treatment

present; 6.7% if one was present; and 1% if none was present.

Secondary prevention identifies pregnant patients who are at increased risk for preterm labor. It then provides education, monitoring of uterine activity and cervical changes, ready access to medical care, and medical interventions as necessary to prolong gestation. These include the use of progesterone prophylaxis. Some of these strategies are identified in Table 62.25.

Tertiary prevention focuses on 11th-hour intensive perinatal care. This includes tocolysis, the use of antibiotics and corticosteroids, maternal transport to a tertiary care center, emergency cerclage, the appropriate mode of delivery, and neonatal intensive care.

Despite scientific advances and the implementation of various prevention and treatment programs, most proximate

Table 62.25 Secondary prevention strategies.

Risk assessment in prenatal care
Improved sufficiency of the content of prenatal care
Repeated education regarding warning signs and symptoms of preterm labor
Early-diagnosis programs
Home uterine activity monitoring, cervical length, oncofetal fibronectin
Early medical intervention
Medications, surgery, early referral
Reduced maternal physical activity
Maternal work leave
Eliminate barriers to care (access, access, access)
Education, education, education

causes of preterm birth remain unpreventable. Even if all of the appropriately eligible patients (ideally, previous spontaneous preterm birth presenting for prenatal care between 16 and 20 weeks) were treated with 17P, there would only be a very modest reduction in national prematurity.⁴⁴⁷ Therefore, large reductions in prematurity are not a reasonable expectation in the foreseeable future.

Prematurity prevention programs have been applied to 20 million pregnant women in France since the early 1970s, with women at low risk gaining the greatest benefits. In the USA, most premature births still occur in low-risk pregnant women because of factors which are, as yet, unidentifiable; therefore, prevention strategies may provide the greatest benefits for these low-risk women.

Key points

- At 24 weeks' gestation, the neonatal survival rate is more than 50%.
- The risk of preterm birth and/or delivery of a LBW infant is affected by race.
- The prediction of a preterm birth is difficult, but risk-scoring cervical ultrasound and fFN testing can help determine which patients are at risk.
- Preterm labor symptoms are often not specific, and contractions experienced are not always 'textbook' contractions.
- A history of previous preterm birth is a strong risk factor for recurrent preterm birth.
- Urogenital tract infections can play a causative role in preterm labor.
- Tocolysis may provide neonatal benefits by allowing maternal administration of steroids and/or transfer to a tertiary care center.
- Care should be taken to exclude contraindications to tocolysis early in the management of preterm labor; a complete medical history and physical examination is recommended in order to select the most appropriate agent.
- The management of multiple gestations requires additional precautions to be taken when using tocolysis.
- An ultrasound provides important information in the management of preterm labor.
- Amniocentesis can be of benefit in the analysis of patients presenting with preterm labor.
- Long-term usage of indomethacin requires close monitoring of the amniotic fluid index (AFI) and frequent Doppler studies of the fetal ductus arteriosus flow.
- Magnesium sulfate is currently the drug of choice for tocolysis at most institutions.

- 14 Combination therapy for tocolysis should be used cautiously, but may allow for prolongation of pregnancy.
- 15 Oral nifedipine has a similar tocolytic efficacy to magnesium sulfate and beta-agonists.
- 16 17P may decrease the incidence of preterm delivery in patients with a history of spontaneous preterm birth.
- 17 Steroids decrease the neonatal incidence of RDS, IVH, and possibly NEC, and are best administered at between 24 and 34 weeks' gestation.
- 18 Steroid administration can negatively affect glucose control in diabetics.
- 19 A single course of steroids has been shown to be of benefit; repeat dosing is not clinically indicated unless the patient is remote from her last treatment.
- 20 There is no proven advantage of an elective Cesarean delivery for the vertex preterm infant.

Definitions

Prelabor rupture of the membranes (PROM) refers to rupture of the chorioamniotic membranes before the onset of labor.¹ The “latency period” is the interval between PROM and the onset of labor. There is no agreement about the length of the interval between rupture of the membranes and the onset of labor required to diagnose PROM. This period of time has been proposed in different reports, to last from 1 to 12 h.^{2–9} Some authors have suggested the term “prolonged PROM” to describe a latency period longer than 24 h, but such usage is uncommon.^{2,10,11} The consequences of PROM depend on the gestational age. Therefore, this condition has been classified as “preterm PROM” or “term PROM,” depending upon whether the episode occurs prior to or after 37 weeks of gestation.^{2–12} The term “previable PROM” has been applied to gestations in which this complication occurs before 23 weeks,¹² while “preterm PROM remote from term” refers to the time-frame between viability to about 32 weeks, and “PROM near term” is that which occurs between 32 and 36 weeks.¹²

Frequency, timing, and site of membrane rupture

Frequency

Term PROM occurs in approximately 10% of patients, while the frequency of preterm PROM is 2–3.5%.^{5,13–17} Preterm PROM accounts for 30–40% of preterm deliveries and therefore is a leading clinically identifiable cause of preterm birth as well as a major contributor to perinatal morbidity and mortality.^{2,5,13,14,16–19} It has been estimated that, in the United States, approximately 150 000 women experience preterm PROM every year.²⁰

When do membranes normally rupture?

This question was addressed by a collaborative study in which an effort was made to avoid artificial rupture of the fetal membranes during labor.²¹ Figure 63.1 shows the proportion of women with spontaneous rupture of membranes as a function of cervical dilatation. Most patients had spontaneous rupture of membranes at the end of the first stage of labor; hence, the rationale for defining PROM as rupture of membranes before the onset of labor.

Where is the site of membrane rupture?

The site of rupture is generally located in the most dependent part of the uterine cavity in close proximity to the cervix. This has been demonstrated using endoscopy in patients with preterm PROM.²² After invasive procedures such as fetoscopy, rupture of membranes can occur away from the cervix. However, the frequency with which spontaneous rupture of membranes occurs away from the most dependent part of the uterus (“high leak”) is unknown.

Fetal membranes

What are the fetal membranes?

The term “fetal membranes” is applied to an anatomic structure that includes amnion and chorion (which are of fetal origin) and portions of decidua (of maternal origin). Bell and McParland proposed to refer to this structure as the “amnio-chorial-decidual unit.”²³ Figure 63.2 displays the microscopic anatomy of the human amnion and chorion, as described by Bourne in 1960.²⁴ The amnion is derived from the cytotrophoblast and consists of an epithelium, which faces the amniotic cavity, a compact layer responsible for most of the strength of the amnion, as well as a spongy layer interposed between the amnion and chorion.^{25–27} The spongy layer allows

the amnion to slide over the fixed chorion. The chorion contains several connective tissue layers, of which the outermost is closely attached to, and often indistinguishable from, the decidua capsularis. The amniochorial–decidual unit is fundamentally an extracellular matrix structure endowed with unique cellular components: amnion, chorion, and decidua. Figure 63.3 displays the distribution of collagen and other extracellular matrix components in the different layers of the amniochorial–decidual unit.

What are the changes in the fetal membranes during spontaneous rupture of membranes?

Examination of the chorioamniotic membranes from patients undergoing elective Cesarean delivery at term with intact membranes has demonstrated that membranes apposed to the

Figure 63.1 Rupture of membranes as a function of cervical dilatation and state of labor. Percentage distribution for 517 normal spontaneous deliveries without medication or maneuvers; vertex presentation. From ref. 21 with permission from the World Health Organization.

cervix have localized morphologic changes which have been referred to as a “zone of altered morphology” (ZAM).²⁸ ZAM is proposed to encompass an area of about $119 \pm 21 \text{ cm}^2$ ²⁹ and is characterized by marked swelling and disruption of the connective tissue, thinning of the trophoblast layer, and thinning or absence of the decidua.²⁸ Moreover, Bell and McParland²³ demonstrated that the ZAM has increased programmed cell death (apoptosis). A population of mesenchymal cells in the chorion switches their phenotype to activated myofibroblasts.³⁰ This phenotype has been proposed to emerge when the extracellular matrix is exposed to stress forces caused by stretching of the membranes during uterine growth and uterine contractions. Myofibroblasts are thought to provide a counteractive contractile force to protect the membranes. Changes in extracellular matrix composition in the ZAM include a significant decrease in the density of collagens I, III, and V, and increased expression of tenascin-C³¹ and osteonectin.³² These proteins are expressed during tissue remodeling and wound healing, suggesting that the membranes exhibit a similar response. Increased intrauterine pressure during labor is likely to exert pressure over this weakened area of the membranes (ZAM), resulting in membrane rupture. Preliminary observations by Bell and Malak suggest that the changes in the ZAM are more extensive in preterm PROM.^{28,33,34}

Biophysical properties of membranes that rupture prematurely

A critical question is whether the membranes that rupture prematurely are inherently weaker, and whether such weakness is generalized or localized. The earliest experiments designed to investigate this question were probably those performed by Poppel in 1863³⁵ and Duncan in 1869.³⁶ Duncan dropped cannonballs onto membranes stretched over a ring to determine their tensile strength. Since that time, most investigators have hypothesized that membranes rupturing prematurely are inherently weaker.

Figure 63.3 Schematic representation of the structure of the fetal membranes at term. The extracellular matrix composition of each layer and the production sites of matrix metalloproteinases (MMP) and tissue inhibitors of metalloproteinases (TIMP) are shown. From ref. 38 with permission from the Massachusetts Medical Society.

Indeed, during pregnancy, the chorioamniotic membranes undergo elastic distention or stretch. The intrauterine surface area increases during gestation (as measured by ultrasound *in vivo*); however, the surface area of the membranes, as measured *in vitro*, increases to a lesser extent.³⁷ During labor, membrane rupture has been attributed to a generalized weakening of the membranes due to repeated stretching.³⁸ Evidence in support of this view is that the tensile strength of membrane specimens obtained after labor is lower than that of those obtained by Cesarean delivery in the absence of labor.³⁹

However, despite testing with various devices, it has been difficult to demonstrate significant differences in the bursting tension between prematurely ruptured and nonprematurely ruptured membranes.^{40–48} Membranes that rupture before labor have decreased elasticity.^{41,46} It has been proposed that these membranes have focal areas of weakness rather than a generalized weakening.^{38,47–50} The use of computer modeling of the biomechanical properties of the chorioamniotic membranes (Lavery's computer model) suggests that acute or chronic stress may act on these weaker points and result in rupture of membranes.^{47,48}

Biochemical studies

Collagen concentration of fetal membranes and PROM

The chorioamniotic membranes are essentially connective tissue structures.^{34,51,52} As collagen determines the tensile strength of fibrous connective tissue, there has been considerable interest in investigating collagen biochemistry in the setting of PROM. Two studies have shown that total collagen content is reduced in the amnion of women with preterm PROM.^{51,52} Skinner and coworkers⁵¹ found that total collagen concentration was lower in the amnion of women with PROM than in that of women with intact membranes.

Subsequently, Kanayama and colleagues⁵² reported that total collagen content was lower in the amnion of patients with preterm PROM than in those with preterm delivery with intact membranes. The difference in collagen content in preterm PROM was attributed to a decrease in type III collagen, which provides elastic tensility to tissues. These investigators could not demonstrate a decrease in total collagen content in the amnion of patients with term PROM,

suggesting biochemical differences between term and preterm PROM.

Three other studies have not confirmed a reduction in collagen content in fetal membranes in PROM. Al-Zaid and associates⁴⁰ found no change in total membrane collagen content (amnion and chorion) in patients with PROM between 30 and 38 weeks of gestation and those with spontaneous or artificial rupture of membranes at term. Evaldson et al.⁵³ were also unable to document a difference in total membrane collagen content between women with preterm PROM and those with intact membranes at term. However, because there is a progressive decrease in amnion collagen content with advancing gestational age,⁵¹ it would seem that the amnion tissue for the control group should have been obtained from women with preterm delivery without PROM rather than from women at term.^{40,53}

Importantly, Vadillo-Ortega et al.⁵⁴ reported no differences in total amnion collagen content between women with PROM and without PROM at term. However, the amnion of women with PROM contained a higher percentage of soluble collagen (by acid extraction) than the amnion of women with intact membranes. It is possible that this increase in the percentage of soluble collagen represents active collagen degradation before its final digestion. Indeed, the authors found increased collagenolytic activity in the amnion homogenates of women with PROM.

Hydroxyproline is the most abundant amino acid present in collagen, and its concentration is considered to be a parameter of collagen content in a given tissue.⁵⁵ In addition, there is evidence of a relationship between hydroxyproline content per cm² of amnion and its mechanical properties (such as elasticity and work required to rupture the amnion). The concentration of this amino acid in the amnion decreases with gestational age.⁵⁵ There is, however, no evidence that PROM is associated with a generalized reduction in the hydroxyproline content of amnion.⁵⁵

The inconsistencies among studies addressing the association between collagen content in the fetal membranes and PROM have been attributable to: (1) differences in the type of samples (amnion versus chorioamnion); (2) the gestational age at delivery; (3) the sampling site (near rupture site versus distant from the rupture site); and (4) the units used to measure the collagen content (per unit weight versus per unit area of membrane).⁵⁵

The association of proteolytic activity in the fetal compartment and PROM

Accumulating evidence supports a role for increased proteolytic activity in the mechanisms responsible for PROM.^{56–81} Artal et al.⁶¹ demonstrated that incubation of chorioamniotic membranes with pseudoamniotic fluid for 24h induced changes in their mechanical properties that predisposed to membrane rupture. These changes were prevented by the addition of protease inhibitors, indicating that enzymatic mechanisms may participate in the weakening of the membranes. Moreover, Kanayama et al.⁵⁶ reported that a trypsin-like bioactivity (measured by a chromogenic substrate assay) was significantly higher in the amniotic fluid of women with PROM than in the amniotic fluid of women with intact membranes.

Matrix metalloproteinases (MMPs) are proteases that can degrade several components of the chorioamniotic membranes (see Table 63.1). The amnion, chorion, and decidua are sources of MMPs and their tissue inhibitors (TIMP-1 and TIMP-2).^{57,58,64,78,82–88} TIMPs act to inhibit the activity of MMPs by covalently binding to the enzyme, and these inhibitors are deactivated by reduction and alkylation. Accumulating evidence supports the role of MMPs in both preterm and term PROM. Indeed, preterm PROM has been associated with high amniotic fluid concentrations of immunoreactive MMP-1, MMP-8,^{84,85} and the active form of MMP-9,⁸⁶ but with low amniotic fluid concentrations of the active form of

Table 63.1 Matrix metalloproteinase (MMP) classification and their concentration changes in amniotic fluid from patients with PROM.^{57,58,64,78,82–88}

MMP type	Substrate or MMP inhibition	Term PROM	Preterm PROM

TIMP-1	MMP-9, MMP-2, MMP-1, MMP-3, MMP-8	No change	No change
TIMP-2	Pro MMP-2, MMP-1, MMP-3, MMP-8	No change	Low

MMP-2⁸⁶ and immunoreactive TIMP-2.⁸⁸ However, no significant changes were reported in the amniotic fluid concentration of MMP-13⁸³ and TIMP-1.⁸⁹ In contrast, PROM at term has been associated with high amniotic fluid concentrations of the active form of MMP-9,⁸⁶ but not of other MMPs (see Table 63.1).

MMPs may also be implicated in the mechanisms of membrane rupture among patients with polyhydramnios. Indeed, patients with polyhydramnios have significantly higher amniotic fluid concentrations of MMP-1 and MMP-13 than those with normal amniotic fluid volume after controlling for gestational age.⁹⁰

Recent observations suggest that changes in the MMP concentration in the fetal compartment may precede the clinical presentation of PROM. High amniotic fluid concentrations of MMP-8, between 14 and 21 weeks, have been associated with a high risk of preterm PROM in the index pregnancy [odds ratio (OR) 3.4; 95% confidence interval (CI) 1.2–9.9].⁹¹

Other proteases and their inhibitors have also been implicated in the mechanisms of membrane rupture. For example, products of neutrophils, such as neutrophil elastase (NE), are released into the amniotic fluid during the inflammatory process and may contribute to the weakening of chorioamniotic membranes. NE is a serine protease capable of extracellular degradation of connective tissues including elastin,⁹² proteoglycans, fibronectin,⁹³ laminin,⁹⁴ and collagen types I, III, and IV.^{95,96} The activity of this enzyme is naturally inhibited by secretory leukocyte protease inhibitor (SLPI)⁷³ and other protease inhibitors.⁹⁷ An imbalance between NE and its protease inhibitors has been implicated in the mechanisms of membrane rupture. Indeed, preterm PROM is associated with a high amniotic fluid concentration of NE, whereas both term and preterm labor are associated with a reduced amniotic fluid concentration of SLPI.⁹⁸ This is consistent with a recent report in which a genome-wide approach was used to identify deficient expression of proteinase inhibitor 3 in preterm PROM (proteinase inhibitor 3 is an inhibitor of elastase).⁹⁹

A role for the fetus in preterm PROM

Romero et al.¹⁰⁰ have proposed that the human fetus plays a role in preterm PROM. The basic concept is that, when there is a hostile intrauterine environment, the fetus may initiate labor with intact or ruptured membranes. However, rupture of the membranes would accelerate exit from the hostile environment, because the initiation of parturition is faster after a spontaneous “amniotomy.” The evidence in support of this view is that fetuses with preterm PROM have higher median plasma concentrations of MMP-9 than fetuses with preterm labor and intact membranes (preterm PROM: 128.6 ng/mL, range 18.8–1690 versus preterm labor: 93.7 ng/mL, range 13.2–738.5; $P = 0.04$),¹⁰⁰ and that this elevation in MMP-9 is not extended to other markers of the fetal inflammatory response, such as the fetal plasma concentration of interleukin (IL)-1 β and tumor necrosis factor (TNF)- α soluble receptors.

Moreover, the concentrations of IL-1 β , sTNF-R1, and sTNF-R2 in fetal blood were higher in fetuses with preterm labor and intact membranes than in those with preterm PROM. This suggests a dissociation between the behavior of proinflammatory cytokines and MMP-9. If the hypothesis that the human fetus plays a role in eliciting preterm PROM is correct, then the question remains: why do some fetuses – even in the presence of infection – resort to preterm labor with intact membranes and others to preterm PROM? Romero et al.¹⁰⁰ have proposed that the choice of initiating preterm labor with intact or rupture of membranes depends on environmental and genetic factors. For example, an insult such as intrauterine infection may lead to preterm PROM in cases in which there is a genetic predisposition to overproduction of MMPs, and to preterm labor with intact membranes if the genetic endowment is to overproduce uterotonic agents.

A role for selective cytokines in maintaining membrane integrity

Bryant-Greenwood's laboratory^{101–103} has proposed a role for the cytokine preB-cell colony-enhancing factor (PBEF) and IL-8 in membrane homeostasis during pregnancy. The authors reported that the gene expression of PBEF and IL-8 is upregulated after distention of the membranes *in vivo* and *in vitro*.^{102,103} PBEF and IL-8 have been proposed to prevent membrane rupture by facilitating the stretching of the membranes. This could be accomplished, among other ways, by the antiapoptotic properties of PBEF¹⁰⁴ and IL-8.¹⁰⁵ Thus, during uterine growth, IL-8 and PBEF will be produced, protecting the chorioamniotic membranes against apoptosis.¹⁰¹

Rupture of membranes as an obstetric syndrome

The current taxonomy of disease in obstetrics is largely based on the clinical presentation of the mother and not the mechanism responsible for disease. For example, the term “rupture of membranes” refers to the clinical condition in which a patient is leaking amniotic fluid. However, this term does not inform the clinician as to whether the condition is caused by an infection, a vascular insult, a weakness in the structure of the membranes, trauma caused by an invasive procedure (endoscopy), or other mechanisms of disease. Romero¹⁰⁶ has proposed that the classification of disease in obstetrics is at a stage in which we recognize syndromes. The features of these obstetrical syndromes are: (1) multiple etiologies; (2) chronicity; (3) frequent fetal involvement; (4) adaptive clinical manifestations; and (5) predisposition due to gene–environment interaction.¹⁰⁷

Preterm PROM is one of the “great obstetrical syndromes.”¹⁰⁶ Multiple pathologic processes can lead to preterm PROM (see below). The chronic nature of the pathologic process leading to preterm PROM can be inferred from the

observations that women with a short cervix (≤ 25 mm),¹⁰⁸ a positive fetal fibronectin (FFN) in vaginal fluid,¹⁰⁸ bacterial vaginosis,¹⁰⁸ and bleeding in the first and second trimesters of pregnancy^{108–110} are at risk for the subsequent development of preterm PROM. Fetal involvement has been demonstrated, as conventional microbiologic techniques have indicated that 10% of all fetuses with preterm PROM show evidence of fetal bacteremia.¹¹¹ However, these techniques may underestimate the fetal attack rate for infection. We have proposed that PROM is not the result of an accident, but rather a mechanism of host defense in the context of intrauterine infection, and that spontaneous rupture of membranes occurs to facilitate the drainage of an infected cavity (intra-amniotic infection), as well as to initiate labor (amniotomy is often followed by the onset of labor in term or preterm gestation). The adaptive nature of the response when rupture of membranes is not associated with infection remains to be determined. Finally, there is evidence that genetic factors predispose to preterm PROM. Polymorphisms for genes coding for MMP-1,¹¹² MMP-9,¹¹³ and MMP-8¹¹⁴ in the fetus have been associated with spontaneous rupture of membranes in case-control studies. Environmental factors, such as bacterial vaginosis^{108,115} or a proinflammatory vaginal milieu,¹¹⁶ have also been associated with PROM. Evidence for a gene-environment interaction for preterm birth has been demonstrated between bacterial vaginosis and a polymorphism for the proinflammatory cytokine, TNF- α .^{117,118} In addition, Estrada-Gutierrez et al.¹¹⁹ have suggested that there are factors in maternal blood which may regulate connective tissue degradation in the amniochorion. However, such evidence is not yet available for preterm PROM. It is also possible that gene-gene interactions are operative. The genetic predisposition for preterm PROM is likely to result from the effect of multiple alleles, which individually confer a small risk of preterm PROM. Finally, the possibility of epigenetic changes must also be considered. Collectively, the evidence reviewed in this paragraph supports the view that preterm PROM is not a single condition, but a syndrome.

Mechanisms of disease implicated in preterm PROM

Intra-amniotic infection/inflammation

Intra-amniotic infection/inflammation has been implicated in term and preterm PROM. Preterm PROM is associated with positive amniotic fluid cultures in approximately 30% of cases.¹²⁰ However, when amniocenteses are performed at the time of the onset of labor, 75% of patients have microbial invasion of the amniotic cavity (MIAC).¹²¹ This suggests that a fraction of patients may have infection prior to clinical rupture of membranes and that, in some patients, infection occurs after membrane rupture. The best evidence indicating that intra-amniotic infection and inflammation precede preterm PROM derives from a number of studies in which amniotic fluid cultures for microorganisms^{122–124} and pro-

inflammatory cytokines and MMP-8¹²⁵ were measured in the amniotic fluid of women undergoing midtrimester amniocentesis. Some women in whom MIAC was detected will present with preterm PROM shortly after amniocentesis (i.e., hours or days) or weeks after the procedure.^{122–124}

Vascular pathology

Arias et al.¹²⁶ reported that histologic examination of the placenta of women who delivered with preterm PROM identified two major subclusters of patients: those with acute histologic chorioamnionitis and another group with vascular lesions of the placenta. Interestingly, sometimes, patients with vascular lesions also had inflammatory lesions (histologic chorioamnionitis).¹²⁷ The specific vascular lesions included “failure of physiologic transformation of the spiral arteries,” atherosclerosis, fibrinoid necrosis of the decidual vessels, and decidual vessel thrombosis consistent with decidual vasculopathy.¹²⁸ We have proposed that some patients who bleed in the first trimester of pregnancy have a disorder of endometrial hemostasis.¹²⁹ Vaginal bleeding may predispose to membrane rupture by causing a separation between the chorioamnion and the decidua, which weakens the fetal membranes.¹²⁹ Alternatively, during the formation of a retroplacental clot, thrombin is generated.¹³⁰ This enzyme can stimulate the production of MMP-1¹³¹ and MMP-3¹³⁰ by decidual cells, and MMP-9, in turn, by amniochorionic membranes.¹³² These MMPs can degrade fibrillar collagen (type I and III) and other components of the extracellular matrix of the chorioamniotic membranes¹³³ (see Table 63.1). The mechanisms responsible for defective endometrial hemostasis during pregnancy have not been identified. The observation that the only manifestation of intrauterine infection may be vaginal bleeding¹²⁹ indicates an association between vaginal bleeding in the first and second trimesters of pregnancy, endometrial bleeding/deficient hemostasis, and intrauterine infection. This association is important because women with preterm PROM often have clinical or subclinical abruptions, and histologic examination of the membranes indicates that acute chorioamnionitis is frequent in patients with abruption.¹³⁴

Uterine cervical pathology

Women with operations in the lower genital tract, such as cervical conization^{135,136} or previous spontaneous abortions,¹³⁷ are at greater risk of preterm PROM. For example, Buchmayer et al.¹³⁷ reported that a history of two or more spontaneous abortions was associated with an OR of 4.1 (95% CI 2.2–7.8) for preterm PROM. The pathophysiologic link between cervical pathology and PROM has not been established. We propose that integrity of the cervix is important to prevent ascending intrauterine infection and maintain the integrity of the lower pole of the membranes. Untimely shortening of the cervix,^{138,139} loss of the mucus plug, funneling, and dynamic changes in the cervix may predispose to ascending infection or the generation of a localized area of weakness in close proximity to the internal cervical os (this process may be unrelated

to infection, but mediated through an inflammatory process). Moreover, the loss of the mucus plug may reduce the ability of the innate system to prevent ascending intrauterine infection.^{140–142} This hypothesis would explain the link between a short cervix and subsequent preterm PROM.¹⁰⁸

Acquired or congenital connective tissue disorders

Patients with Ehler–Danlos syndrome are at increased risk of preterm PROM if they carry an affected fetus.¹⁴³ This observation suggests that a connective tissue disorder, which can affect the membranes (the chorioamniotic membranes are fetal tissues), may predispose to preterm PROM. However, the attributable risk of mendelian disorders for preterm PROM is extremely low. Polymorphisms in the promoter region of genes encoding for MMPs may also predispose to membrane rupture (MMP-1,¹¹² MMP-8,¹¹⁴ MMP-9¹¹³). Each of these polymorphisms may confer a mild to moderate risk, but this risk may be increased in patients who have a relative deficiency of vitamin C. There is some evidence that acquired conditions

such as a relative deficiency of vitamin C, which is crucial for the synthesis of collagen,¹⁴⁴ may predispose to preterm PROM.^{145,146}

Clinical risk factors for membrane rupture

A comprehensive analysis of risk factors associated with preterm PROM was conducted by Harger et al.¹⁴⁷ using a multicenter case–control study. The demographic factors and the medical, obstetric, gynecologic, and sexual histories of 341 women with preterm PROM (20–36 weeks) were compared with those of 253 control subjects matched for maternal age, gestational age, parity, type of care (private versus clinic), and previous vaginal or Cesarean delivery.¹⁴⁷ Multiple logistic regression analysis demonstrated that three factors associated with preterm PROM were: (1) previous preterm delivery; (2) vaginal bleeding during the index pregnancy; and (3) cigarette smoking (Table 63.2). Similar findings have been reported in a case–control study of 138 patients with preterm PROM and 267 control subjects. Vaginal bleeding, smoking, and low socioeconomic class were also found to be independent risk factors for preterm PROM.¹⁴⁸ In a large, multicenter, observational cohort study, Mercer et al.¹⁰⁸ reported the risk factors for preterm PROM (less than 35 weeks), stratified according to parity (see Table 63.3). Ladfors et al.,¹⁴⁹ in a large cohort study conducted in Sweden, reported that primiparity (OR 2.0, 95% CI 1.5–2.6), PROM in a previous pregnancy (OR 3.0, 95% CI 1.6–5.5), bleeding in the first trimester (OR 3.0, 95% CI 1.6–5.9), and premature contractions (OR 2.2, 95% CI 1.2–4.0) were associated with PROM at or near term. In conclusion, vaginal bleeding, a short cervix (≤ 25 mm), a history of previous spontaneous preterm delivery (with intact or ruptured membranes), and smoking are risk factors for preterm PROM in the index pregnancy.

Table 63.2 Clinical risk factors for preterm premature rupture of the membranes (multivariate analysis).

Risk factors	Odds ratio	95% confidence interval
Previous preterm delivery	2.48	1.40–2.48
Cigarette smoking	2.08	1.37–3.13
No bleeding during pregnancy	1.00	–
First-trimester bleeding	2.38	1.47–3.86
Second-trimester bleeding	4.42	1.62–12.03
Third-trimester bleeding	6.44	1.81–22.91
Bleeding during more than one trimester	7.43	2.16–25.60

Review of the evidence linking specific risk factors to preterm PROM

Previous preterm PROM

The risk of preterm PROM in a subsequent pregnancy is 4% if the patient's first pregnancy went to term and was not complicated by preterm PROM. In contrast, the recurrence rate of preterm PROM is 21%, while that of term PROM is 26%.¹³⁵ These observations are based on the data set from the Collaborative Perinatal Project, in which patients with two successive singleton pregnancies were studied ($n = 5230$) (see Table 63.4).¹³⁵ Several investigators have confirmed the high recurrence rate of preterm PROM. For example, Asrat et al.¹⁵⁰ reported a 32% (95% CI 23.9–40.5) recurrence risk in 121 patients with previous preterm PROM. Similar observations were made by Ekwo et al.,^{151,152} who reported that women with preterm PROM had a 6.3 times higher risk of recurrence than those in the control group. Mercer¹² reported that women with prior preterm PROM had a 13.5-fold increase in the risk of preterm PROM at less than 28 weeks in a subsequent gestation.

Vaginal bleeding

Vaginal bleeding in the index pregnancy is a major risk factor for preterm PROM.^{147,148,153,154} Harger et al.¹⁴⁷ reported that vaginal bleeding in at least one trimester occurred in 41.4% (141/341) of patients with preterm PROM and 17.3% (44/253) of cases without this complication ($P = 0.001$). Multivariate analysis demonstrated that vaginal bleeding remained a significant risk factor for preterm PROM after adjustment for other covariates. Vaginal bleeding during the first trimester was associated with a twofold increase in the risk of preterm PROM; when occurring during the second or third trimester, the risk of preterm PROM was increased four- and sixfold respectively. Importantly, vaginal bleeding occurring in more than one trimester was associated with a sevenfold increase in preterm PROM.¹⁴⁷ More recently, Weiss et al.¹⁰⁹ reported that the presence of heavy bleeding in the first trimester, defined as a blood loss similar to menses, was associated with an increased risk for preterm PROM (OR 3.2%, 95% CI

1.8–5.7). Moreover, Yang et al.¹¹⁰ reported an extensive study of the relationship between vaginal bleeding and preterm PROM. Information was collected about the number of bleeding episodes, in which trimester they occurred, and their duration. The risk factors associated with preterm PROM were: bleeding in the first trimester only [relative risk (RR) 1.9, 95% CI 1.1–3.3], multiple bleeding episodes (RR 2.5, 95% CI 1.2–4.9), and duration of bleeding of more than 1 day (RR 2.0, 95% CI 1.1–3.5).

The precise mechanisms by which vaginal bleeding may lead to preterm PROM are unknown. One possibility is that decidual bleeding with clot formation impairs the nutritional support of the membranes, subsequent stretching of the weakened area leads to rupture, and the blood clot acts as a nidus for ascending infection. An alternative explanation is that this ascending infection may cause deciduitis manifested by vaginal bleeding. Another potential explanation is that thrombin, an enzyme released during coagulation, stimulates the production of matrix-degrading enzymes,^{130,131} which participate in the degradation of the chorioamniotic membranes as mentioned above.

Smoking

Controversy exists regarding the risk of preterm PROM among smokers. Naeye¹³⁵ found no association between smoking and preterm PROM [incidence of preterm PROM in smokers and nonsmokers: 5.3% (34/635) versus 6.7% (43/635), respectively]. On the other hand, Meyer and Tonascia¹⁵⁵ reported that the risk of preterm PROM before 34 weeks was more than three times higher for smokers than for nonsmokers (Fig. 63.4). Evaldson and associates¹³⁶ confirmed this observation in a case-control study which showed that people who smoked more than 10 cigarettes per day were significantly more prone to having preterm PROM than those

Table 63.4 Previous PROM as a risk factor for subsequent PROM (term or preterm).

First pregnancy	Second pregnancy, preterm PROM (%)	Second pregnancy, full-term PROM (%)
Preterm delivery, with PROM	21	17
Preterm delivery, no PROM	10	13
Term delivery, with PROM	7	26
Term delivery, no PROM	4	17

PROM, premature rupture of membranes. From ref. 135 with permission from Lippincott Williams & Wilkins.

Figure 63.4 Risk of premature rupture of membranes (PROM) for smoking and nonsmoking mothers, according to gestational age at delivery (admission diagnosis, rupture of membranes only). From ref. 155 with permission from Elsevier.

who did not. Harger et al.¹⁴⁷ found that smoking throughout pregnancy doubled the risk of preterm PROM (OR 2.1, 95% CI 1.4–3.2). Patients who smoked but stopped during pregnancy did not have a higher risk of PROM than women who never smoked (OR 1.6, 95% CI 0.8–3.3). In two case–control studies, Ekwo et al.^{151,152} established, after multivariate analysis, that smoking increased the risk of preterm PROM (adjusted OR 4.9, 95% CI 1.5–16.8 and adjusted OR 7.9, 95% CI 0.9–69.7, respectively). In a study of 307 women with preterm PROM, Williams et al.¹⁵⁶ found that the adjusted relative risk for preterm PROM of women who had ever smoked during pregnancy was 1.6 times that of control subjects (95% CI 1.1–2.4). There was no correlation between the number of cigarettes smoked per day and the risk of preterm PROM. Hadley et al.¹⁵⁷ reported a case–control study of 133 women with preterm PROM and 133 matched control subjects and found that smoking more than 10 cigarettes per day was a significant independent predictor of preterm PROM (OR 2.8, 95% CI 1.7–4.6). A dose–response relationship was established between smoking and preterm PROM. In conclusion, the majority of the literature suggests that smoking is a risk factor for preterm PROM.

Ethnicity

Most of the evidence suggests that individuals of African–American origin have an increased risk of preterm PROM. Adams et al.¹⁵⁸ reported no differences in the incidence of preterm PROM between Caucasian ($n = 1026$) and African–American ($n = 842$) women. However, African–American women had a higher risk of preterm PROM between 20 and 28 weeks of gestation than Caucasian women (hazard ratio 3.81, 95% CI 1.04–13.99).¹⁵⁸ Schieve and Handler¹⁵⁹ reported a study that included 32 017 patients (13 010 African–Americans and 19 007 Caucasians). African–American women had a higher rate of preterm PROM than Caucasian women [3.9% (516/13 010) versus 1.7% (325/19 007), respectively; $P < 0.001$]. This difference remained after adjusting for medical insurance type (a surrogate indicator of socioeconomic status). Women of African–American origin who had Medicaid or a self-payment program had a relative risk of preterm PROM of 1.8 (95% CI 1.5–2.3) and an excess risk of 22.9% (in comparison with Caucasian women). Unexpectedly, the differences between ethnic groups were even more pronounced among women with private insurance. African–American patients had a higher rate of preterm PROM than Caucasians (RR 2.2, 95% CI 1.7–2.8). The excess risk was calculated to be 24.3%.¹⁵⁹ Similar findings have been reported by Meis et al.¹⁶⁰ Among women who delivered low birthweight neonates, those of African–American origin had a higher risk of PROM than Caucasian patients (OR 1.82, 95% CI 1.45–2.28).¹⁶⁰ In contrast, Odibo et al.,¹⁶¹ in a study addressing the value of a short cervix in the prediction of preterm PROM in 321 patients at risk of preterm delivery, reported that individuals of African–American origin were at increased risk of preterm birth, but not of

preterm PROM. Collectively, these data suggest that African–Americans are at increased risk of preterm PROM, but that the excessive risk cannot be explained by socioeconomic status. The relevant question is whether there could be a genetic predisposition for preterm PROM. For example, Fortunato et al.¹⁶² demonstrated that the fetal membranes of African–American women produced higher MMP-9 concentrations than those of Caucasian women when the membranes were exposed to bacterial endotoxin. Moreover, Ferrand et al.¹¹³ demonstrated that fetal carriage of a 14 CA repeat in the promoter of the gene encoding for MMP-9 is associated with preterm PROM, and Fujimoto et al.¹¹² demonstrated that a polymorphism in the promoter region of the gene for MMP-1 (nt-1607) also conferred an increased risk of preterm PROM (OR 2.29, 95% CI 1.09–4.82). Wang et al.¹¹⁴ studied single nucleotide polymorphisms in the MMP-8 promoter in neonates of African–American women. The combination of a three minor allele haplotype (–799T/–381G/+17G) was associated with a significantly higher risk of preterm PROM (OR 4.63, 95% CI 2.01–11.94). In contrast, the combination of the three major allele haplotype (–799C/–381A/+17C) had a protective effect against preterm PROM (OR 0.52, 95% CI 0.36–0.75).¹¹⁴ Thus, individuals of African–American origin may have a genetic predisposition to preterm PROM. Studies conducted in Hispanics by our group indicate that there are maternal and fetal haplotypes that appear to increase the risk of preterm PROM, and that these haplotypes are different from those previously identified in individuals of African–American origin.¹⁶³ Moreover, we have found that “fetomaternal incompatibility” for certain genes may predispose to preterm PROM. One interpretation of these results is that there are genetic factors that predispose to PROM, and that these may vary among ethnic groups.

Sexual intercourse

Naeye and Peters,¹⁶⁴ using data from the Collaborative Perinatal Project, concluded that coitus during the last month (9–30 days before delivery) was not associated with preterm PROM. Subsequently, Naeye¹³⁵ reanalyzed the data using a different time-frame for coitus (last 9 days before delivery) and reported an association between coitus and preterm PROM.

Mills et al.¹⁶⁵ reported a study in which patients were interviewed at the time of delivery to determine the occurrence of sexual intercourse during pregnancy. The authors concluded that coitus within 1 month of delivery was not associated with a higher incidence of PROM at any gestational age.

In the multicenter case–control study reported by Harger et al.,¹⁴⁷ the percentage of patients who had sexual intercourse at arbitrary intervals before PROM (less than 48 h, more than 48 h but less than 1 week, 1 week to 1 month, and more than 1 month) was higher in the control group than in women with preterm PROM. These observations are in agreement with the findings of other authors who used a smaller sample size.^{166,167} In contrast, Ekwo et al.¹⁶⁸ reported the results of a prospective study in which women were interviewed within 72 h of

delivery. They found that patients with preterm PROM were more likely to have had sexual intercourse in the missionary position during the previous 4 weeks when compared with matched control subjects (adjusted OR 2.4, 95% CI 1.2–5.0). Other sexual activities were not associated with an increased risk of preterm PROM. Moreover, no connection was found between sexual activity and term PROM. We conclude that, with the possible exception of intercourse in the missionary position late in pregnancy, little evidence implicates coitus *per se* in the etiology of PROM. However, to the extent that sexual intercourse may be the method of transmission for sexually transmitted diseases associated with PROM (i.e., *Neisseria gonorrhoeae*), this behavior may confer some risk.

Vitamin C and trace elements

Vitamin C is involved in the metabolism of collagen and has been proposed to play an important role in the maintenance of the integrity of the chorioamniotic membranes.¹⁶⁹ Evidence in support of this view includes: (1) the rate of PROM is higher among patients with low maternal plasma ascorbic acid concentrations than among those with normal plasma concentrations [14.6% (13/89) in patients with a level of 0.20 mg/dL or less versus 1.4% (1/69) in patients with a level of 0.60 mg/dL or more];¹⁷⁰ (2) decreased concentrations of vitamin C in leukocytes at 20 weeks of gestation have been associated with the subsequent development of PROM;¹⁴⁵ (3) *in vitro* studies demonstrated that increasing concentrations of vitamin C in culture media decreased MMP-1, MMP-2, and MMP-9 enzymatic activity and concentrations;¹⁷¹ (4) Barrett et al.¹⁴⁶ reported a decreased amniotic fluid concentration of vitamin C in women with PROM; and (5) the total ascorbic acid concentration is significantly lower in the amniotic membranes from patients with preterm PROM than from control subjects (PROM median: 0.0265 mol/g tissue, range 0.008–0.129 versus control median: 0.034 mol/g tissue, range 0.009–0.135; $P = 0.01$).¹⁷²

Casanueva et al.¹⁶⁹ reported a randomized, double-blind controlled study of vitamin C supplementation, in which women with singleton gestations at less than 20 weeks were randomized to vitamin C supplementation (100 mg/day) ($n = 52$) or placebo ($n = 57$).¹⁶⁹ Supplementation with vitamin C was associated with a reduction in the rate of PROM of 74% (RR 0.26, 95% CI 0.078–0.837).

Copper deficiency has been shown to inhibit the maturation of collagen and elastin, although studies of the association of copper levels during pregnancy and PROM have shown conflicting results. Artal et al.¹⁷³ reported that, while patients with term PROM had lower copper concentrations in maternal and umbilical cord sera than patients with artificial rupture of membranes during labor, there was no difference in membrane copper content. These findings were not confirmed by a subsequent study by Kiilholma and colleagues,¹⁷⁴ who found no differences in maternal or fetal serum copper concentrations between term patients with and without PROM. On the other hand, umbilical cord (but not maternal) serum copper and

ceruloplasmin levels were significantly lower in patients with preterm PROM than in those with preterm delivery without PROM.

Two studies have addressed the relationship between zinc and PROM. Kiilholma and colleagues¹⁷⁴ found no significant difference in maternal and umbilical cord zinc serum concentrations between patients with preterm PROM and those with preterm delivery with intact membranes. A limitation of this study is that serum zinc reflects only a minor proportion of the total body zinc. In another study, a maternal zinc index was calculated (a sum of measurements of zinc in maternal blood, scalp and pubic hair, and colostrum) and was found to be lower in patients with term PROM than in those without this condition.^{174,175} On the other hand, magnesium¹⁷⁶ and calcium¹⁷⁷ supplementation in pregnancy has no effect on the incidence of preterm PROM.^{176,177}

Elevated maternal serum alpha-fetoprotein concentration (MSAFP)

One study reported that women with an elevated second-trimester MSAFP (more than 2.0 multiples of the median) have a significantly increased risk of subsequent preterm PROM (OR 10.4, 95% CI 3.6–29.4),¹⁷⁸ while two other studies demonstrated no such association.^{179,180} The possible association between preterm PROM and elevated MSAFP suggests that leakage of fetal proteins into the maternal circulation may predispose to PROM. This, however, remains speculative.

Previous operations on the genital tract

There are no consistent results on the effect of cervical surgery on the risk of PROM.^{181,182} While some studies demonstrated a higher frequency of PROM among patients with a history of cervical conization or dilation and curettage (D&C),^{135,136,183} other studies could not demonstrate an association between a history of surgical manipulation and PROM after controlling for confounding variables.^{147,181,182}

Pelvic examinations and PROM

Lenihan¹⁸⁴ reported a randomized prospective trial in which women at 37 weeks of gestation were randomized to either weekly pelvic examinations or none at all. PROM was more common in women who underwent repeated pelvic examinations than in the control group [18% (32/174) versus 6% (10/175), $P < 0.001$]. In contrast, McDuffie et al.¹⁸⁵ performed a prospective randomized trial of weekly cervical examinations beginning at the 37th week of gestation versus none at all, and found no differences in the rate of PROM, chorioamnionitis, or neonatal infectious morbidity between the two management policies.

Main et al.¹⁸⁶ reported the results of a preterm delivery prevention program in which women at risk of preterm delivery were randomized to either biweekly pelvic examinations or standard obstetric care. No significant difference in the frequency of PROM was noted between the two groups [50%

(8/16) versus 28.6% (4/14)]. This observation was subsequently confirmed with a larger sample size.¹⁸⁷ Holbrook et al.,¹⁸⁸ in a retrospective review of patients enrolled in a preterm birth prevention program that called for weekly cervical examinations between 20 and 37 weeks, found no increase in rates of preterm PROM, chorioamnionitis, or postpartum endometritis. While most reports do not seem to support an etiologic role for digital examination of the cervix in PROM, the technique of the digital examination is probably important. An examination in which the endocervical canal is probed with the examining finger may dislodge or damage the mucus plug and carry bacteria into close proximity to the membranes. An examination limited to the fornix and external os would not carry a risk of this kind. However, such examination is uninformative for effacement. Sonographic examination can provide information regarding cervical length without the risk of dislodging the mucus plug. We, therefore, do not see the justification for performing repeated cervical examinations during pregnancy if ultrasound is available.

Colonization and infection of the lower genital tract with selective microorganisms

Evidence supports an association between endocervical infection with *Chlamydia trachomatis* and *N. gonorrhoeae* and the development of PROM, but not with colonization with group B *Streptococcus*, genital *Mycoplasmas*, or the presence of bacterial vaginosis in low-risk populations and the development of PROM.^{111,189} The relationship between colonization/infection or a change in the bacterial ecosystem and the subsequent development of preterm PROM is reviewed below.

Bacterial vaginosis and vaginal inflammation

An association between bacterial vaginosis (BV) and preterm PROM has been reported in some studies, largely in high-risk patients. However, the results are not consistent. For example, Kurki et al.¹¹⁵ reported that women with a diagnosis of bacterial vaginosis (BV) between 8 and 17 weeks of gestation had a high risk of preterm PROM (OR 7.3, 95% CI 1.8–29.4). In the Prediction of Prematurity Study, BV was found to be a modest risk factor for preterm PROM before 37 weeks¹⁰⁸ (see Table 63.3). These results contrast with those of a large cohort study of 10 397 women at low risk of preterm delivery, in which no association was found between BV and PROM.¹⁹⁰

An explanation for the inconsistent results is that only a subset of patients with BV is at risk of preterm birth. Such a subset may represent patients with vaginal inflammation, which can be detected by determining the number of neutrophils in vaginal fluid. The conventional diagnosis of BV relies only on the classification of the microbial flora of the vagina. Using these criteria, approximately 20% of women will have BV, and most will not deliver a preterm neonate or have preterm PROM. There is evidence that patients with vaginal inflammation (with or without BV) may be at risk of subsequent preterm delivery. For example, Simhan et al.¹¹⁶

reported that patients with vaginal inflammation (defined as vaginal pH > 5 and more than five neutrophils per oil field) in the midtrimester had a higher risk of preterm PROM remote from term in the index pregnancy (for preterm PROM between 24 and 32 weeks: OR 11.7, 95% CI 2.8–49.5). A full discussion of the subject is available for interested readers.¹⁹¹

As BV confers a modest risk of spontaneous preterm birth and preterm PROM, it is not surprising that recent trials in low-risk patients have not demonstrated that antibiotic treatment can reduce the rate of spontaneous preterm delivery. For example, a randomized clinical trial conducted by the Network of Maternal Fetal Medicine Units concluded that treatment of asymptomatic BV with metronidazole during pregnancy did not prevent spontaneous preterm deliveries [metronidazole 5.1% (48/953) versus placebo 5.7% (55/966), RR 0.9, 95% CI 0.6–1.3] or spontaneous rupture of the membranes [4.2% (40/953) versus 3.7 (36/966), RR 1.1, 95% CI 0.7–1.8].¹⁹²

In contrast, a recent systematic review conducted by McDonald et al.¹⁹³ reported that, among patients with a history of preterm delivery, treatment for BV during pregnancy reduced the risk of preterm PROM (OR 0.14, 95% CI 0.05–0.38). We interpret the conclusions of this systematic review as indicating that a subgroup of patients with BV may benefit from treatment. Such patients may be those who deploy an exaggerated proinflammatory response (hyper-responders) to BV in the vaginal mucosa or the hyporesponders.^{116,191}

Group B *Streptococcus* (GBS)

Colonization with GBS is not a risk factor for spontaneous preterm delivery or preterm PROM. However, once preterm delivery is impending, colonization is a risk factor for adverse neonatal outcome.

Regan and colleagues¹⁹⁴ reported that PROM before the onset of labor or contractions was more common in women with cervical colonization of GBS at the time of delivery than in noncarriers [15.3% (134/877) versus 7% (411/5829), $P < 0.005$]. Matorras et al.¹⁹⁵ reported that patients with positive perineal GBS cultures had a higher rate of PROM than patients with negative cultures [26.4% (32/121) versus 17.8% (158/890), $P < 0.05$]. Among GBS carriers, those who also had a positive cervical culture had a higher rate of PROM than those with a negative cervical culture [41.7% (10/24) versus 19% (8/42), $P < 0.05$].

Patients with PROM had a higher frequency of positive cultures for GBS on admission than those with intact membranes [15.6% (7/45) versus 3.8% (3/80), $P < 0.05$].¹⁹⁶ Women with PROM colonized with GBS had increased incidence of chorioamnionitis, endometritis, and neonatal infections, as opposed to women with PROM and negative GBS cultures.¹⁹⁷ There are inconsistent reports concerning the effect of GBS colonization and the duration of the latency period in patients with PROM.^{197,198} Maxwell and Watson¹⁹⁹ reported that antibiotic treatment of patients with preterm PROM

(26–33 weeks) and positive cultures for *N. gonorrhoeae*, GBS, or both resulted in a similar latency period until delivery and frequency of postpartum fever as in patients with negative cultures. However, the incidence of pneumonia was higher in infants born to mothers with positive cervical cultures (OR 6.9, 95% CI 2.1–22.8).¹⁹⁹ In conclusion, GBS colonization is not associated with an increased risk of preterm PROM.²⁰⁰ Therefore, treatment of colonized patients will not reduce the rate of PROM.

Chlamydia trachomatis

A positive endocervical culture for *C. trachomatis* is an indication for treatment. In pregnant women, the rate of positive cultures has been reported to be 8%.²⁰¹ Among patients with positive *C. trachomatis* cultures, PROM was more common in those with positive serum IgM than in those with negative IgM [41.1% (7/17) versus 7.0% (4/53), $P < 0.01$].²⁰¹ Similar findings were reported by Sweet et al.²⁰² A positive *C. trachomatis* culture at the first perinatal visit was associated with a relative risk of 2 for preterm PROM and a population attributed risk of 9%.²⁰² Moreover, Alger et al.¹⁹⁶ reported that *C. trachomatis* was isolated more frequently from patients with preterm PROM than from women in the control group [44% (23/52) versus 15% (13/84), $P < 0.01$]. Collectively, this evidence suggests that infection with *C. trachomatis* with a humoral immune response (positive IgM) is a risk factor for preterm PROM.

Neisseria gonorrhoeae (NG)

The precise risk for preterm PROM conferred by NG endocervicitis is unknown. This is probably attributable to a long history of screening and treatment of NG during pregnancy. An association between NG and PROM has been recognized clinically based on studies examining the frequency of NG isolation at the time of the diagnosis of PROM. For example, Amstey and Steadman²⁰³ reported an association between PROM and preterm delivery and maternal colonization with NG. Positive cultures for NG were found in 4.4% of patients (222/5065). The prevalence of prolonged PROM (more than 24 h) was significantly higher in women with positive endocervical, endometrial, or placental cultures for NG than in women with negative cultures [75% (9/12) versus 37% (18/49), $P < 0.05$].²⁰⁴ PROM was more common in women with positive cultures than in those with negative cultures [26% (52/198) versus 19% (799/4246), $P < 0.01$].^{203,205} However, the prevalence of PROM in women with positive cervical cultures during pregnancy was not significantly higher than in a matched control group [28.1% (50/178) versus 25.4% (98/386), not significant].⁷ Given the standard of practice to screen and treat for NG, calculations of the attributable risk and magnitude of risk for preterm PROM are difficult to make and have limited practical value.

Trichomonas vaginalis (TV)

There is controversy concerning whether colonization with TV and symptomatic vaginitis caused by this organism predispose

to preterm PROM. For example, Minkoff et al.²⁰⁶ reported a study in which 233 patients had cultures performed at the time of their first prenatal visit (mean 13.8 ± 3.6 weeks). The frequency of positive cultures for TV was 14.6% (34/233). Women who subsequently developed PROM (term and preterm) had a higher rate of positive cultures for TV in early pregnancy than women with intact membranes [27.5% (11/40) versus 12.8% (19/148), $P < 0.03$]. Stepwise logistic regression analysis showed that a positive culture for TV was associated with an “estimated probability” of 1.42 for PROM ($P < 0.03$). In the same study, patients with positive vaginal cultures for *Bacteroides* species had an estimated probability of 2.8 ($P < 0.03$) for preterm PROM. *Staphylococcus epidermidis* was associated with an estimated probability of 1.57 ($P < 0.02$) for PROM.²⁰⁶

Even though a positive culture for TV may be associated with a modest increase in the risk for spontaneous preterm delivery, perhaps through preterm PROM, randomized clinical trials of antimicrobial agents in women with positive cultures for TV have not reduced the rate of preterm birth. A randomized clinical trial in which women ($n = 617$) were allocated to receive either metronidazole or placebo reported no differences in the rates of preterm delivery (< 37 weeks) with PROM between the two study groups [metronidazole 4.4% (14/315) versus placebo 4.2% (12/289), RR 1.1, 95% CI 0.5–2.3].²⁰⁷ In contrast, the rates of preterm delivery due to preterm labor and intact membranes were significantly higher in the metronidazole group [metronidazole 10.2% (32/315) versus placebo 3.5% (10/289); RR 3.0, 95% CI 1.5–5.9].²⁰⁷ Unexpectedly, a recent study reported that treatment of low-risk patients with positive vaginal culture for TV at 23–26 weeks increases the risk of preterm PROM (OR 1.4, 95% CI 1.03–1.8).²⁰⁸ The authors concluded that treatment of low-risk asymptomatic pregnant women with positive cultures for TV is not recommended.²⁰⁷ Perhaps there is a difference between asymptomatic women with a positive culture and patients who have clinical manifestations of vaginitis caused by TV.

Genetic factors

Preterm PROM could be considered a “common complex disorder,” a term used in modern genetics to refer to a condition resulting from the interaction of genes and the environment. A complex disorder does not follow the pattern of mendelian inheritance. The likelihood of the phenotype (i.e., PROM) may result from gene–gene interaction, gene–environment interaction, and a combination thereof.

Evidence in support of the genetic predisposition for preterm PROM is the association between preterm PROM and Ehler–Danlos syndrome. Barabas²⁰⁹ reported a retrospective study to determine the birth characteristics of patients with Ehler–Danlos syndrome. Birth histories were available for 18 of these patients. The rate of prematurity was 77% (14/18), and preterm PROM occurred in 92% (13/14) of those neonates delivered preterm. Of note, only one of the 16

unaffected siblings had preterm PROM, and this occurred in a twin gestation in which one of the twins was affected. In a recent study, the pregnancy outcome of 46 women with Ehler–Danlos syndrome was compared with that of 33 unaffected women. There were no significant differences in the frequency of preterm PROM between affected and unaffected women. In contrast, preterm PROM occurred in 34% (31/91) of the affected fetuses, compared with 18% (10/55) of the unaffected fetuses ($P = 0.03$).¹⁴³ Several candidate genes have been associated with preterm PROM, and the results of these studies are presented in Table 63.5. Collectively, these data provide additional evidence that the fetal genotype plays an important role in the occurrence of preterm PROM.

Midtrimester fetal heart rate deceleration and subsequent preterm PROM

Decelerations in the second trimester may be associated with the subsequent occurrence of preterm PROM. Indeed, among patients with a singleton gestation who delivered before 32 weeks, those with decelerations between 24 and 27 weeks of gestation had a higher frequency of subsequent PROM than those without decelerations [60.0% (39/65) versus 37.1% (13/35), $P < 0.05$].²¹⁰ The authors concluded that periodic or episodic decelerations during the late second trimester were associated with the occurrence of preterm PROM in the index pregnancy.²¹⁰ It is unclear why patients destined to have preterm PROM have a higher frequency of second-trimester decelerations.

Consequences of premature rupture of the membranes

The main consequences of preterm PROM are spontaneous onset of labor leading to prematurity,^{211–213} infection,¹²⁰ abruptio placentae,²¹⁴ fetal death,²¹⁵ and the oligohydramnios sequence. This section will review, in detail, these conditions. One concept that has been generally overlooked is that PROM carries a risk of maternal death. The prevalence of maternal death associated with PROM was 0.2% in 1959 and decreased to 0.03% (1/3400) in 1982.^{18,216}

Preterm parturition

Preterm PROM is associated with impending preterm delivery in most cases.^{211–213} Cox and associates²¹¹ managed 298 patients with preterm PROM expectantly (no steroids, tocolytics, and prophylactic antibiotics were administered), and amniocenteses were not performed. Of the 267 patients who gave birth to infants weighing ≥ 750 g, only 7% remained undelivered for more than 48 h after admission.

Wilson and coworkers²¹² reported on the outcome of 143 patients with preterm PROM managed expectantly. Eighteen percent of patients remained undelivered after 1 week of admission. Maternal febrile infectious morbidity (antepartum

and postpartum) occurred in 10% of patients. The neonatal death rate was 13.1% (18/137).

The most comprehensive study of the natural history of preterm PROM was reported by Nelson et al.,²¹³ who evaluated the outcome following expectant management of 511 women with a singleton gestation and preterm PROM between 20 and 36 weeks. Fifty-two percent of patients delivered within 48 h, whereas 12.9% remained undelivered after 1 week. The perinatal death rate was 8.4% (43/511). Not surprisingly, most deaths occurred at gestational ages of less than 28 weeks [42.7% (35/82)]. Maternal infection occurred in 21.7%, and the occurrence of fetal death was strongly associated with infection. The perinatal mortality was higher in neonates born to infected mothers with preterm PROM before 28 weeks than after 28 weeks [46.6% (14/30) versus 1.2% (1/81)], as was also true for infection-related morbidity (36% versus 19.8%).

Infection

Rupture of membranes may be associated with maternal or fetal infection. Maternal infection can be expressed as clinical chorioamnionitis. However, most women who have MIAC do not have clinical evidence of infection,²¹⁷ such as fever, leukocytosis, etc. This section will review the prevalence, microbiology, fetal attack rate, frequency of fetal inflammation, and short- and long-term consequences of infection/inflammation in preterm PROM.

What is the prevalence of MIAC in PROM?

The prevalence of positive amniotic fluid cultures in women with preterm PROM is 32.4% (473/1462)¹²⁰ (see Table 63.6), and is 34.3% (11/32) in term PROM.²¹⁸ However, this represents a minimum estimate of the frequency of infection, because: (1) Frequency is dependent upon isolation of microorganisms with standard microbiologic techniques, which underestimate the true rate of infection. The application of molecular microbiologic techniques (cultivation independent) has yielded a higher rate of microbial footprints. Moreover, patients who have a positive polymerase chain reaction (PCR) result for microorganisms, but a negative culture, have comparable outcomes to those who have a positive amniotic fluid culture for microorganisms;²¹⁹ (2) Amniocentesis is rarely performed if the patient presents in labor. Yet, there is evidence that patients with preterm PROM and labor have a higher rate of MIAC than patients with preterm PROM without labor;¹²¹ and (3) Amniocentesis is less frequently performed in patients who have reduced volumes of amniotic fluid. Several studies have demonstrated that the lower the volume of amniotic fluid, the higher the rate of positive amniotic fluid cultures.^{220–222} Normal amniotic fluid has antimicrobial properties that have been attributed to the presence of natural antimicrobial peptides,^{223–226} such as epithelial²²⁷ and neutrophil defensins.²²⁴ Oligohydramnios may be associated with decreased availability of these antimicrobial peptides

and, therefore, impaired innate immunity. Alternatively, fetal infection/inflammation may lead to redistribution of fetal blood flow, reduction in fetal urine production, and oligohydramnios. The net effect is that oligohydramnios is associated with an increased frequency of intra-amniotic infection and inflammation.

What are the microorganisms isolated in MIAC?

In preterm PROM, genital mycoplasmas (*Ureaplasma urealyticum* and *Mycoplasma hominis*) are the most frequent isolates from the amniotic fluid, followed by *Streptococcus agalactiae*, *Fusobacterium* species, and *Gardnerella vaginalis*. Polymicrobial infection is found in 26.7% (43/161) of cases^{111,121,228–232} and an inoculum size greater than 10⁵ colony-forming units/mL is found in 23% (6/26) of patients for whom quantitative microbiology was performed.²³² The most common microorganisms isolated from women with term PROM are *U. urealyticum*, *Peptostreptococcus*, *Lactobacillus*, *Bacteroides* species, and *Fusobacterium*.²¹⁸ Microorganisms isolated from the amniotic fluid in women with term and preterm PROM are qualitatively similar.

What are the consequences of MIAC?

Patients with MIAC are more likely to develop chorioamnionitis, endometritis, and neonatal sepsis than patients with negative amniotic fluid cultures on admission.^{65,111,121,220,228–241} Table 63.7 shows the rate of these complications in studies in which antibiotics were not used before delivery. Garite and Freeman²³⁷ reported that the frequency of respiratory distress syndrome (RDS) was twofold higher in neonates born to

women with positive amniotic fluid cultures than in those born to women with negative cultures. Two explanations for these findings can be considered. First, patients with a positive amniotic fluid culture are generally at a lower gestational age than those with a negative amniotic fluid culture. Therefore, the higher incidence of RDS may reflect a greater degree of prematurity. Second, some cases of respiratory difficulty may be due to pneumonia rather than RDS.^{242–244}

Is MIAC related to the onset of labor in preterm PROM?

The onset of labor in the setting of PROM has traditionally been considered an early sign of intrauterine infection. One study has examined the relationship between MIAC and the onset of preterm labor in women with PROM.¹²¹ Patients in labor on admission had a higher rate of positive amniotic fluid cultures than women admitted with preterm PROM but not in labor [39% (24/61) versus 26% (41/160), *P* = 0.049]. Moreover, 75% of patients who were not in labor on admission, but subsequently went into spontaneous labor, had a positive amniotic fluid culture around the time of onset of labor.

Zlatnik et al.²³² conducted a unique study in which the results of amniotic fluid cultures were not used in patient management. A higher proportion of patients with positive amniotic fluid cultures delivered within 7 days, compared with those with negative cultures [positive cultures 89% (8/9) versus negative cultures: 45% (9/20), *P* = 0.04]. These data support a relationship between MIAC and the onset of preterm labor.

*Inclusive of chorioamnionitis and endometritis.

Are there differences in the inoculum size and type of microorganisms between women in labor and not in labor with preterm PROM?

Zlatnik et al.²³² reported that four of six patients with a colony count greater than 10^4 /mL were delivered within 72 h, compared with none of three with counts lower than 10^4 /mL. However, this difference did not reach statistical significance. Similarly, Romero et al.¹²¹ reported that patients with preterm PROM in active labor on admission had a higher inoculum size than women not in labor [colony counts higher than 10^5 were found in 55% (10/18) versus 23% (6/26) respectively; $P < 0.05$]. These data suggest a possible relationship between proliferation of microorganisms and the onset of preterm labor. On the other hand, the rate of polymicrobial infection was not different between the two groups. Microbial invasion limited to *Mycoplasma* was found in only 8% of patients in labor versus 20% not in labor.

Can intra-amniotic infection resolve without treatment?

Romero et al.¹²¹ performed a second amniocentesis in 12 women who originally had a negative Gram stain of the amniotic fluid but a positive amniotic fluid culture. One patient had a first amniotic fluid culture positive for *Fusobacterium* species, but the second amniotic fluid culture obtained at the time of the spontaneous initiation of labor showed no growth. It is unclear whether this observation represents a failure of culture or a true resolution of MIAC. The initiation of labor and the observation that this patient had histologic chorioamnionitis makes the second possibility less likely. In 11 patients, the microorganisms recovered from the second amniocentesis were the same as those retrieved from the first, but the colony count was higher in all instances. This indicates that, once MIAC has occurred, it has a progressive course. Whether this is the natural history of intra-amniotic infection in the midtrimester of pregnancy or in patients who have viral colonization of the amniotic fluid is unknown.

Can treatment with antibiotics in patients with intra-amniotic infection alter the natural history?

This question was addressed by Romero et al.,²⁴⁵ who reported that the latency period was shorter and the neonatal morbidity higher in a cohort of patients with preterm PROM who had a positive culture for *U. urealyticum* (without antibiotic treatment) than in those with sterile amniotic fluid. Gauthier et al.²⁴⁶ treated patients with preterm PROM and positive amniotic fluid cultures for *U. urealyticum* with a 1-week course of erythromycin. The latency period and the frequency of chorioamnionitis and neonatal sepsis in the treated group were not different from those of patients with sterile amniotic fluid. The observation that patients undergoing midtrimester amniocenteses who had a positive fluid culture or positive antibodies for *U. urealyticum* followed by preterm delivery, low birthweight infants, and fetal death suggests that some infections are chronic in nature.²⁴⁷

Does antibiotic administration to patients with preterm PROM prevent subsequent microbial invasion or eradicate existing infection at the time of initiation of treatment?

A recent study investigated the course of MIAC in 46 patients with preterm PROM.²⁴⁸ All underwent amniocentesis upon admission, with an 18% prevalence of intra-amniotic inflammation (defined as an amniotic fluid white blood cell count $\geq 100/\text{mm}^3$) and a 15% prevalence of MIAC. Patients without evidence of intra-amniotic inflammation or MIAC were treated with ampicillin and erythromycin for 7 days. Those with intra-amniotic inflammation or MIAC were treated with ceftriaxone, clindamycin, and erythromycin for 10–14 days. At the time of the second amniocentesis, six of the seven patients with a prior diagnosis of MIAC were again positive for microorganisms. Of 18 patients with intra-amniotic inflammation, only three showed no evidence of inflammation after antibiotic treatment. Of note, among patients with no evidence of intra-amniotic inflammation or MIAC at

admission, 32% (9/28) developed inflammation despite therapy. Five of the nine patients in question had positive amniotic fluid cultures. These observations suggest that systemic treatment with these antibiotics may not alter the natural course of MIAC in preterm PROM.

Can the fetus be infected *in utero*? Does this influence the latency period?

Evidence of fetal infection was provided by Carroll et al.,²⁴⁹ who performed amniocentesis and cordocentesis at the time of presentation with PROM. The frequency of positive fetal blood culture was 10.3% (10/97). The authors found that, for patients with positive amniotic fluid and fetal blood cultures, the median time to delivery was 2 days (range 1–5 days), compared with 41 days (range 1–161 days) for patients with negative cultures in both amniotic fluid and fetal blood. In the case of patients with MIAC and negative fetal blood cultures, the median interval to delivery was 9 days (range 1–37 days).²⁴⁹

It is noteworthy that the microorganisms isolated from septic newborns are similar to those found in the amniotic fluid. In a study of 221 patients with preterm PROM, six cases with culture-proven neonatal sepsis were found.¹²¹ In five of these cases, the microorganisms were the same as those found in the amniotic fluid; in the remaining case, the amniotic fluid culture 48 h before delivery had been negative.¹²¹ The practical implication of this observation is that an amniocentesis performed before delivery may provide microbiological information helpful in guiding antibiotic choice in the newborn.

Can the fetus deploy an inflammatory response?

The first evidence that the fetus can mount an inflammatory response was reported some years ago.²⁵⁰ The authors coined the term “fetal inflammatory response syndrome” (FIRS) to refer to an elevation in the fetal plasma concentration of IL-6 (> 11 pg/mL) that was associated with severe neonatal morbidity²⁵⁰ and a shorter cordocentesis-to-delivery interval.²⁵¹

Fetal microbial invasion or other insults result in a systemic fetal inflammatory response that can progress toward multiple organ dysfunction, septic shock, and perhaps death in the absence of timely delivery. Evidence of multisystemic involvement in cases of FIRS includes increased concentrations of fetal plasma MMP-9,¹⁰⁰ an enzyme involved in the digestion of type IV collagen and in the pathophysiology of preterm PROM.²⁵² Moreover, several fetal organs including the hematopoietic system,^{253–255} adrenals,²⁵⁶ heart,²⁵⁷ brain,^{258,259} lungs,^{260,261} and skin²⁶² have been proposed to be target organs during FIRS.

Pathologic examination of the umbilical cord is an easy approach to determine whether fetal inflammation was present before birth. Funisitis and chorionic vasculitis are the histopathologic hallmarks of FIRS.²⁶³ Funisitis is associated with endothelial activation, a key mechanism in the development of organ damage,²⁶⁴ and neonates with funisitis are at increased risk of neonatal sepsis²⁶⁵ and long-term handicaps,

such as bronchopulmonary dysplasia²⁵⁹ and cerebral palsy.²⁶¹ Indeed, newborns with funisitis are at more than a twofold increased risk of IVH²⁶⁶ and have an 11-fold risk of development of periventricular echolucencies.²⁶⁷ In the context of FIRS, the combination of inflammatory changes in the brain and fetal systemic hypotension may increase the likelihood of brain injury.²⁶⁸ Collectively, these observations suggest that a subset of fetuses presenting with preterm PROM have bacteremia and/or FIRS that may contribute to fetal organ damage.

Microbial invasion: cause or consequence of premature rupture of the membranes?

The traditional view has been that MIAC is the consequence of membrane rupture. However, evidence suggests that PROM may be the result of subclinical infection and inflammation. Naeye and Peters¹⁶⁴ reported in 1980 that patients with preterm PROM 1–4 h before the onset of labor had a higher prevalence of histologic chorioamnionitis than patients who delivered preterm without PROM (Table 63.8). Because it is unlikely that inflammation of the chorioamniotic membranes develops in 4 h, these data suggest that, in these cases, histologic chorioamnionitis precedes rather than follows PROM. Several lines of evidence suggest that the most likely cause of histologic chorioamnionitis is subclinical infection. Bacteria have been recovered from 72% of placentas with histologic chorioamnionitis.²⁶⁹ Furthermore, we have demonstrated a good correlation between a positive amniotic fluid culture for microorganisms and histologic chorioamnionitis.²⁷⁰

MIAC can also be the consequence of PROM. The frequency of positive amniotic fluid cultures increases with time. Indeed, 75% of patients who were quiescent on admission and subsequently went into labor had a positive amniotic fluid culture.¹²¹ However, only 25% of these patients had a positive culture on admission, and the remaining 50% became positive during the latency period.¹²¹ These observations are consistent with those of Naeye and Peters,¹⁶⁴ who showed that the incidence of histologic chorioamnionitis increases with the duration of the latency period.

The authors reported that histologic chorioamnionitis (defined as the presence of 4–15 neutrophils in the chorionic plate) in PROM was two- to threefold more common when rupture of membranes occurred just before the onset of labor

Table 63.8 Gestational age at membrane rupture and frequency of histopathologic chorioamnionitis.¹⁶⁴

	20–28 weeks (%)	29–32 weeks (%)	33–37 weeks (%)
Rupture of membranes after onset of labor	23	15	11
Premature rupture of membranes 1–4 h before onset of labor	48	29	32

than when it occurred after labor began.¹⁶⁴ This suggests that inflammation (and probably infection) is in many cases not only a consequence of PROM, but it may also be its cause.

Abruptio placentae

Abruptio placentae occurs more frequently in patients with preterm PROM than in those with preterm labor and intact membranes (2.29% versus 0.86% respectively; RR 3.58, 95% CI 1.74–7.39).²¹⁴ The same conclusion has been previously reported in a systematic review²⁷¹ and a population-based epidemiologic study.²⁷² The mechanisms responsible for separation of the placenta in preterm PROM have not been determined. Nelson and associates²⁷³ proposed that leakage of fluid after PROM may lead to a disproportion between the placental and uterine surfaces that would favor placental separation. Evidence in support of this concept is the observation that, in the context of preterm PROM, the incidence of abruptio placentae increases with the severity of oligohydramnios (12.3% for patients with a vertical pocket of 1–2 cm versus 3.5% among those with a vertical pocket > 2 cm).²⁷⁴ However, two groups of investigators using subjective means to estimate amniotic fluid volume could not confirm this observation.^{275,276}

An alternative hypothesis to explain the relationship between abruptio placentae and preterm PROM postulates that a disorder of decidual hemostasis leads to separation of the membranes from the decidua, with subsequent compromise of their nutritive support, weakening of the membranes, and eventual rupture. Indeed, patients with abruptio placentae after preterm PROM have a higher incidence of vaginal bleeding before rupture and during the latency period than patients without abruptio placentae. In order to evaluate the mechanism of abruption-related preterm delivery, Mackenzie et al.¹³⁰ studied MMP-3 production and expression in primary decidual cell cultures incubated in a medium of steroids plus or minus thrombin. MMP-3, as well as its mRNA, was significantly inhibited by estradiol plus progesterone versus estradiol alone. Interestingly, thrombin elicited a dose-dependent reversal of this progesterone inhibition of MMP-3.

Infection/inflammation within the decidua could also facilitate premature placental detachment. Indeed, there is an association between histologic chorioamnionitis and abruptio placentae.^{134,277} The relative risk of abruption is 9.03 (95% CI 2.80–29.15) when chorioamnionitis is associated with preterm

PROM.²¹⁴ One mechanism for this link has been proposed by Lockwood et al.²⁷⁸ Thrombin, an enzyme released during hemostasis, can enhance IL-8 expression by decidual cells. IL-8 is a chemokine able to recruit neutrophils. The inflammatory process resulting from neutrophil infiltration could induce degradation of extracellular matrix and membrane rupture.

Pulmonary hypoplasia

Pulmonary hypoplasia is characterized by a decrease in the number of lung cells, airways, and alveoli.^{279,280} Its frequency is related to gestational age at the time of membrane rupture, and its presence increases the risk of neonatal death and other complications such as pneumothorax and persistent pulmonary hypertension.

Three studies looked specifically at pulmonary hypoplasia in the context of PROM. Vergani et al.²⁸¹ conducted a prospective study of patients with PROM before 28 weeks of gestation managed conservatively. Pulmonary hypoplasia was diagnosed at autopsy or in the neonates based on radiographic findings. The frequency of pulmonary hypoplasia was 28% (15/54). Gestational age at the time of PROM and presence of oligohydramnios, but not the latency period, were independent predictors of the subsequent development of pulmonary hypoplasia.²⁸¹

Rotschild et al.²⁸⁰ studied 88 neonates born to mothers with PROM occurring before 29 weeks and a latency period of at least 1 week (Table 63.9). The prevalence of pulmonary hypoplasia was 16% (14/88). Gestational age at the time of PROM, but not the duration of the latency period or the severity of oligohydramnios, was associated with pulmonary hypoplasia. The risk of pulmonary hypoplasia when PROM occurs at 19 weeks was 50%, whereas it was only 10% when the membranes ruptured at 25 weeks (Fig. 63.5). This has been confirmed by animal experimentation.²⁸²

Winn et al.²⁸³ prospectively studied 163 patients with preterm PROM from 15 to 28 weeks of gestation. Pulmonary hypoplasia was diagnosed at autopsy or by radiographic findings using the same criteria as Vergani et al.²⁸¹ The incidence of pulmonary hypoplasia was 12.9% (21/163). The authors reported that gestational age at rupture of the membranes, latency period, and either the initial or the average amniotic fluid index (AFI) had significant influence on the development of pulmonary hypoplasia.

Table 63.9 Role of pulmonary hypoplasia in neonatal morbidity and mortality.²⁸⁰

	Pulmonary hypoplasia % (no.)	No pulmonary hypoplasia % (no.)	Odds ratio (95% confidence interval)	P-value (by Fisher's exact test)
Neonatal death	71 (10/14)	11 (8/74)	20.6 (4.5–105)	< 0.001
Pneumothorax	64 (9/14)	15 (11/74)	10.3 (2.5–44.8)	< 0.001
Persistent pulmonary hypertension	43 (6/14)	11 (8/74)	6.2 (1.4–27.2)	< 0.01

Figure 63.5 Curve relating probability of pulmonary hypoplasia to gestational age at rupture of membranes derived from estimated logistic equation: Probability of pulmonary hypoplasia = $1/(1 + e^{-7.27 + 0.38 \text{ GAR}})$. From ref. 280 with permission from Elsevier.

The role of duration of rupture of membranes in the development of pulmonary hypoplasia is not clear. Univariate analysis demonstrated an association between the duration of rupture of membranes and the occurrence of pulmonary hypoplasia.^{281,284–286} However, there is an inverse relationship between the duration of the latency period and the gestational age at the time of membrane rupture. Multivariate analysis has not shown a significant effect of the duration of PROM in the development of pulmonary hypoplasia.²⁸¹

Whereas Rotschild et al.²⁸⁰ reported that the severity of oligohydramnios was not a factor in the development of pulmonary hypoplasia, both Vergani et al.²⁸¹ and Winn et al.²⁸³ reported that amniotic fluid volume was an independent predictor of the development of pulmonary hypoplasia. The discrepancy between studies may be explained by the: (1) determination of amniotic fluid volume; (2) exclusion of patients; and (3) definition of pulmonary hypoplasia.

The mechanisms responsible for pulmonary hypoplasia in PROM are poorly understood.^{287–296} Experimental evidence suggests that oligohydramnios caused by drainage of the amniotic cavity leads to pulmonary hypoplasia. Traditionally, oligohydramnios has been thought to lead to extrinsic compression of the fetal thorax, impairing lung growth. An alternative view is that oligohydramnios reduces lung fluid volume, and this in turn is responsible for pulmonary hypoplasia. Experimental and clinical evidence supporting the importance of lung fluid in the pathogenesis of pulmonary hypoplasia includes the following: (1) chronic tracheal drainage causes pulmonary hypoplasia in fetal sheep;²⁸⁹ (2) laryngeal atresia associated with renal agenesis (Fraser syndrome) results in normal pulmonary development despite severe oligohydramnios;²⁹⁴ and (3) oligohydramnios is often associated with decreased intra-amniotic fluid pressure.²⁹⁵

Several biometric and biophysical parameters have been used for the antenatal prediction of pulmonary hypoplasia, including thoracic circumference,²⁹⁶ thoracic circumference compared with femoral length,^{297,298} or abdominal circumference.^{299,300} Other methods used include lung length,³⁰¹ perinatal fluid flow during fetal breathing movements,³⁰² breathing-related modulation of ductus arteriosus flow,³⁰³ amniotic fluid volume,²⁸¹ pulmonary artery Doppler velocimetry,³⁰⁴ and various formulas.^{300,305,306} No single index has been confirmed independently to have adequate sensitivity and specificity to make it clinically useful.

Serial amniocentesis has been proposed for the prevention of pulmonary hypoplasia. Fisk et al.³⁰⁷ performed serial transabdominal amniocentesis in nine women with midtrimester oligohydramnios (six with preterm PROM and three whose fetuses had lower urinary tract obstructions). Preterm labor occurred in four women between 3 and 12 weeks after the last procedure. One patient developed clinical chorioamnionitis 2 days after her sixth infusion; there was one case of placental abruption. At delivery, three of nine fetuses survived, and five of six neonates who died had normal lung-to-body ratios, suggesting that this management may decrease the risk of pulmonary hypoplasia. Evidence of lung hypoplasia was present in one infant who died and in one who lived. Nakayama et al.³⁰⁸ have generated experimental evidence that maintenance of amniotic fluid volume by saline infusion in pregnant rabbits could prevent pulmonary hypoplasia. The role of serial amniocentesis in the clinical management of PROM remains experimental.

Fetal compression syndrome

The fetal compression syndrome was originally described in the context of oligohydramnios and renal agenesis.³⁰⁹ Classically, it includes limb position deformities and craniofacial defects that are thought to result from physical compression inhibiting fetal growth and movement.^{310,311} Nimrod et al.²⁸⁵ reported an incidence of 12% in women with preterm PROM, most occurring when the latency period was longer than 5 weeks. Blott et al.²⁸⁷ found that 46% (14/30) of infants born after prolonged membrane rupture (more than 4 weeks) had limb deformities. The median duration of rupture in the group with deformities was 28 days, compared with 9 days in infants without deformities.

Fetal growth restriction

Preterm delivery resulting from patients with preterm labor and intact membranes or preterm PROM has been associated with “fetal growth restriction.” Most studies are cross-sectional and have not separated preterm PROM from preterm labor with intact membranes.^{312,313} One interesting study determined the fetal growth rate for biometric parameters in a cohort of 69 singleton pregnancies complicated with preterm PROM (24–31 weeks) and who remained undelivered

for more than 14 days. The mean growth velocity of the head and abdominal circumference was significantly lower than that of the control group ($n = 345$ normal pregnancies). Neonates who had intraventricular hemorrhage (IVH), periventricular leukomalacia (PVL), or cerebral palsy had a lower growth velocity than those not affected by these disorders.³¹⁴

Fetal death

The rate of fetal death in preterm PROM is approximately 1% when this complication is diagnosed after 24 weeks and 15% if PROM occurs before.²⁰ The etiology of fetal death remains unknown. Fetal infection, placental abruption, fetal growth restriction and umbilical cord prolapse or accident (resulting from compression in cases of severe oligohydramnios) have been implicated.

Fetal death, in the context of intrauterine infection, has been attributed to microbial invasion of the fetus, where the unborn child fails to deploy an inflammatory response sufficiently intense to stimulate labor. Indeed, histologic chorioamnionitis (maternal inflammatory response) is nine times more frequent than funisitis (a fetal inflammatory response) in patients with stillbirth.³¹⁵ In this case, *in utero* fetal death would represent failure of the host response mechanisms dealing with intrauterine infection. This concept is supported by a genetic association study which demonstrated that fetal carriage of the allele 2 of the gene encoding for the IL-1 receptor antagonist (IL-1ra) is associated with fetal death.³¹⁶ An excess of IL-1ra in the fetal compartment may limit the ability of the fetus to deploy a proinflammatory response and limit the effectiveness of the mechanisms available for host defense, including the ability to initiate labor to exit a hostile intrauterine environment.

Diagnosis of prelabor rupture of the membranes

Traditionally, the diagnosis of PROM has been based on clinical findings and bedside tests. The following section will review the accuracy of these tests in the diagnosis of PROM.

Presenting symptoms

The most common presentation of PROM is a watery vaginal discharge or a sudden gush of fluid from the vagina, as reported by the patient. Questioning the patient about the timing of the initial loss of vaginal fluid, color and consistency of the discharge, and any odor may help to differentiate PROM from loss of the mucus plug in early labor, vaginal discharge associated with infection, normal leukorrhea of pregnancy, and urinary incontinence (sometimes present in pregnancy), as well as to determine the presence of blood or meconium in the amniotic fluid.

Vaginal examination

Evaluation of the patient begins with a sterile speculum examination. Visualization of a vaginal pool or obvious leakage of fluid from the cervix into the posterior fornix is considered to be evidence that PROM has occurred. Increasing intra-abdominal pressure may assist in the visualization of this sign. If no fluid is present in the posterior fornix, the patient can be re-examined after resting in the supine position to allow for accumulation of fluid in the posterior fornix. Additionally, a speculum examination allows for collection of vaginal and cervical cultures and amniotic fluid to assess fetal lung maturity, while ruling out cord prolapse.

A sterile swab of fluid should be obtained from the posterior fornix and placed on a clean glass slide and on a piece of nitrazine paper. Amniotic fluid, when put on a slide and allowed to dry, will show arborization (“ferning”) under the microscope at low magnification.³¹⁷ This method has an overall accuracy of 95%.³¹⁸ Rare false-positive ferning results have been described in association with fingerprints on the slide or contamination with semen and cervical mucus.^{319,320} False-negative results (5–10%) may be caused by dry swabs or by contamination with blood.^{317,321,322} The slide should be evaluated after at least 10 min of drying to decrease the false-negative rate.³²³

Does a digital examination increase the risk of infection?

The traditional view has been that “once an examination has been performed, the clock of infection starts to tick.” Several studies have addressed the clinical consequences of digital examination in the setting of PROM.^{324–327}

Adoni and coworkers³²⁴ reported a study in which the latency period and incidence of chorioamnionitis were evaluated in patients with preterm PROM (26–34 weeks) who underwent a digital examination or a sterile speculum examination. The latency period was longer in patients undergoing speculum examination than in those examined digitally (9.5 ± 1.5 days versus 3.1 ± 0.5 days, $P < 0.005$). No significant difference in the incidence of chorioamnionitis was found. Lewis and associates³²⁵ prospectively collected data on 271 singleton pregnancies with preterm PROM. The authors reported that patients who underwent digital examination had shorter latency periods than those who had speculum examination (digital examination 2.1 ± 4.0 days versus speculum examination 11.3 ± 13.4 days, $P < 0.0001$) (Fig. 63.6).

Sukcharoen et al.³²⁷ performed a retrospective study in which women with preterm PROM had digital examinations ($n = 50$) or speculum examinations ($n = 65$). The authors reported no differences in latency periods or neonatal outcomes in the study groups. However, patients who underwent digital examinations had a higher frequency of chorioamnionitis [digital examination 12% (6/50) versus speculum examination 3.1% (2/65), $P < 0.05$].

Schutte and colleagues³²⁶ retrospectively examined the incidence of neonatal infection in patients with PROM according

Figure 63.6 Effect of digital examination on latency period ($P < 0.001$ for all groups).³²⁵

to the interval between initial digital vaginal examination and delivery. The incidence of neonatal infection was higher in patients examined more than 24 h before delivery than in those whose first vaginal examination occurred less than 24 h before delivery [33% (11/33) versus 5% (14/280), $P < 0.0001$]. Although this study has been widely cited in support of the view that digital vaginal examination increases the risk of infection, the design of this study constrains the strength of this conclusion. For example, the policy at the institution in which the study was performed was not to perform digital examinations in patients with PROM unless delivery was anticipated within 24 h. Uterine contractions may have been an early sign of infection, rather than labor, in some patients.

The only justification for performing a digital examination is to determine cervical status. In the preterm gestation, this information rarely alters clinical management but, in the term gestation, the cervical state may be a factor influencing decisions regarding induction. There is a strong relationship between the results of sterile speculum examination and digital examination of the cervix. This was demonstrated in a study in which visual speculum and digital cervical examinations in women in labor were performed by two separate blinded examiners within 5 min of each other. Visual examination underestimated actual cervical dilation by only 0.6 cm (95% CI 0.58–0.62).^{328–330} The major objection to a digital examination in the setting of PROM is that it may unnecessarily increase the risk of ascending infection, and the information it provides can be obtained by sterile speculum examination.

Biochemical studies for the detection of amniotic fluid in the vagina

The biochemical properties of the amniotic fluid are the basis in distinguishing it from other fluids that can be observed in the vagina (i.e., cervical secretions, urine, and semen). The normal

pH of the vagina during gestation is 4.5–5.5, and that of the amniotic fluid is 7.0–7.5. Nitrazine paper turns from yellow to blue when exposed to any alkaline fluid (i.e., pH of 7.0 or more), and the use of nitrazine paper has been reported to have an accuracy of 93.3%³¹⁸ in determining the presence of amniotic fluid in the vagina. False-positive results range from 1% to 17% and can result from alkaline urine, blood, semen, vaginal discharge in cases of bacterial vaginosis, or *Trichomonas* infection.³³¹ False negatives may occur in up to 10% of cases.

Additional biochemical tests for the diagnosis of PROM include diamine oxidase (DAO) activity,³³² prolactin levels,^{333–335} alpha-fetoprotein (AFP; sensitivity 94.5% and specificity 95.4%),^{333,336} and insulin-like growth factor-binding protein-1 (IGFBP-1).³³⁷ AFP has been reported to be better than prolactin and more practical than DAO assay with an overall accuracy of 98%.^{337,338} IGFBP-1 determinations have a sensitivity of 74.4% and a specificity of 92.6%.³³⁹ Overall, the sensitivity, specificity, positive and negative predictive values of the different diagnostic tests presented today in comparison with the nitrazine test are good (Table 63.10).^{340–345} However, the lack of available bedside kits for these tests hampers their clinical use.

The assay for FFN is useful in the identification of patients at risk of preterm and term labor and imminent delivery. However, doubts still exist about its diagnostic value in PROM.³⁴⁶ Eriksen et al.³⁴⁷ reported that, for the detection of term PROM, FFN had a sensitivity of 98.2%, but a specificity of only 26.8%. Although the authors proposed that the false positives were the result of the detection of small amounts of amniotic fluid not detected by clinical tests (pool, nitrazine, and ferning), an alternative explanation is that a positive FFN detects degradation of the extracellular matrix in the fetal–maternal interface that precedes the clinical onset of labor rather than PROM. Support for the hypothesis derives from the observation that patients without PROM but with positive cervical FFN are more likely to deliver within 72 h than those with negative cervical FFN.^{346,348–355} In conclusion, the detection of cervicovaginal FFN is not specific for PROM.

Transabdominal injection of dye

When the diagnosis of preterm PROM is not clear, a transabdominal injection of dye (indigo carmine, Evans blue, fluorescein) into the amniotic cavity may be used for confirmation.^{356–359} Methylene blue should not be used as it may cause fetal methemoglobinemia.^{360–362} A tampon in the vagina can document subsequent dye leakage in cases of PROM.

Initial assessment of patients presenting with preterm prelabor rupture of the membranes

The initial evaluation of a patient with preterm PROM includes: (1) accurate assessment of gestational age; (2) exclu-

sion of occult cord prolapse; (3) estimation of fetal weight and presentation; (4) evaluation of the risk of infection; (5) determination of lung maturity; and (6) assessment of fetal well-being.

Ultrasound examination in the evaluation of patients with preterm PROM

The initial ultrasound examination aims to: (1) assess fetal viability, biometry, and presentation; (2) quantify amniotic fluid volume; (3) rule out fetal anomalies; and (4) confirm gestational age. The sonographic examination of fetuses with PROM is challenging due to the reduced amniotic fluid volume. For example, sonographic estimates of fetal weight have been shown to underestimate the birthweight.^{363–365}

Diagnosis of intrauterine infection in preterm PROM

Amniocentesis is used for the evaluation of the microbiological state of the amniotic cavity and of fetal lung maturity in the patient with preterm PROM.³⁶⁶ Results of amniotic fluid analysis provide a rational approach to the management of preterm PROM. Patients without evidence of infection/inflammation and lung immaturity could be managed expectantly, whereas those with evidence of infection could be managed using algorithms tailored to the gestational age (see section on Management).

Garite and coworkers²³¹ were the first to propose the use of amniocentesis in the evaluation of the microbiological state of the amniotic cavity and of fetal lung maturity in the patient

with preterm PROM. Subsequently, several investigators reported studies in which amniocentesis had been used in the management of PROM. Relevant issues are the success rate of fluid retrieval, the value of the information obtained, and the risk associated with the procedure.

Table 63.6 gives the success rate of amniotic fluid retrieval by transabdominal amniocentesis in the published reports.^{121,229,231,233–235,237,245} Retrieval rates vary from 49% to 96% in published series. The wide disparity in retrieval rates is probably attributable to differences in practice among institutions (e.g., although Garite and associates excluded all patients with anterior placentas and oligohydramnios, subsequent studies have not considered these conditions as contraindications for amniocentesis). Better ultrasound technology, color Doppler, and a skilled maternal–fetal medicine specialist make amniocentesis possible in most cases of PROM.

One randomized clinical trial examined the value of amniocentesis in preterm PROM.³⁶⁷ Forty-seven patients (26–34 weeks of gestation with an accessible amniotic fluid pocket) were randomized to amniocentesis or no amniocentesis. Indications for induction of labor included positive Gram stain of amniotic fluid or mature fetal lungs, as determined by a lecithin-to-sphingomyelin (L/S) ratio of more than 2.0 or positive phosphatidylglycerol (PG). Neonates born to women who had amniocenteses had a lower incidence of “fetal stress” during labor (diagnosed by fetal heart rate tracing) and a shorter hospital stay than those born to women who were randomized not to have amniocenteses [“fetal distress”: 4% (1/24) versus 32% (7/22), $P < 0.05$; hospital stay (median): 8.5 days versus 22 days, $P < 0.01$]. No

differences in the rate of neonatal sepsis, maternal chorioamnionitis, or endometritis were noted between the two groups. This study had limited power to detect differences in neonatal morbidity.

The analyses of amniotic fluid used to detect the presence of MIAC or intra-amniotic inflammation include: (1) Gram stain; (2) a quantitative white blood cell (WBC) count; (3) glucose concentration (Table 63.11); and (4) microbial cultures for aerobic and anaerobic bacteria, as well as genital mycoplasmas. Patients with a negative Gram stain (read by experienced personnel) and a high WBC count (more than 30 cells/ μ L) are at high risk of having microbial invasion with genital mycoplasmas, which are not visible on Gram stain examination. Lower concentrations of glucose in amniotic fluid (< 10 mg/dL) can serve as an additional marker for MIAC. The results of amniotic fluid culture may take days to be available. Therefore, most centers rely on the determination of intra-amniotic inflammation because the outcome of preterm PROM in patients with intra-amniotic inflammation is similar to those with MIAC proven with standard microbiological techniques.³⁶⁸ Table 63.11 summarizes the diagnostic criteria and predictive values of different amniotic fluid tests in detecting positive amniotic fluid cultures in patients with preterm PROM.²⁴¹ Amniotic fluid IL-6 performed best in detecting MIAC, as well as in identifying patients at risk of impending preterm delivery and neonatal complications. We have shown that amniotic fluid IL-6 is a sensitive test for the prospective diagnosis of acute histologic chorioamnionitis [IL-6 of more than 17 ng/mL had a sensitivity of 79% (23/29) and

specificity of 100% (21/21)], significant neonatal morbidity (sepsis, RDS, pneumonia, IVH, BPD, and necrotizing enterocolitis), and neonatal mortality [IL-6 of more than 17 ng/mL had a sensitivity of 69% (18/26) and a specificity of 79% (19/24)].³⁶⁹ Other rapid tests reported for the detection of MIAC include amniotic fluid catalase,²³⁶ α_1 -antitrypsin,⁶⁵ limulus amebocyte lysate test,²⁴⁰ and bacterial PCR.³⁷⁰

Recently, a novel diagnostic test, a rapid bedside enzyme-linked immunosorbent assay (ELISA) for the detection of MMP-8 in amniotic fluid, was developed. This kit has been reported to have high accuracy in the identification of patients with MIAC and inflammation among patients with preterm labor and intact membranes.³⁷¹ Future studies may determine the utility of this test in the identification of patients with intra-amniotic infection/inflammation among those with preterm PROM.

The risk of amniocentesis, when performed by experienced individuals, appears to be extremely low. Yeast and colleagues³⁷² specifically addressed this issue in 91 patients with preterm PROM in whom amniocenteses were performed. A retrospective review of neonatal records uncovered no evidence of fetal trauma with any procedure. This study also found that the incidence of spontaneous labor in patients who underwent amniocentesis was no different from that of patients who did not undergo amniocentesis secondary to oligohydramnios or an anterior placenta. The authors concluded that their study failed to show that amniocentesis may induce labor.

Assessment of lung maturity

Lung maturity can be assessed from the amniotic fluid obtained by amniocentesis or from the vaginal pool. The latter has the advantage of being less invasive and more feasible in patients with oligohydramnios. Amniotic fluid from the vaginal pool can be collected in three ways: (1) from the posterior vaginal fornix by sterile speculum examination; (2) in a clean bedpan maintained under the patient; or (3) using obstetric perineal pads left in place for 12–24 h to ensure saturation.^{373–376} The success rate in obtaining fluid within 48 h with these noninvasive techniques ranges from 54% to 100%.^{375,376} Using a vulval pad to detect PG, Estol et al.³⁷⁷ found a sensitivity of 88%, specificity of 76%, positive predictive value of 34%, and negative predictive value of 98%. Lewis et al.³⁷⁸ investigated the value of a rapid antibody agglutination method (Amniostat FLM) to detect PG in vaginal pool samples. Thirty-six of 201 patients between 26 and 36 weeks of gestation had positive PG, and none of the infants born to these mothers developed RDS. PG was detectable only after 30 weeks of gestation.

The reliability of lung maturity tests from amniotic fluid collected vaginally has been challenged.^{379,380} This section reviews the correlation between the L/S ratio and PG results in amniotic fluid obtained by amniocentesis and from the vaginal pool. Shaver and associates³⁷³ compared the phospholipid profile of paired amniotic fluid samples in 28 patients with preterm PROM. No significant difference was found in the concentrations of PG, phosphatidylinositol, phosphatidylethanolamine, and phosphatidylserine in amniotic fluid obtained by the two sampling methods. The L/S ratio was higher in fluid collected transvaginally than in fluid collected transabdominally, but this difference did not reach statistical significance (Fig. 63.7). The only phospholipid clearly increased by vaginal contamination was lysolecithin.

Figure 63.7 Scatterplot showing the relationship between lecithin/sphingomyelin (L/S) ratios of vaginal and amniocentesis fluid. From ref. 373 with permission from Elsevier.

Dombroski et al.³⁸¹ reported a study in which amniotic fluid was obtained by amniocentesis in patients at term in labor. Thirty minutes after artificial rupture of membranes, a vaginal sample of amniotic fluid was collected. L/S ratios obtained from amniotic fluid in the vaginal pool samples were significantly lower than those obtained by amniocentesis. However, in 22% (6/27) of cases, L/S ratios were higher in the vaginal pool samples than in amniocentesis.

Several studies have examined the value of PG determinations in amniotic fluid obtained transvaginally. Stedman et al.³⁷⁴ reported that, of 25 patients with PROM between 26 and 34 weeks, 60% (15/25) had positive PG and none of their neonates developed RDS (within 72 h of the test). Among the newborns of the 10 patients with negative PG, four developed RDS. Similarly, Brame and MacKenna³⁷⁵ reported no cases of neonatal RDS in 36 patients with PG found in vaginal fluid. Table 63.12 shows the frequency of the presence of PG in fluid obtained from the vaginal pool according to gestational age. Twelve percent of patients with a gestational age of less than 32 weeks had PG present.³⁷⁸

The possibility that bacterial contamination from vaginal secretions may lead to false-positive PG results has been raised by Schumacher and associates,³⁸⁰ who reported that one patient had PG detected in the fluid from the vaginal pool, but not in fluid retrieved by transabdominal amniocentesis. The neonate developed respiratory insufficiency that was attributed to either RDS or pneumonia (the amniotic fluid culture was positive for bacteria). These investigators also demonstrated that bacteria might be a source of PG. Therefore, excessive bacterial contamination may alter the results of PG determinations. It would seem prudent to minimize the interval between sample collection and assay in the hope of preventing bacterial growth in the sample.

Three studies have reported neonatal outcome and L/S ratio results in preterm PROM (Table 63.13).^{375,376,382} In two of the studies, a mature L/S ratio was an indication for delivery.^{376,382} In the third study, the presence of PG was used as an indication for delivery.³⁷⁵ The data are consistent: with a mature L/S ratio, the risk of RDS is extraordinarily small. An L/S ratio of more than 2.0 was found in 103 patients, and none of the neonates developed RDS.

Table 63.12 Frequency of positive phosphatidylglycerol in vaginal pool samples.

Gestational age (weeks)	n (%)	Gestational age (weeks)	n (%)

33–34	19/97 (19.6)	33–34	16/80 (20)
35–36	20/41 (48.7)	35–36	13/34 (38.2)
Total ³⁷⁵	47/214 (22)	Total ³⁷⁸	36/191 (19)

Table 63.13 Vaginal pool lecithin/sphingomyelin (L/S) ratio and neonatal outcome.

First author	L/S ratio	No respiratory distress syndrome	Respiratory distress syndrome
Goldstein ³⁸²	$\geq 2, < 2$	5, 0	0, 3
Golde ³⁷⁶	$\geq 2, < 2$	26, –	0, –
Brame ³⁷⁵	$\geq 2, < 2$	72, 36	0, 19

In addition to these clinical studies, data generated from experimental observations provide further support for the lack of effect of vaginal contamination on the L/S ratio results. Sbarra and colleagues³⁸³ demonstrated that cervical and vaginal washings are generally devoid of lecithin and sphingomyelin (in 9/10 cases) and, thus, these secretions are unlikely to alter L/S results. Two studies determined that the introduction of amniotic fluid (obtained by transabdominal amniocentesis) into the vagina results in little change in the L/S ratio.^{383,384} In most cases (21/23), amniotic fluid had L/S ratios of more than 2.0 and, therefore, the effect of vaginal contamination in immature L/S ratios was not adequately tested.

The available evidence indicates that fetal lung maturity studies can be performed on amniotic fluid obtained from the vagina, and that a mature L/S ratio or the presence of PG is associated with a very low risk of RDS. Moreover, this noninvasive, low-risk approach allows for serial L/S and PG determinations.

What is the optimal management of patients with a mature phospholipid profile?

A mature phospholipid test has been demonstrated in approximately 50% of patients with preterm PROM at gestational ages of less than 34 weeks.^{229,231,367} Garite and associates²³¹ reported that none of the neonates with an L/S ratio of 1.8 or greater developed RDS. The incidence of this complication in neonates with immature L/S ratios was 33% (5/15).

Two randomized clinical trials have been reported thus far. In the first, 47 patients with preterm PROM (less than 36 weeks) and mature amniotic fluid indices were randomized to either prompt delivery ($n = 26$) or expectant management ($n = 21$).³⁸⁵ A mature test was defined as an L/S ratio above 2.0 or a foam stability index (FSI) of 47 or more (often from vaginal fluid). There was no difference in perinatal mortality between the two groups. There were no cases of RDS in the expectant management group, but two in the prompt delivery group. One newborn died from severe hyaline membrane disease (birthweight 900g, vaginal FSI = 48), whereas the other neonate survived (birthweight 1700g, vaginal L/S = 2.0). There were no differences in the rate of neonatal sepsis or other neonatal complications in the two groups. However, the only two cases of intracranial hemorrhage (grade not stated) occurred in the prompt delivery group. Maternal chorioam-

nionitis was more common in the expectantly managed group than in the delivery group [38% (8/21) versus 8% (2/26), $P < 0.02$]. The predictive value of a mature test based on the FSI was 97% (94/97).

Mercer et al.³⁸⁶ reported the results of a randomized clinical trial in which 93 women with mature amniotic fluid phospholipid studies (vaginal or transabdominal amniocentesis FSI ≥ 47) were randomized to induction of labor with oxytocin or expectant management (bedrest). Maternal chorioamnionitis was more frequent in the expectant group. However, this difference did not reach significance [27.7% (13/47) versus 10.9% (5/46), $P = 0.06$]. There were no significant differences in the Cesarean delivery rate or in the incidence of confirmed neonatal sepsis between the groups. Suspected sepsis was higher in neonates born to women in the expectant group [59.6% (28/47) versus 28.3% (13/46), $P = 0.003$], as was antibiotic administration and septic workups. However, neonatologists were not blinded to treatment allocation.

Assessment of fetal well-being

The goal of fetal evaluation is to identify fetal infection/inflammation or a pathologic process that increases the risk of antepartum or neonatal death. Methods of fetal surveillance include nonstress test and the components of the biophysical profile. This section will examine the experience with each test in preterm PROM.

Nonstress test (NST)

The differential diagnosis of a nonreactive NST is: (1) prematurity; (2) infection; and (3) hypoxia. The interpretation and significance and management of fetal heart rate decelerations associated with umbilical cord compression due to oligohydramnios are also a challenge.

Are fetuses of mothers with preterm PROM expected to have nonreactive NSTs?

Surprisingly, fetuses with preterm PROM between 24 and 37 weeks have a significantly higher incidence of reactive tracings than gestational age-matched counterparts with intact membranes.^{387–389} This has been attributed to “accelerated fetal central nervous system maturation” and umbilical vein compression with resulting fetal heart rate accelerations.³⁹⁰ Thus, lack of reactivity should not be ascribed to prematurity without further investigation.

A nonreactive NST is frequently observed in fetuses with MIAC. Table 63.14 presents the diagnostic indices of a nonreactive NST in the prediction of total infectious morbidity (i.e., proven or suspected neonatal sepsis, MIAC, and maternal chorioamnionitis). Three studies^{391–393} have found the NST to be an insensitive predictor of infection-related outcome. A major issue is the high false-positive rate (approximately 35%) of the NST for the detection of infection. Therefore, a nonreactive NST is not sufficient to diagnose infection. Evaluation of other biophysical parameters and the results of

amniocentesis are recommended before delivery can be indicated (see below).

Assessment of amniotic fluid volume

Is oligohydramnios always present in PROM?

Contrary to what is generally believed, rupture of membranes is not necessarily associated with oligohydramnios. Jackson et al.³⁹⁴ noted that the AFI in patients with preterm PROM remains stable after the membranes rupture, with the mean AFI on admission being 5.9 ± 2.5 cm and on the day of delivery 5.4 ± 2.0 cm. Moreover, Vintzileos et al.³⁹⁵ reported that 65.5% (59/90) of patients with PROM had a vertical pocket of amniotic fluid > 2 cm, while 15.5% (14/90) had a vertical pocket between 1 and 2 cm. Only 19% (17/90) had a vertical pocket of < 1 cm.

Is amniotic fluid volume assessed with ultrasound an index of impending preterm delivery and infection?

Several studies have examined the relationship between oligohydramnios and outcomes in PROM. Patients with a vertical amniotic fluid pocket < 1 cm have a shorter latency period and

a higher incidence of chorioamnionitis and neonatal sepsis than those with a vertical pocket > 2 cm (Table 63.15).³⁹⁵ Similar findings were reported by Gonik et al.²²¹ Women with a vertical amniotic fluid pocket of < 1 cm had a higher incidence of chorioamnionitis and endometritis than those with an amniotic fluid pocket of > 1 cm. No difference in the duration of the latency period was found between the two groups.²²¹

Hadi et al.³⁹⁶ reported that chorioamnionitis occurred in 26.4% of women with an amniotic fluid pocket < 2 cm. Similarly, Lao and Cheung³⁹⁷ used a cutoff of 2 cm as the largest pocket of amniotic fluid to define oligohydramnios, and found that the frequency of chorioamnionitis and funisitis was higher in patients with oligohydramnios than in those without reduced amniotic fluid volume (chorioamnionitis: 55.3% versus 29.3%; funisitis: 44.7% versus 16.7%). A reduction in amniotic fluid volume was also associated with MIAC.

The diagnostic indices of oligohydramnios in predicting infection in both the mother and fetus are presented in Table 63.16. Collectively, these data indicate that there is an association between reduced amniotic fluid volume and maternal or neonatal infection-related morbidity and MIAC. The reason

†Amniotic fluid index < 5 cm.

for the high rate of infection in patients with oligohydramnios is unknown. One possibility is that decreased amniotic fluid volume may deprive patients of the antibacterial properties of normal amniotic fluid^{223–226,398} and, therefore, predispose them to infection. Alternatively, intra-amniotic infection may alter amniotic fluid dynamics, leading to a reduction in fluid volume. Yoon et al.³⁹⁹ proposed that redistribution of blood flow away from the kidneys may take place as part of the host response to microbial products, perhaps leading to oligohydramnios.

Fetal heart rate decelerations and amniotic fluid index

Patients with decelerations have a lower AFI than those without decelerations (4.32 ± 1.67 cm versus 6.47 ± 3.59 cm, $P < 0.01$).⁴⁰⁰ This observation suggests that cord compression due to oligohydramnios may be the mechanism behind variable decelerations observed in patients with PROM.

Fetal breathing movements

Preterm PROM is associated with a significant and prolonged reduction in fetal breathing movements lasting approximately 2 weeks.^{401,402} This phenomenon seems to be related to rupture of membranes *per se*, rather than to infection, hypoxia, or intrauterine growth restriction, even though the precise mechanisms are unknown. Membrane rupture leads to a reduction in intra-amniotic pressure and, thus, favors loss of lung fluid. Teleologically, a reduction in fetal breathing may be a mechanism to protect against lung fluid loss and pulmonary hypoplasia.

Vintzileos et al.^{403,404} were the first to document an association between infection and decreased fetal breathing activity in preterm PROM. Subsequently, we confirmed these findings and documented that women with positive amniotic fluid cul-

tures had fewer and shorter episodes of fetal breathing activity than women with negative amniotic fluid cultures.⁴⁰⁵ The total time spent breathing differed dramatically between the two groups (Fig. 63.8).

The presence of fetal breathing has a very high negative predictive value (approximately 95%) for MIAC and neonatal sepsis. However, the absence of breathing activity has a limited positive predictive value (approximately 50%) for either of these two outcomes and, thus, it cannot be used as an indication for delivery (Table 63.17). Therefore, the presence of breathing indicates that infection is unlikely.

Why should breathing be reduced in cases of infection? The evidence in support of a role for prostaglandins includes: (1) sepsis is associated with increased plasma concentrations of prostaglandins; (2) prostaglandin administration to fetal lambs reduces breathing activity;⁴⁰⁶ and (3) decreased fetal breathing movements in PROM are associated with increased concentrations of prostaglandin E2 in fetal plasma obtained by cordocentesis.⁴⁰⁷

Fetal body movements

Intra-amniotic infection is associated with a dramatic reduction in fetal body movements (Fig. 63.8).⁴⁰⁵ The diagnostic indices are displayed in Table 63.17.⁴⁰⁸ Decreased fetal motion in the context of infection may be the counterpart of the reduction in motor behavior observed during the course of febrile illnesses in adults and children. We have proposed that IL-1 and TNF- α released in the course of infection may be responsible for this phenomenon (R. Romero, personal communication).

Biophysical profile (BPP)

The BPP has been found to be helpful in the management of patients with PROM.^{387,390–393,403,405,409–413} Vintzileos et al.,⁴⁰³

using logistic regression analysis, demonstrated that each component of the BPP contains useful information for the prediction of infection-related morbidity (defined as maternal chorioamnionitis, possible neonatal sepsis, and proven neonatal sepsis). In their first study, a modified BPP scoring system that incorporated placental grading (with a maximal score of 12) was used. A BPP score of seven or less was much better than any single component of the BPP in the prediction of infection-related outcome. Placental grading was the only parameter that had no predictive value, hence its exclusion from subsequent studies. The diagnostic indices of a BPP score ≤ 7 (performed 24h before delivery) were: sensitivity 94%, specificity 97%, positive predictive value 95%, and negative predictive value 97% in a population with a prevalence of

infection-related outcome of 30%. This study was observational in nature and, thus, the BPP was not used for patient management.

Subsequently, Vintzileos et al.⁴¹⁴ compared the outcome of pregnancy in patients managed with serial BPPs with two historical control groups: (1) expectant management without BPP or amniocentesis; and (2) management with a single amniocentesis on admission. A BPP score ≤ 7 on two examinations 2h apart was used as an indication for delivery. An abnormal score required a nonreactive NST and absence of fetal breathing. The results of this study indicated that patients managed with daily BPPs had a lower rate of overall neonatal sepsis (suspected and culture proven) than patients in either control group. This study did not provide the frequency of other

indices of neonatal morbidity (e.g., RDS, IVH, duration of mechanical ventilation) in the different groups. This issue is important, as 14 patients who were delivered because of a low BPP score showed no evidence of neonatal infection and, thus, could be considered false positives. If intervention was not associated with an increased rate of other neonatal complications, management with serial BPPs would seem a reasonable approach. The investigators found that the BPP had limitations when the interval between the test and delivery was longer than 24h, and that maternal infection without fetal infection was not correlated with the results of the BPP scoring. Vintzileos and Knuppel³⁹⁰ subsequently reported on 111 fetuses with preterm PROM followed with daily BPPs, and found that, as more of the biophysical activities became compromised, the higher the incidence of infection-related complications (Table 63.18).

It is noteworthy that, subsequent to this work, three studies^{409,410,413} reported an association between the results of the BPP and infection-related outcomes, and three others could not confirm such an association.^{411,412} Our explanation for the apparent discrepancy is that studies reporting negative results used the BPP at less frequent testing intervals (48- to 72-h intervals) than the daily testing used in positive reports.

BPP and the results of amniocentesis

Four studies have examined the relationship between components of the BPP scoring and amniotic fluid culture results retrieved by transabdominal amniocentesis.^{391,393,405,412} Goldstein et al.⁴⁰⁵ made a key observation linking fetal breathing and movements with the likelihood of MIAC: (1) the presence of fetal breathing movements for 30s or more ruled out intra-amniotic infection; (2) if fetal breathing was absent or lasted less than 30s and body movements were decreased (lasting less than 50s), MIAC was detected in all cases; and (3) in intermediate cases (normal fetal body movements but compromised fetal breathing movements), 64% of women had positive amniotic fluid cultures.

Table 63.19 Prediction of positive amniotic fluid cultures: biophysical profile versus total fetal activity.

	Biophysical profile	Total fetal activity

Figure 63.9 Receiver operator characteristic curve for the association between total fetal activity (open circles) and biophysical profile (closed circles) to MIAC. From ref. 412 with permission from John Wiley & Sons Ltd on behalf of the ISUOG.

Roberts et al.⁴¹² compared the diagnostic performance of the BPP with that of total fetal activity (the sum of fetal breathing and body movements in a 30-min period of observation) in the prediction of a positive amniotic fluid culture. Although both methods correlated significantly with the presence of MIAC, the specificity of total fetal activity greater than 10% was significantly better than that of the BPP (Table 63.19; Fig. 63.9). Gauthier et al.³⁹³ reported that the likelihood of a positive amniotic fluid culture was inversely related to the BPP score (Table 63.20). However, 61% (33/54) of patients with positive amniotic fluid cultures had a BPP of eight or more, which may reflect that their fetuses were unaffected.

Devoe et al.⁴¹⁵ examined the ability of the BPP to predict the latency period in 25 women with PROM between 28 and 30 weeks of gestation. The diagnostic indices of the BPP in predicting delivery within 72 h are shown in Table 63.21. In other studies, the sensitivity of the BPP to predict delivery within 72h varied from 0% to 80%.^{392,393,403,405,411} The relationship between a low BPP and the impending onset of labor can be understood in the context that the FIRS (which may be reflected as a low BPP score) is followed by the impending

onset of labor in patients with preterm PROM. In summary, there is compelling evidence that a low BPP score is associated with infection-related outcomes.

C-reactive protein

Several studies have examined the value of C-reactive protein (CRP) in monitoring the patient with preterm PROM.^{416–422} Most studies indicate a strong relationship between an elevated maternal serum CRP and the presence of histologic chorioamnionitis. Diagnostic indices, cutoff values, and the definition of infection-related morbidity for the different studies are shown in Table 63.22.

In terms of the prediction of a positive amniotic fluid culture, Yoon et al.⁴²³ compared the performance of maternal serum CRP and WBC count with that of the amniotic fluid WBC count in the identification of MIAC, clinical histologic chorioamnionitis, and significant neonatal morbidity. The

amniotic fluid WBC count was a better predictor than maternal serum CRP in the identification of MIAC.⁴²³

DiNaro et al.⁴²⁴ recently provided evidence indicating that the determination of vaginal fluid CRP can be used in the identification of the fetus with funisitis, the histologic counterpart of FIRS. The rationale for this observation is that CRP in vaginal fluid is thought to be of fetal origin. Thus, an elevation in vaginal CRP concentration is an indicator of a fetal acute-phase response.

Thompson et al.⁴²⁵ reported a study of fetal serum CRP obtained by cordocentesis in patients with preterm PROM. A fetal CRP of more than 0.8 mg/dL was found in five of six fetuses with positive fetal blood cultures. In contrast, when the CRP concentration was less than 0.6 mg/dL, none of 11 fetuses had positive cultures. These results may extend to the assessment of fetal plasma and umbilical cord cytokines. Some evidence indicates that neonates with an elevated umbilical

cord IL-6 (a cytokine that stimulates the production of CRP) are at increased risk for the development of short- and long-term complications such as PVL,⁴²⁶ cerebral palsy,²⁵⁸ and BPD.³⁶⁹

Management of patients with preterm PROM

The management of patients with preterm PROM depends on the gestational age at the time of membrane rupture (see Fig. 63.10).

Previable PROM (< 24 weeks of gestation)

(see Fig. 63.11)

The major complications of previable PROM are maternal infection, late abortion/preterm labor, low neonatal survival, and a high risk of neurologic handicap.^{427,428} Patients are generally offered two options: pregnancy termination or expectant management. The presence of intra-amniotic inflammation/infection in amniotic fluid analysis carries a poor prognosis because of the risk of spontaneous preterm

labor as well as fetal morbidity. A more vexing problem is when the preterm PROM occurs in a previable gestation, but delivery occurs when the infant is viable and at very high risk of death and neurologic handicap if survival is achieved. Table 63.23 demonstrates the outcome of patients before viability. Management of these patients requires an in-depth discussion involving the parents, neonatologists, and obstetricians and careful documentation in the medical record. The value of antibiotic or corticosteroid administration in previable PROM has not been established. Leakage of amniotic fluid after second-trimester amniocentesis should be considered as a separate entity from previable PROM. It occurs in 1.2% of patients and is usually transient in nature.⁴²⁹ The risk of delayed PROM in these cases is no different from that in the general population.⁴³⁰

PROM remote from term (24 weeks to 31 weeks and 6 days of gestation) (see Fig. 63.12)

The management goals are: (1) to exclude intra-amniotic infection/inflammation; and (2) to institute expectant management in patients without documented infection/inflammation.

Intra-amniotic infection/inflammation and its management

The most accurate method for the diagnosis of intra-amniotic infection/inflammation is amniocentesis. Once intra-amniotic infection/inflammation is identified in patients between 24 and 31 completed weeks of gestation, the optimal management is a challenge: the earlier the gestational age, the more difficult the dilemma. In patients who are close to 32 weeks of gestation, delivery would avoid continuous exposure to microbial products and inflammatory agents, and is unlikely to increase neonatal morbidity. These patients are managed in our unit with detailed counseling, antibiotic administration, and delivery. In contrast, in patients close to 24 weeks of gestation, the option of parenteral administration of antibiotics is considered to eradicate intra-amniotic infection and inflammation. Patients are informed that this alternative may prolong pregnancy, eradicate intra-amniotic infection, and reduce the risk of extreme prematurity, but that it requires intensive surveil-

lance and repeat evaluation of the amniotic cavity to ensure eradication of microorganisms and reduced intra-amniotic inflammation (as gauged by the amniotic fluid WBC count). Despite these interventions, the risks of infection and prematurity are not eliminated. Broad coverage is recommended before the results of cultures are available, and this approach should be modified once the specific microorganisms involved are identified. The choice of antibiotics is informed by the results of microbial cultures. Our choice for broad-coverage antibiotics includes azithromycin, clindamycin, and ampicillin. We have also used a combination of ceftriaxone, clindamycin, and erythromycin for 10–14 days.²⁴⁸ Azithromycin is included because *U. urealyticum* is the most frequent microorganism found in the amniotic cavity.²¹⁷

Antibiotic treatment aimed at the eradication of intra-amniotic infection should not be confused with prophylactic treatment, which is now considered the standard of care for

§Two weeks after admission.

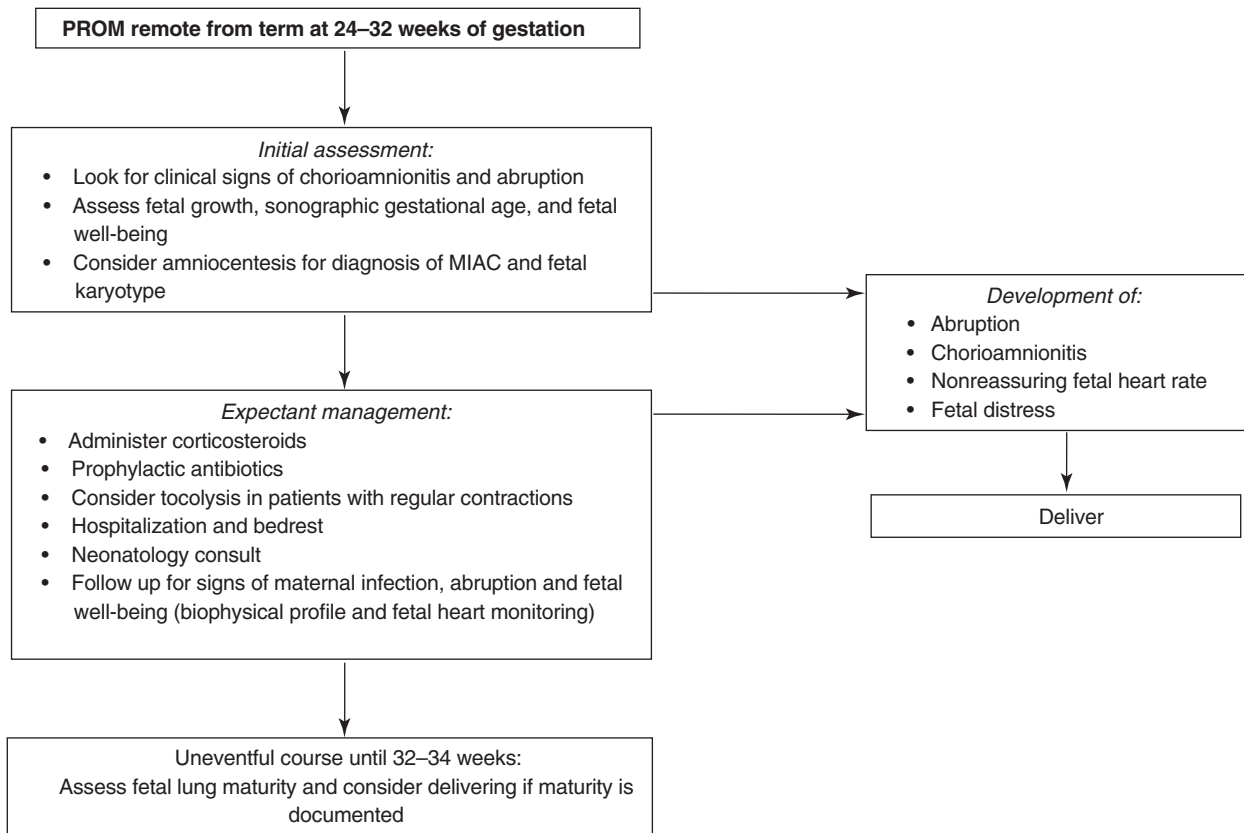

Figure 63.12 Management of PROM remote from term (between 24 weeks and 31 weeks and 6 days of gestation). MIAC, microbial invasion of the amniotic cavity. Modified from Mercer BM. *Clin Perinatol* 2004;31:765–782⁴³² with permission from Elsevier.

patients with preterm PROM, regardless of whether the inflammatory/infection state of the amniotic fluid is known. Thus, patients in this gestational age range, without evidence of infection and inflammation, are given prophylactic treatment with antibiotics (ampicillin and erythromycin).

In summary, the management of PROM between 24 and 31 completed weeks comprises: (1) maternal and fetal inpatient surveillance in a tertiary medical center; (2) administration of corticosteroids to accelerate fetal lung maturity;⁴³¹ and (3) antibiotic administration, which may be therapeutic or prophylactic.^{432,433}

“Prophylactic” antibiotic administration

Antibiotic administration has now become the standard of care in patients with preterm PROM. This practice is based upon the results of several randomized clinical trials, in which antibiotic administration was associated with prolongation of pregnancy, a reduced rate of maternal chorioamnionitis,⁴³⁴ and a reduced frequency of neonatal morbidity, measured as “composite neonatal outcome.”⁴³⁵ This approach

has often been referred to as “prophylactic” antibiotic administration. However, this may be a misnomer. One-third of women with preterm PROM have a positive amniotic fluid culture on admission.¹²⁰ Furthermore, the frequency of MIAC increases as the patients are being observed in the antepartum ward to the point that, at the time of the onset of labor, 75% of patients will have a positive amniotic fluid culture for microorganisms.¹²¹ These studies were conducted before the administration of prophylactic antibiotics and demonstrate that microorganisms are present at admission, and also that secondary infection of the amniotic cavity occurs during expectant management. It would be inaccurate to refer to “prophylactic” administration as therapy instituted with patients who have a proven infection (one-third of all patients). Antimicrobial therapy may prolong pregnancy by controlling microbial proliferation of an existing infection and preventing secondary infection/inflammation. However, antibiotic administration is not uniformly efficacious in eradicating microbially proven intra-amniotic infection.²⁴⁸

Several investigators have conducted randomized clinical trials to assess the potential benefits of prophylactic antibiotic administration in patients with preterm PROM.^{435–448}

Mercer et al.⁴⁴⁹ reported a randomized clinical trial in which patients were allocated to receive intravenous ampicillin (2 g every 6 h) and erythromycin (250 mg every 6 h for 48 h, followed by oral amoxicillin and erythromycin base (every 8 h for 5 days) versus placebos. Recruitment was restricted to patients with a gestational age ranging between 24 and 32 weeks. GBS carriers were identified and treated, and tocolysis and steroids were not administered after randomization. The primary outcome of the trial was a composite variable that included any of the following: fetal or infant death, RDS, severe IVH, stage II or III of necrotizing enterocolitis (NEC), or sepsis within 72 h of birth.⁴⁴⁹ Antibiotic administration was associated with prolongation of pregnancy and a significant reduction in the rate of RDS (RR 0.83, 95% CI 0.69–0.99), NEC (RR 0.4, 95% CI 0.17–0.95), clinical chorioamnionitis, and the composite primary outcome, which is an index of fetal/infant morbidity and mortality (RR 0.84, 95% CI 0.71–0.99). These differences were not demonstrated in GBS carriers, an observation attributable to antibiotic administration to patients allocated to the placebo group for this clinical indication, and thus obscuring the potential effects of antibiotic administration.⁴⁴⁹

In the ORACLE study,⁴³⁵ 4826 women with preterm PROM were randomly assigned to: (1) erythromycin; (2) co-amoxiclav (amoxicillin and clavulanic acid); (3) erythromycin and co-amoxiclav; and (4) placebo. The study included patients before 36 weeks and 6 days from 161 medical centers. Tocolysis and corticosteroid administration were left to the discretion of the attending physician. The primary outcome measure was a composite variable, which included neonatal death, chronic lung disease, or major cerebral abnormality before discharge from the hospital.

Among neonates of patients with singleton gestations allocated to erythromycin only, fewer had the primary composite outcome than those in the placebo group [11.2% (125/1111) versus 14.4% (166/1149), $P = 0.02$]. Erythromycin treatment alone significantly reduced the proportion of patients delivering within 48 h in comparison with the placebo group. The combination of erythromycin with co-amoxiclav significantly reduced the proportion of patients delivering within 1 week of admission. Similarly, co-amoxiclav administration alone, or in combination with erythromycin, significantly reduced the proportion of patients delivering within 48 h and within 7 days from admission, compared with the placebo group.⁴³⁵

The neonatal effects of erythromycin treatment included a reduction in the need for exogenous surfactant, in neonates needing 21% O₂ administration for 48 h after delivery, as well as a reduction in positive neonatal blood cultures.⁴³⁵ Co-amoxiclav had a similar effect on the proportion of neonates needing 21% O₂ administration for 48 h after delivery. Of note, the rate of suspected and proven NEC was significantly higher in the group of neonates whose mothers were treated

with co-amoxiclav as a single or combined therapy. The authors attribute their findings to the wide and nonspecific effect of this broad-spectrum antibiotic, which may change the flora of premature neonates and induce the growth of pathologic bacteria that induce NEC.⁴³⁵

Lovett et al.⁴⁵⁰ did not demonstrate an association between prophylactic antibiotic treatment of patients with preterm PROM with co-amoxiclav and an increased incidence of NEC in comparison with placebo. The studies differ in the antibiotic regimen, as well as in the gestational age at inclusion and the number of patients. Therefore, comparison of the studies is difficult. The recommendation of the investigators in the ORACLE I trial was to use erythromycin and avoid using co-amoxiclav in patients with preterm PROM.⁴³⁵ Recently, a systematic review by Kenyon et al.^{451,452} confirmed these results.

According to Kenyon et al.,⁴⁵² the number of patients needed to treat to prevent one adverse outcome remains high [chorioamnionitis: 10 (95% CI 7–34); delivery within 48 h: 9 (95% CI 6–20); delivery within 7 days: 7 (95% CI 5–15); neonatal infection: 17 (95% CI 12–50); and abnormal cerebral ultrasonography before discharge: 69 (95% CI 35–1842)]. It is possible that the wide confidence intervals reflect the range of gestational ages of patients included in the systematic review.

Can antibiotic treatment of women with documented MIAC alter the natural history of preterm PROM?

The traditional view has been that clinical chorioamnionitis should be managed by immediate delivery, and this view has been extended to the management of MIAC.⁴⁵³ There is evidence that both these conditions can be treated *in utero* without interruption of pregnancy. Ogita and colleagues⁴⁵⁴ first reported the successful treatment of established chorioamnionitis with antibiotic treatment via a transcervical catheter. Subsequently, we reported that giving antibiotics to a mother with preterm PROM at 29 weeks and an amniotic fluid culture positive for *Bacteroides bivius*, *Veillonella parvula*, and *Peptococcus* without clinical signs of chorioamnionitis resulted in eradication of MIAC.⁴⁵⁵ In a second case, we were successful in eradicating *U. urealyticum* from the amniotic cavity with antibiotic treatment.⁴⁵⁶

The effects of antibiotics on the natural history of MIAC in patients with preterm PROM has been reported by Gomez et al.²⁴⁸ Patients who underwent amniocentesis upon admission and those without evidence of intra-amniotic inflammation or MIAC were treated with ampicillin and erythromycin for 7 days. In contrast, patients with intra-amniotic inflammation or MIAC were treated with ceftriaxone, clindamycin, and erythromycin for 10–14 days. Patients who remained undelivered after the conclusion of the course of antibiotics underwent a second amniocentesis. Six of seven patients who had MIAC at the time of the first amniocentesis still had positive amniotic fluid cultures for microorganisms after a full course of antibiotic treatment. Of the 18 patients with intra-amniotic inflammation, most (15/18) still showed evidence of an ele-

vated WBC count in amniotic fluid after antibiotic administration. Therefore, antibiotic administration did not eradicate MIAC or intra-amniotic inflammation. Moreover, among patients with no evidence of intra-amniotic inflammation, 32% (9/28) developed inflammation despite therapy and, among those without MIAC, 55% (5/9) developed a positive amniotic fluid culture.²⁴⁸ These data raise important questions about the effect of antibiotics and the nature of the invading microorganisms in preterm PROM. Long-term follow-up studies of infants enrolled in the randomized clinical trials are urgently needed because antibiotic treatment of intrauterine infection in animals has been associated with neurologic lesions similar to PVL. Even though the ORACLE I trial observed that the number of neurosonographic lesions was lower in patients who received treatment with erythromycin, it remains to be proven whether the rate of long-term handicap will be lower in these infants.

Should corticosteroids be administered to patients with preterm PROM remote from term?

A systematic review included 13 randomized clinical trials and demonstrated a reduction in the incidence of RDS, IVH, and NEC (RR 0.56, 95% CI 0.46–0.70; RR 0.47, 95% CI 0.31–0.70; RR 0.21, 95% CI 0.05–0.82 respectively).⁴⁵⁷ A nonsignificant trend of reduced neonatal mortality was observed. Moreover, no increase in neonatal and fetal infection was observed.⁴⁵⁷ Steroid treatment was associated with a modest, yet significant, increase in the risk of puerperal endometritis (RR 2.42, 95% CI 1.38–4.24), but no significant increase in neonatal sepsis. Similar findings were reported by Crowley^{458,459} in an earlier meta-analysis, which included fewer trials.

Clinical investigators have compared expectant management with steroid administration for 48 h followed by delivery. However, induction of delivery immediately after steroid administration is associated with an increased risk of RDS and, therefore, is best avoided.⁴⁵⁹

The 1994 National Institutes of Health Consensus Conference recommended the use of corticosteroids in pregnancies complicated by preterm PROM with expected delivery between 24 and 30–32 weeks of gestation.⁴³¹ This recommendation was based largely on data suggesting that the incidence of IVH was lower in neonates exposed to corticosteroids.⁴³¹ The modest increased risk of puerperal infection is considered to be easy to manage. A meta-analysis comparing the outcome of treatment with antibiotics and steroids versus antibiotics without steroids found that steroid administration diminished the beneficial effects of antibiotics in reducing the rate of chorioamnionitis, endometritis, neonatal sepsis, and IVH.⁴⁶⁰ It seems that this issue requires further study, particularly when MIAC has been demonstrated by amniocentesis. Steroids may compromise the fetal host response to microbial products and potentially increase the risk of adverse outcome.

How many courses of corticosteroids should be administered?

Repeated courses of corticosteroids have been used to enhance their effects. However, recent data, based upon studies in humans and animals, have raised questions about the safety of repeated corticosteroid administration. Guinn et al.⁴⁶¹ performed a double-blind, randomized, controlled trial, in which women at risk of preterm delivery received one course of betamethasone or dexamethasone at admission, and were randomly allocated for subsequent weekly courses of either betamethasone ($n = 256$) or placebo ($n = 246$) until 34 weeks of gestation or delivery. There were no significant differences in the frequency of composite neonatal morbidity (severe RDS, BVD, severe IVH, PVL, proven sepsis, NEC, or perinatal death) between the study groups [weekly course 22.5% (56/256) versus single course 28% (66/246), $P = 0.16$]. However, when the analysis was stratified by gestational age, patients who delivered between 24 and 27 weeks and received a single course had a higher rate of composite neonatal morbidity and severe RDS than those in the weekly course group. An important limitation of this study is that the authors did not control for the use of surfactant, which was more frequent in the single course group [single course 24% (59/246) versus the weekly course 15.6% (40/256), $P = 0.01$].⁴⁶¹

In animal experiments, multiple courses of corticosteroids have been associated with low birthweight in term and preterm sheep, as well as small head diameters in term sheep.⁴⁶² Among human neonates born between 27 and 29 weeks of gestation, repeated courses of betamethasone were associated with a smaller neonatal head circumference than those exposed to a single course (multiple courses 25.5 ± 1.6 cm versus single course 26.5 ± 1.4 cm, $P = 0.02$).⁴⁶³ Similarly, French et al.⁴⁶⁴ reported the results of a cohort study that included 477 singleton infants born at less than 33 weeks of gestation. The authors performed a multivariate analysis, which indicated that multiple corticosteroid courses were associated with a significant reduction in birthweight ($P = 0.01$) and head circumference ($P = 0.002$).⁴⁶⁴

Tocolysis

Tocolysis has been employed to attempt to delay delivery and reduce perinatal complications in preterm PROM. Seven randomized clinical trials have studied the effect of tocolysis on pregnancy prolongation and perinatal outcome. Two trials addressed the issue of prophylactic administration of oral ritodrine to patients not in labor,^{465,466} while four have examined the effectiveness of intravenous tocolysis in patients with uterine contractions,^{467–470} and one has compared short-term (24 h) with long-term tocolysis.⁴⁶⁷

Levy and Warsof⁴⁶⁶ randomized 42 women with preterm PROM to receive oral ritodrine (10 mg orally every 4 h) versus no medication or placebo. Drugs were given until the onset of labor. A latency period of more than 7 days was noted more frequently in patients receiving ritodrine than in the control

subjects [47% (10/21) versus 14.2% (3/21), $P = 0.04$]. The only perinatal death occurred in the control group. No differences in perinatal morbidity or mortality were documented between groups.

Dunlop and associates⁴⁶⁵ randomized 48 women to receive oral ritodrine versus no tocolysis and then subrandomized each group to receive prophylactic antibiotics (cephalexin) versus no antibiotics. The result was a four-limb randomization with 12 patients per group. Steroids were given to all patients. No difference in outcome (perinatal mortality and RDS) was observed between patients receiving ritodrine versus no tocolysis. Therefore, the evidence is inconclusive as to the usefulness of oral tocolysis.

Of the four randomized trials of intravenous tocolysis, only one used a double-blind placebo design.⁴⁶⁷ The other three compared tocolysis with bedrest.^{468–470} Overall, no change in maternal or neonatal morbidity and mortality was demonstrated between the study group and the control group. Tocolysis, however, resulted in some degree of pregnancy prolongation in three of the trials.^{467,469,470}

In the trial by Christensen and coworkers,⁴⁶⁷ ritodrine administration was associated with a significant decrease in the proportion of women delivering within 24 h after membrane rupture [ritodrine 0% (0/24) versus placebo 37.5% (6/16), $P < 0.05$]. However, no difference in pregnancy prolongation after 24 h was observed between the treatment group and the control group. In the study by Weiner and colleagues,⁴⁷⁰ the duration of pregnancy was greater in patients receiving tocolysis than in those allocated to bedrest [105 h (SD 157 h)]. Post-hoc analysis indicated that tocolysis administration resulted in significant pregnancy prolongation for patients with gestational ages of less than 28 weeks at the time of membrane rupture (bedrest 53.4 h versus tocolysis 232.8 h, $P = 0.05$). This was not associated with a demonstrable reduction in perinatal morbidity or mortality. No difference in pregnancy prolongation was noted in patients with a gestational age greater than 28 weeks. The authors concluded that there was no justification for tocolysis after 28 weeks of gestation. An unresolved issue is whether the prolongation observed in patients with gestational ages of less than 28 weeks (mean prolongation 5 days) could have some beneficial effect. Steroids were not used in this trial.

Garite and associates⁴⁶⁸ randomized 79 women with a gestational age of 25–30 weeks to receive either intravenous tocolysis with ritodrine (followed by oral therapy) or expectant management. Steroids were not administered. No difference in pregnancy prolongation or perinatal morbidity and mortality was observed between the two groups. It should be noted that 16 of 39 patients randomized to the tocolytic limb did not receive the treatment.

Matsuda et al.⁴⁶⁹ conducted a trial of 81 women with preterm PROM who were allocated to either intravenous antibiotics and tocolysis ($n = 39$: ritodrine and MgSO_4 if ritodrine alone failed) and bedrest ($n = 42$). Patients with clinical chorioamnionitis, positive amniotic fluid Gram stain, and fetal

distress on heart rate monitoring were excluded. Steroids were not used. Patients who received tocolysis and antibiotics had a longer latency period than those in the control group (longer than 48 h 87% versus 50%; and longer than 7 days, 39% versus 12%). No differences in the rate of clinical chorioamnionitis or proven neonatal sepsis (13% versus 12%) were noted. However, suspected neonatal sepsis was significantly higher in the women receiving tocolysis and antibiotics (39% versus 17%). Given that antibiotic administration results in prolongation of the latency period, the value of tocolysis cannot be ascertained.

A randomized trial conducted over a 7-year period in 240 patients with PROM (26 and 35 weeks of gestation) allocated women to short-term tocolysis (24 h i.v.) or long-term tocolysis (24 h i.v. followed by oral therapy until delivery).⁴⁷¹ Women were excluded if the Bishop score was 5 or more or if tocolysis failed in the first 24 h. No difference was found in the duration of the latency period between the two groups. Chorioamnionitis (RR 2.47, 95% CI 1.42–4.66) and postpartum endometritis (RR 1.74, 95% CI 1.10–2.75) were more common in those receiving long-term tocolysis; no differences in neonatal outcome were noted.

Because three of the randomized clinical trials of intravenous tocolysis suggest that treatment results in some prolongation of pregnancy, it is relevant to determine whether enough time could be gained to complete steroid administration and reduce the incidence of RDS.^{467,469,470} Meta-analysis of the four trials indicates that tocolysis does result in prolongation of pregnancy of more than 48 h. However, because no study has shown an improvement in maternal or neonatal outcomes, there is no evidence to support the use of intravenous tocolysis in women with PROM.

Should a cervical cerclage be removed in a patient who presents with preterm PROM?

Cerclage removal has been advocated to reduce the risk of infection-related complications,⁴⁷² while leaving the cerclage in place has been recommended to prolong pregnancy.

Yeast and Garite⁴⁷³ reported the results of a case-control study in which the outcome of patients with a cervical cerclage removed after preterm PROM was compared with that of patients with PROM of a similar gestational age. There was no difference in the incidence of chorioamnionitis or other infectious complications and neonatal outcome between the two groups. The interval between PROM and delivery was not significantly different between patients with and without cerclage. Blickstein and associates⁴⁷⁴ reported similar findings after comparing the outcome of 32 patients with cerclage and 76 without cerclage. In contrast, Goldman and colleagues⁴⁷⁵ compared the outcome of 46 women with preterm PROM in whom the cerclage was not removed with that of 46 women with preterm PROM without cerclage. Patients with a cerclage had a significantly shorter PROM-to-delivery interval and lower gestational age at delivery than patients without the cerclage. However, the rates of chorioamnionitis, other

infection-related complications, and neonatal outcome were not different between the two groups. Ludmir et al.⁴⁷⁶ evaluated the role of immediate cerclage removal in preterm PROM in 30 women. In 20 women, the cerclage was removed immediately after the diagnosis of ruptured membranes was made, while in 10 women, the cerclage was retained after the membranes ruptured. Thirty-three patients with preterm PROM without cerclage served as control subjects. A greater proportion of women with a cerclage left in place delivered after 48 h [90% (9/10) versus 50% (10/20) respectively]. However, perinatal mortality was significantly higher in infants born to women in whom cerclage was retained in comparison with immediate removal or the control group [70% (7/10) versus 10% (2/20) versus 18% (6/33) respectively]. Seventy-one percent of the neonatal morbidity was attributable to sepsis. The authors did not use broad-spectrum antibiotic treatment, which may explain this observation.⁴⁷⁶

McElrath et al.⁴⁷⁷ reported a randomized clinical trial conducted over 12 years comparing removal ($n = 288$) versus nonremoval ($n = 114$) of cerclage in patients with preterm PROM. All patients were treated with antibiotics and corticosteroids. Patients with retained cerclage had a lower gestational age at membrane rupture and delivered earlier than patients in whom cerclage was removed. However, there was no difference in the latency period between the groups. Neonatal mortality was higher among patients in whom the cerclage was kept. This difference became nonsignificant when the analysis was stratified into three gestational age groups (< 28 , $28-30$, and > 30 weeks). There were no significant differences in the rate of RDS, IVH, and neonatal sepsis between the study groups.⁴⁷⁷

In summary, patients with preterm PROM and a cerclage could be managed by leaving the cerclage in place and maintaining close surveillance to detect maternal and/or fetal infection.

Home care versus hospital care

Technical Bulletin no. 15 of the American College of Obstetricians and Gynecologists suggested that, "management in hospital or in selected patients at home with careful observation is feasible" in preterm PROM.⁴⁷⁸ The potential disadvantages of home care include the risk of delivering a preterm infant outside a tertiary center and the implicit delay in obstetric intervention if fetal distress or infection occurs. The advantages of home care include decreased costs and psychological benefits to the patient.

Two studies have compared home care with hospital care. The first, a small, randomized trial of women with PROM at less than 37 weeks of gestation, had strict criteria for home care.⁴⁷⁹ Only patients undelivered after 72 h (60% delivered in less than 72 h), in cephalic presentation, with negative amniotic fluid culture (by amniocentesis), cervical dilation of less than 4 cm on speculum examination, and at least one amniotic fluid pocket of more than 1 cm (22% had oligohydramnios) were eligible for participation. Follow-up

included biweekly NST, weekly ultrasound examination, and corticosteroid administration. Fifty-five patients were randomized, 27 to home care and 28 to remain in hospital. There was no difference in the latency period, gestational age at delivery, chorioamnionitis [11.1% (3/27) versus 14.3% (4/28)], neonatal morbidity [3.7% (1/27) versus 7.1% (2/28)], RDS [3.7% (1/27) versus 7.1% (2/28)], or neonatal pneumonia [18.5% (5/27) versus 10.7% (3/28)].⁴⁷⁹

The second study of home care was a retrospective study of patients with preterm PROM between 20 and 30 weeks of gestation, in which 19 of 21 women undelivered after 7 days were discharged home.⁴⁸⁰ All patients had "adequate or slightly diminished amniotic fluid volume." Eleven of 19 women delivered at term. No neonatal deaths occurred, and there was one case of maternal and neonatal sepsis in a woman managed at home [she was infected with human immunodeficiency virus (HIV)]. One case of neonatal sepsis occurred in an infant born to a woman who was managed in hospital and delivered preterm.

The data available are insufficient to recommend management of preterm PROM outside tertiary care centers. We believe that fetuses with preterm PROM require careful surveillance, which is rarely available outside a hospital environment.

When to induce?

Expectant management of patients presenting with preterm PROM remote from term is the standard of care today.^{20,432,433} This management significantly reduces the neonatal complications related to prematurity,^{20,432,433} however, the longer the latency period, the higher the risk of chorioamnionitis and abruption.^{385,481-483}

Cox and Leveno⁴⁸⁴ performed a prospective study comparing induction versus expectant management of patients presenting with preterm PROM between 30 and 34 weeks. There were no significant differences in neonatal morbidity. However, chorioamnionitis was significantly higher in the expectant management group [2% (1/61) versus 15% (10/68), $P = 0.009$]. Of note, 74% (50/68) of the expectant management group delivered within 72 h.

The timing of delivery is a determinant of the presence of major, but not minor, composite neonatal morbidity. Indeed, major composite neonatal complications (RDS, IVH, intubation, BPD, seizure, NEC, bowel perforation, retinopathy of prematurity, meningitis, pneumonia, primary pulmonary hypertension, and patent ductus arteriosus) decrease substantially after 32 weeks of gestation.⁴⁸⁵ In contrast, minor composite neonatal outcomes (hyperbilirubinemia, transient tachypnea of the newborn, hyper- or hypoglycemia, and hyper- or hyponatremia) decrease only after 34 weeks of gestation (Fig. 63.13). Mercer et al.³⁸⁶ demonstrated that, in patients with preterm PROM, delivery after 32 weeks of gestation was not associated with a significant increase in neonatal morbidity. The development of chorioamnionitis, placental abruption, or a nonreassuring fetal heart rate tracing often

Figure 63.13 Composite major (solid line, square marks) and minor (solid line, circle marks) neonatal morbidity rates for infants born after preterm premature rupture of membranes according to gestational age of delivery. Composite neonatal major morbidity was defined as the presence of any of the following: intraventricular hemorrhage, respiratory distress syndrome, intubation, bronchopulmonary dysplasia, sepsis, seizure, necrotizing enterocolitis, bowel perforation, meningitis, pneumonia or primary pulmonary hypertension, patent ductus arteriosus, or retinopathy of

prematurity. Composite neonatal minor morbidity was defined as the presence of any of the following: hyperbilirubinemia, transient tachypnea of the newborn, or metabolic disturbances (hyper- or hypoglycemia or hyper- or hyponatremia). Outcome data for each gestational age group were compared with the respective outcome of a reference group of women with preterm premature rupture of membranes who delivered at 36 weeks to 36 weeks and 6 days of gestation. * $P < 0.05$. From ref. 485 with permission.

requires induction of labor and delivery, regardless of gestational age.

What are the complications associated with expectant management?

This question has been addressed by many studies, and is summarized in Table 63.23.^{486–495} Fetal and neonatal complications include pulmonary hypoplasia, oligohydramnios sequence, RDS, IVH, neonatal sepsis, and NEC. Perinatal survival rates by gestational age in patients with early preterm PROM are displayed in Tables 63.23 and 63.24. The rate of stillbirth reached 15–26% in previable PROM; overall, there were 111 stillbirths and 237 neonatal deaths⁴⁹⁶ (these figures exclude the study by Rib et al.,⁴⁹⁴ in which no distinction was made between stillbirths and neonatal deaths). Intrauterine fetal deaths were not systematically reported in all studies.

The main maternal complications of expectant management of preterm PROM are chorioamnionitis (39%), endometritis (14%), placental abruption (3%), and postpartum hemorrhage due to retained placenta that requires curettage (12%).⁴⁸⁹ No relationship between the duration of membrane rupture and chorioamnionitis has been noted. However, cases of septicemia requiring a hysterectomy, septic shock, and maternal death were reported.^{486–488,490}

Expectant management prolonged pregnancy by more than 1 week in 49.8% (254/510),^{486–491,493,495} more than 2 weeks in 28% (114/407),^{486,488,489,493–495} and more than 1 month in 19.2% of cases (71/370).^{486,487,489,490,495} An inverse relationship

Rib ⁴⁹⁴	19–22	0/8 (0)
	22–23	9/20 (45)
	24–26	12/17 (70.6)

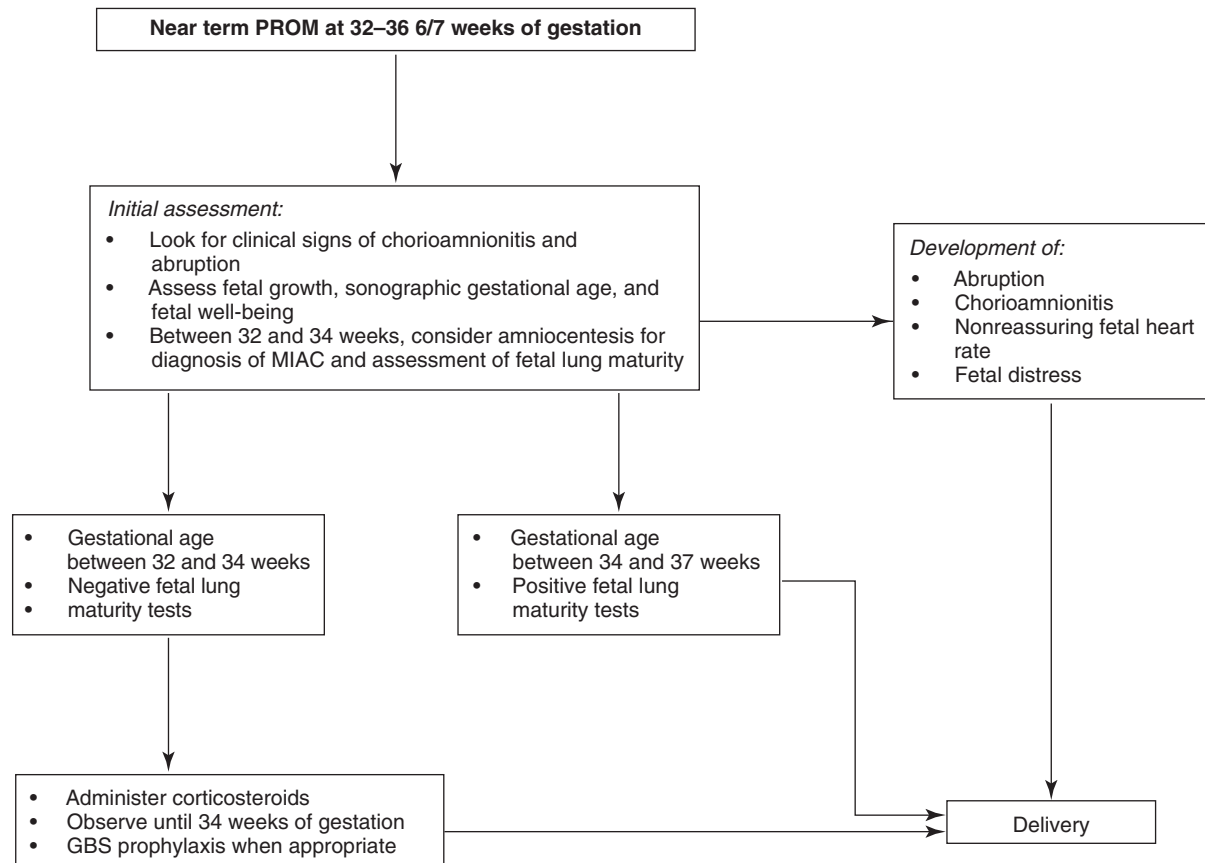

Figure 63.14 Management of near term PROM (between 32 and 37 weeks of gestation). MIAC, microbial invasion of the amniotic cavity; GBS, group B *Streptococcus*. Modified from Mercer BM. *Clin Perinatol* 2004;31:765–782⁴³² with permission from Elsevier.

between gestational age at preterm PROM and the latency period was noted in four studies.^{486,490–492}

PROM near term (32–36 6/7 weeks of gestation) (see Fig. 63.14)

Mercer et al.³⁸⁶ demonstrated no differences in the maternal and neonatal outcomes of expectant management and induction of labor. However, there was a trend toward a higher incidence of maternal chorioamnionitis in the expectant management group.³⁸⁶ Cox and Leveno⁴⁸⁴ reported a higher incidence of maternal chorioamnionitis. The conventional view is to perform amniocentesis for fetal lung maturity between 32 and 34 weeks and, if the result is positive, to proceed with induction of labor in order to reduce maternal morbidity.^{432,484,497} In cases with negative fetal lung maturity, the management is not clear. Some physicians will choose expectant management until 34 weeks, while others will administer corticosteroids and induce labor 48 h later.⁴⁹⁸ There are not sufficient data in the literature to support either course of action.

In a survey that was conducted in the USA during 2003 among members of the Society of Maternal Fetal Medicine, 42% will induce labor in patients presenting with premature PROM and positive lung maturity at 32 weeks.⁴⁹⁸ In cases with unknown fetal lung maturity, 58% will postpone delivery to 34 weeks of gestation.⁴⁹⁸ In summary, patients between 32 and 34 weeks need assessment of lung maturity and, if positive, the patients should be offered induction of labor. In cases without fetal lung maturity, there are not sufficient data as to the optimal management approach. Mercer¹² proposed that women with PROM after 34 weeks should be delivered.

The role of amnioinfusion in preterm PROM

Oligohydramnios is a risk factor for the development of abnormal fetal heart rate patterns during labor.⁴⁹⁹ Experimental evidence obtained in rhesus monkeys indicates that loss of amniotic fluid is associated with the appearance of variable fetal heart rate decelerations that disappear after fluid volume is replaced.⁵⁰⁰ A similar phenomenon has been observed in women with rupture of membranes. Moberg and coworkers⁵⁰¹

reported that patients with preterm PROM had a higher incidence of Cesarean delivery for fetal distress than patients with preterm labor and intact membranes [7.9% (21/267) versus 1.5% (2/130) respectively, $P < 0.05$]. Seventy-six percent of patients who underwent Cesarean delivery for fetal distress in the PROM group had fetal heart rate patterns consistent with umbilical cord compression. Miyazaki and Taylor⁵⁰² were the first to report a clinical trial in which saline amnioinfusion was used in 42 patients in labor with five or more consecutive repetitive variable decelerations or prolonged decelerations (< 100 b.p.m. for at least 3 min) that did not respond to changes in maternal position and oxygen therapy. Amnioinfusion provided relief from repetitive variable decelerations in 67% (19/28) of cases and of prolonged decelerations in 85.7% (12/14).

Subsequently, Miyazaki and Nevarez⁵⁰³ compared amnioinfusion with standard management of variable decelerations in 96 patients. Amnioinfusion was associated with a significant reduction in the severity and occurrence of variable decelerations and prolonged decelerations (amnioinfusion 51% versus non-infusion group 4.2%, $P < 0.01$). This effect was more dramatic in nulliparous patients. A significant reduction in the incidence of Cesarean delivery for fetal distress was noted in nulliparous, but not in multiparous, patients.

Nageotte and associates⁵⁰⁴ compared prophylactic amnioinfusion versus no infusion in a randomized clinical trial of 61 women in preterm PROM in early labor. Patients who received an amnioinfusion had significantly lower incidence of severe decelerations during both the first and the second stage of labor. The incidence of Cesarean delivery for fetal distress was also lower in patients receiving amnioinfusion than in the control group [3% (1/29) versus 22% (7/32), $P = 0.06$]. No umbilical cord pH data were reported.

A meta-analysis of randomized clinical trials using transcervical amnioinfusion has demonstrated that this procedure is associated with a significant reduction in the rate of Cesarean delivery (OR 0.48, 95% CI 0.30–0.77), variable decelerations, 1- and 5-min Apgar score of less than 7, umbilical artery pH of less than 7.20, and meconium aspiration syndrome. The reduction in Cesarean delivery may also lead to a decrease in endometritis.⁵⁰⁵ Potential complications of intrapartum amnioinfusion include uterine overdistention, elevated intrauterine pressure, and amniotic fluid embolism.⁵⁰⁶ In conclusion, the balance of the evidence supports the use of transcervical amnioinfusion in preterm PROM when there are fetal heart rate abnormalities. However, a recent randomized controlled trial (RCT) in patients admitted at ≥ 36 weeks with thick meconium staining of the amniotic fluid failed to demonstrate a beneficial effect of transcervical amnioinfusion.⁵⁰⁷

The value of transabdominal infusion in the management of PROM remote from term was assessed recently in a RCT in which women with PROM between 24 weeks and 32 weeks and 6 days were allocated to transabdominal amnioinfusion ($n = 17$) or expectant management ($n = 17$). Women in the amnioinfusion group received weekly serial amnioinfusion of

isotonic sodium chloride if the AFI was below the fifth percentile and/or a median pocket of amniotic fluid was < 2 cm. The mean volume infused was 250 mL. The transabdominal amnioinfusion was associated with a lower risk of delivery within 7 days (RR 0.18, 95% CI 0.04–0.69).⁵⁰⁸

Another use of amnioinfusion is to improve fetal visualization in cases of severe oligohydramnios. Amnioinfusion was first used by Gembruch and Hansmann⁵⁰⁹ to improve sonographic imaging in cases of midtrimester oligohydramnios. Fisk et al.³⁰⁷ reported improved fetal visualization after expansion of the amniotic volume in a significant number of cases (amnioinfusion was successful in 58/61 cases, enabling sonographic visualization of fetal anatomy in 51 cases). There was one inadvertent aspiration of fetal blood at 34 weeks of gestation followed by profound bradycardia necessitating delivery. The neonate died from pulmonary hypoplasia. Four other fetal losses may have been procedure related.

Prelabor rupture of the membranes at term

The management of patients with PROM at term includes: (1) exclusion of cord prolapse; (2) detection of infection; and (3) evaluation of fetal well-being. If any evidence exists of fetal compromise or infection, induction of labor or delivery is the management of choice. For other patients, the relevant management issues include deciding between (1) induction or expectant management and (2) when and how induction should be undertaken.^{510–533}

The natural history of term PROM is that 90% of women will be in spontaneous labor within 24 h.⁵³³ Nulliparous women have a longer latency period than multiparous women.^{516,523,528} Patients with an unfavorable cervix at presentation and those who are not in labor within 6 h of rupture of membranes generally do not initiate labor spontaneously within 24 h and represent a management dilemma.⁵³²

The largest clinical trial in term PROM⁵¹⁷ included 5041 patients who were randomly allocated to four groups: (1) immediate induction with oxytocin; (2) expectant management followed by induction with oxytocin after 4 days; (3) induction of labor with vaginal prostaglandin E_2 (1–2 mg, followed by i.v. oxytocin; if not in labor in 4 h, a second dose of prostaglandin E_2); and (4) expectant management followed by induction of labor with prostaglandin E_2 , if labor had not begun within 4 days. The primary outcome of the trial was probable neonatal infection (clinical and laboratory signs). Secondary outcomes were the need for Cesarean delivery and women's evaluation of their treatment. The results showed no difference in neonatal infection and Cesarean delivery rate between the induction groups (oxytocin versus prostaglandin E_2). However, the incidence of chorioamnionitis was lower in patients allocated to induction of labor. Women's satisfaction with their obstetric care was higher for those allocated to induction of labor.

Table 63.25 Pooled odds ratios (ORs) and confidence intervals (CIs) for three treatment policies of term prelabor rupture of the membranes and outcome variables of interest. From ref. 524 with permission from Lippincott Williams & Wilkins.

	Chorioamnionitis		Endometritis		Cesarean delivery		Neonatal infection	
	OR	CI	OR	CI	OR	CI	OR	CI
Oxytocin vs. conservative	0.91	0.51–1.62	0.78	0.50–1.21	1.24	0.89–1.73	0.73	0.47–1.13
Prostaglandins vs. conservative	0.68	0.51–0.91	0.81	0.53–1.23	0.95	0.76–1.20	1.06	0.67–1.66
Prostaglandins vs. oxytocin	1.55	1.09–2.21	0.78	0.23–2.63	0.67	0.34–1.29	1.50	0.91–2.45

Mozurkewich and Wolf,⁵²⁴ in their meta-analysis of 23 studies including 7493 women, demonstrated that induction of labor is superior to expectant management. The meta-analysis compared three policies: (1) immediate induction with oxytocin; (2) induction of labor with vaginal or endocervical prostaglandin E₂ gel suppositories or tablets; and (3) expectant management that has sometimes included delayed induction with oxytocin. The frequency of chorioamnionitis and endometritis was significantly lower in patients undergoing immediate induction of labor with oxytocin than in those managed expectantly (OR 0.67, 95% CI 0.52–0.85 and OR 0.71, 95% CI 0.51–0.99 respectively). The rate of chorioamnionitis was significantly higher in patients who received vaginal prostaglandins than in those induced with immediate administration of oxytocin, but lower than that of patients in the expectant management group (OR 1.55, 95% CI 1.09–2.21 and OR 0.68, 95% CI 0.51–0.91 respectively). The rates of Cesarean delivery and neonatal infection were not different among the three management schemes (Table 63.25). Based on these data, we endorse a policy of immediate induction of labor in patients with term PROM. Antibiotic administration is justified before Cesarean delivery for obstetric indications or for carriers of GBS.

Tan and Hannah⁵³⁴ performed a meta-analysis of 18 trials comparing induction of labor with oxytocin versus expectant management in patients with PROM at or near term. Induction of labor with oxytocin was associated with a lower risk of chorioamnionitis (OR 0.63, 95% CI 0.51–0.78), endometritis (OR 0.72, 95% CI 0.52–0.99), and neonatal infection (OR 0.64, 95% CI 0.44–0.93). Cesarean delivery rates were not statistically different. Oxytocin was associated with a more frequent use of pain medication and internal fetal heart rate monitoring. Another meta-analysis of 15 RCTs by Lin et al.⁵³⁵ included: (1) six studies ($n = 453$) of misoprostol versus placebo or expectant management; and (2) nine studies ($n = 1130$) of misoprostol versus oxytocin for labor induction with term PROM. Surprisingly, there were no significant differences in the frequency of chorioamnionitis, neonatal sepsis, or Cesarean delivery among the study groups. Similarly, a recent systematic review of induction of labor versus expectant management for term PROM by Dare et al.⁵³⁶ did not find differences in the rate of Cesarean deliveries and neonatal infection. However, the frequency of chorioamnionitis and endometritis was higher in the expectant management group.⁵³⁶

Expectant management at home of patients with PROM at term is not recommended. This recommendation is based upon the report by Hanna et al.⁵³⁷ that home care was associated with an increased risk of neonatal infections (OR 1.97, 95% CI 1.00–3.90) and Cesarean delivery in patients not colonized with GBS (OR 1.48, 95% CI 1.03–2.14).

Novel treatment techniques

Attempts have been made to seal the site of rupture (mostly in iatrogenic cases). These techniques are at the current time in developing stages. However, a description is included because patients or their physician may inquire about these techniques.

Fibrin glue

Fibrin glue is a mixture of fibrinogen, thrombin, and cell fibrin that is injected under ultrasound guidance onto the site of rupture. Genz⁵³⁸ treated 19 patients, with a success rate of 60%. However, Kurz and Hick⁵³⁹ (using the same procedure) reported a small series in which there were no successes.

Baumgarten and Moser⁵⁴⁰ used an intracervical approach to apply the sealant, following a cervical cerclage in 26 women, with a success rate of 65% (success was defined as the percentage of surviving infants). Pregnancy was prolonged for more than 28 days in six women, and no cases of chorioamnionitis were documented. Uchide et al.⁵⁴¹ reported a case of intracervical fibrin glue instillation and cervical cerclage in which the pregnancy lasted from 24 weeks (time of rupture) to 31 weeks of gestation. Catalano and Zardini⁵⁴² reported five cases in which intracervical instillation of fibrin glue resulted in successful pregnancy prolongation. Similar results were found by Sciscione et al.⁵⁴³ in 12 patients (13 fetuses) with previable PROM using fibrin sealants. All patients had an increase in the AFI and diminution of leakage. The fetal survival rate was 53.8%.

Amniopatch

This approach consists of transabdominally injecting platelets and cryoprecipitate to seal the membranes. The basis for this approach is that the amnion is avascular and, therefore,

unable to initiate platelet activation, fibrin deposition, and other events required for wound healing in vascular tissues. The procedure consists of administering platelets (0.5 units) followed by cryoprecipitate (a source of fibrinogen). Quintero et al.⁵⁴⁴ pioneered this approach in 1996 and subsequently reported the experience in 28 cases.⁵⁴⁵ A key observation is that this approach is successful when applied to rupture of membranes occurring after procedures such as fetoscopy. The rate of successful sealing of the membranes is 64% (18/28). Among the successful cases, one patient had a miscarriage, one patient terminated the pregnancy due to a chromosomal abnormality, and one neonate died of meningitis 2 weeks after discharge from the neonatal intensive care unit. Of the 10 unsuccessful cases, three neonates were alive and well. Some cases resulted in fetal death ($n = 3$), voluntary termination of pregnancy ($n = 2$), and miscarriage ($n = 2$). This option can be offered to patients who have membrane rupture after amniocentesis, skin biopsies, fetal shunts, and diagnostic operative fetoscopy. Precise knowledge of the site of rupture is unnecessary. The hemostatic material does not need to be injected into the site of rupture, and appears to find its way to the defect and seals it. The possibility of fetal death must be explained to patients. This phenomenon has been attributed to the possible effect of vasoactive agents released during the course of platelet activation.

Physical barrier to stop leakage

A group from Lithuania evaluated 16 women between 22 and 32 weeks of gestation with PROM in whom a “cervical cup” was inserted to stop leakage.⁵⁴⁶ Outcomes were compared with 19 women with preterm PROM. The average AFI in the women having the adapter almost doubled, whereas the AFI

did not change in control subjects. No infections occurred in mothers or infants in either group. The aim of increasing the amniotic fluid volume was to enable easier amniocentesis.

O'Brien et al.⁵⁴⁷ had implemented a treatment protocol for patients presenting with previable PROM including amniocentesis, cervical cerclage, and administration of gelatine sponge into the amniotic cavity. Eight of 15 fetuses (53%) reached viability, two of whom were intrauterine fetal demise, and six were discharged home alive. However, three fetuses had talipes equinovarus and bilateral hip dysplasia, while two fetuses had torticollis. This might be an effective, although aggressive, mode of treatment, but further studies are needed to investigate the origin of the higher rate of musculoskeletal disorders. A surgical approach to sealing the membranes in patients with spontaneous rupture and no evidence of infection and inflammation is being explored. The procedure relies on the placement of a graft with laser welding. This has been attempted in animals, but the procedure is still experimental in humans.^{545,548}

Acknowledgments

This work was conducted by members of the Perinatology Research Branch of the National Institute of Child Health and Human Development (NICHD) of the National Institutes of Health (NIH) and funded by the Intramural Program of NICHD/NIH.

This chapter was published in previous editions of this book. The current version has been substantially changed. The authors wish to acknowledge the contribution of authors of previous chapters. In particular, the current authors and the editors gratefully acknowledge the intellectual contributions of Dr Neil Athayde, Dr Eli Maymon, and Dr Percy Pacora.

Key points

- 1 Term PROM occurs in approximately 10% of patients, while the frequency of preterm PROM is 2–3.5%.
- 2 The “zone of altered morphology” (ZAM) is an anatomical structure that includes amnion and chorion (of fetal origin) and portions of decidua (of maternal origin) apposed to the cervix, which undergoes morphologic changes before the onset of labor.
- 3 It has been proposed from biophysical studies of chorioamniotic membranes of patients with PROM that the membranes have focal areas of weakness rather than a generalized weakening.
- 4 Evidence supports the role of matrix metalloproteinases (MMPs), proteases that can degrade several components of the chorioamniotic membranes, in both preterm and term PROM.
- 5 Preterm PROM is associated with positive amniotic fluid cultures in approximately 30% of cases, while 75% of patients have microbial invasion of the amniotic cavity (MIAC) when amniocenteses are performed at the time of onset of labor.
- 6 The most important risk factor for preterm PROM is a previous preterm delivery.
- 7 Vaginal bleeding, a short cervix (≤ 25 mm), a history of previous spontaneous preterm delivery (with intact or ruptured membranes), and smoking are risk factors for preterm PROM in the index pregnancy.
- 8 The risk of PROM in a subsequent pregnancy is 4% if the patient's first pregnancy went to term and was

not complicated by PROM, while the recurrence rates are 21% for preterm PROM and 26% for term PROM.

- 9 The main consequences of preterm PROM are: (1) spontaneous onset of labor leading to prematurity; (2) infection; (3) abruptio placentae; (4) fetal death; and (5) the oligohydramnios sequence.
- 10 The prevalence of positive amniotic fluid cultures in women with preterm PROM is 32.4%, whereas in term PROM, the prevalence is 34.3%.
- 11 In preterm PROM, genital mycoplasmas (*Ureaplasma urealyticum* and *Mycoplasma hominis*) are the most frequent isolates from the amniotic fluid, followed by *Streptococcus agalactiae*, *Fusobacterium* species, and *Gardnerella vaginalis*.
- 12 The frequency of positive fetal blood culture is about 10% among patients with preterm PROM.
- 13 The risk of pulmonary hypoplasia when PROM occurs at 19 weeks has been found to be 50%, yet it was only 10% when the membranes ruptured at 25 weeks.
- 14 The accuracy of ferning in the diagnosis of PROM is 95%.
- 15 Fetal lung maturity studies can be performed on amniotic fluid obtained from the vagina. A mature lecithin/sphingomyelin (L/S) ratio or the presence of phosphatidylglycerol (PG) in these samples is associated with a very low risk of respiratory distress syndrome (RDS).
- 16 The diagnostic indices of a BPP score ≤ 7 (performed 24 h before delivery) for the prediction of infection-related morbidity (defined as maternal chorioamnionitis, possible neonatal sepsis, and proven neonatal sepsis) were: sensitivity 94%, specificity 97%, positive predictive value 95%, and negative predictive value 97%, in a population with a prevalence of infection-related outcome of 30%.
- 17 The natural history of term PROM is that 90% of women will be in spontaneous labor within 24 h.
- 18 Expectant management at home of patients with PROM at term was associated with an increased risk of neonatal infections and Cesarean delivery in patients not colonized with group B *Streptococcus* (GBS).
- 19 In patients with preterm PROM, delivery after 32 weeks of gestation is not associated with a significant increase in neonatal morbidity.
- 20 Patients with preterm PROM and a cerclage could be managed by leaving the cerclage in place and maintaining close surveillance to detect maternal and/or fetal infection.

Prolonged pregnancy

Curtis L. Lowery and Paul Wendel

Prolonged pregnancy may be defined as any pregnancy that continues past 294 days.^{1,2} It is well established that the prolonged pregnancy is associated with increased maternal and fetal morbidity and mortality.^{3–5} Postdatism implies that the pregnancy has endured longer than the estimated due date of 40 weeks. The postmature syndrome is associated with intrauterine growth restriction and occurs when there is placental insufficiency often caused by an aging placenta.^{6–8} The most common cause of the prolonged pregnancy is inaccurate dating. Ultrasound has proved effective in reducing the number of inappropriate inductions.^{9,10} Anencephaly and adrenal hypoplasia have been associated with prolonged pregnancy, and both share a common feature of pituitary insufficiency, and show an absence of the usually high estrogen levels that characterize normal pregnancy.^{11,12} Despite improvements in pregnancy dating, the prolonged pregnancy continues to present a significant problem for healthcare providers.

Definitions

Multiple terms including postterm, prolonged, postdates, and postmature have been used to describe pregnancies exceeding their due date. The lack of standardized definitions has made comparison between studies on the prolonged pregnancy extremely difficult. Postterm or prolonged pregnancy should be the preferred terminology for the pregnancy extended beyond 42 weeks. Postmaturity is a neonatal diagnosis and should be used to describe the infant with recognizable clinical features associated with postmaturity, including peeling, parchment-like skin, and meconium staining of skin, membranes, and the umbilical cord. In addition, these infants may also have overgrown nails, well-developed creases on the palms and soles, abundance of scalp hair, little vernix or lanugo hair, scaphoid abdomen, and minimal subcutaneous fat.^{13,14} Like most medical conditions, the syndrome exhibits a continuum that varies from mild placental insufficiency to a more severe medical problem with significant growth restriction and a greater probability of associated hypoxia.

Incidence

Around 20% of women cannot remember their last menstrual period and, when there is late entry to prenatal care, there is often confusion regarding the dating of the pregnancy.¹⁵ The incidence of prolonged pregnancy varies from 3% to as high as 14%, depending on whether first-trimester ultrasound dating or last menstrual period dating has been used to determine the estimated date of delivery.^{10,16} Women with one previous prolonged pregnancy have a 30% chance of a recurrent prolonged pregnancy.¹⁷ In centers in which patients are seen early in pregnancy and have ultrasounds in the first trimester, the incidence of the prolonged pregnancy has been reduced by half to two-thirds.^{10,16} Perinatal mortality has been noted to increase in pregnancies with unknown dates.¹⁸ It is possible that some of these deaths are due to a failure to diagnose the prolonged pregnancy. It is also important to remember, when managed conservatively, 40–50% of women will deliver within 4–5 days of the 42nd week.¹⁹

Maternal and fetal risks

Maternal risks

The maternal risks from the prolonged pregnancy are associated with the increased need for operative delivery in both spontaneous and induced labor. Controversy remains as to whether spontaneous labor has a lower incidence of operative delivery than those patients who require induction.^{20,21} There may also be an increase in fetal macrosomia and uteroplacental insufficiency, which predisposes the patient to an increased incidence of operative delivery. Conservative therapy and awaiting labor may not avoid the need for operative interventions resulting from these problems.^{22,23} The National Institute of Child Health and Human Development Network of Maternal-Fetal Medicine Units reported that induction of labor in pregnancies ≥ 41 weeks was not associated with a significant increase in Cesarean delivery rates

Table 64.1 Summary odds ratios for Cesarean section in randomized trials of elective induction versus expectant management.*

Group	Odds ratio	95% confidence interval
By gestational age:		
< 41 weeks	0.6	0.35–1.03
> 41 weeks	0.87	0.77–0.99
By parity:		
Primigravid	0.75	0.64–0.88
Multigravid		
Bishop score < 6	1.02	0.75–1.38
By overall Cesarean section rate:		
< 10%	0.89	0.58–1.39
> 10%	0.87	0.77–1.00
By class of induction agent:		
Oxytocin	0.85	0.74–0.98
Prostaglandins	0.84	0.65–1.08

Data from Crowley (2000);⁹ odds ratios < 1 indicate that the Cesarean section rate was lower in the elective induction group.

compared with awaiting spontaneous labor. In this study, 440 patients with uncomplicated pregnancies at 41 weeks' gestation were randomized to either immediate induction of labor ($n = 265$) or expectant management ($n = 175$). The Cesarean delivery rate was not significantly different in the expectant (18%), prostaglandin E₂ gel (23%), or placebo gel (18%) groups.²⁴

In the Canadian Multicenter study involving 3407 women at > 42 weeks' gestation, there was a statistically significant lower Cesarean section rate in the induction group of 21.2% compared with the conservatively managed group with a Cesarean section rate of 24.5%.²⁵ The higher Cesarean section rate was felt to be the result of a greater incidence of fetal distress in the conservatively managed group. A later cost estimate of this trial showed that induction of labor was associated with a significantly lower cost (US\$2502 versus US\$2684).²⁶ In Table 64.1, data from the Cochrane database are summarized, and it would appear from these studies that the prolonged pregnancy is associated with an increased need for operative vaginal delivery, induction of labor, and Cesarean section. The study shows that inductions prior to 42 weeks may reduce the need for Cesarean sections.

Fetal and neonatal risks

Multiple studies have demonstrated an increased risk of perinatal mortality after 42 weeks.^{6,16,27–42} Perinatal mortality reaches its nadir at 39–40 weeks and then increases as pregnancy exceeds 41 weeks.⁴³ These deaths occur during the antepartum, intrapartum, and neonatal period as the result of events related to either uteroplacental insufficiency or through the development of fetal macrosomia and commonly associ-

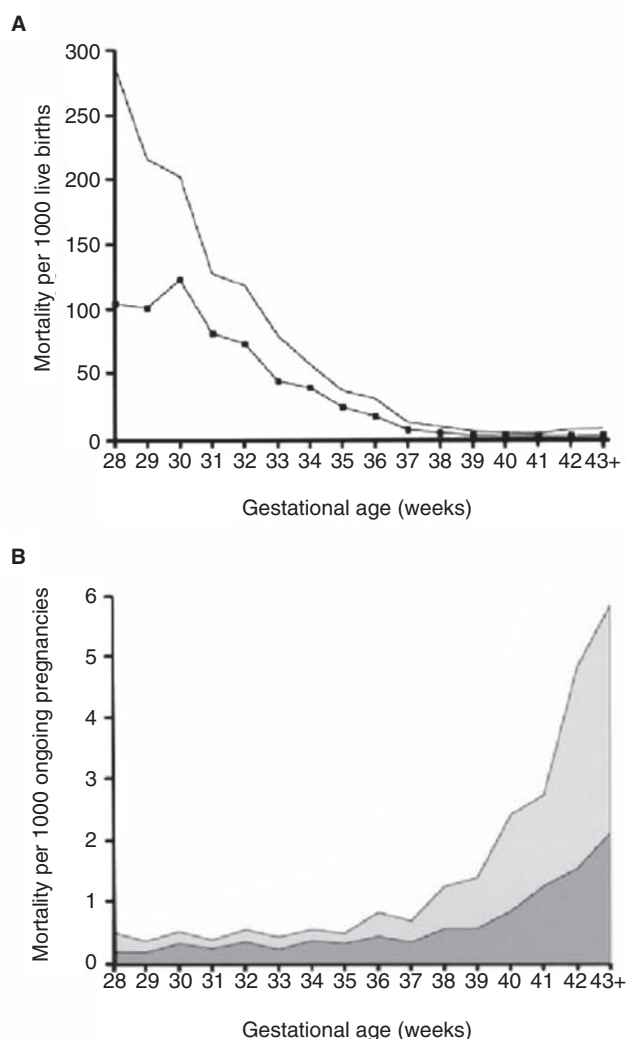

Figure 64.1 (A) The rates of stillbirth (■) and infant mortality (—) for each week of gestation from 28 to 43+ weeks expressed per 1000 live births. (B) The rates of stillbirth (dark gray) and infant mortality (light gray) in the same population of 171 527 singleton births expressed as a function of 1000 ongoing (undelivered) pregnancies. Data from Hilder et al.⁴⁴ (with permission of Blackwell Science Ltd).

ated birth trauma. During the antepartum period, the fetus may suffer hypoxic ischemic insults that can result in either stillbirth or intrauterine growth restriction and the development of the postmature syndrome.

Traditional reports of stillbirth rates have commonly used, as the denominator, the number of deaths per 1000 newborns. This estimate fails to provide a realistic risk assessment, which is the number of deaths per continuing pregnancies. Stillbirth rates should be reported based on a denominator that will provide the most appropriate statement of risk. Studies have shown that pregnancies that continue beyond 42 weeks have an increased risk of stillbirth (see Fig. 64.1A) but, when the risk of stillbirth is expressed as a function of ongoing

Table 64.2 Observed relationship between gestational age and stillbirth risk.

Study	Location	Dates	<i>n</i>	Stillbirth risk per 1000													
				Denominator: 1000 deliveries in specified gestational week								Denominator: 1000 continuing pregnancies

From ref. 58.

pregnancies (stillbirth divided by total births), the mortality rate is even greater. In a retrospective study by Hilder et al.⁴⁴ of 177 527 singleton births (1989–1991), the rate of stillbirths increases sixfold from 0.35 per 1000 ongoing pregnancies at 37 weeks to 2.12 per 1000 ongoing pregnancies at 43 weeks (see Fig. 64.1B). This difference was even more striking when the infant mortality statistics were included, showing an eight-fold increased risk of pregnancy loss (stillbirth plus death within the first year of life) from 0.7 per 1000 ongoing pregnancies at 37 weeks to 5.8 per 1000 pregnancies at 43 weeks' gestation (Table 64.2).

The literature has been inconsistent in reporting the frequency and type of antenatal surveillance of the prolonged pregnancy.² No single method of fetal assessment has proved superior in either sensitivity or specificity of fetal evaluation in the prolonged pregnancy, and there have been no randomized, controlled trials in which surveillance was compared with no surveillance. The Agency for Healthcare Research and Quality (AHRQ) published an evidence-based report/technology assessment on the management of the prolonged pregnancy.^{45,46} A detailed description of the tests used to evaluate the prolonged pregnancy is undertaken in the chapter entitled "Normal and abnormal placentation." This group estimated that, if the perinatal mortality rate was 1.2 per 1000 births at 41 weeks, a randomized trial would need over 40 000 women in each arm to determine a twofold difference in the risk of stillbirth between two competing methods of surveillance. As with most tests, there is a tradeoff between specificity and sensitivity. Tests that are more sensitive are usually less specific. As it has been well established that the probability of adverse fetal outcome increases with increasing gestational age, then antepartum tests with high negative predictive values are needed. Data reported by Bochner et al.⁴⁷ are consistent with this concept and showed positive predictive values for adverse outcomes were better when testing began at 42 weeks (21.1% versus 11.9% at 41 weeks), but negative predictive values were worse (98.5% at 42 weeks versus 99.1% at 41 weeks). Assuming that induction of labor does not carry increased perinatal risk, planned induction of labor at any gestational

age should always result in fewer adverse perinatal outcomes than continuing pregnancies with testing strategies.

A fetal mortality rate of 1.12 per 1000 was reported in a review of 8038 consecutive postterm pregnancies with twice-weekly antepartum fetal surveillance protocols using nonstress tests, fluid indices, and biophysical profiles as needed.^{9,48} As noted above, most prolonged pregnancies occur as a result of poor dating and are often not in fact prolonged. Combined with improved antepartum fetal surveillance, it will be difficult to show that induction of labor at 41 weeks as opposed to 42 weeks will significantly improve mortality rates.

Most of the excessive perinatal mortality associated with a prolonged pregnancy occurs in the intrapartum and neonatal periods.⁴⁹ Intrapartum asphyxia and meconium aspiration were implicated in 25% of the deaths. Also, 5.4 per 1000 post-term infants compared with 0.9 per 1000 term infants exhibited early neonatal seizures. Meconium aspiration syndrome is significantly increased in these patients.^{29,50–54}

Fetal macrosomia

It is important to remember that the most common complication of the prolonged pregnancy is fetal macrosomia. Macrosomia has been defined as newborn birthweights of either 4000 g or 4500 g. Macrosomia can result in dystocia and associated brachio-plexus injuries and fractures. In a study by Pollack et al.,⁵⁵ 21% of the pregnancies beyond 41 weeks had infants weighing more than 4000 g, and 4% of these fetuses weighed more than 4500 g. Labor induction, Cesarean delivery, fetal macrosomia, and shoulder dystocia are also significantly increased.⁵¹ The clinical significance of birthweights between 4000 and 4500 g is unclear, but it has been well established that shoulder dystocia is greatest for infants weighing > 4500 g.^{53,56,57}

As both mother and fetus are at risk from macrosomia, attempts have been made to determine fetal weights in prolonged pregnancies. Table 64.3 reports on test performance characteristics for studies outlining the association between estimated fetal weights and macrosomia, as compiled by

Table 64.3 Accuracy of antenatal fetal weight estimation for predicting macrosomia.

Study	Screening test threshold	Rate of abnormal tests	Outcome threshold	Rate of outcome event	Sensitivity	Specificity	Positive predictive value	Negative predictive value
Chauhan et al. (1995)	> 4000g	0.21	> 4000g	0.26	0.61	0.92	0.73	0.87

Myers et al.⁵⁸ for the AHRQ publication *Management of prolonged pregnancy: evidence report/technology assessment no. 53*. Chauhan et al.⁵⁹ compared estimates of fetal weight by clinicians using Leopold maneuvers in early labor with ultrasound measures with the actual newborn birthweights (see Table 64.3). In this study, the clinical estimates were significantly better at estimating within 10% of actual weight than ultrasound calculations (clinical 65.4% versus sonographic 42.8%; $P < 0.005$). Chervenak et al.⁶⁰ calculated fetal weights in 317 women followed conservatively for the management of prolonged pregnancy. In this study, 24% of women had infants born weighing more than 4000g and, of this group, 22% versus 10% of the control subjects ($P < 0.01$) had Cesarean sections for protracted disorders. The sensitivity of ultrasound for predicting birthweight > 4000g was 61%, specificity 91%, positive predictive value 70%, and predictive value 87%. In Table 64.3, we see the effects of test threshold on outcome prediction.

Gilby et al.⁶¹ compared fetal abdominal circumference measurements of 34–38cm and prediction of birthweight > 4000g. At 34cm, 38% of the population was selected; however, when 38 cm was used, only 5% of the population met this threshold. At the 34-cm threshold, the sensitivity was 99%, while at 38 cm, the sensitivity was only 54%. The specificity was much lower at 65% for the less stringent 34-cm value, whereas the 38-cm measurement gave a specificity of 97%. The positive predictive values yielded 9% and 37% respectively. Similar results were obtained from the 1997 O'Reilly-Green and Divon⁶² study when comparing ultrasound weight calculated thresholds (4191–4500g). From these comparisons, we can determine that stringent thresholds for

the diagnosis of macrosomia yield poor sensitivities but improved specificities and positive predictive values. The obvious question is where the threshold for intervention should be set. In 1996, Rouse et al.⁶³ performed a cost analysis finding that, if Cesarean sections are performed on all pregnancies with estimated fetal weights of 4500g, 3695 Cesarean sections at a cost of US\$8 million would be performed to prevent one permanent brachioplexus injury. There are limited data to support whether induction of labor in patients with estimated fetal weights between 4000 and 4500g reduces newborn or maternal morbidity. Methods for prediction of birthweights more than 4500g in the routine prolonged pregnancy are imprecise. There is no evidence that ultrasound-guided clinical decision-making can accurately identify macrosomia and whether the use of this modality can change clinical outcomes.

Management

While there is no clear consensus as to the most clinically correct method for the management of the prolonged pregnancy in recent times, most physicians now plan inductions at 41 or 42 weeks. While there is an increased incidence of stillbirth with increasing gestational age, this incidence does not become significant until 42 weeks, and most studies have shown no clear benefit from the induction of labor versus conservative management with aggressive fetal assessment. The two big questions to be answered are whether induction of labor before 42 weeks increases the incidence of Cesarean section and does this approach result in a greater cost than

conservative therapy? The absolute goal for the management of the prolonged pregnancy is to reduce newborn morbidity and prevent all stillbirths, while at the same time keeping the Cesarean section and operative vaginal delivery rates as low as possible.

Pregnancy dating

The most important way to minimize the incorrect diagnosis of postterm pregnancy is to establish accurate pregnancy dating as early as possible. With accurate dating, making decisions regarding induction or conservative management can be improved based upon more objective information. The estimated delivery date (EDD), as calculated from the last menstrual period (LMP), can be used reliably in women with regular normal menstrual cycles, especially when these women are seen early in the pregnancy and a detailed history is obtained during their first visits. It is important to remember that many women cannot accurately recall their LMP, particularly when they start prenatal care late in their pregnancies. In women for whom there is uncertainty regarding their pregnancy dating, an ultrasound in the first or second trimesters should be obtained. The crown-rump length can determine gestational age to within 5 days.^{10,64} Most clinicians accept the variation in ultrasonography generally as ± 7 days up to 20 weeks of gestation, ± 14 days between 20 and 30 weeks of gestation, and ± 21 days beyond 30 weeks of gestation. The use of ultrasound dating in these situations has significantly reduced the false diagnosis of prolonged pregnancy.^{16,64,65}

When the ultrasound measurements differ from the LMP by more than these ranges, ultrasound estimates of EDD should be used. Serial measurements of symphysis fundal height may be useful in identifying the occasional case of growth restriction or macrosomia; however, these measurements are of no value in establishing gestational age. Again, ultrasound measurements should be obtained when there are variations in the fundal height before clinical interventions are undertaken.

Induction versus expectant management

Physicians concerned about adverse events in patients beyond 40 weeks' gestation lean toward induction of labor. A stillbirth occurring during this period is often viewed as preventable among patients and physicians alike, who often believe that induction of labor may have avoided this untoward event. In the NIH-sponsored Maternal-Fetal Medicine Network trial, induction of labor at 41 weeks was compared with expectant management. The expectant management group's surveillance consisted of nonstress testing and amniotic fluid assessment. There were 265 patients in the induction group and 175 patients in the expectant management group. The rate of Cesarean section was similar between the two groups, with no difference in perinatal deaths.²⁴

In the Canadian Multicenter postterm pregnancy trial by Hannah et al.,²⁵ singleton pregnancies at 41 weeks or more

were assigned to induction or antepartum monitoring. Patients in the monitored group were asked to perform kick counts each day, while receiving nonstress testing three times a week and amniotic fluid assessment two to three times per week. The monitored patients were delivered at 44 weeks or the time at which there were maternal or fetal indications. In this study, which was performed in 22 hospitals over a period of 5 years, perinatal morbidity and mortality were not statistically significant between groups, whereas Cesarean section rates were significantly lower in the induction of labor group.

In a study at Parkland Hospital performed by Alexander et al.,⁶⁶ a retrospective analysis assessed 56 317 pregnancies delivered with gestational ages > 40 weeks. These patients were separated into three groups as determined by the gestational age at delivery, making 29 136 at 40 weeks, 16 386 at 41 weeks, and 10 795 at 42 weeks. Patients with hypertension, prior Cesarean, diabetes, fetal malformations, breech presentation, and placenta previa were excluded. Labor complications including need for oxytocin, prolonged second stage of labor, overall length of labor, need for forceps delivery, and Cesarean section all increase with increasing gestational age. Neonatal outcomes were similar across all three groups. This study concluded that routine induction at 41 weeks would likely increase the need for operative obstetrics without changing neonatal outcome.

In a systematic review with meta-analysis, Sanchez-Ramos et al.⁶⁷ reviewed computerized databases, references and published studies, and textbook chapters in all languages to identify randomized, controlled trials evaluating induction and expected management of labor for postterm pregnancies. The primary outcome assessments were Cesarean delivery rates and perinatal mortality. Sixteen studies met the inclusion criteria, and women allocated to induction management compared with those who underwent expectant management had lower Cesarean section rates (20.0% versus 22.1%) [odds ratio (OR) 0.88; 95% confidence interval (CI) 0.78–0.99]. Perinatal mortality rates did not differ significantly between the groups; however, a sample size of 16 000 patients would be required for a power of 80% to detect a 50% reduction in perinatal mortality. This review concluded that a policy of labor induction at 41 weeks' gestation for uncomplicated singleton pregnancies would reduce Cesarean section delivery rates without compromising perinatal outcomes.

Similarly, a meta-analysis of 19 controlled trials for prolonged pregnancy at or beyond 290 days compared induction with intention to await spontaneous labor.⁴⁷ Conservative management was associated with a higher Cesarean section rate, 20.6% compared with 19.5%. The OR for perinatal mortality was 0.18 in favor of induction (95% CI 0.04–0.80).⁴⁶

Induction of labor

The Bishop score was first reported in 1964 and has been used since that time as a tool to predict the success of induction.⁶⁸

Table 64.4 Components of the Bishop score.

Examination findings	Score			
	0	1	2	3
Dilatation (cm)	Closed	1–2	3–4	> 5
Effacement (%)	0–30	40–50	60–70	> 80
Station	–3	–2	–1 or 0	+1, +2
Consistency	Firm	Medium	Soft	–
Position of cervix	Posterior	Midposition	Anterior	–

The Bishop score is based on five components: cervical dilation, cervical effacement, cervical consistency, cervical position, and the fetal station (see Table 64.4). From Bishop's original work, when the score was > 9, 100% of the cases were successfully induced.⁶⁹ Studies to date have provided only limited information that Bishop's scoring predicts the success of induction.⁷⁰ Hendrix et al.⁷¹ evaluated Bishop score in women to determine its ability to predict the success of induction. This group concluded that the Bishop score was of limited value in predicting successful induction as there was no significant difference in the Bishop score between 253 women who delivered vaginally and 38 women who required Cesarean section. Several groups have reported that the Bishop score suffers from significant intraobserver variability, which may explain the poor predictive value of the test.⁷² Given the intraobserver variability, the demonstrated poor predictive power, and the demonstrated success rates of induction protocols, Bishop scoring in the prolonged pregnancy should have limited applications.

Induction protocols

Based on current evidence, induction of labor at 41 weeks should be effective in reducing mortality. Many different approaches to cervical ripening and induction of labor have been reported. At present, there is no universally agreed upon method for the induction of labor. Recently, there has been a report of a randomized, controlled trial of castor oil for the promotion of labor. In this study, 52 women given 60 mg of castor oil were compared with 48 women with no treatment. In the castor oil group, 57.7% of the subjects went into labor within 24 h, but only 4.2% of the control patients experienced labor ($P < 0.001$).⁷³ Cesarean section rates were 19.2% in the castor oil group and 8.3% in the nontreatment group ($P = 0.20$). The most recent Cochrane review and AHRQ-evidenced reports on the management of prolonged pregnancy both felt that this was a significant finding.⁴⁵

Sweeping or stripping of the membranes is a simple procedure performed during pelvic examination in which a finger placed in the cervix is swept in a circular fashion detaching the amniotic membranes from the cervical tissues. This procedure is felt to initiate labor due to the local release of

prostaglandins when the membranes are detached. Most studies have shown that sweeping of the membranes can initiate labor in the term patient.^{74–81} These studies have failed to show an increase in any adverse outcomes including infections or bleeding. Sweeping or stripping of the membranes appears to be a safe and effective method to aid in the induction of labor. As it is impossible to predict which patients will not be delivered at 41 weeks, a policy of stripping of membranes between 38 and 40 weeks does not seem justified. In those patients at 40 weeks or more with good pregnancy dating, consideration should be given to membrane stripping.

There have been a large number of trials that have evaluated the effects of inducing agents in the promotion of labor. Variations in patient populations and the relatively low number of women studied in each of these trials make it exceedingly difficult to arrive at definitive statements about the benefits and risks of these agents for use in the prolonged pregnancy. As a general rule, the more effective these agents are in initiating labor and shortening induction to delivery times, the more likely are these agents to produce uterine hyperstimulation and the subsequent associated fetal distress.⁴⁵ Prostaglandin E₂ (PGE₂) appears to be more effective than oxytocin, and misoprostol is more effective than PGE₂. Sweeping of the amniotic membranes may decrease the need for inducing agents.

Summary

Prolonged pregnancy is the preferred term to be used when pregnancies continue past 294 days. The incidence of prolonged pregnancy varies from 3% to 14%, and the most common cause of the prolonged pregnancy is inaccurate pregnancy dating. Approximately 20% of women cannot remember their last menstrual period. Studies have shown that, when women obtain prenatal care in the first trimester and have ultrasound performed when pregnancy dating is in question, the incidence of prolonged pregnancy is reduced by at least 50%. The postmature syndrome is a neonatal diagnosis made when newborns exhibit peeling, parchment-like skin, meconium staining of the skin, overgrown nails, abundant scalp hair, and minimal subcutaneous fat. This condition is likely the result of uteroplacental insufficiency and is associated with a greater probability of associated hypoxia. Maternal risks from the prolonged pregnancy are associated with an increased need for induction of labor, operative vaginal delivery, and increased need for Cesarean sections. Induction of labor at or beyond 41 weeks does not increase the incidence of Cesarean section and may be associated with a decrease in stillbirth rates and perinatal morbidity and mortality. As the incidence of stillbirth is low prior to 42 weeks, antepartum testing in the low-risk patient is probably not indicated prior to this time. Cervical ripening may reduce induction to delivery times, but may also increase uterine hypertonicity and fetal distress. Every attempt should be made to obtain accurate

pregnancy dating as early as possible. Induction of labor at 41 weeks does not increase Cesarean section rates or preg-

nancy cost and may reduce the incidence of stillbirth and newborn morbidity and mortality.

Key points

- 1 Prolonged pregnancy may be defined as any pregnancy that continues past 294 days.
- 2 Prolonged pregnancy is associated with increased maternal and fetal morbidity and mortality.⁴⁻⁶
- 3 The most common cause of the prolonged pregnancy is inaccurate dating.
- 4 Postterm or prolonged pregnancy should be the preferred terminology for the pregnancy extending beyond 42 weeks.
- 5 Postmaturity is a neonatal diagnosis and should be used to describe the infant with recognizable clinical features associated with postmaturity including peeling, parchment-like skin, and meconium staining of skin, membranes, and the umbilical cord, with a possible incidence of overgrown nails, well-developed creases on the palms and soles, abundance of scalp hair, little vernix or lanugo hair, scaphoid abdomen, and minimal subcutaneous fat.^{14,15}
- 6 Around 20% of women cannot remember their last menstrual period and, when there is late entry to prenatal care, there is often confusion regarding the dating of the pregnancy.¹⁶
- 7 The maternal risks from the prolonged pregnancy are associated with the increased need for operative delivery in both spontaneous and induced labor.
- 8 Induction of labor at 41 weeks does not increase Cesarean section rates or pregnancy cost and may reduce the incidence of stillbirth and newborn morbidity and mortality.
- 9 Multiple studies have demonstrated an increased risk of perinatal mortality after 42 weeks.^{7,17,28-43}
- 10 Perinatal mortality reaches its nadir at 39-40 weeks and then increases as pregnancy exceeds 41 weeks.⁴⁴
- 11 Studies have shown that pregnancies that continue beyond 42 weeks have an increased risk of stillbirth, but when the risk of stillbirth is expressed as a function of ongoing pregnancies (stillbirth divided by total births), the mortality rate is even greater.
- 12 Assuming that induction of labor does not carry increased perinatal risk, planned induction of labor at any gestational age should always result in fewer adverse perinatal outcomes and testing strategies.
- 13 Most of the excessive perinatal mortality associated with a prolonged pregnancy occurs in the intrapartum and neonatal periods.⁵⁰
- 14 Conditions associated with prolonged pregnancy include intrapartum asphyxia, meconium aspiration, neonatal seizures,⁵⁰ fetal macrosomia resulting in dystocia and associated brachio-plexus injuries and fractures, anencephaly, and adrenal hypoplasia with pituitary insufficiency.^{12,13}
- 15 Given the intraobserver variability, the demonstrated poor predictive power, and the demonstrated success rates of induction protocols, Bishop scoring in the prolonged pregnancy should have limited applications.
- 16 The most important way to minimize the incorrect diagnosis of postterm pregnancy is to establish accurate pregnancy dating as early as possible.
- 17 In women for whom there is uncertainty regarding their pregnancy dating, an ultrasound in the first or second trimesters should be obtained.
- 18 The crown-rump length can determine gestational age to within 5 days.^{10,66}
- 19 When the ultrasound measurements differ from the last menstrual period by more than the ranges shown, then ultrasound estimates of EDD should be used: up to 20 weeks' gestation, ± 7 days; between 20 and 30 weeks' gestation, ± 14 days; beyond 30 weeks' gestation, ± 21 days.
- 20 Induction of labor at or beyond 41 weeks does not increase the incidence of Cesarean section and may be associated with a decrease in stillbirth rates and perinatal morbidity and mortality.

Anesthesia in the high-risk patient

Danny Wilkerson and Richard B. Clark

Normal parturients require special anesthetic considerations because of the physiological changes of pregnancy. Patients in high-risk categories have concomitant disease states that increase their risk of morbidity or mortality. Understanding and evaluating these comorbidities allow for the maximum provision of safe anesthesia in labor and spontaneous vaginal delivery or Cesarean section. The goal of maintaining fetal well-being, maternal cardiovascular stability, and uteroplacental blood flow must remain paramount. There are many high-risk categories but this chapter will focus on the topics below; recommendations and special considerations for these commonly encountered high-risk conditions are given.

Obesity

Obesity can be defined as a body mass index of ≥ 30 (BMI; equal to weight in pounds divided by height in inches squared $\times 703$, or weight in kilograms divided by height in meters squared). Extreme or morbid obesity is defined as a BMI ≥ 40 (see Table 65.1).¹ Obesity is associated with increased morbidity and mortality and with certain disease states including diabetes mellitus, coronary artery disease, and hypertension.² It is also associated with profound physiological changes, such as an increase in oxygen consumption, carbon dioxide production, and alveolar ventilation. An increase in abdominal mass forces the diaphragm cephalad, accentuating the decrease in functional residual capacity (FRC) and expiratory reserve volume (ERV; Fig. 65.1).

In obesity, the work of breathing is increased. The increase in adipose tissue over the chest wall together with poor lung compliance resembles a restrictive lung disease. The lithotomy, supine, and Trendelenburg positions accentuate the reduction in lung volume. This, together with the decrease in FRC and ERV, may lead to ventilation/perfusion mismatch, hypoxemia, and postoperative atelectasis.

The pickwickian syndrome (obesity-hypoventilation syndrome) may occur in pregnancy and is characterized by somnolence, hypercarbia, right-sided heart failure, and chronic

hypoxemia.³ It may be associated with obstructive sleep apnea and so difficult airway management should be anticipated. Obesity is also associated with an increase in gastric volume, poor gastric emptying, and hyperacidity as well as an increased risk of aspiration.⁴

Intravenous narcotics in the laboring obese patient should be used cautiously because of the risk of respiratory compromise. Continuous lumbar epidural anesthesia is the preferred regional anesthetic technique for pain relief during labor although some practitioners use combined spinal epidural (CSE) or single-shot spinal techniques. All three may be technically difficult in the morbidly obese patient.

In obesity, anesthesia for Cesarean section and labor must include a thorough evaluation of the airway. A difficult intubation must be anticipated and planned for. Regional anesthesia is preferred to general anesthesia; if general anesthesia is selected, a rapid sequence induction with endotracheal intubation must be performed. Patients should receive an H₂ antagonist and a nonparticulate antacid preoperatively. Extubation should be performed when the patient is awake with airway reflexes intact.

For Cesarean section, it is appropriate to use regional anesthesia to achieve a T4–T6 spinal level; spinal epidural, CSE, or epidural techniques can be used. Some practitioners advocate a continuous spinal technique if an inadvertent dural puncture occurs during attempted epidural placement.⁵ Left uterine displacement (LUD) and supplemental oxygen by mask are standard.

Hypertensive disorders in pregnancy

Hypertensive disorders in pregnancy include gestational hypertension, preeclampsia, eclampsia, preeclampsia superimposed on chronic hypertension, and chronic hypertension. The first three disorders were previously known as pregnancy-induced hypertension (PIH)⁶ (see Table 65.2). Most of these disorders result in hypertension, proteinuria, and edema, and may cause seizures. Hypertension of 140/90 mmHg or more is

termed mild preeclampsia, whereas a pressure of 160/110 mmHg results in severe preeclampsia. These conditions are associated with a decreased blood volume and there are many implications for the anesthesiologist.⁷ The remainder of this discussion will focus on preeclampsia. The circulation in preeclampsia can be characterized as hyperdynamic (see Table 65.3).

The standard treatment for preeclampsia is magnesium sulfate. A 4-g bolus is given intravenously, followed by 2 g/h intravenously. The therapeutic blood levels are 4.0–6.0 mequiv/L. Although magnesium is not specific for preeclampsia, it has been found to be very effective. Magnesium sulfate has a peripheral and a central action, and is used primarily to treat or prevent seizures. Antihypertensives such as hydralazine, labetalol, and methyldopa are utilized to control blood pressure. The HELLP syndrome [a group of symptoms that occur in pregnant women who have (H) hemolytic anemia, (EL) elevated liver enzymes, and (LP) low platelet count] may develop. Monitoring of the central circulation (central venous pressure) or use of a pulmonary artery catheter may be indicated.

Anesthesia for labor and delivery in the preeclamptic patient is necessary and desirable; we believe that lumbar epidural anesthesia is the preferred method. Blood volume is reduced in preeclampsia and, therefore, before the block is given, infusion of a balanced salt solution begins, with the aim of administering at least 500 cm³. A further infusion may be given if hypotension occurs after the block takes effect. If a clotting disorder is present, spinal or epidural anesthesia may be contraindicated because of the risk of an epidural hematoma. Obtaining a prothrombin time, partial thromboplastin time (PTT), and platelet count is standard practice in the severely preeclamptic woman. If there are obvious signs such as bruising or bleeding at the intravenous site, or into the Foley catheter, an epidural should be avoided. A dramatic drop in the platelet count over a 2–3 h period indicates a worsening of the preeclampsia and cautious clinical judgment should be used when deciding whether to place an epidural catheter. Thromboelastography (TEG) may also be helpful.⁸ In a retrospective survey of Cesarean delivery in severely preeclamptic patients, Hood and Curry⁹ found no difference in hemodynamic effects between those receiving spinal anesthesia and those receiving epidural anesthesia.

Preeclamptic patients may require a Cesarean section for delivery and we believe that regional anesthesia is preferable. For many years, there was a prejudice against regional anesthesia because of the fear of profound hypotension. With the recognition that there is a decrease in blood volume in preeclampsia and the use of liberal amounts of balanced salt solution (1000 cm³), hypotension is much less of a problem. The significant work of Wallace and colleagues¹⁰ has shown that spinal, epidural, or general anesthesia can all be used successfully for Cesarean section in preeclamptic patients. General anesthesia is less desirable than regional but may be necessary if regional anesthesia is not possible; for example

clotting defects may contraindicate regional anesthesia. General anesthesia carries with it the risks of regurgitation and aspiration, and also severe hypertension on endotracheal intubation and surgical incision. Antihypertensives should be given before and after induction if necessary. The anesthetic technique consists of induction with thiopental, followed by administration of succinylcholine, intubation, and maintenance with 50% nitrous oxide/oxygen, and 0.5% isoflurane. A narcotic is given intravenously to the mother after delivery. Nondepolarizing neuromuscular blocking agents may be needed for abdominal relaxation. The anesthesiologist must be aware of the synergistic action of muscle relaxants and magnesium. Extubation should take place with the patient awake and with airway reflexes intact.

Prematurity

The premature infant is generally considered to have a gestational age of 20–37 weeks and a weight of less than 2500 g.¹¹ However, some small for gestational age infants with a low birthweight are born near term. A more appropriate definition is therefore preterm infant. About 7–8% of deliveries in the USA are preterm.

It would seem inherently obvious that these small, fragile infants should not be subjected to the effects of maternally administered depressants such as narcotics and tranquilizers. Very little information has been published on this subject, although one older study¹² found no differences in the Apgar scores of infants when meperidine was used during labor.¹² It is recommended, however, that these drugs be kept to a minimum during labor.¹³

Mothers in preterm labor are often treated with drugs that inhibit labor. Ritodrine was popular for several years but has been associated with pulmonary edema. Magnesium sulfate is now frequently used for the treatment of preterm labor. The anesthesiologist must be aware of the effect that this therapy has on the motor end plate and that it can also alter the response of vasopressor agents.

Preterm infants should not be subjected to the hazards of precipitous delivery as this can cause cerebral trauma. Because of this, and to minimize the use of depressant drugs, lumbar epidural anesthesia is considered to be the best option for vaginal delivery.¹³ Spinal or epidural anesthesia is preferred for abdominal delivery, so that neonatal depression can be minimized.

Cardiac disease

About 1% of all pregnancies are complicated by heart disease, and 60–80% of these complications are caused by congenital heart disease.¹⁴ The remainder of cases are mostly valvular, caused by rheumatic heart disease. The New York Heart Association (NYHA) has provided a simple way of classifying the

Table 65.1 Body mass index.

BMI	Normal						Overweight					Obese

Table reprinted from National Heart Lung and Blood Institute. World Wide Web URL: <http://www.nhlbi.nih.gov>.

To use the table, find the appropriate height in the left-hand column labeled “height.” Move across to the given weight (in pounds). The number at the top of the column is the BMI for that height and weight.

Figure 65.1 Changes in lung mechanics in obese and nonobese patients. In obesity, functional residual capacity (FRC) decreases at the expense of expiratory reserve volume (ERV). Closing capacity (CC) remains normal. From Vaughan RW. Pulmonary and cardiovascular derangements in the obese patient. In: Brown BR, ed. *Anesthesia and the obese patient*. Philadelphia, PA: FA Davis; 1982:26, with permission.

Table 65.2 Diagnosis of hypertensive disorders complicating pregnancy.

Hypertensive disorder	Characteristics
Gestational hypertension	Blood pressure $\geq 140/90$ mmHg for first time during pregnancy No proteinuria
Preeclampsia	Blood pressure $\geq 140/90$ mmHg after 30 weeks' gestation Proteinuria ≥ 300 mg/24 h or $\geq 1+$ on dipstick reading
Eclampsia with preeclampsia	Seizures that cannot be attributed to other causes in a woman
Preeclampsia superimposed on chronic hypertension	New onset proteinuria ≥ 300 mg/24 h
Chronic hypertension	Blood pressure $\geq 140/90$ mmHg before pregnancy or diagnosed before 20 weeks' gestation

extent of heart failure. Class I and II patients have a maternal mortality rate of 1% or less, whereas class III or IV patients have a maternal mortality rate of 5–15% and a perinatal mortality rate of 20–30%.¹⁵ Most deaths from cardiac disease in pregnancy are parturients with right-to-left shunts or stenotic heart disease.

Left-to-right shunts occur with congenital lesions such as patent ductus arteriosus (PDA), ventricular septal defect (VSD), and atrial septal defect (ASD). These patients usually tolerate pregnancy well. Early epidural placement with a slow

onset of anesthesia is preferred, using saline for loss of resistance (LOR) instead of air, to prevent paradoxical air emboli. Epidural analgesia prevents maternal increases in systemic vascular resistance (SVR) and catecholamine levels. Increases in SVR may lead to pulmonary hypertension. Hypercarbia and acidosis may lead to an increase in pulmonary vascular resistance and should be avoided.

Eisenmenger syndrome is caused by a left-to-right shunt which results in an increase in pulmonary artery pressure if left untreated. This fixed, high pressure can change the

Figure 65.2 Pathophysiology of Eisenmenger syndrome. RA, right atrium; LA, left atrium. Reprinted from Hughes SC, Levinson G, Rosen MA, eds. *Shnider and Levinson's anesthesia for obstetrics*, 4th edn. Philadelphia, PA: Lippincott Williams & Wilkins; 2002:469, with permission.

Table 65.4 Eisenmenger syndrome: anesthetic considerations.

Avoid decreases in systemic vascular resistance
Avoid decreases in venous return
Avoid increases in pulmonary vascular resistance (e.g., hypercarbia, acidosis, hypoxia)

Reprinted from Hughes SC, Levinson G, Rosen MA, eds. *Shnider and Levinson's anesthesia for obstetrics*, 4th edn. Philadelphia, PA: Lippincott Williams & Wilkins; 2002:469, with permission.

primary left-to-right shunt into a right-to-left shunt (Fig. 65.2), leading to hypoxemia and right ventricular failure.¹⁶ Labor analgesia can be accomplished with a lumbar epidural, intrathecal opioids, or a pudendal block early in the second stage of labor. Care must be taken to avoid pain, hypoxemia, hypercarbia, and acidosis, which will increase pulmonary vascular resistance and increase the right-to-left shunt (Table 65.4). Maintenance of intravascular volume, venous return, and an adequate SVR is essential. For anticoagulated parturients in which regional anesthesia is contraindicated, a patient-controlled anesthesia (PCA) with remifentanyl may be a good option.¹⁷

Primary pulmonary hypertension may be treated with supplemental oxygen, inhaled nitric oxide, nitroglycerin, prostaglandins, or calcium channel blockers. Single-shot spinal anesthesia should be avoided; slow induction of continuous epidural anesthesia is preferred. Increases in pulmonary artery pressures caused by general anesthesia for Cesarean section can be minimized using a narcotic-based induction and maintenance technique. The use of pulmonary artery catheters is controversial.

The most common cyanotic heart lesion is tetralogy of Fallot. This consists of VSD, overriding aorta, right ventricular outflow tract obstruction, and right ventricular hypertro-

phy. Care should be taken to avoid a decrease in SVR, as with single-shot spinal anesthesia, which may cause shunt increase and a worsening hypoxemia. Labor and delivery analgesia is best managed with systemic medications and a pudendal block.¹⁸ Spinal opioids can offer a good alternative, and epidural can be used with caution.¹⁸ The goal is to avoid a decrease in SVR, and to maintain a sufficient venous return and adequate intravascular volume. Hypotension, straining, or coughing is best avoided. General anesthesia is usually well tolerated but hypotension and “bucking” should be avoided.^{19,20} It is advisable to maintain a normal or slightly increased SVR.²¹

Most mild to moderately symptomatic pregnant patients with valvular disease tolerate epidural anesthesia for labor and it is recommended as it eliminates pain and tachycardia. Patients with severe symptomatic aortic stenosis may not tolerate even mild hypotension or tachycardia. During the first stage of labor, intrathecal narcotics have been used, followed by a pudendal block in the second stage. Myocardial depression with halogenated agents during general anesthesia should be avoided. Maintenance of sinus rhythm, adequate SVR, and intravascular volume and venous returns are a must.

Peripartum cardiomyopathy is characterized by biventricular hypokinesis, low cardiac output, and elevated filling pressures. Its onset is often insidious and its etiology is unknown. The maternal mortality rate is high. Management is supportive with treatment of symptomatic heart failure. Vaginal delivery or Cesarean section may be facilitated by epidural anesthesia,²¹ unless the patient has a contraindication to regional anesthesia. General anesthesia for Cesarean section may result in profound myocardial depression.²² Echocardiography and invasive pressure monitoring can prove invaluable. The use of a continuous spinal anesthetic for Cesarean section in a patient with severe recurrent peripartum cardiomyopathy has been reported.²³

Neurological disease

Multiple sclerosis

Multiple sclerosis is a demyelinating disease of the central nervous system. It is a progressive disease with intermittent exacerbations and remissions. The etiology is unknown and treatment includes symptomatic care and physical therapy. There is a tendency for remission during pregnancy; however, in the 3- to 6-month period after delivery there may be an increase in exacerbations of symptoms.²⁴

The data currently available do not contraindicate regional anesthesia for labor, delivery, or Cesarean section. There is a high incidence of postpartum relapse, regardless of the type of anesthesia delivered. A dilute solution of local anesthetic, with or without opioid, may be used safely for labor analgesia.²⁵ Conditions known to exacerbate multiple sclerosis, such as stress, infection, and hyperpyrexia, should be avoided.²⁶

Myasthenia gravis

Myasthenia gravis is characterized by episodes of muscle weakness, which is made worse by activity. It is an autoimmune disorder; antiacetylcholine receptor antibodies are produced which destroy acetylcholine receptors and produce an antibody-induced blockade of any remaining receptors.²⁷ This affects muscles of respiration, laryngeal muscles, and facial and ocular muscles. The disease does not affect cardiac or smooth muscle contraction; however, an electrocardiogram (ECG) should be obtained because there have been reports of focal myocardial necrosis in patients with myasthenia gravis.²⁸ The degree of bulbar involvement and respiratory compromise should be thoroughly evaluated. The course of the disease varies during pregnancy. Anticholinesterases, which increase the amount of acetylcholine available, are the first line of treatment. Corticosteroids, plasmapheresis (decreases antibody levels), and thymectomy have been used in the treatment of myasthenia gravis.

Myasthenia gravis does not affect the first stage of labor; however, a vacuum-assisted or forceps delivery is often required for the second stage. Cesarean section should be reserved for obstetric indications. Drugs that can potentiate muscle weakness, for example magnesium sulfate, should be avoided.

For labor, epidural analgesia is the preferred method of pain relief.²⁹ Parenteral opioids should be used cautiously to avoid further respiratory compromise. Plasma cholinesterase activity is decreased, which may prolong the half-life of ester local anesthetics if used for epidural analgesia. If the CSE technique is used, the increased risk of respiratory depression from intrathecal opioids must be considered.

For Cesarean delivery, regional anesthesia is preferred.³⁰ The small amount of local anesthesia used for spinal anesthesia allows either amide or ester local anesthetic agents to be used safely. General anesthesia may be preferred in patients with significant respiratory compromise, in order to secure the airway and avoid any further respiratory compromise that could be produced with regional anesthesia.³¹ Propofol, ketamine, and thiopental may be used for induction, with rapid sequence induction being used; however, succinylcholine may not be metabolized as rapidly. Myasthenia gravis patients are extremely sensitive to nondepolarizing muscle relaxants, which should be used cautiously, if at all. Postoperative ventilation may be required, especially in patients with severe bulbar involvement. Neuromuscular blockade should be monitored with a nerve stimulator. It must be remembered that volatile agents potentiate muscle relaxants. Because symptoms of myasthenia gravis may worsen postoperatively, the myasthenia gravis patient should be monitored in an acute care area.

Substance abuse

Many pregnant patients use both legal and illegal drugs that can have dire consequences on both mother and fetus.

The following discussion will focus on the commonly used illicit drugs.

Opioids

Opioids can be smoked, inhaled, or injected intravenously or intramuscularly. Heroin appears to be the most common opioid abused during pregnancy although fentanyl, meperidine, morphine, and methadone are also abused; polysubstance abuse is also common.³² Opioid exposure during pregnancy is associated with preterm labor, chorioamnionitis, intrauterine growth restriction (IUGR), and placental abruption. Neonates of opioid addicts can exhibit narcotic withdrawal, hyperthermia, seizures, and an increased risk of sudden infant death syndrome (SIDS). Other maternal complications include thrombophlebitis, HIV, AIDS, hepatitis, and endocarditis.³³

The administration of anesthesia can be complicated by limited intravenous access and the need for emergency Cesarean section because of fetal distress. The patient may present in opioid withdrawal, acutely opioid intoxicated, or even in opioid overdose. If the newborn of an opioid addict presents with respiratory depression then the infant should be given ventilation assistance, but naloxone should not be administered as this may precipitate acute withdrawal syndrome. Regional anesthetic techniques are preferred unless there is a contraindication;³² however, HIV is not a contraindication for regional anesthesia.³⁴ Intravenous drug abusers are prone to an increased incidence of epidural abscesses, therefore a neurological assessment should be carried out before regional anesthesia is administered. The addict's daily narcotic dose should be met, and opioid agonist-antagonists should be avoided. General anesthesia can be provided with the typical induction agents. Cross-tolerance is not a problem during maintenance provided the patient's physiological opioid requirements are met.

Cocaine

Cocaine is a local anesthetic of the ester group. Its potent sympathomimetic effects (hypertension, vasoconstriction, myocardial effects) result primarily from inhibition of reuptake of norepinephrine at nerve terminals.³⁵ Cocaine can cause complications such as placental abruption, fetal demise *in utero*, premature labor and delivery, fetal distress (leading to emergency Cesarean section), uterine rupture, uteroplacental insufficiency, and spontaneous abortion. Maternal hypertension, seizures, and hyperreflexia, as a result of acute cocaine intoxication, may be confused with preeclampsia/eclampsia. Smoking "crack" cocaine can lead to significant pulmonary problems.

Anesthetic considerations revolve around the acutely intoxicated patient with catecholamine excess, or the chronically catecholamine-depleted addict. Early placement of labor epidural will decrease maternal pain, lower catecholamine

levels, and potentially minimize increases in uterine vascular resistance (potentially benefiting a compromised fetus). Hypertension may be treated with hydralazine, labetalol, or nitroglycerin.³⁶ Small doses of benzodiazepine may prove helpful. Seizures in the acutely intoxicated patient may be treated with thiopental and airway protection, oxygenation, and ventilation. Hypotension may be increased in cocaine abusers who are volume depleted. Ephedrine may be ineffective in the catecholamine-depleted cocaine abuser; hypotension that is refractory to ephedrine can be treated with incremental doses of phenylephrine.

For Cesarean section, the epidural level can be raised slowly to achieve a T4 level. Spinal anesthesia can be administered provided that adequate hydration and LUD are used, and vasopressors are immediately available. General anesthesia for Cesarean section in cases of fetal distress can be complicated by maternal tachycardia, hypertension, arrhythmias, and myocardial ischemia, and the anesthesiologist should be prepared to treat these complications. Nitroprusside may be needed if there is a hypertensive crisis.

Key points

- 1 Patients in high-risk categories have concomitant disease states that increase the risk of morbidity or mortality.
- 2 Obesity is associated with increased morbidity and mortality, and with disease states, including diabetes mellitus, coronary artery disease, and hypertension.
- 3 Obesity increases oxygen consumption, carbon dioxide production, and alveolar ventilation, and decreases functional residual capacity and expiratory reserve volume.
- 4 In the obese patient, regional anesthesia is preferred for labor and delivery, including Cesarean section.
- 5 General anesthesia in the obese parturient requires a thorough airway examination and an anticipation of a difficult intubation.
- 6 Hypertensive disorders in pregnancy include gestational hypertension, preeclampsia, eclampsia, chronic hypertension, and preeclampsia superimposed on chronic hypertension.
- 7 Wallace and colleagues¹⁰ have shown that spinal, epidural, and general anesthesia can all be used successfully for Cesarean section in preeclamptic patients.
- 8 Delivery of the premature infant is best accomplished with lumbar epidural anesthesia for vaginal delivery, and spinal or epidural anesthesia for Cesarean section.
- 9 Patients with left-to-right cardiac shunts usually tolerate pregnancy well.
- 10 The most common cyanotic heart lesion is tetralogy of Fallot.
- 11 Peripartum cardiomyopathy is characterized by biventricular hypokinesis, low cardiac output, and elevated filling pressures.
- 12 Data available at present do not contraindicate regional anesthesia for labor, delivery, or Cesarean section in patients with multiple sclerosis and myasthenia gravis.
- 13 For patients with myasthenia gravis, epidural analgesia is the preferred method of pain relief during labor.
- 14 Patients with myasthenia gravis are extremely sensitive to nondepolarizing muscle relaxants, and these should be used cautiously, if at all.
- 15 Heroin appears to be the most common opioid abused during pregnancy.
- 16 Opioid exposure during pregnancy is associated with preterm labor, placental abruption, intrauterine growth restriction, and chorioamnionitis.
- 17 HIV is not a contraindication for regional anesthesia.
- 18 The addict's daily narcotic dose should be met.
- 19 Cocaine use during pregnancy can cause complications such as placenta abruption, fetal demise *in utero*, spontaneous abortions, uterine rupture, premature labor and delivery, uteroplacental insufficiency, and fetal distress.
- 20 Ephedrine may be ineffective in the catecholamine-depleted cocaine abuser.

Puerperium and lactation: physiology of the reproductive system

Judy M. Hopkinson, Pamela D. Berens, and E. Albert Reece

The puerperium is typically described as the postpartum period approximately 6–8 weeks after delivery, during which time many physiologic changes of pregnancy will revert to their prepartum state.

Reproductive system

Involution of the uterus is most dramatic on the first day after delivery. From a uterine weight of about 1100g at term, by 24h postpartum, the uterine fundus is typically palpable near the umbilicus. Two weeks postpartum, the uterus is no longer palpated on abdominal examination and, at 6 weeks, it will return to a weight of less than 100g, although commonly heavier than the prepregnancy weight. Ultrasound evaluation of the postpartum uterus suggests a slight increase in puerperal uterine size in women delivered via Cesarean, although little difference in involution is noted between breastfeeding and formula-feeding mothers.^{1,2} Some studies suggest an increased uterine size during the puerperium in multiparous women, although others do not support this finding.^{3,4} Fluid and debris may be noted in the uterine cavity of asymptomatic women in the midpuerperium.⁵

Initially, postpartum women experience a discharge of decidua and blood known as lochia rubra. This becomes more watery and pale, referred to as lochia serosa and, finally, the more yellow to whitish lochia alba. Total lochial volume is estimated at 200–500 mL.⁶ The mean duration of lochia is 33 days with 15% of women continuing to experience lochial discharge at 6 weeks postpartum.⁷ The duration of lochia does not appear to be well correlated with lactational status.

Painful postpartum uterine contractions are commonly referred to as “afterpains.” This appears to be more problematic in multiparous women.⁸ Breastfeeding mothers frequently note an association of afterpains with nursing episodes due to oxytocin release. Holdcroft et al.⁹ noted that 96% of women reported pains during breastfeeding, with the intensity of these pains being significantly associated with parity. Mean duration and number of contractions were also

related to parity. Nonsteroidal anti-inflammatory agents such as ibuprofen may be used for analgesia.

Cervix and vagina

Immediately after vaginal delivery, the cervix has a loose, pliable tone, and may have several small excoriations. Over the first week postpartum, the cervix assumes a more typical gross appearance, although it may remain slightly dilated for the first few days. Persistent heavy bleeding and a continued open cervical os should alert the physician to the possibility of retained placental fragments. Cervical dysplasia may regress in the postpartum period. Kaplan et al.¹⁰ studied 157 women with antepartum cervical squamous intraepithelial neoplasia and their subsequent postpartum course. Sixty-two percent of patients with low-grade antepartum dysplasia had regression, while only 6% experienced disease progression, although 60% developed recurrent disease within 5 years. All 28 cases of antepartum high-grade dysplasia in this study persisted postpartum.

The typical rugated appearance of the vagina is temporarily lost, with it appearing more edematous, vascular, and smooth after delivery. Rugae typically reappear about 3 weeks postpartum as these changes resolve. The vagina may initially appear relatively estrogen deficient in postpartum lactating women or women using progesterone-only contraception. A vaginal lubricant may be beneficial if dyspareunia occurs.

Hormonal regulation

Resumption of ovulation and subsequent menses differs greatly in breastfeeding compared with nonbreastfeeding mothers. Nonlactating mothers experience ovulation on average 45 days after delivery with return of menses in many by 7–9 weeks postpartum. Lactating mothers experience a delayed and much more variable return to both ovulation and menstruation, which may relate to specific breastfeeding practices.^{11,12} Lactational amenorrhea is useful in predicting the return of fertility in nursing women. During the first 6 months

after delivery, women who are amenorrheic and breastfeeding frequently (≥ 8 times/24 h) without giving supplements have a less than 2% risk of pregnancy.^{13–19}

The control of fertility generated by lactation is incompletely understood. Current theory suggests a prolactin-mediated dysfunction of the gonadotropin-releasing hormone (GnRH) pulse generator in the hypothalamus as the underlying cause of lactation-related reduction in fertility.²⁰

Urinary system

The urinary system and pelvic floor are altered by pregnancy and the birthing process. Intravenous fluids and oxytocin (which is antidiuretic during infusion) may increase postpartum diuresis. Conduction anesthetics may also disrupt neural bladder control. Urinary retention with overdistention, urinary tract infection, and stress urinary incontinence are common transient problems. Dilation of the ureters may persist for 3 months or more postpartum.^{21,22}

Lactation

Exclusive breastfeeding during approximately the first 6 months of life with continued breastfeeding through at least the second half of infancy is associated with reduced risk of adverse outcomes in mother and infant²³ (Table 66.1). Environmental factors have a marked influence on breastfeeding success. Obstetric practices must be evaluated for their potential impact on lactation performance.

Mammary development

Figure 66.1 illustrates the general anatomic structures of the developed human breast. Recently, ultrasound imaging of the lactating breast has raised questions regarding the permanent existence of lactiferous sinuses.²⁴ During pregnancy, lobuloalveolar growth increases dramatically. Terminal end buds differentiate into alveoli composed of a single layer of milk-secreting epithelial cells surrounding a central lumen. Alveoli are surrounded by myoepithelial cells and capillaries. The lumen of the alveoli empty into intralobular ducts, which coalesce to form a central duct in each lobe exiting through one of 5–9 ductal orifices.

Onset of milk production and early lactation failure

By 16 weeks' gestation, the breast is fully competent to produce milk. This is prevented by the high level of circulating progesterone, which blocks prolactin activation of alfa-lactalbumin formation. Onset of copious milk production (lactogenesis stage II or LS-II) begins after delivery of the placenta and subsequent fall in progesterone.²⁵ The mean time for LS-II is 50–73 h postpartum.²⁶ LS-II occurs later following stressful deliveries²⁷ and in primiparous,²⁸ obese,^{29–31} and diabetic²⁶ women. Delayed onset of LS-II is a risk factor for premature weaning, and these dyads should be monitored closely.

Tissue swelling and edema are common during LS-II, but the experience of painful engorgement varies. Analgesics are appropriate treatment for pain. Skilled assistance may be needed to achieve effective latch and efficient milk removal.

Table 66.1 Associations between breastfeeding and risk of adverse outcomes.

Adverse outcome	Infant risk		Maternal risk
	During breastfeeding	After weaning	
Gastrointestinal and respiratory illnesses	Decreased ¹²⁷	Decreased if exclusively BF for >3 months ^{127,128}	
Celiac disease	Decreased ¹²⁹	Delayed onset/possibly reduced severity ¹²⁹	
Wheezing	Decreased ¹³⁰	Decreased ¹³⁰	
Urinary infections	Decreased ¹²⁷		
Diabetes		Decreased ^{131,132}	Decreased ¹³³
Leukemia		Decreased ^{134,135}	
Atopic dermatitis	Decreased		
Obesity		Decreased ^{136,137}	
Chron's disease		Decreased ¹²⁹	
Rheumatoid arthritis		Decreased ¹³⁸	Decreased ¹³⁹
Breast cancer			Decreased ¹⁴⁰
Ovarian cancer			Decreased ¹⁴¹
Bone density			Temporary decrease followed by increase over baseline with resumption of menses ^{142,143}
Visual acuity	Increased ¹²⁷		
Cognition/psychomotor performance		Increased ^{144,145}	

Figure 66.1 Anatomy of the human breast. (Copyright 1980 CIBA-GEIGY Corporation. Reproduced with permission from the Clinical Symposia by Frank H. Netter, MD. All rights reserved.)

Early lactation failure or partial inhibition of milk production can result from primary glandular insufficiency, retained placenta,²⁵ and severe postpartum hemorrhage resulting in ischemic pituitary necrosis and Sheehan's syndrome.³²

Regulation of milk volume

Following LS-II, milk production increases to a mean of 750 mL/day by 4 weeks after delivery and remains there throughout exclusive breastfeeding.³³ For individual women, milk volume increases or decreases in response to alterations in mammary stimulation and the degree of breast emptying.

Prolactin is the primary endocrine regulator of milk production. Baseline levels vary with physiological state. Prolactin increases from 8–14 ng/mL prepregnancy to 200–500 ng/mL at

term, and declines to 30–40 ng/mL between 180 and 360 days of lactation. Suckling causes a sharp rise in prolactin levels at all stages of lactation through at least the second year.^{34–37} Suckling triggers a prolactin rise, which peaks at 30 min and returns to baseline after 2.5–3.0 h. Relationships between milk production and prolactin levels are not straightforward. This may reflect numerical or functional differences in prolactin receptors.

Pituitary release of oxytocin is triggered by suckling, auditory, olfactory, or emotional cues.³⁸ Unlike prolactin, oxytocin can be released through a conditioned reflex. Milk ejection results from oxytocin-induced contraction of myoepithelial cells surrounding the alveoli. Lactiferous ducts then increase in diameter facilitating milk flow.²⁴

Weaning and involution of the mammary gland

Involution of the mammary gland is triggered by prolonged milk stasis and termination of suckling. Peaker and Wilde³⁹ detected a feedback inhibitor of lactation (termed FIL), which accumulates during milk stasis and blocks the secretion of milk constituents. Locally produced serotonin has been identified as a possible candidate for FIL,⁴⁰ although additional milk proteins may be involved.

Composition of human milk

Human milk is a complex, highly structured fluid containing a wide variety of nutrients and other bioactive factors, which impact infant growth, development, and immune function. Its composition is dynamic, varying with duration of lactation, degree of breast emptying, during a nursing, with the mother's diet, with maternal antigen response, maternal genotype, and other particulars. Changes over the course of lactation appear to match the changing needs of the growing infant.⁴¹ Human milk components are multifunctional, serving not only as nutrients but also in a variety of ways that promote infant health and development. Proteins, for example, are a source of peptides, amino acids, and nitrogen, but are also involved in the development of the immune response (immunoglobulins), nonimmunologic defense (lactoferrin, lysozyme), growth stimulation (neural growth factor), and other functions. Carbohydrates provide nutritional support (lactose) and prevent bacterial adhesion to mucosal surfaces (oligosaccharides).^{42–46} Human milk oligosaccharides (HMOs) are dietary fibers that pass through the digestive tract largely intact,⁴⁷ acting as prebiotics and presumably promoting gastric motility. Concentrations of HMOs vary over time^{48–52} and this, along with variations in the type of oligosaccharides present, may be genetically determined.^{44,48,49,53,54}

Colostrum, the initial milk produced in the first 3–7 days postpartum, is uniquely suited for the neonate. It contains a threefold higher protein concentration than mature milk, higher concentrations of immunoglobulins, leukocytes, and other immunologically active proteins, and lower concentrations of lactose, energy, and fat than more mature milk.⁵⁵ Throughout lactation, the specificity of secretory immunoglobulin A (SIgA) in milk depends on the mother's antigen exposure and response. In this sense, human milk is location specific. Infants themselves can control the nutrient content of received milk by varying the degree of breast emptying. Fat content (and calorie density) increases with the degree of breast emptying, progressing from low-fat “foremilk” to high-fat “hindmilk” during the course of a feed. The influence of maternal diet is more pronounced among malnourished women and relatively minor among those with normal body nutrient stores. The role of maternal genotype in milk composition – particularly oligosaccharide and cytokine content – is the subject of current research.^{54,56}

Maternal diet and milk composition

In well-nourished women, normal dietary fluctuations influence the flavor and odor of milk, which influences infant dietary preferences.⁵⁷ In general, the nutrient content of milk is more responsive to maternal diet during lactation in malnourished than in well-nourished women.⁵⁸ Women can and do produce adequate and abundant milk on inadequate diets.³⁴ Complicated “rules” about diet during lactation that fail to consider the mother's nutrient stores and dietary preferences can undermine maternal resolve to breastfeed.⁵⁹

Two nutrients may not be supplied in adequate amounts in milk from normal, well-nourished women: vitamin K⁶⁰ and vitamin D.⁶¹ Routine intramuscular injection of vitamin K1 at birth provides all the vitamin K needed. The American Academy of Pediatrics recommends daily supplementation with 200 IU of vitamin D to all infants unless they consume at least 500 mL/day vitamin D-fortified formula or milk.⁶²

Other nutritional deficiencies may be observed in breastfed infants of severely malnourished or diet-restricted mothers, including deficiencies in vitamin B12, folic acid, ascorbic acid, iodine, zinc, and carnitine.^{63–65} Without supplements, strict vegans will eventually develop B12 deficiencies and produce milk deficient in B12.^{66,67} Infants may become symptomatic before the mother.⁶⁷ Although infant symptoms can be partially reversed with B12 shots, neurologic deficits can be irreversible. Vegetarians should consume B12 supplements, particularly during pregnancy and lactation. Other circumstances that may lead to B12-deficient breast milk are: (1) severe maternal malnutrition – particularly if accompanied by intestinal parasites and resulting nutrient malabsorption;^{68,69} (2) gastric bypass surgery or partial gastrectomy.^{70,71} In these cases, maternal oral supplementation may not be sufficient, and intravenous vitamin B12 may be required.⁷⁰

Maternal fat intake affects the relative concentration of milk fatty acids without appreciably altering total fat content. For example, while all human milk contains docosahexanoic acid (DHA), 10-fold elevations can result from increased maternal dietary intake. DHA is critical for neurologic development. In a supplementation study, children's mental processing scores at age 4 years correlated with maternal intake of DHA and eicosapentanoic acid during pregnancy.⁷² Supplementation during lactation alone has not been found to improve mental functioning,⁷³ but may improve psychomotor functioning.⁷⁴ Conversely, milk cholesterol levels do not respond to maternal diet, and are elevated in mothers with familial hypercholesterolemia.⁷⁵

Milk ascorbic acid (AA) content can be low if maternal intakes are low, and low (but not average or high) milk AA can be doubled or tripled by increasing maternal dietary intake.⁷⁶ Similarly, maternal dietary intake normally influences milk iodine content only when maternal status is inadequate⁷⁷ or iodine intake is extremely elevated.⁷⁸ Milk iodine is reduced in healthy mothers who smoke cigarettes,⁷⁹ and is inversely related to milk perchlorate levels (an environmental contaminant).⁸⁰

Contaminants in human milk

Environmental contaminants are ubiquitous. An extensive review of research on contamination of human milk was published by LaKind et al. in 2004.⁸¹ In spite of the ubiquitous presence of contaminants in human milk, breastfed infants are healthier than infants who are not breastfed. Much work remains to be done to identify circumstances in which the adverse effects of milk contaminants may outweigh the adverse effects of failure to provide human milk.

Exercise and calorie restriction diets during lactation

While postpartum women lose an average of 0.5–1.0 kg/month after postpartum diuresis,^{82,83} individual weight loss varies. The myth that breastfeeding assures postpartum weight loss is prevalent, and prenatal education regarding the realities of postpartum weight management is advisable. In the US, each pregnancy increases the risk of becoming overweight by 60% and the risk of obesity by 110%.⁸⁴ Failure to return to prepregnancy weight by 6 months postpartum increases the risk of obesity a decade later.⁸⁵ In spite of the estimated 650 kcal/day required to support full lactation, breastfeeding has little impact on short-term postpartum weight loss in societies where food is abundant.⁸⁶ Energy required for lactation is derived from increased intake in preference to body fat mobilization.⁸⁷

Obese women have lower breastfeeding initiation rates^{30,88–90} and shorter breastfeeding durations than women of normal weight. Breastfeeding women who desire to initiate or increase weight loss may be advised to begin moderate calorie restriction (500 kcal/day) and regular exercise after breastfeeding is well established. Severe calorie restriction may be associated with decreased milk production.⁹¹ Early warning signs include infant loss of appetite, irritability, or restlessness, and maternal fatigue. In all cases, dyads should be closely monitored for signs of compromised milk production.

Exercise has no apparent impact on milk composition, excluding a temporary rise in lactate after prolonged, heavy exercise.⁹² Mineral content of milk did not change in response to exercise in a randomized crossover trial comparing the phosphorus, calcium, magnesium, sodium, and potassium content of milk from women at rest with milk from the same women at 10, 30, and 60 min after maximal graded exercise.⁹³ Similarly, in well-nourished women, maternal dietary intake has relatively little impact on milk mineral content.^{77,94} Larson-Meyer⁹² published an excellent review on the effect of exercise on postpartum women and their offspring. Women should be advised to consume a balanced diet during calorie restriction to protect their health.

Prenatal and perinatal practices and conditions that affect breastfeeding

Breastfeeding should be recommended at the initial prenatal examination. Further education can be offered during prenatal care for women planning to breastfeed and those initially

inclined to formula feed. Women with specific concerns such as breast implants, prior breast surgery, inverted nipples, time constraints, or lack of confidence should be educated regarding their particular situation. Prior breast reduction or other surgery involving a periareolar incision should prompt counseling regarding the importance of communicating that information to the pediatrician and the need to monitor infant growth. Multiparous women should be questioned regarding their prior breastfeeding experiences, and any concerns should be addressed.

Cigarettes

Smoking cessation is strongly encouraged during pregnancy. Parents who continue to smoke should do so in an environment that is away from the newborn. Nicotine and its metabolite cotinine are present in human milk. Urinary cotinine levels in breastfed infants of smoking mothers have been reported to be 10-fold higher than those of formula-fed infants.⁹⁵ Importantly, however, neurologic deficits associated with maternal cigarette smoking in formula-fed infants were not observed in a comparison group of infants breastfed for > 3 weeks.⁹⁶

Caffeine

Peak caffeine levels in breast milk are reached about 1 h after ingestion and are typically about 1% of the maternal dose.⁹⁷ Thus, infants should receive only a very small percentage of the maternal dose. However, clearance of caffeine in the infant is slower than in the adult.⁹⁸ Rare concerns with irritability and insomnia have been reported, but would be unlikely with occasional and moderate consumption.

Alcohol

Alcohol consumption should be avoided during pregnancy. Excessive consumption of alcohol should be avoided by new parents regardless of the planned infant feeding method because of the implications for parenting skills. Research has suggested that the consumption of ethanol has a potentially deleterious effect on the quantity of breast milk consumed by the baby. Milk transfer decreased during breastfeeding for 4 h after maternal alcohol consumption and then increased 8–16 h after consumption ceased.⁹⁹ These studies do not support the folklore that small amounts of alcohol improve lactation.

In general, after consumption of a relatively small amount of alcohol and the passage of sufficient time so that the mother no longer feels the effects of the alcohol, breastfeeding can resume. Using a nomogram published by Ho et al.,¹⁰⁰ a 140-pound lactating woman would require 2 h and 19 min after consuming one drink to achieve a zero level of milk alcohol.

Substances of abuse

Substances of abuse are contraindicated during pregnancy and lactation. The exception is methadone supplied within the context of a successful maintenance program. Mothers on methadone should be monitored carefully and the infant

Table 66.2 Contraindications for breastfeeding.

Condition	Contraindication
Substances of abuse (except methadone maintenance program and free of other drugs)	Absolute
Alcohol abuse	Absolute
Chemotherapeutic agents	Absolute or relative (depending on prior fetal exposure, duration of agent, and particular agent involved)
Maternal HIV	Absolute in US Relative in non-US regions with insufficient access to formula or clean water
Maternal HSV infection of nipple	Temporary cessation from involved nipple/areola until lesions resolved
Active untreated maternal tuberculosis	Temporary until after treatment established
Radioactive ^{131}I therapy	Absolute due to long half-life and potential to concentrate in thyroid and breast
Infant galactosemia	Absolute

observed for methadone withdrawal after delivery regardless of feeding method. Breast milk exposure may mitigate neonatal abstinence syndrome, but is not sufficient to prevent withdrawal.¹⁰¹ Mothers engaging in continued substance abuse postpartum should be provided with support services for drug dependency treatment and counseled not to breastfeed. A study of breast milk from 11 mothers who admitted using drugs during pregnancy detected cocaine in six of the specimens.¹⁰² It is suspected that cocaine has a high milk to plasma ratio. Serious adverse effects have been reported. Similarly, marijuana has a high milk to plasma ratio, suggesting that it is concentrated in breast milk.¹⁰³

Medication use

Advice regarding the use of a medication during breastfeeding should reflect not only the efficacy of the drug in treating the mother's condition but also the impact of the drug on lactation and the breastfed infant. Few studies examine drug use during lactation, and specialized references are required to formulate appropriate advice. Those drugs that have been shown to be safe for use during breastfeeding and/or those used in pediatric populations are generally preferred. Thus, the drug of choice for a particular condition may well differ depending on whether or not the mother is breastfeeding. The healthcare provider should review available information with the parents and discuss their individual situation. The age, weight, and health of the child, in addition to the amount of breast milk in the diet and any medications the child is taking, should be considered when choosing which medication is the best choice. Many characteristics of medications influence their potential to pass into breast milk and then reach and affect the breastfed child. These include the molecular weight, half-life, pH, protein binding, lipid solubility, oral bioavailability, and acid stability.

Maternal health problems

Table 66.2 lists circumstances in which breastfeeding is contraindicated. Table 66.3 lists concerns regarding breastfeeding by women with specific diseases.

Thyroid disease

Postpartum thyroid dysfunction is common and, occasionally, lactation difficulties in the previously successfully breastfeeding mother could be a presenting symptom of thyroid dysfunction. Breastfeeding can be continued during many treatments for either hypothyroidism or hyperthyroidism. Radioactive ablation of the thyroid with ^{131}I is not recommended during breastfeeding.

Diabetes mellitus

The gestational diabetic will not need further therapy after delivery, although her infant is still at risk of neonatal hypoglycemia, and infant glucose monitoring is warranted within 30min of birth. Some gestational diabetics have previously undiagnosed diabetes. Therefore, it is recommended that gestational diabetics undergo glucose testing at the postpartum visit. Insulin can be continued safely during lactation. Metformin has been studied in a small number of breastfeeding women.¹⁰⁴ No adverse reactions were noted in the infants. Owing to the concern over lactic acidosis, use in either a mother or an infant with renal dysfunction may not be advisable.

Cystic fibrosis (CF)

Recent studies have shown that electrolyte concentrations in the breast milk of women with CF are within normal limits as the mammary gland does not reabsorb sodium in excess of water.^{105–107} Preliminary information indicates that women with CF can breastfeed while receiving close monitoring of their disease.

Maternal phenylketonuria (PKU)

Limited data indicate that a mother with PKU under strict dietary control should be allowed to breastfeed. Although milk phenylalanine concentrations are dramatically elevated,¹⁰⁸ successful management of PKU and breastfeeding have been described with complementary low phenylalanine infant formula in women using strict dietary control.¹⁰⁹

Table 66.3 Maternal disease and breastfeeding considerations.

Infection	Route of transmission	Breastfeeding considerations
HIV	Blood and body fluids	Contraindicated in US and regions where safe alternatives to breast milk are available
Hepatitis A	Fecal and oral	Continued breastfeeding; encourage good hygiene
Hepatitis B	Blood and body fluids	Continued breastfeeding; infant to receive hepatitis B immunoglobulin (HBIG) within 12h of birth and hepatitis B vaccination
Hepatitis C	Blood and body fluids	Continued breastfeeding; no difference in transmission rate (~4%) in breastfed versus formula-fed infants. Some experts recommend temporary interruption of breastfeeding when bleeding nipples are present
Cytomegalovirus	Respiratory	Continued breastfeeding of healthy term infant Breastfeeding of premature infant during infection deserves individual consideration
Herpes simplex virus	Direct contact	Continued breastfeeding unless lesions on nipple/areola (see above). Cover lesions in potential contact with infant, good hygiene
Varicella virus	Respiratory, direct contact	Maternal primary infection: infant varicella immune globulin (VZIG) and possible vaccination depending on infant age Maternal shingles: continued breastfeeding, cover lesions in potential contact with infant and encourage good hygiene. Consider VZIG

Human immunodeficiency virus (HIV)

The current estimate of the prevalence of HIV in pregnant US women is 1–2 per 1000. Without treatment, the transmission rate from mother to child related to pregnancy and delivery is approximately 25%. Antiretroviral therapy with zidovudine during pregnancy and labor with infant treatment during the first 6 weeks postpartum and not breastfeeding reduces the risk of transmission to approximately 6–8%. Women with an unknown HIV status prior to labor account for 40% of mother to child transmission of HIV in the US. Optimal treatment in labor with the use of intrapartum zidovudine or initiating infant therapy by 48h of life significantly reduces the risk of transmission. The recommendation to avoid breastfeeding should also be provided in this situation. For women with unknown HIV status upon entry to the labor suite, rapid HIV testing could allow for treatment and recommendations that could significantly improve outcome.

Support strategy for mother and infant

Intrapartum influences

During an uncomplicated pregnancy and delivery, the infant can be given to the mother at delivery, and breastfeeding initiation should be encouraged within the first hour after birth. Labor companionship and support have been associated with improved breastfeeding initiation and continuation rates.^{110–112} Avoidance of unnecessary interventions is recommended. Having staff trained in lactation support can mitigate potential obstacles to breastfeeding that may present with complicated pregnancies and/or medical interventions associated with delivery.

Labor induction and delivery method

Studies evaluating the influence of labor induction on breastfeeding success reach varying conclusions and may be confounded by maternal confidence or intentionality. In a study by Out et al.,¹¹³ women undergoing medically indicated labor induction were more likely to continue their antepartum intention to breastfeed than women in the “elective” induction group. Similarly, emergent Cesarean delivery appears to be a more significant obstacle to breastfeeding success than non-emergent Cesarean delivery.^{114,115} Delayed onset of lactation in mothers undergoing Cesarean delivery has also been reported.¹¹⁶ Grajeda and Perez-Escamilla¹¹⁷ found that primiparous vaginally delivered women experienced onset of lactation at day 2.9 on average as opposed to day 3.4 for those undergoing emergent Cesarean delivery. No difference was noted related to mode of delivery in multiparas.

Regional anesthesia appears to be associated with improved lactation performance compared with general anesthesia.^{118,119} Patient-controlled analgesia with morphine or continuous extradural anesthesia in the initial postoperative period is preferred over the use of meperidine because of the association of meperidine with an adverse effect on infant suckling behavior.¹²⁰

Maternal–infant contact

The vigorous term infant with clear amniotic fluid may be placed on the maternal abdomen at delivery. The family may participate in cutting the cord if the situation is deemed appropriate. The infant can then be dried, stimulated, and placed skin to skin with the mother with warm blankets placed over the dyad to maintain the infant’s temperature. Infant interventions such as vitamin K injection, the application of

Table 66.4 Breastfeeding information for new parents.

-
- 1 Normal milk production is quite low until after the onset of lactogenesis stage II between the first and fifth days postpartum
 - 2 Most infants nurse 8–14 times/day in the first 1–2 weeks. This decreases to 7–10 times/day by 4 weeks
 - 3 Each infant's "demand" breastfeeding frequency reflects his own developmental status and nursing skill as well as the mother's milk flow
 - 4 After the third day of life, exclusively breastfed infants usually soak six or more diapers and have three or more stools of 1 tablespoon or greater/day
 - 5 Infant stools normally change from dark (green or brown) to mustard yellow by the fifth day. This happens after the mother's milk "comes in" and the baby begins to receive larger volumes of milk, which clears the meconium from the gastrointestinal tract
 - 6 Healthcare provider should be notified promptly if urine or stool patterns deviate from norms indicated in items 4 and 5 or if parents are concerned about adequacy of infant intake or maternal milk production
-

ophthalmic ointment, newborn screening, and measurements may be obtained later. The mother can be encouraged to breastfeed soon after delivery, ideally within the first hour after birth. A Cochrane review evaluating 17 studies found a significant positive impact of skin to skin contact on the maintenance of infant body temperature, infant glucose levels, and continued breastfeeding at 1 and 3 months.¹²¹

Unless medically indicated, newborn interventions should be delayed until after the first hour of life. In an ideal situation, these procedures can be performed in the room of the new family. The family should be encouraged to room in with the infant and breastfeed on demand. Rooming in will facilitate the acquisition of parental roles and the development of nonverbal parent–infant communication skills, such as recognition of infant hunger and satiety cues required for successful breastfeeding.

Latch and milk transfer during feeding should be assessed by trained personnel within 8 h prior to hospital discharge. Pre-discharge teaching should include the elements listed in Table 66.4. Parents should be advised to report promptly deviations from normal urine and stool patterns or concerns about low milk production to the healthcare provider. Breastfed infants discharged 1–2 days after delivery should return to their healthcare provider in the first few days after discharge to assure that the mother's milk has come in, infant weight loss has ceased, and jaundice and dehydration are not significant.

Common problems in postpartum care

Mastitis

Mastitis occurs in approximately 9.5% of breastfeeding women during the first 12 weeks postpartum.¹²² Risk factors

include unrelieved engorgement or plugged ducts, past history of mastitis, and nipple trauma which provides a portal of entry for the offending organisms. *Staphylococcus aureus* is the most common organism cultured from the mastitic breast.

Signs and symptoms of mastitis include an erythematous, tender breast, fever, and flu-like symptoms such as myalgia, nausea, and headache. A localized tender knot in the breast in the absence of symptoms of infection suggests a plugged duct, which can be managed with frequent nursing and warm compresses. Persistent breast masses should be pursued regardless of lactation status. More diffuse firmness in both breasts in the initial week postpartum is suggestive of engorgement and is usually associated with normal or low-grade fever. The presence of a fluctuant palpable and tender mass in the mastitic breast is suggestive of a breast abscess.

Mastitis is treated with a penicillinase-resistant antibiotic such as Dicloxacillin or a cephalosporin for 10–14 days. If symptoms do not improve after 24–48 h of therapy, milk should be cultured for resistant organisms, and the breast should be re-examined for possible abscess. Nonsteroidal anti-inflammatory agents such as ibuprofen are useful in pain control. In addition to antibiotic therapy, breastfeeding should be assessed, and factors that predisposed to the infection should be addressed, such as latch difficulties leading to nipple trauma. Otherwise, the mother may be more likely to experience a recurrent episode of infection. Breastfeeding the healthy, term infant during treatment of mastitis should be continued, and excellent drainage of the infected breast is important in recovery. Abrupt weaning during mastitis increases the risk of abscess.

The risk of breast abscess is 0.4% for breastfeeding women generally, and 3% for those with mastitis.¹²³ Management of breast abscesses requires the use of antibiotics with the addition of drainage of the abscess collection. Prior management using open incision and drainage is being replaced by repeat ultrasound-guided aspirations of the abscess either with or without the placement of a drainage catheter.^{124–126}

Contraception

If the patient is using lactational amenorrhea as a means of contraception, provision should be made for easy access to additional contraception at 6 months, or sooner if the need arises. Nonhormonal contraceptive options do not affect breast milk composition or quantity. If a hormonal contraceptive is chosen, a progesterone-only alternative has less potential impact on milk supply. In breastfeeding mothers, estrogen-containing contraceptive options have the theoretical concern of adversely affecting milk supply. If a breastfeeding mother is inclined to pursue an estrogen-containing option, the lower estrogen dosage appears prudent. The mother should be counseled regarding the potential for an adverse effect on milk supply, and the contraceptive should be initiated as late after established lactation as possible.

Low milk production

If a mother expresses concern about low milk production in the early postpartum period, the infant should be evaluated and the mother assessed for possible causes of failed LS-II (see Onset of milk production and early lactation failure). If infant status is normal and the child is exclusively breastfed, maternal concerns likely reflect misinterpretation of infant behavior. If the infant is not thriving or is receiving formula supplements, it suggests that maternal milk volume is low. Medications and over-the-

counter drugs should be reviewed for potential impact on milk production. If no medical or pharmacologic cause is apparent, milk volume usually increases in response to increased frequency of breast stimulation (nursing or pumping) and/or the increased degree of breast emptying (improved infant latch or breast massage during nursing). Referral to a certified lactation consultant is appropriate for both perceived and confirmed low milk production.

Key points

- 1 In controlled studies, lack of breastfeeding and/or earlier introduction of supplements and weaning are associated with increased risk of a variety of adverse outcomes in mothers and infants (see Table 66.1).
- 2 Onset of copious milk production (stage II lactogenesis) begins after delivery of the placenta in response to the subsequent fall in circulating progesterone. Delay of lactogenesis stage II beyond day 5 postpartum should prompt evaluation.
- 3 Failed lactogenesis can result from primary glandular insufficiency, retained placenta, or severe postpartum hemorrhage resulting in ischemic pituitary necrosis and Sheehan's syndrome.
- 4 When engorgement becomes severe, analgesics are appropriate treatment for pain, and immediate skilled assistance may be needed to achieve effective latch on and efficient milk removal.
- 5 In established lactation, milk volume averages 750 mL/day and increases or declines in response to alterations in mammary stimulation and the degree of breast emptying.
- 6 The nutrient content of human milk is conveyed to the infant within, and does not exist apart from, a redundant milieu of anti-infective, growth-stimulating, and anti-inflammatory agents.
- 7 Strict vegetarians should consume vitamin B12 supplements during pregnancy and lactation for their own health and to prevent vitamin B12 deficiencies in their infants.
- 8 In spite of the ubiquitous presence of environmental contaminants in human milk, breastfed infants are healthier than infants who are not breastfed.
- 9 Breastfeeding women who desire to lose weight may be advised to initiate moderate caloric restriction (500 kcal/day below maintenance levels), consume a balanced diet, and undertake regular exercise after breastfeeding is well established.
- 10 During the first 6 months postpartum, women who are amenorrheic and breastfeeding frequently (≥ 8 times/24 h) without giving supplements have a less than 2% risk of pregnancy.
- 11 Women with specific breastfeeding-related concerns, such as breast implants, prior breast surgery, inverted nipples, time constraints, or lack of confidence, should be educated regarding their particular situation.
- 12 Advice regarding medication use during breastfeeding should be formulated only after reviewing information on that medication, exploring alternative treatments, and discussing that individual situation with the parents. The age, weight, and health of the child, in addition to the amount of breast milk in the diet and medications the child is taking, should all be considered when prescribing medication for breastfeeding women.
- 13 Maternal contraindications to breastfeeding are rare and include continued use of substances of abuse, rare chemotherapeutic and other medications, and maternal HIV infection. Temporary interruption is warranted with maternal herpes simplex virus (HSV) involving the nipple and untreated maternal tuberculosis.
- 14 Having staff trained in lactation support can help to minimize the impact of potential obstacles to breastfeeding, which may present with medically complicated pregnancies and/or medical interventions associated with delivery.
- 15 During an uncomplicated pregnancy and delivery, the infant can be placed skin to skin with the mother at delivery with warm blankets covering them, and breastfeeding initiation should be encouraged within the first hour after birth.
- 16 In the initial postCesarean period, patient-controlled analgesia with morphine or continuous extradural anesthesia is preferred over the use of meperidine because of the association of meperidine with poor infant suckling behavior in the early postpartum period.
- 17 New parents should be specifically and carefully advised of the ranges of normal for volume of colostrum, time of onset of copious milk production, frequencies of infant feeding, stooling, and urination, and the timing of meconium passage, with clear instructions to contact the care provider should the infant deviate from expected norms (Table 66.4).

- | | |
|--|---|
| <p>18 Breastfed infants discharged 1–2 days after delivery should return to their healthcare provider in the first few days after discharge to assure that the mother's milk has come in, infant weight loss has ceased, and jaundice and dehydration are not significant.</p> | <p>19 Evaluation of persistent breast masses should be pursued regardless of lactation status.</p> <p>20 Breastfeeding the healthy, term infant should be continued during treatment of mastitis with antibiotics; excellent drainage of the infected breast is important in maternal recovery.</p> |

The Newborn Infant

Premature birth and neurological complications

Alan Hill

Prematurity is a major risk factor for neonatal brain injury. Recent statistics indicate that the rate of premature delivery has increased during recent decades such that very low birth-weight (VLBW) infants now comprise approximately 1.5% of live births and more than 85% of such infants survive. However, enthusiasm over the improved survival of VLBW infants is tempered by concern regarding the high risk of neurological morbidity in survivors, e.g., approximately 5–15% develop cerebral palsy and an additional 25–50% have developmental disabilities affecting cognitive function, behavior, and school performance.^{1–3} In addition, survivors have an increased incidence of non-neurological problems (e.g., congenital anomalies, respiratory infections, and sudden infant death syndrome).

In this chapter, discussion is limited to a review of the major types of cerebral injury that occur in premature infants, e.g., germinal matrix–intraventricular hemorrhage (GMH–IVH) and its complications of periventricular hemorrhagic infarction (PVI) and posthemorrhagic hydrocephalus (PHH), hypoxic–ischemic injury, and common metabolic disturbances. Although hemorrhagic and hypoxic–ischemic injury are discussed separately, there is a close relationship between these two major categories of premature brain injury.

Anatomic and physiological features of the premature brain

The specific patterns of brain injury observed in the premature newborn are related to unique anatomic and physiological features of the immature brain as follows.

Vascular supply of the premature brain

Subependymal germinal matrix

The subependymal germinal matrix is a richly vascularized site of active cellular proliferation located immediately ventrolateral to the lateral ventricles in the premature brain (Fig. 67.1).

It is a source of neuronal precursors between 10 and 20 weeks of gestation, followed by production of glioblasts during the third trimester. These latter elements subsequently differentiate into oligodendroglia and astrocytes. The size of the germinal matrix decreases progressively during gestation until it has virtually disappeared by term. The immature, fragile, endothelium-lined vessels have a propensity to rupture, causing a GMH, which may then break through the adjacent wall of the lateral ventricles to produce IVH.^{1,3}

Arterial blood supply

The arterial supply of the premature brain is a major determinant of the unique patterns of hypoxic–ischemic injury. Thus, injury occurs predominantly in the relatively avascular periventricular white matter in the border zones (watershed areas) between the long penetrating branches of the middle and posterior cerebral arteries, in the posterior white matter around the trigone of the lateral ventricles, and in the border zones between long penetrators of the middle and anterior cerebral arteries in the frontal periventricular white matter around the foramen of Monro. The cerebral cortex is relatively resistant to hypoxic–ischemic insult because of the rich, interarterial anastomoses of meningeal vessels during early development of the arterial system.^{1,4}

Venous drainage

Whereas arterial blood supply plays a major role in the genesis of hypoxic–ischemic injury, the distinctive deep venous drainage of the premature brain may render particular sites (e.g., the subependymal germinal matrix) vulnerable to hemorrhage. Thus, there is a sharp reversal in the direction of venous flow at the confluence of the choroidal, thalamostriate, and medullary veins where they form the terminal and internal cerebral veins, which predisposes to venous stasis. This, in turn, may cause an increase in intravascular pressure proximally and capillary rupture, especially in situations associated with elevations in venous pressure (e.g., labor, delivery, and asphyxia).^{1,3,5,6}

Figure 67.1 Coronal section of pathological specimen of brain of premature infant: note paucity of gyri, bilateral germinal matrix hemorrhage (arrows), and intraventricular hemorrhage.

Cerebrovascular autoregulation

Cerebrovascular autoregulation is the homeostatic mechanism that maintains constant cerebral perfusion over a wide range of systemic arterial pressures. This mechanism appears to be incompletely developed in a subset of premature newborns, resulting in a “pressure-passive” relationship between systemic blood pressure and cerebral perfusion and increased risk of ischemic and hemorrhagic brain injury.^{1,3,7}

Composition of cerebral tissue

The relatively close packing of cortical neurons and lack of Nissl substance in the premature brain makes it difficult to detect cortical neuronal necrosis after hypoxic–ischemic insult. Furthermore, the normally high water content in the premature brain makes it unlikely that cerebral edema plays a major role in the pathogenesis of hypoxic–ischemic injury. The propensity for cystic cavitation of periventricular lesions relates to this relatively high water content, together with the paucity of myelin and poor astroglial response of the premature brain.^{1,4} In addition, advances in cellular neurobiology provide increasing evidence that white matter injury in the premature newborn arises, in part, because of a unique developmental vulnerability of oligodendrocyte precursor cells. Cell death and necrosis appear to occur via apoptosis.^{1,4,8,9} This raises the possibility that apoptotic cell death and white matter injury may be preventable by using free radical scavengers.¹⁰

Figure 67.2 Periventricular leukomalacia on T1-weighted MRI of premature infant at age 3 days: note germinal matrix hemorrhage on left (arrow) and layered hemorrhage in third ventricle and occipital horns of lateral ventricles.

Major types of cerebral injury in the premature newborn

Germinal matrix–intraventricular hemorrhage (GMH–IVH)

As discussed previously, GMH–IVH originates from spread of GMH into the ventricular system (Figs 67.1 and 67.2). The incidence of GMH–IVH has declined in recent decades to less than 20%.³ However, because the incidence of GMH–IVH correlates closely with the degree of prematurity, the improved survival of extremely premature infants suggests that GMH–IVH will remain a significant problem. GMH–IVH occurs during the first 24 h of life in approximately 50% of cases and before 3 days of age in 90%.¹

Pathogenesis

The pathogenesis of GMH–IVH is multifactorial and includes a combination of intravascular, vascular, and extravascular factors that are summarized in Table 67.1.

Diagnosis and clinical features

All premature newborns are at risk of GMH–IVH, particularly those who require mechanical ventilation and/or sustain hypoxic–ischemic insult or other major systemic complications (e.g., sepsis, pneumothorax). In infants with severe GMH–IVH, hemorrhage may be suspected on the basis of clinical features (e.g., abnormal neurological signs, decreasing hematocrit, hypotension, bulging fontanelle, and metabolic acidosis). However, GMH–IVH can be diagnosed on the basis of clinical criteria alone in only 50% of cases.¹ Definitive diagnosis requires confirmation by neuroimaging, usually by cranial ultrasonography (Fig. 67.3). Because extension of GMH–IVH may occur during the first week, routine screening by ultrasonography between 7 and 14 days of age is often performed in all infants < 30 weeks' gestation in order to demonstrate the maximal extent of hemorrhage. Subsequently, serial ultrasound scanning and close clinical surveillance may be necessary for the identification of potential complications, e.g., during subsequent months.¹¹

Table 67.1 Pathogenetic factors for intraventricular hemorrhage.

Disturbed cerebrovascular autoregulation
Altered cerebral blood flow (increase or decrease, fluctuating pattern)
Increased cerebral venous pressure
Disturbance of coagulation
Fragility and poor mechanical support of germinal matrix vasculature
Increased fibrinolytic activity within germinal matrix
Decreased extravascular tissue pressure

Complications of germinal matrix–intraventricular hemorrhage

Posthemorrhagic hydrocephalus (PHH)

Progressive ventricular dilation has been reported to develop in approximately 35% of premature infants with GMH–IVH. Progressive hydrocephalus with increased intracranial pressure may develop rapidly after major GMH–IVH, either related to a large volume of intraventricular blood or because of obstruction or impaired reabsorption of cerebrospinal fluid. More commonly, progressive ventriculomegaly develops gradually, over several weeks, related principally to obliterative arachnoiditis in the posterior fossa that obstructs the flow of cerebrospinal fluid. Such ventricular dilation may resolve or arrest spontaneously in approximately 65% of cases, usually within 4 weeks of onset. In the remainder, intervention is usually required by temporizing measures to drain cerebrospinal fluid (e.g., serial lumbar punctures, external ventriculostomy, placement of a subcutaneous reservoir, subgaleal shunt) or, rarely, pharmacological interventions with medications to decrease cerebrospinal fluid production (e.g., acetazolamide). In instances in which progressive ventricular dilation continues, placement of a permanent ventriculoperitoneal shunt may be required.¹ When planning intervention, it is critical to distinguish between progressive hydrocephalus with increased intracranial pressure and ventriculomegaly related principally to cerebral atrophy, which is associated with normal intracranial pressure. In many instances, the two processes may coexist.^{3,12} Recent data after 1994 suggest that the natural history of posthemorrhagic ventriculomegaly may be evolving, in that the overall incidence has decreased to

Figure 67.3 Coronal cranial ultrasound at age 7 days: note resolving germinal matrix hemorrhage on right (arrow).

Figure 67.4 Coronal cranial ultrasound: note periventricular hemorrhage infarction (PVI) on right (arrow).

approximately 25% of infants with GMH–IVH. However, in this cohort, ventriculomegaly arrested or resolved spontaneously in only 33%.¹³

Periventricular hemorrhagic infarction (PVI)

Hemorrhagic necrosis in the periventricular white matter (PVI) is observed in approximately 15% of infants with IVH, most commonly in association with large GMH (Fig. 67.4). These parenchymal lesions may be extensive and are either unilateral or strikingly asymmetric, often with a fan-shaped appearance.^{1,14} Neuropathological and radiological studies have demonstrated that PVI is not simply an extension of GMH–IVH, but rather represents venous infarction from obstruction of flow in the terminal vein in the subependymal region by an ipsilateral large GMH or GMH–IVH.¹⁵ Thus, this lesion is distinct from secondary hemorrhage into areas of periventricular leukomalacia (PVL), which is bilateral (discussed later). However, distinction between the two lesions is often difficult, and both lesions frequently coexist.¹⁶

Hypoxic–ischemic cerebral injury

Complications of intrapartum hypoxic–ischemic insult associated with preterm delivery, together with a high incidence of postnatal cardiorespiratory problems (e.g., respiratory distress syndrome, patent ductus arteriosus, apnea of prematurity), render the premature infant at high risk of hypoxic–ischemic cerebral injury. The specific neuropathological patterns relate

Table 67.2 Major patterns of hypoxic–ischemic cerebral injury in the premature newborn.

Pattern	Major anatomic location
Selective neuronal necrosis	Diencephalon, thalamus, brainstem
Periventricular leukomalacia	Periventricular white matter, particularly in peritrigonal region (bilateral)
Focal/multifocal necrosis	Cortex and white matter
Periventricular hemorrhagic infarction	Periventricular white matter, unilateral or asymmetric

principally to the stage of maturation of the immature brain (Table 67.2).

Selective neuronal necrosis

During the third trimester, neurons in the thalamus, hypothalamus, and brainstem appear to be particularly vulnerable to hypoxic–ischemic insult.^{17,18} In one neuropathological series, pontine neuronal necrosis was documented in 46% of premature infants with IVH, all of whom had died of respiratory failure.¹⁹

Periventricular leukomalacia (PVL)

As discussed previously, ischemic injury in the premature brain principally involves the periventricular watershed zones of

arterial supply in white matter. In addition, there is often more diffuse white matter injury related to diffuse loss of early differentiating oligodendroglia.^{1,4} Considerable advances have been made in the understanding of the pathogenesis of PVL.^{4,20} Thus, in addition to the role of vascular anatomic factors in the periventricular region and the pressure-passive cerebral circulation observed in some unstable premature newborns (discussed previously), there appears to be an intrinsic vulnerability of early, differentiating oligodendrocyte precursors to attack by free radicals, leading to apoptotic cell death.^{4,8,9} In addition, there is mounting evidence of direct injury to white matter from inflammatory mediators (e.g., endotoxins, cytokines). The possible role of inflammatory factors has been suggested by epidemiological studies and studies of placental pathology, which suggest an increased incidence of PVL in preterm infants of mothers with chorioamnionitis.^{20–23}

Neuropathological studies reveal a spectrum of severity of PVL ranging from minor reduction in the quantity of myelin and gliosis to extensive encephalomalacia. Neuropathological studies have also emphasized the frequent association between PVL and GMH–IVH in as many as 75% of infants.¹⁹

The diagnosis of PVL during the neonatal period cannot be based reliably on clinical criteria and must be established by detection of abnormalities on serial neuroimaging. Cranial ultrasonography may demonstrate transient increased echogenicity in periventricular white matter during the first days of life, followed by the development of echolucent cysts in these regions after several weeks in severe cases and ventricular dilation after several months^{1,24,25} (Fig. 67.5). However, correlative neuropathological studies have demonstrated the relatively poor sensitivity of ultrasonography for detection of PVL (approximately 70% of mild cases are not diagnosed consistently).²⁶ More recently, studies with magnetic resonance imaging (MRI), especially diffusion-weighted studies, may identify less severe white matter lesions.^{17,27}

The clinical features of PVL in the premature newborn are variable, and detailed neurological examination may be difficult in the presence of complex life support apparatus. The principal long-term neurological sequela of PVL is motor handicap (e.g., spastic diplegia or quadriplegia). Injury to optic radiation may result in visual impairment, and more diffuse white matter injury may result in behavioral disturbances and intellectual deficits.¹ The possible role of PVL in causing abnormal cerebral cortical neuronal organization and significant intellectual deficits, because of either injury to subplate neurons or late migrating astrocytes, awaits further clarification.²⁸

In older children with cerebral palsy who were born prematurely, the clinical suspicion of PVL as the cause can be confirmed by documentation of characteristic abnormalities on brain imaging [computed tomography (CT) or MRI]. Abnormalities on CT scans performed after 6 months of age include ventriculomegaly with irregular ventricular walls and reduction in the quantity of periventricular white matter, particularly in the peritrigonal region, and prominent sylvian fissures

Figure 67.5 Coronal cranial ultrasound at age 5 weeks: note cystic periventricular leukomalacia (arrows) more prominent on the right.

(Fig. 67.6).²⁹ Similar abnormalities may be recognized with greater definition by MRI (Fig. 67.7).³⁰

Focal–multifocal brain necrosis

Focal ischemic cerebral lesions associated with arterial occlusion occur uncommonly in premature infants. In one large series, none was observed in infants who were less than 28 weeks of gestational age. Five percent of all cases of infarction occurred in infants between 28 and 32 weeks, and 10% occurred in infants between 32 and 37 weeks of gestation. Multiple small scattered infarcts, related to occlusion of small vessels, are more common in this age group than in term infants.³¹ Focal cerebral necrosis in the premature brain frequently results in cavitation, with the formation of porencephalic cysts or multicystic encephalomalacia. Neurological sequelae (e.g., cerebral palsy, mental retardation, and seizures) are variable and correlate with the anatomic location and the extent of cerebral injury.¹

Bilirubin encephalopathy

Unconjugated hyperbilirubinemia in the newborn may result in kernicterus, which involves localized staining of basal ganglia and brainstem nuclei associated with microscopic neuronal destruction. Despite the extensive literature on bilirubin metabolism, its central nervous system toxicity remains poorly understood.

Bilirubin staining of the brain has been documented in premature newborns even at relatively low bilirubin levels, often in regions of the brain injured by other insults (e.g., PVL). In

Figure 67.6 Periventricular leukomalacia on axial CT scan at age 2 years: note dilated lateral ventricles with irregular ependymal border, paucity of white matter, and deep sulci (arrows).

addition, bilirubin staining without structural neuronal injury has been documented in premature infants with moderate hyperbilirubinemia.^{1,32} Interestingly, sick premature newborns do not generally demonstrate the classic neonatal neurological encephalopathy or later kernicterus. Furthermore, there is no proven definite relationship between moderate hyperbilirubinemia and neurological outcome in premature newborns. Because extrapyramidal movement abnormalities are less common in infants born prematurely, the possibility exists that the maturational stage of the brain at the time of insult may be critical in determining neurological sequelae, as is the case in hypoxic-ischemic cerebral injury. To date, there is some evidence that hearing loss may be the major manifestation of bilirubin neurotoxicity in the premature newborn.^{1,32, 33}

Hypoglycemic brain injury

Transient hypoglycemia occurs commonly in the stressed premature newborn, often in association with hypoxic-ischemic cerebral injury. At present, many issues remain unresolved, including the threshold and duration of significant hypoglycemia, as well as the suspected additive and potentiating effects of hypoglycemia in the context of other types of

Figure 67.7 Periventricular leukomalacia on T1-weighted MRI at age 3 years: note ventriculomegaly with irregular ependymal border, almost complete loss of white matter, and deep sulci abutting ependyma.

insult.^{34,35} Furthermore, there may be an important role for glucose in the regulation of cerebral blood flow, in that moderate hypoglycemia has been shown to be associated with a two- to threefold increase in cerebral blood flow.³⁶ The clinical significance of this observation remains to be determined, e.g., its role in an increased risk of GMH-IVH. Severe hypoglycemia has become a relatively rare problem in most neonatal units because of routine frequent monitoring of blood glucose levels and early intravenous glucose supplementation.

Prevention and management of hemorrhagic and hypoxic-ischemic brain injury

Although hypoxic-ischemic cerebral injury and GMH-IVH have distinct pathogenetic mechanisms, in many instances, similar strategies for intervention are used to decrease both types of injury. For practical purposes, major approaches to management are discussed in terms of the timing of intervention, i.e., antepartum, intrapartum, or postpartum (Table 67.3).

Table 67.3 Prevention and management of cerebral injury.*Antepartum intervention*

Prevention of premature delivery

Intrauterine transport

Pharmacological interventions: corticosteroids, others (?)

Intrapartum interventions

Avoidance of prolonged labor (?)

Delivery by Cesarean section (?)

Postnatal interventions

Adequate ventilation

Prevention and correction of hemodynamic disturbances

Correction of coagulation abnormalities

Pharmacological interventions (?): indomethacin

Antepartum interventions**Prevention of premature delivery**

Although the prevention of premature delivery receives ongoing major attention, current public education programs and medical interventional strategies appear to be losing ground, in that the incidence of premature delivery has actually increased during the last two decades.^{1–3} Major strategies for such prevention are discussed in detail elsewhere in this book.

One approach to the prevention of preterm delivery that is particularly appealing involves the treatment of women with bacterial vaginosis with antimicrobial agents, which may also decrease premature rupture of membranes and chorioamnionitis, which, in turn, are associated with adverse neonatal outcome including GMH–IVH and PVL.³⁷

Intrauterine transportation

If premature delivery is unavoidable, concerted effort should be directed toward transfer of the mother to a high-risk perinatal center before delivery to ensure the optimal condition of the infant at birth as well as the availability of state-of-the-art neonatal management to minimize postnatal complications.

Prenatal pharmacological interventions

Prenatal pharmacological interventions for the prevention of premature delivery and, hence, possibly GMH–IVH and its complications are under investigation.

Antenatal tocolytic therapy

Attempts to stop premature labor by aggressive tocolytic therapy have been disappointing,³⁸ and there is concern that tocolytic agents may affect fetal systemic hemodynamics and cerebral perfusion, thereby increasing the risk of GMH–IVH and PVL.

Antenatal corticosteroids

Antenatal corticosteroids, administered primarily to induce fetal lung maturation, thereby reducing the risk of respiratory

distress syndrome, also have the additional beneficial effects of stabilizing cell membranes in other organs, including vessels of the germinal matrix.³⁹ Numerous controlled trials indicate that antenatal corticosteroids reduce mortality as well as the overall incidence and severity of IVH. Furthermore, even an incomplete course of antenatal corticosteroid treatment is beneficial in that regard.⁴⁰ Clearly, there is convincing evidence to suggest that prompt treatment with antenatal corticosteroids may be indicated for most women who are at imminent risk of preterm delivery.

Other medications

Although earlier studies suggested that antenatal phenobarbital and vitamin K may be associated with a reduction in GMH–IVH, recent comprehensive reviews of the combined data from all clinical trials for the Cochrane Database failed to demonstrate a benefit from either medication. Further well-designed clinical trials are required to determine the usefulness of these medications.^{41,42}

Intrapartum management

Because approximately 50% of cases of GMH–IVH occur within the first 24 h of life, careful consideration must be given to the role of intrapartum factors in the pathogenesis of GMH–IVH. Mechanical forces on the compliant skull of the premature infant during uterine contractions and vaginal delivery may result in considerable perturbations of fetal cerebral hemodynamics. Despite earlier conflicting data about the role of labor and mode of delivery as a risk factor for IVH, the data suggest that prolonged labor and vaginal delivery may increase the risk of IVH in very low birthweight infants.^{43,44} Clearly, further investigations are needed to clarify the role of specific obstetric factors.

Postnatal interventions**Adequate ventilation of the newborn**

Immediate provision of adequate ventilation to prevent ongoing hypoxemia and hypercarbia is of major importance in the management of the premature newborn. Major advances in the management of respiratory distress syndrome have occurred in recent years. Contrary to initial expectations, the reported prevalence of IVH in surfactant-treated infants is higher than in control subjects, related perhaps to fluctuations in cerebral hemodynamics associated with the rapid changes in the lung mechanics of surfactant-treated infants.⁴⁵ The risk of IVH or PVL associated with newer methods of ventilation (e.g., high-frequency oscillatory ventilation and nitric oxide therapy) have not been clarified to date.¹²

Prevention and correction of hemodynamic disturbances

Rapid fluctuations in systemic hemodynamics may result in significant perturbations of cerebral perfusion, especially in the context of impaired cerebrovascular autoregulation in the

immature brain. Avoidance of prolonged labor and vaginal (especially breech) delivery may be significant in this regard.^{43,44} Systemic hemodynamic disturbances have been documented during management in the intensive care setting, e.g., routine monitoring, handling, tracheal suctioning. The use of muscle paralysis with pancuronium appears to be particularly effective in preventing pneumothorax, as well as abrupt fluctuations in cerebral blood flow associated with tracheal suctioning and other routine handling procedures. Thus, comprehensive analysis of data for the Cochrane Database demonstrated significant reduction in GMH-IVH after neuromuscular paralysis.⁴⁶ However, because long-term pulmonary and neurological effects are uncertain, routine pancuronium is not recommended for ventilated newborns.

Correction of coagulation abnormalities

Although abnormal coagulation is a risk factor for the development of GMH-IVH, review of combined data from randomized trials has failed to support the routine use of fresh frozen plasma, albumin, or blood substitutes, in that there was no reduction in severe GMH-IVH, mortality, or cerebral palsy.⁴⁷

Pharmacological interventions

Prophylactic indomethacin, used to treat symptomatic ductus arteriosus, is associated with a reduction in severe GMH-IVH and no apparent long-term adverse effects.⁴⁸

Neurological outcome in the premature newborn

The long-term neurological outcome of the premature newborn is determined principally by the extent of parenchymal hypoxic-ischemic injury and the occurrence of complications of GMH-IVH (e.g., PHH and PVI), rather than the occurrence of GMH-IVH itself. The significance of metabolic derangements (e.g., moderate hyperbilirubinemia, asymptomatic hypoglycemia) is less well established. The major factors that may assist in the prediction of neurological outcome are listed in Table 67.4.

The neurological examination of the premature infant is often limited by the presence of complex life support appara-

Table 67.4 Useful factors for predicting neurological outcome.

Neurological examination (seizures, abnormalities that persist to 40 weeks' postconceptional age)
Location and extent of periventricular ischemic/hemorrhagic lesions documented by cranial ultrasonography or computed tomography
Posthemorrhagic hydrocephalus (associated with cerebral atrophy, surgical drainage required)
? Other metabolic disturbances (e.g., hyperbilirubinemia, hypoglycemia)

tus. Nevertheless, certain clinical features (e.g., occurrence of seizures) correlate closely with poor neurological outcome.⁴⁹ Clinically recognizable seizure activity occurs uncommonly in the premature newborn because the immaturity of cortical interconnections tends to impede the propagation of abnormal electrical discharges. Electroencephalography may assist in the more accurate documentation of seizures. Serial neurological examinations are also invaluable for accurate prediction of outcome.⁵⁰

In addition to clinical examination, detailed assessment of the precise location and extent of cerebral injury by neuroimaging is of major predictive value. Thus, follow-up studies of VLBW infants report severe neurological abnormalities in those with major cranial ultrasonographic abnormalities. However, occasionally, if there is only minor parenchymal involvement or if injury is localized to a relatively clinically silent region of the brain, especially the frontal or occipital regions, the eventual handicap may be surprisingly mild.¹

Several studies have a high incidence of major neurological sequelae in infants with PHH, especially in those who require a ventriculoperitoneal shunt. Although poor outcome is related to concomitant parenchymal injury and in part to shunt-related complications (e.g., infection, shunt obstruction), there is increasing evidence that progressive PHH itself may be detrimental.^{51,52} The occurrence of major sequelae in children born prematurely who had abnormal neuroimaging is not surprising. More concerning is the mounting evidence of neurodevelopmental abnormalities in children who had normal neonatal cranial ultrasound scans.⁵³

Key points

- 1 Premature delivery occurs in approximately 1.5% of live births, and more than 85% of very low birthweight infants (birthweight < 1500g) survive.
- 2 The topography of hemorrhagic and hypoxic-ischemic brain injury in premature newborns relates to unique

- 3 Diagnosis of the various types of hemorrhagic and hypoxic-ischemic premature brain injury in the newborn period can be made on the basis of clinical

features alone in only a minority of cases. Accurate diagnosis usually requires confirmation by neuroimaging, usually cranial ultrasonography. Routine screening by ultrasonography is recommended in premature newborns of < 30 weeks' gestation between 7 and 14 days of age and should be repeated at term.

- 4 Germinal matrix–intraventricular hemorrhage (GMH–IVH) originates from hemorrhage from fragile vessels in the subependymal germinal matrix, which then ruptures through the wall of the lateral ventricles to cause IVH.
- 5 The incidence of GMH–IVH in premature newborns has declined to less than 20%, and long-term sequelae are usually related more to its major complications (posthemorrhagic hydrocephalus and periventricular hemorrhagic infarction) and to parenchymal ischemic injury than to GMH–IVH itself.
- 6 Progressive posthemorrhagic hydrocephalus (PHH), related to obstruction of cerebrospinal fluid by obliterative arachnoiditis in the posterior fossa, usually develops gradually over weeks and may arrest or resolve spontaneously in 35–65% of cases. Such PHH with increased intracranial pressure must be distinguished from ventriculomegaly related to cerebral atrophy. This distinction may be difficult, and both causes of ventricular enlargement may coexist.
- 7 Periventricular hemorrhagic infarction (PVI) occurs as a result of hemorrhagic venous infarction from obstruction of the terminal vein by ipsilateral large GMH. It may be visualized on cranial ultrasonography as a unilateral, fan-shaped lesion with ipsilateral large GMH.
- 8 Periventricular leukomalacia (PVL) is the major pattern of hypoxic–ischemic brain injury in premature newborns, which results in long-term sequelae of spastic diplegia and often visual impairment.
- 9 Periventricular leukomalacia may be distinguished from periventricular hemorrhage infarction on cranial ultrasonography, in that it appears as bilateral, increased echoes in periventricular white matter in the first days of life, whereas PVI is mostly unilateral.
- 10 Approximately 70% of mild cases of PVL may remain undetectable by cranial ultrasonography. MRI, especially diffusion-weighted studies, may identify less severe white matter injury.
- 11 The pathogenesis of PVL relates to hypoxic–ischemic insult affecting watershed zones of arterial supply in periventricular white matter in the immature brain. Impaired cerebrovascular autoregulation, intrinsic vulnerability of oligodendrocyte precursors to free radical attack, and direct white matter injury from inflammatory mediators, e.g., cytokines, endotoxins, are considered to be major pathogenetic factors.
- 12 PVL may be followed by reduced volume of cortical gray matter at term, as documented on MRI studies. This may account for later cognitive dysfunction.
- 13 Central nervous system toxicity of unconjugated hyperbilirubinemia remains poorly understood in premature newborns, in that they often do not demonstrate neonatal encephalopathy or classic features of kernicterus.
- 14 Hearing loss may be the major manifestation of bilirubin neurotoxicity in infants born prematurely.
- 15 The threshold and duration of significant hypoglycemia that results in cerebral injury as well as its suspected synergistic effect with hypoxia–ischemia remain unresolved. Moderate hypoglycemia is associated with a two- to threefold increase in cerebral blood flow.
- 16 Antenatal corticosteroids reduce mortality as well as the overall incidence and severity of GMH–IVH, perhaps by reducing the risk of hemodynamic disturbances from respiratory distress syndrome and by stabilization of vessels in the germinal matrix.
- 17 Prolonged labor and vaginal delivery appear to increase the risk of GMH–IVH in very low birthweight infants.
- 18 Neuromuscular paralysis with pancuronium in premature newborns who require mechanical ventilation is associated with significant reduction in GMH–IVH.
- 19 Long-term neurological sequelae in infants born prematurely correlate closely with the abnormal neurological examination at term and the extent of abnormalities on neuroimaging, especially MRI.
- 20 Approximately 5–15% of infants born prematurely develop cerebral palsy, and an additional 25–50% develop cognitive and behavioral difficulties.

Common problems of the newborn

Fernando R. Moya and Matthew Laughon

Neonatal adaptation to extrauterine life

At birth, the infant must adapt quickly to the more demanding extrauterine environment, in which he or she must take control of vital functions such as gas exchange and body temperature regulation. In preparation for birth, many adaptations are initiated *in utero*, particularly with the onset of labor. Many of the problems that newborns exhibit over the first several days after birth arise from difficulties with this transition.

Circulatory adaptation

The fetal circulation is characterized by a low systemic resistance and a high pulmonary vasomotor tone. *In utero*, the placenta serves as the organ for gas exchange. The distribution of the cardiac output is markedly different between the fetus and the adult. Approximately 30–40% of the fetal cardiac output is conveyed through both umbilical arteries to the placenta. This systemic blood has a PO_2 of approximately 25–30 mmHg and a PCO_2 of 40–45 mmHg. There is a small, but progressive, decrease in umbilical arterial PO_2 with advancing gestational age. However, because this is paralleled by an increase in fetal hemoglobin, the oxygen content of the blood remains constant.¹ After circulation through the placenta, the umbilical venous PO_2 rises to 35–55 mmHg, whereas the PCO_2 drops to 35–40 mmHg. This more oxygenated blood returns to the right atrium via the umbilical vein and the inferior vena cava. The stream from the inferior vena cava is directed preferentially across the foramen ovale to the left atrium, left ventricle, and ascending aorta, thereby perfusing primarily the head and neck vessels as well as the coronary arteries. A smaller fraction of the inferior vena cava return mixes with the superior vena cava flow and passes into the right ventricle and pulmonary artery. During fetal life, the pulmonary vascular resistance is high and opposes pulmonary blood flow. Less than 10% of the fetal cardiac output goes through the lungs and, on returning through the pulmonary

veins, mixes with more oxygenated blood in the left atrium. Most of the pulmonary artery blood flow crosses into the descending aorta through the ductus arteriosus (DA). The high pulmonary vascular resistance is secondary to the low fetal PO_2 , underventilation of the fluid-filled fetal lungs, and the predominance of prostaglandins promoting increased pulmonary vasomotor tone.²

At birth, several events determine a rapid change in the circulatory pattern, ultimately separating the pulmonary and systemic circuits. With the clamping of the cord, systemic vascular resistance increases. The initiation of lung expansion increases the alveolar oxygen concentration and the PO_2 of the blood perfusing the lungs. This increase in oxygenation as well as local production of endogenous vasodilators, such as nitric oxide (NO) and prostacyclin, result in an increase in pulmonary blood flow. The increased venous return to the left atrium via pulmonary veins and the increase in systemic vascular resistance elevate left atrial pressure above that of the right atrium. This causes a functional closure of the foramen ovale. Anatomic closure of this structure usually happens in the weeks following birth, but it may remain open for life. The increased pressures on the systemic circuit, along with the decrease in pulmonary artery pressure, reverse the ductal flow to a predominantly left-to-right shunt. Ductal closure results from constriction of its spiral musculature in response to a higher PO_2 and predominant stimulation of constrictor prostaglandins. The decreasing radius of the DA compromises the nourishment of its endothelium, which ultimately necroses, obliterating its lumen. Permanent anatomic ductal closure may occur up to several weeks after birth. When the DA remains patent, the sustained left-to-right shunt can lead to substantial pulmonary overflow and pulmonary edema. The ability of the DA to respond to oxygen and prostaglandins may be markedly reduced in very immature neonates; hence the higher incidence of symptomatic DA at lower gestational ages. Hypoxemia, the lack of lung expansion, and acidosis at birth are both causes of a persistently elevated pulmonary vascular resistance that can interfere with the transition of the circulation from the fetal to the adult pattern.

Lung expansion and initiation of breathing

The human fetus initiates respiratory movements late in the first trimester of gestation. Subsequently, these movements become stronger and more organized and, near term, there is a pattern of regular breathing at rates similar to those found after birth. Just before the initiation of labor, fetal breathing decreases from 75–85% to only about 15–30% of the time. In preparation for birth, the fetal lungs undergo several changes. The biochemical maturation of the lung in terms of surfactant production is discussed elsewhere in this textbook. *In utero*, the fetal lungs are filled with a fluid rich in chloride ($> 150 \text{ mEq/L}$) and relatively free of protein ($< 0.3 \text{ mg/mL}$). The volume of fluid that occupies the alveolar spaces and airways is similar to the functional residual capacity (FRC) during the neonatal period, namely 30–35 mL/kg body weight.³ Fetal lung fluid is produced at an hourly rate of 4–6 mL/kg body weight. Before delivery, production of fetal lung fluid decreases and active reabsorption begins. This is secondary to hormonal changes that occur with the onset of labor, such as increases in circulating catecholamines and elevations in arginine vasopressin.⁴ At birth, a small proportion of the lung fluid that occupies the airways is squeezed out of the trachea during passage through the birth canal. The majority of the lung fluid is reabsorbed from the alveolar spaces into the pulmonary circulation, which increases with lung expansion in a process involving several ion transporters such as Na-K ATPase and epithelial sodium channels (ENaC).⁵ Approximately 10–15% of this fluid is reabsorbed into the pulmonary lymphatics. The clearance of lung fluid continues for several hours after birth.

To expand the lungs at birth, the infant must generate a large transpulmonary pressure and overcome the resistance of the fluid-filled airways.³ Initial respiratory efforts can generate transpulmonary pressures of 80–90 cmH₂O. This may explain why the spontaneous occurrence of pneumothorax in healthy newborns is not uncommon. The FRC is rapidly established with the first several breaths; however, this may continue to expand to a lesser degree several hours after birth. Infants born by elective Cesarean section have smaller lung volumes than those observed in vaginally delivered newborns.⁶ This difference may persist for up to 48 h after birth. Infants born by Cesarean section with preceding labor constitute an intermediate group. Very immature neonates may have difficulties establishing an adequate FRC with the first few breaths, particularly if they lack adequate amounts of surfactant. The synthesis and metabolism of pulmonary surfactant are discussed in Chapter 6.

Thermoregulation

In utero, the heat generated by the fetus is dissipated by the placenta. Because of the higher metabolic rate of the fetus, its temperature is at or slightly above the maternal core temperature. When there is maternal fever or placental insufficiency,

the ability of the fetus to transfer heat to the mother can be impaired, and the infant may be born with an elevated body temperature.

Heat is exchanged by conduction, convection, evaporation, and radiation. The relative importance of any of these forms of heat exchange varies, depending on the clinical situation. For instance, at birth, the infant is delivered from a fluid, warm environment to cooler and dry surroundings. Hence, evaporation is the main source of heat loss right after delivery.⁷ Unless the infant is dried soon after birth, preferably with warm towels or blankets, rapid cooling will occur. If the term infant is not in need of resuscitation or assistance in transition (suctioning of meconium, poor respiratory effort), close contact with the mother's skin may serve to decrease the surface area for evaporation and to gain heat through conduction from the mother. This beneficial effect in temperature control is in addition to the immeasurable gains that result from early mother–infant bonding.

The newborn infant is at a significant disadvantage in terms of temperature control because of a relatively large surface area, poor thermal insulation from the environment, decreased ability to generate heat through physical activity (shivering thermogenesis), and, especially, no ability to adjust his or her own protection (clothing) from the thermal stress of the environment. Preterm and growth-retarded infants are at an even higher risk of heat loss and hypothermia. Small preterm infants have an incomplete development of the stratum corneum of the skin and poor keratinization. The smaller the infant, preterm or growth retarded, the fewer subcutaneous fat stores it has, which act as insulation from the environment.

For body temperature to remain constant, heat must be generated at the same rate at which it is lost. Neonates have difficulties not only with heat loss, but also with heat production. Most heat production in the newborn is chemically derived from the breakdown of high-energy triglycerides (nonshivering thermogenesis) stored preferentially in brown fat.⁷ This is distributed in the subscapular areas, around the great vessels of the neck and thorax, and around the adrenal glands. Brown fat has numerous capillaries and sympathetic nerve endings. In response to catecholamine stimulation, heat generated through triglyceride breakdown is transferred into the circulation for distribution throughout the body. When the availability of brown fat and substrates is decreased (preterm or growth-retarded infant) or this mechanism is impaired (hypoxia, drugs), heat production is markedly decreased and hypothermia may ensue. The consequences of hypothermia are hypoglycemia, metabolic acidosis, lethargy, and increased oxygen requirements. Also, hypothermia has been associated with a higher mortality at all gestational ages.

After delivery and drying, the newborn should be cared for in a “neutral thermal environment.” This refers to that environmental temperature at which the energy expenditure and oxygen consumption for heat production and maintenance of a normal body temperature is the lowest. The neutral thermal

environment varies inversely with gestational age and postnatal age.⁸

Asphyxia and neonatal resuscitation

During the transition period from fetal life to extrauterine existence, asphyxia, now more commonly known as either neonatal or perinatal depression, is one of many adverse events that may affect the ability of the neonate to survive or to develop to its fullest potential. Although there is disagreement on the definition of asphyxia or neonatal/perinatal depression,^{9,10} the term generally refers to “a condition of impaired blood gas exchange leading, if it persists, to progressive hypoxemia and hypercapnia.”¹¹ Most of the disagreements in its diagnosis arise from attempting to define asphyxia objectively based on Apgar score, fetal heart rate alterations, umbilical cord blood gases, the presence of neurologic abnormalities during the neonatal period, or a combinations of these and other factors. With this approach, asphyxia can be diagnosed reliably only in severely depressed infants. Asphyxia occurs in 2–9 per 1000 births; however, a recent epidemiologic report demonstrates a 90% decrease in the diagnosis of asphyxia from 1991 to 2000.¹²

Mechanisms that result in acute fetal asphyxia usually interfere with the ability of the placenta to exchange oxygen and carbon dioxide. When poor perfusion of the uteroplacental circulation (e.g., maternal hypotension) or separation of the placenta from its insertion (e.g., in abruptio placentae) occurs, the primary consequence is fetal hypoxemia; superimposed ischemia may take place. When the umbilical circulation is compromised (e.g., cord prolapse), the primary consequence is fetal hypercarbia. The severity and rate of progression of asphyxia are highly variable. Asphyxiated infants redistribute cardiac output to the brain, myocardium, and adrenal glands at the expense of blood flow to less vital areas such as the gut, kidneys, muscle, and skin. In addition, the resulting hypoxemia and acidosis may compromise myocardial function to a point at which cardiac output drops. This compromises further oxygen delivery to the tissues.

The best approach to the management of asphyxia is prevention and anticipation. Although asphyxia occurs primarily in high-risk pregnancies, a sizeable proportion of asphyxiated neonates still present without warning. For this reason, per-

sonnel skilled in initiating resuscitation must be present at all deliveries.¹³ At birth, an initial assessment of the infant is made. If the infant appears depressed, then the initial steps of resuscitation include: providing warmth; positioning the infant to open the airway and clearing it as necessary; drying, stimulating, and repositioning; plus giving oxygen as necessary. If there is a history of meconium in the amniotic fluid, management may include endotracheal intubation and suctioning, although this is now reserved primarily for nonvigorous infants¹⁴ (see section on Meconium aspiration syndrome). Moreover, the efficacy of attempting perineal suctioning in the presence of meconium-stained amniotic fluid has been questioned.¹⁵ Subsequent actions are focused on establishing adequate respirations and circulation, and evaluating the neonate.¹⁶

The Apgar score is a useful method to assess the neonate during the early period of transition, as well as to evaluate the response to interventions such as resuscitation (Table 68.1). Respirations, heart rate, and color are more useful in assessing neonatal status and need for intervention than the other components of the Apgar score. Thus, appropriate interventions should not be delayed until the 1-min Apgar score is obtained. A repeat Apgar score must be obtained at 5 min after birth in all infants and every 5 min thereafter up to 20 min of age or until the neonate achieves two consecutive scores above 7 if he/she was depressed at birth. The Apgar score is influenced by gestational age.¹⁷ After performing the initial resuscitative steps, infants who are vigorous, are breathing spontaneously, and have a heart rate above 100 need to be observed closely. Blow-by oxygen must be supplied to those who remain cyanotic despite adequate respirations and heart rate. If the infant is apneic, has inadequate respirations, or has a heart rate below 100, current guidelines recommend initiating positive pressure ventilation with 100% oxygen.^{13,16} However, there is increasing evidence that resuscitation with room air is as effective as 100% oxygen and may result in less mortality in near-term or term infants.^{18,19} Thus, if resuscitation is initiated with less than 100% oxygen, supplemental oxygen up to 100% should be administered if there is no appreciable improvement within 90 s following birth.¹⁶ A good response is primarily indicated by rapid increases in heart rate, although improvements in color and initiation of spontaneous respiratory efforts are also indicators of a positive response. Persistent or prolonged apnea may be a sign of asphyxia or depression by narcotics. Nalox-

Table 68.1 The Apgar score.

Sign	0	1	2
Heart rate	Absent	< 100 b.p.m.	> 100 b.p.m.
Respirations	Absent	Weak cry; hypoventilation	Good, strong cry
Muscle tone	Flaccid	Some flexion	Active motion
Reflex irritability	No response	Grimace	Cough or sneeze
Color	Blue or pale	Body pink; extremities blue	Completely pink

Table 68.2 Medications for delivery room resuscitation.

Drug	Indication	Dose	Route
Epinephrine	Asystole or heart rate of < 60 despite positive pressure ventilation with 100% oxygen and chest compressions	0.01–0.03 mg/kg or 0.1–0.3 mL/kg of 1:10 000 solution up to 0.1 mg/kg or 0.3–1 mL/kg of 1:10 000 solution	i.v. i.t.
Sodium bicarbonate	Metabolic acidosis	2 mEq/kg The use of 4.2% solution is recommended	i.v.
Naloxone (Narcan)	Respiratory depression and maternal exposure to narcotics in previous 4 h	0.1 mg/kg The use of 0.4 mg/mL or 1.0 mg/mL solutions is recommended	i.v., i.t., s.c., i.m.
Volume expander: normal saline, whole blood	Evidence of hypovolemia	10 mL/kg	i.v.

i.m., intramuscular; i.t., intracheal; i.v., intravenous; s.c., subcutaneous.

one (Narcan) can be given in neonates with poor or absent respiratory efforts exposed to maternally administered narcotics within 4 h of delivery.

When the heart rate is less than 60 beats per minute (b.p.m.) and there is no rapid response to positive pressure ventilation, chest compressions must be initiated to maintain an acceptable cardiac output. After 30 s without improvement, epinephrine should be administered. At this time, endotracheal intubation must be performed if it has not been done previously. The main indications for endotracheal intubation are persistent apnea, need for positive pressure ventilation for several minutes, and lack of response to resuscitative maneuvers.¹⁶

The medications needed for delivery room resuscitation are listed in Table 68.2. Administration of epinephrine, preferably intravenously, usually results in a rapid increase in heart rate and cardiac output. The dose may be repeated after 5 min if there is no response. Reasons for poor response to epinephrine are significant acidosis and hypovolemia. If acidosis is suspected, an effort should be made to obtain arterial blood gases. Current guidelines acknowledge that correction of metabolic acidosis with sodium bicarbonate is controversial.¹⁶ Hypovolemia should be suspected when there is a poor response to resuscitation and evidence of poor perfusion, especially if there is a history of abruption, tight nuchal cord, or bleeding. Ideally, group O Rh-negative whole blood should be used when bleeding and acute anemia are suspected. However, crystalline solutions such as normal saline and lactated Ringer's are more readily available and are usually effective.

Infants who suffer any degree of perinatal depression must be observed closely during the first 24–48 h after birth. Vital signs, neurologic findings, and functioning of other systems must be assessed periodically. Multiorgan dysfunction involving the kidneys, liver, and heart is common among neonates with severe perinatal depression.^{20,21} Finally, it is very difficult to correlate asphyxia, using any definition, with long-term neurodevelopmental outcome.^{22–24} Recent clinical trials have

suggested that institution of hypothermia may be of some benefit in reducing the likelihood of a poor outcome among term and near-term neonates born with significant depression and signs of hypoxic–ischemic encephalopathy.^{25,26}

Respiratory problems

Signs of respiratory distress, such as tachypnea, retractions, nasal flaring, end-expiratory grunting, and cyanosis, may be the result of many diseases, some of which involve systems other than the respiratory system (Table 68.3). An adequate history and thorough physical examination may be sufficient to suspect or diagnose the etiology of the respiratory distress. Nevertheless, part of the workup of any neonate with signs of respiratory distress generally includes obtaining a chest radiograph and determining arterial blood gases, even if there is no need for supplemental oxygen.

Respiratory distress syndrome

Respiratory distress syndrome (RDS) due to surfactant deficiency and lung immaturity is one of the most common causes of respiratory difficulty in the neonatal period. Acute and chronic complications resulting from RDS or its treatment remain as frequent causes of morbidity and mortality in neonatal intensive care units.²⁷ The most important risk factor for the development of RDS is preterm birth. The incidence of RDS varies inversely with gestational age and can be as high as 60–70% among infants less than 28–29 weeks of gestation. Conversely, RDS is seldom seen beyond 38 weeks of gestation. Additional risk factors are male sex, Cesarean section delivery, perinatal asphyxia, second twin pregnancy, and maternal diabetes. Preterm delivery is associated with variable degrees of immaturity of surfactant metabolism. Infants who develop RDS have lower amounts of surfactant phospholipids and

Table 68.3 Common causes of respiratory distress in the newborn.

C. Central nervous system disorders (cerebral edema, hemorrhage, infection)

proteins in the airway than control subjects.^{28,29} This deficiency may be the result of abnormalities of surfactant synthesis, secretion, reutilization, or combinations of these factors. Among very immature neonates, there is also substantial structural lung immaturity. The relative importance of this aspect has become more apparent with surfactant replacement therapy. Alterations in lung mechanics that persist after surfactant administration are primarily a reflection of the anatomic immaturity of the preterm lung. Both surfactant deficiency and structural lung immaturity lead to decreased pulmonary compliance and atelectasis. Hypoxemia develops as a consequence of the resulting right-to-left intrapulmonary shunting. Hypercarbia may also occur due to hypoventilation of the lungs. Lack of ductal closure is a common finding among small infants with RDS. This may provide the route for left-to-right shunting and, potentially, pulmonary edema. Leakage of pulmonary capillaries due to hyperemia, hypoxic injury to the alveolar and capillary walls, and volutrauma (overstretching of lung tissue) gives access to plasma proteins into the alveolar sacs. Several of these proteins can inhibit surfactant function.^{30,31} Thus, capillary leakage may play an important role in the pathogenesis of RDS by inactivation of secreted surfactant.

The clinical signs of RDS are tachypnea, nasal flaring, grunting, retractions, and cyanosis in room air. Decreased air entry is found on auscultation. Because these signs are common to other diseases such as pneumonia and heart disease, the diagnosis of RDS is based not only on clinical assessment, but also on the presence of radiographic findings, such as a diffuse

reticulogranular pattern, poor lung expansion, and air bronchograms. Because this radiographic pattern is also observed with group B streptococcal pneumonia, exclusion of the possibility of infection is necessary.³² Typically, in neonates not treated with exogenous surfactant, the severity of RDS increases up to 48–72 h, followed by a gradual improvement. This phase is often preceded by or occurs in association with a marked diuresis. The clinical course of RDS is substantially modified by the administration of exogenous surfactant; however, the timing of diuresis is not influenced by this therapy.^{33,34}

The management of infants with RDS involves general measures such as maintenance of vital signs and thermoregulation, fluid and electrolyte management, nutritional support, and correction of hematologic or acid–base abnormalities. Specific measures consist of oxygen therapy and the use of positive airway pressure, either continuously (CPAP) or by assisted ventilation.³⁵ The goals of this therapy are to maintain acceptable arterial blood gases with as little support as possible, in order to minimize the likelihood of volutrauma and oxygen toxicity. Because neonates have mostly fetal hemoglobin, an arterial PO_2 between 50 and 70 mmHg is sufficient to saturate 90–95% of the hemoglobin. Higher values are not needed and can be deleterious. In fact, it is also possible that arterial PO_2 values slightly below 50 mmHg (saturation readings generally between 85% and 90%) may be as safe in the early neonatal period. Infants receiving oxygen or any form of ventilator assistance must be monitored closely with pulse oximetry and intermittent blood gas analysis. Also, PCO_2 values of less than 40–45 mmHg should be avoided because they have been associated with a higher risk of developing bronchopulmonary dysplasia.³⁶ The role of high-frequency ventilation in the management of infants with RDS remains controversial and is generally reserved for specific instances such as the presence of severe air leaks and pulmonary interstitial emphysema.³⁷

Administration of exogenous surfactant has become the standard of therapy for infants with RDS who are intubated.^{33,38,39} Several types of exogenous surfactant are available for use in neonates. Currently available surfactant preparations consist of either synthetic mixtures of phospholipids or extracts of animal lung surfactant; the latter are currently the most used type (Table 68.4). Animal-derived lung surfactants contain specific surfactant proteins, which are important for the function of surfactant. Their animal origin is of some concern; however, to date, no major significant immune reaction to these proteins has been demonstrated.^{40,41} Clinical trials of newer generation surfactants that contain synthetic peptides that mimic the action of surfactant proteins have shown substantial efficacy and may become widely used in the future.^{42,43} Administration of surfactant can be performed at birth (prophylactic) or after RDS has already been diagnosed (rescue/treatment). With the prophylactic approach, many infants are intubated and may be given surfactant unnecessarily. However, this approach has been shown

Table 68.4 Composition of exogenous surfactants.

Surfactant	Source	Contents	Initial dose (mL/kg)
Exosurf	Synthetic	DPPC, hexadecanol, tyloxapol	5
Survanta	Minced cow lung with synthetic lipids added	Phospholipids, SP-B, SP-C	4
Infasurf	Calf lung lavage	Phospholipids, SP-B, SP-C	3
Curosurf	Pig lung	Phospholipids, SP-B, SP-C	2.5
Surfaxin	Synthetic, new generation	DPPC, PG, synthetic SP-B-like peptide	5.8

DPPC, dipalmitoyl-phosphatidylcholine; SP, surfactant proteins; PG, phosphatidylglycerol.

to result in improved survival in very immature infants in systematic reviews of the subject.⁴⁴ Soon after intratracheal administration of a dose of surfactant, rapid improvements in oxygenation and lung compliance are observed, especially with preparations containing surfactant proteins or a synthetic mimic of them. Accordingly, ventilatory support can be decreased rapidly. Nonetheless, these effects can be transient, and repeat doses of surfactant may be necessary. Administration of surfactant, whether as prophylaxis or as rescue therapy, results in substantial decreases in neonatal mortality and a markedly lower incidence of air leaks such as pneumothorax, pneumomediastinum, and pulmonary interstitial emphysema. The occurrence of complications such as intraventricular hemorrhage and bronchopulmonary dysplasia (BPD), however, has not decreased consistently with surfactant replacement therapy.^{38,39}

Despite widespread availability of surfactant replacement, RDS and other complications of prematurity continue to be responsible for a substantial proportion of deaths and morbidity among preterm infants. Thus, all efforts directed toward prevention of preterm delivery need to be continued and strengthened. In addition, attempts to accelerate fetal maturation with antenatal corticosteroids must be undertaken whenever feasible.⁴⁵ Despite multiple animal studies and promising preliminary clinical data, the addition of thyrotropin-releasing hormone to prenatal corticosteroid therapy has not been shown to be more effective than corticosteroids alone to prevent RDS in the era of widespread surfactant use.⁴⁶ Currently available data strongly suggest that prenatal administration of corticosteroids followed by postnatal surfactant replacement for those infants who develop RDS is the best possible approach to the prevention and treatment of RDS and its complications.⁴⁷

Bronchopulmonary dysplasia

Most neonates with RDS recover completely from their lung disease within the first week after birth. Some, however, develop a form of chronic respiratory disease called BPD. The diagnosis of BPD is based on the presence of tachypnea, retractions, and supplemental oxygen requirement at 28 days after birth. However, a more stringent diagnostic criterion for BPD of need for oxygen therapy at 36 weeks adjusted gestational

age has been recommended because it has been shown to be a more specific predictor of long-term pulmonary morbidity in very low-birthweight infants.^{48,49} Associated chest radiographic findings in infants with BPD include interstitial fibrosis, cystic changes, hyperinflation, and segmental atelectasis. The term chronic lung disease of prematurity (CLD) defined on the basis of clinical criteria (oxygen requirement) only, at either 28 days of age or 36 weeks adjusted gestational age, has also been used to describe infants with prolonged needs for supplemental oxygen due to lung disease. As neonatal intensive care has become more sophisticated over the past three decades, the survival of very low-birthweight infants has increased dramatically, and BPD is now seen in very small infants who did not have RDS or pneumonia in the first week after birth.⁵⁰ This “new BPD” seems to be more the consequence of chronic inflammation, deleterious effects of cytokines and other mediators, and an arrest of the process of normal lung development.⁵¹ The incidence of BPD or CLD varies according to the definition used and the population studied, but is clearly inversely proportional to gestational age. In a retrospective study of 1625 infants with birthweights between 700 and 1500 g treated in eight major medical centers in the United States, the incidence of CLD, defined as an oxygen requirement at 28 days of age, ranged from 6% to 33% in the different medical centers.⁵² Within the entire study population, lower birthweight, white race, and male sex were identified as risk factors for the development of CLD.

The pathogenesis of BPD is multifactorial.^{50–52} Oxygen toxicity and volutrauma have frequently been implicated in the pathogenesis of BPD, but it is very difficult to isolate these factors from the pulmonary immaturity and acute lung injury for which these treatment modalities are used. Pulmonary air leaks, pulmonary edema, patent DA, acquired pneumonia, and poor nutrition are also risk factors for the development of BPD. More recently, it has been reported that various cytokines may play a major role in the pathogenesis of BPD. Moreover, the detrimental effect of these mediators may, in fact, start *in utero*.^{53,54} Pulmonary hypertension and cor pulmonale can be observed in more advanced forms of BPD. Infants with BPD also have an increased susceptibility to severe bacterial and viral infections.

Management of infants with BPD is directed at treating symptoms, optimizing lung growth and healing, supporting general

growth and development, and preventing complications.^{55,56} Treatment strategies include chronic administration of oxygen to attempt to prevent cor pulmonale, aggressive nutritional support, fluid restriction, use of chronic diuretics, bronchodilators, and environmental measures to minimize the risk of respiratory infection. However, the use of many of these interventions is not supported by well-controlled clinical trials.^{57,58} Nonetheless, they are widely used in neonatal intensive care units. Treatment with postnatal corticosteroids has been shown to be of short-term benefit primarily for ventilator-dependent infants with BPD. However, there is increasing evidence of serious adverse neurodevelopmental risks associated with prolonged postnatal corticosteroid therapy.^{59,60} Thus, their use should be extremely limited and should include thorough parental disclosure of the potential side-effects of their use.

The mortality for infants with BPD has decreased over the past decades, but morbidity remains high. Most deaths in infants with BPD are a consequence of cor pulmonale or respiratory infections. In survivors, pulmonary function improves over the first several years of age, although some evidence of increased airway reactivity persists into early adulthood. The association between BPD and long-term neurodevelopmental abnormalities remains a major concern.⁴⁹ With carefully monitored long-term oxygen therapy to reduce the risk of cor pulmonale and aggressive management of nutrition and respiratory infections, the prognosis for infants with BPD may continue to improve.

Meconium aspiration syndrome

Meconium is composed of desquamated cells from the skin and gastrointestinal tract, lanugo, amniotic fluid, and various intestinal secretions, including bile. Whereas meconium is present in the intestine of immature fetuses, it is rarely found in amniotic fluid before 34 weeks of gestation. Beyond this period, meconium can be detected in 10–18% of all deliveries.^{15,61} *In utero* passage of meconium can be a sign of maturation, or it may be triggered by fetal hypoxemia and acidosis. However, there is a poor correlation between meconium staining of the amniotic fluid and umbilical cord acid–base status.⁶¹ Of all infants delivered through meconium-stained amniotic fluid, between 1% and 9% may develop meconium aspiration syndrome (MAS).^{14,15} Many of these cases have delivered through thick meconium.^{62,63}

The presence of meconium in the airway may interfere with the initiation of breathing and may be a cause of difficult resuscitation. In MAS, overall airway resistance is increased, although the airway obstruction is not homogeneous throughout the lungs. Segments of the lungs exhibit alveolar overdistention and air trapping, whereas in others, alveolar collapse predominates. Air leaks (pneumothorax, pneumomediastinum) may frequently be seen among infants with MAS, particularly those who require mechanical ventilation.^{14,15} These alterations lead to variable degrees of ventilation–perfusion abnormalities and intrapulmonary shunting with

resulting hypoxemia.^{64,65} Infants with severe MAS also develop respiratory acidosis. Hypoxemia and acidosis can increase pulmonary vascular resistance and cause right-to-left shunting through the DA, foramen ovale, or both, a condition known as persistent pulmonary hypertension of the newborn (PPHN). This condition may worsen the oxygenation status of the infant. The presence of meconium in the amniotic fluid is a known risk factor for the development of PPHN.⁶⁵ Some infants who have fatal MAS and PPHN have been shown to have excessive development of the muscle layer around the small intra-acinar arterioles of the lung, which predisposes them to PPHN. It has been suggested that these changes result from a chronic and often subclinical hypoxemia *in utero* or subclinical infection.^{66,67} Additional factors that play a role in the pathogenesis of MAS are the chemical pneumonitis induced by the free fatty acids in meconium.⁶⁸

Infants with MAS manifest tachypnea and variable degrees of nasal flaring, retractions, and cyanosis in room air; grunting is less common. The chest appears to be hyperexpanded, and aeration may be decreased on auscultation. Meconium staining of the skin is not uniformly present. Usually, these infants are appropriately grown. However, they may have a low ponderal index, because of recent intrauterine weight loss, or other signs may be present. Radiographic examination reveals hyperexpansion of the lungs, asymmetric areas of atelectasis, and areas that may be completely spared. Pneumothorax and pneumomediastinum are frequent findings.

The management of infants with MAS must begin before delivery. Careful surveillance of fetal well-being is important, particularly if meconium is found in the amniotic fluid. Delivery with intact fetal membranes can obscure the detection of meconium. Detection of meconium in the amniotic fluid mandates the need for the presence of a team skilled in neonatal intubation and resuscitation at delivery.¹⁶ Use of a DeLee catheter to suction the nose and pharynx as soon as the head is delivered and while it is still on the perineum has not been shown to reduce the risk of MAS.¹⁵ Not all infants with meconium-stained amniotic fluid need to be intubated after birth for the purpose of suctioning. The best approach for term infants who have already initiated vigorous respiratory efforts is probably just observation, regardless of the characteristics of the meconium.¹⁴ Efforts to intubate these neonates may be more harmful than helpful. Direct visualization of the larynx and tracheal suctioning is now reserved primarily for infants in need of resuscitation. Thorough endotracheal suctioning will not prevent all cases of MAS.⁶⁹ Furthermore, the use of amnioinfusion also does not prevent MAS.⁷⁰ Subsequent management depends on whether the infant develops clinical signs of MAS. Adequate oxygenation, correction of metabolic acidosis, and support of the circulation are critical to minimize the stimuli for pulmonary vasoconstriction. The routine use of antibiotics in infants with MAS remains controversial.⁷¹ Controlled clinical trials have shown improvements in oxygenation and a lower need for extracorporeal membrane oxygenation (ECMO) with bolus administration of exogenous

surfactant to infants with severe MAS, although this practice remains controversial.^{72,73} A new approach using lavage with surfactant may also prove to be of use in established MAS.⁷⁴

The mortality of infants with MAS used to be as high as 40%, but it has declined dramatically with improvements in care and the availability of ECMO. Most MAS deaths result from PPHN or the consequences of asphyxia. Up to one-third of survivors of MAS may exhibit pulmonary function abnormalities later in childhood, such as airway obstruction and exercise-induced bronchospasm.^{75,76} Meconium contamination of the middle ear at birth may also increase the risk of otitis media in these infants.⁷⁷ The long-term neurologic outcome of infants with MAS can be quite variable and is influenced by the presence or absence of signs of perinatal asphyxia.

Persistent pulmonary hypertension of the newborn

Although right-to-left shunting through the foramen ovale and DA is necessary for fetal survival, persistence of this pattern of circulation results in marked hypoxemia in extrauterine life. Hypercarbia, however, is not a consequence of PPHN. Under normal circumstances, the high fetal pulmonary vascular resistance progressively decreases after birth. Endogenous production of nitrous oxide (NO) seems to play a pivotal role in this process.⁷⁸ With hypoxemia and acidosis, pulmonary vascular resistance will remain high, or it may increase if it had already decreased. Experiments in animal models of PPHN suggest that a lower expression of the enzyme responsible for endogenous NO production, NO synthase, may account for the predisposition to develop PPHN in diseases such as congenital diaphragmatic hernia.⁷⁹ Pulmonary vasoconstriction can also be induced by mediators such as thromboxane A₂ and leukotrienes.⁸⁰ These mediators may play a role in PPHN associated with group B streptococcal infections.

Using an anatomic approach, infants with PPHN can be divided into a group with normal pulmonary vasculature who develop PPHN because of a transient maladaptation (acute asphyxia, pneumonia), another group in which there is underdevelopment of the pulmonary vasculature (pulmonary hypoplasia), and a last group of infants in whom the number of pulmonary vessels is normal, but in whom development of the muscle layer around the intra-acinar arteries is excessive.⁸¹ In the last two groups, the pulmonary vascular abnormalities probably develop days or weeks before birth. Clinically, PPHN has also been classified as primary (i.e., without associated disorders) or secondary to respiratory or other diseases (Table 68.5). A recent study has associated maternal exposure to selective serotonin reuptake inhibitors with a higher likelihood of PPHN.⁸² The diagnosis of PPHN should be suspected when there is a high alveolar to arterial difference of oxygen, even if there is no hypoxemia ($PO_2 < 50$ mmHg). The presence of right-to-left ductal shunting is established clinically by comparing preductal and postductal arterial blood gases or by showing a lower hemoglobin (Hb) saturation in areas perfused by postductal blood with simultaneous preductal readings.

Table 68.5 Diseases commonly associated with persistent pulmonary hypertension of the newborn.

Perinatal asphyxia
Meconium aspiration syndrome
Pneumonia
Respiratory distress syndrome
Polycythemia
Diaphragmatic hernia
Pulmonary hypoplasia
Maternal salicylate use during pregnancy
Maternal selective serotonin reuptake inhibitor use during pregnancy

The absence of ductal shunting does not rule out PPHN as this could be occurring at the level of the foramen ovale. The diagnosis must be done by echocardiography, which also serves to discount the possibility of congenital heart disease and assess myocardial contractility.

The treatment of infants with PPHN is controversial.⁸³ In general, therapy is focused on supporting the systemic circulation by fluid administration and the use of pressor agents, and a series of measures to overcome hypoxemia and acidosis in order to decrease the elevated pulmonary vascular resistance. These have included hyperventilation, alkalization with sodium bicarbonate, and administration of a variety of other medications seeking to dilate the pulmonary vasculature (tolazoline, chlorpromazine, nitroprusside, prostaglandins, nifedipine, amrinone) and provide sedation and muscle paralysis (fentanyl, pancuronium). However, there few if any controlled trials to support the use of most of these therapies.⁸³ A more conservative approach to avoiding the volutrauma resulting from attempts to hyperventilate has been suggested.⁸⁴ With a conservative approach, survival rates of 80–90% have been reported in PPHN.⁸⁵ High-frequency ventilation and ECMO are additional therapies used to treat infants with PPHN.^{86,87} Several controlled clinical trials have shown that the use of inhaled NO therapy improves oxygenation and can reduce the need for ECMO among term infants with PPHN.^{88,89}

Neurologic abnormalities and hearing loss have been reported in up to 50% of survivors of PPHN.^{90,91} However, severe neurodevelopmental impairment is uncommon. It is not well known whether these abnormalities result from hypoxia, associated conditions (hypoglycemia, asphyxia), therapeutic interventions, or combinations of these factors.⁹²

Transient tachypnea of the newborn

The pathogenesis of transient tachypnea of the newborn (TTN) is related primarily to lung fluid reabsorption. This respiratory disease is seen mostly in term or near-term infants but may also affect premature infants.⁹³ With the onset of labor, lung fluid production decreases, and its absorption increases under the influence of catecholamines, vasopressin, and corticosteroids.

Labor markedly influences pulmonary epithelial ion transport so that term infants born by Cesarean section without labor exhibit a delay in the transition from chloride secretion to sodium absorption. Infants with TTN demonstrate a similar abnormality.⁹⁴ Thus, delivery by Cesarean section without labor constitutes a risk factor for TTN.⁹⁵ Some infants who develop TTN have also been shown to have borderline lung maturity on prenatal amniotic fluid analysis.⁹⁶ Additional risk factors are maternal diabetes, prolonged labor, male sex, macrosomia, and asphyxia.⁹⁷ This last complication not only interferes with lung fluid reabsorption, but may also lead to a variable degree of left or combined ventricular failure.^{98,99}

The manifestations of TTN are tachypnea, retractions, grunting, and hyperexpansion of the thorax. These signs are usually manifest by 6–8 h after birth. Onset of respiratory symptoms beyond 24–48 h after birth is usually not due to TTN; hence, other explanations should be sought. The radiologic features of TTN are mild hyperinflation, increased interstitial and vascular markings (primarily around the hilar areas), fluid in the horizontal fissure, and, at times, mild cardiomegaly. Small pleural effusions, mostly on the right side, can be present. A pleural effusion, revealed by radiographic examination where none existed earlier, is more suggestive of infection than of TTN. The presence of radiographic abnormalities indicative of delayed clearance of lung fluid is not necessarily associated with clinical manifestations, especially on radiography performed soon after delivery. There can be variable degrees of hypoxemia and respiratory acidosis. Treatment consists primarily of supportive therapy and administration of supplemental oxygen. Oxygen requirements are variable and can be very high. In addition, some infants may require the use of CPAP or mechanical ventilation for significant respiratory distress or blood gas derangements. The association of TTN with PPHN has also been reported.⁹⁹ The signs of TTN usually last less than 72 h, and pulmonary sequelae are rare.

Hematologic problems

Fetal erythropoiesis occurs primarily in the liver and bone marrow and, to a lesser extent, in the spleen. Extramedullary

erythropoiesis may persist for up to 1–2 weeks after delivery. During the second trimester and early third trimester, over 90% of the hemoglobin of the fetus is HbF, which binds oxygen more avidly than HbA. The p_{50} and p_{90} (i.e., the partial pressure of oxygen at which 50% and 90%, respectively, of the Hb is saturated) are considerably lower in HbF than in HbA. The synthesis of HbA increases as the fetus approaches term, resulting in an increase in total body hemoglobin mass and a decrease in the proportion of HbF to 50–85% of the total.¹⁰⁰ After birth, there is a gradual decline in circulating HbF levels to about 10–15% at 3–4 months of age, and less than 2% by 2 years of age. In certain disorders of HbA synthesis (sickle cell anemia, thalassemia major), the rate of decline of HbF is much slower. The fetal red blood cell has a survival of only 80–90 days.

The normal hematologic values for term infants are seen in Table 68.6. Abnormalities in the white blood cell (WBC) count, such as leukopenia ($< 5000/\text{mL}$), marked leukocytosis ($> 30\,000/\text{mm}^3$), and an increase in the immature–mature neutrophil ratio ($> 0.2\text{--}0.3$) are suggestive of neonatal infection.^{101,102} The platelet count is similar in both preterm and term infants. Although an occasional healthy newborn will have less than $150\,000$ platelets/mL, counts below this level should be considered suspicious; a number below $100\,000/\text{mL}$ is definitely abnormal.

Under normal circumstances, the level of Hb in cord blood is influenced by gestational age and placental transfusion. The increase in Hb with advancing gestation is associated with a mild but significant decrease in umbilical venous PO_2 , ensuring constant oxygen content of the fetal umbilical venous blood throughout gestation. The pool of blood shared by the fetus and the placenta may be preferentially transfused to either of them at the time of delivery. If there is delayed cord clamping, the infant is held lower than the placenta, or if there is a hypoxia-induced increase in placental vascular resistance, the blood volume of the infant may be increased by up to 60%.^{103,104} Conversely, positioning the infant above the placenta or rapid cord clamping may partially deprive the neonate of the placental transfusion. This mechanism may explain the lower cord blood Hb levels observed in neonates born by Cesarean section.

Table 68.6 Normal hematologic values for term newborns.*

Age	Hb (g/dL)	Hct (%)	Reticulocytes (%)	WBC ($\times 10^3/\text{mL}$)	Platelets ($\times 10^3/\text{mL}$)
Cord	16.5 ± 3.0	51 ± 9	3–10	18 ± 9	300 ± 150
1–3 days	18.5 ± 4.0	56 ± 9	3–7	$15 \pm 9^\dagger$	300 ± 150
1 week	17.5 ± 4.0	54 ± 12	$< 2\text{--}3$	12 ± 5	300 ± 150
1 month	14.0 ± 4.0	43 ± 12	–	–	300 ± 150

Anemia

Anemia, defined as a Hb < 13 g/dL in term infants, can be the result of hemorrhage, hemolysis, or decreased red cell production (Table 68.7). It is uncommon to see anemia secondary to combinations of these factors. Clinical and laboratory findings that are helpful in establishing the differential diagnosis of anemia in the newborn are listed in Table 68.8.

Anemia secondary to hemorrhage

Anemia secondary to hemorrhage is a frequent etiology of anemia presenting at birth or soon thereafter. Acute blood loss

presents as signs of hypovolemia including lethargy, poor capillary refill, tachycardia, weak pulses, hypotension, or pallor. Significant blood loss may render an infant unresponsive to the usual resuscitative maneuvers until the intravascular volume depletion is restored. Chronic blood loss over a period of days or weeks permits substantial hemodynamic compensation, so that the main presenting sign is pallor.¹⁰⁵ If the hemorrhage is external, there is no additional bilirubin load to the liver once the postnatal breakdown of Hb begins. This is in contrast to internal hemorrhages (e.g., cephalhematoma) that contribute to elevations in the serum bilirubin and jaundice beyond the first 24–48 h after birth.

External bleeding may be apparent by history (vaginal bleeding in the mother in placenta previa) or physical examination (ruptured umbilical cord). Twin-to-twin transfusion is a type of external hemorrhage that is seen primarily in mono-chorionic twins. The donor twin becomes anemic while the recipient's Hb is increased. Abnormalities of the umbilical cord, such as varices, aneurysm, or velamentous insertion, make it more prone to rupturing; however, a normal umbilical cord may also rupture when stretched excessively, such as in a precipitous delivery, or when attempting to reduce a very tight nuchal cord. Fetal blood loss may occur with an intact tight nuchal cord as the umbilical vein is compressed before the arteries, which continue to direct blood to the placenta.

Substantial bleeding may be occult and thus more difficult to diagnose (fetal-maternal hemorrhage or FMH). FMH is more likely to happen when there are abnormalities of the placenta or instrumentation such as amniocentesis, Cesarean section, or external version. Placental abnormalities such as abruptio placentae, placenta previa, choriocarcinoma, and chorioangioma have been associated with severe FMH.¹⁰⁶ The diagnosis is confirmed by demonstration of fetal erythrocytes in the maternal circulation by Kleihauer-Betke staining or other techniques such as determination of fetal hemoglobin by flow cytometry. The amount of red blood cells lost into the mother can be approximated using several formulas, as reviewed recently by Giacoia.¹⁰⁷

Anemia secondary to hemolysis

Hemolytic anemias usually manifest with pallor and early onset of jaundice, but without signs of hypovolemia. The etiology of hemolysis may be quite variable. ABO or Rh incompatibility and infection are the most common causes of hemolytic anemia in the newborn. Clinical and laboratory findings useful in differentiating hemolysis from other causes of anemia are listed in Table 68.8. ABO hemolytic disease has a wide spectrum from immune hemolysis only, demonstrated by a decreased RBC survival, to severe anemia and, rarely, hydrops fetalis.¹⁰⁸ It usually affects firstborn infants. The diagnosis should be suspected in any newborn with early onset of jaundice with or without significant anemia. Generally, the mother is type O and the infant either type A or type B. The direct Coombs' test can be positive; however, it is often negative because of a low antibody titer and because A or B antigens are more sparsely located in the fetal red blood cells (RBCs). The hemolysis is less aggressive than in Rh isoimmunization.

In contrast, Rh isoimmunization frequently results in more significant degrees of anemia and hyperbilirubinemia.¹⁰⁹ The severity of the hemolysis increases with subsequent pregnancies with Rh-positive fetuses. At birth, affected infants are generally anemic and develop rapidly rising indirect bilirubin levels ($> 0.4\text{--}0.5\text{ mg/h}$). Hepatosplenomegaly is more common than in ABO hemolytic disease. A positive direct Coombs' test is the rule. The blood smear reveals numerous reticulocytes

and nucleated RBCs, but rare spherocytes. In cases with severe hemolysis, thrombocytopenia is often found.

Other causes of immune hemolysis should be suspected in the presence of a positive direct Coombs' test but compatible ABO and Rh types between mother and infant. Minor group sensitization is occasionally a cause of immune hemolysis.¹¹⁰ The maternal history may be suggestive of an autoimmune disorder or of the use of medications capable of inducing an immune hemolytic anemia. In these cases, the maternal direct Coombs' test can be positive.

Viral or bacterial infections are the most common cause of nonimmune hemolysis. These infants usually exhibit signs such as hepatosplenomegaly, petechiae, cutaneous rash, growth retardation, and chorioretinitis. Laboratory findings include thrombocytopenia, leukopenia, evidence of disseminated intravascular coagulation, and increases in direct bilirubin. Abnormalities of the RBC membrane, enzymes, or hemoglobin are uncommon causes of hemolytic anemia in the newborn. Their presence should be suspected with a positive family history, evidence of hemolysis with negative direct Coombs' test, and suggestive findings on a blood smear. The diagnosis is made by identifying the specific defect.

Decreased RBC production

Neonatal anemia due to decreased RBC production is very uncommon. It should be suspected in the presence of anemia with a low reticulocyte count ($< 2\%$) not explained by other obvious causes. Isolated hypoplastic anemia is suggestive of the Diamond-Blackfan syndrome, which also features physical anomalies (cleft palate, abnormal thumbs, ocular defects, short or webbed neck) in 30% of cases. Involvement of WBC and platelet precursors is found in transcobalamin II deficiency and congenital leukemia.

Polycythemia

Polycythemia is defined as a spun peripheral venous hematocrit (Hct) of more than 65%. The site and time of sampling are critical to make the diagnosis.¹¹¹ The venous Hct peaks at 2h after birth and then declines;¹¹² capillary samples are 5–10% higher than simultaneously obtained venous samples. The incidence of polycythemia varies from 1.4% to 1.8% at sea level and is higher at higher altitudes, in small for gestational age (SGA) and large for gestational age infants, and in term and postterm newborns compared with preterm infants.^{113,114} The most common signs and symptoms associated with polycythemia are plethora, lethargy, tachypnea, feeding difficulties, hypotonia, and jitteriness. These signs are also common to other neonatal diseases and are not pathognomonic of polycythemia. Many neonates with venous Hct above 65% are asymptomatic; the majority of those exhibiting symptoms are hyperviscous.^{111,115} However, viscosity measurements are not widely available, and it is uncertain what actually represents hyperviscous values.^{111,116} The symptomatology in these infants may be secondary to sluggish tissue

Table 68.9 Etiology of neonatal polycythemia.

Increased erythropoiesis	Transfusion
Intrauterine hypoxia:	Delayed cord clamping
Small for gestational age	Intentional
Postmaturity	Unassisted delivery
Toxemia	Twin–twin transfusion

blood flow and to associated problems, such as hypoglycemia, hypocalcemia, or asphyxia.

Polycythemia may result from either a chronic increase in the RBC mass or an acute expansion of the circulating blood volume with subsequent increases in Hct when transudation to the interstitial compartment occurs (Table 68.9). *In utero*, hypoxia stimulates erythropoietin production, which in turn promotes erythropoiesis (SGA, postmaturity). These infants are generally not hypervolemic and can have elevated reticulocyte counts.¹¹⁷ Conversely, infants with polycythemia due to transfusion may be hypervolemic.

Although there are no generally accepted criteria for the treatment of polycythemia, most centers will intervene in all infants with central venous Hct above 70% or those with Hct above 65% if they are symptomatic.¹¹⁸ Treatment consists of a partial exchange transfusion to lower the Hct to a range at which blood viscosity will also be much lower. The formula used to calculate the volume to exchange is: volume (mL) = blood volume \times (observed Hct–desired Hct)/observed Hct, where blood volume is 80–100 mL/kg body weight. The use of normal saline or lactated Ringer's for the isovolemic exchange effectively lowers viscosity, although albumin can also be used.^{118,119} However, the long-term benefits of partial exchange transfusion have not been clearly demonstrated. The long-term outcome of these infants depends on the etiology of the problem, and the presence of associated conditions that may also have an effect on neurologic development (hypoglycemia, asphyxia, infection). Regardless of treatment, infants with polycythemia and hyperviscosity are at increased risk of neurologic deficits and developmental delay.^{115,120}

Hyperbilirubinemia

Although all newborns will have elevated levels of serum bilirubin compared with adult standards, not all will have a serum

Table 68.10 Physiologic and pathologic jaundice.

	Physiologic	Pathologic
Time of onset	> 24 h	< 24 h or > 1 week
Peak bilirubin level	8–12 mg/dL	> 12 mg/dL (term) > 12 mg/dL (preterm) > 5 mg/dL/day
Timing of peak	3–4 days	> 1 week (term) > 2 weeks (preterm)

level exceeding 4 mg/dL and become visibly jaundiced.¹²¹ The toxicity of bilirubin results from its binding to key proteins in the cell and mitochondria, leading to the uncoupling of oxidative phosphorylation and resultant lack of internal energy for cellular metabolism, although other mechanisms are also involved.¹²² This is most crucial in tissues of high metabolic rate and with little capability of regeneration (e.g., the brain).

Between 75% and 90% of bilirubin is derived from the breakdown of hemoglobin from either aged RBCs or ineffective erythropoiesis.¹²³ Bilirubin is bound to albumin in the bloodstream and transported to the liver. There, it is conjugated by glucuronyl transferase and excreted through the bile into the intestinal tract. After the first week after birth, intestinal bacteria convert the conjugated bilirubin to stercobilin, excreted in the stool, and to urobilinogen, a water-soluble colorless pigment that is excreted into the urine.

Table 68.10 outlines the primary definitions of physiologic and pathologic jaundice. Pathologic jaundice most commonly results from excess RBC mass as in polycythemia, or excess RBC destruction. Examples of excess destruction include hemolysis (as in hemolytic disease of the newborn), RBC defects (e.g., spherocytosis), and internal hemorrhages (e.g., cephalhematoma). Several factors, such as acidosis, hypoxia, hypothermia, and medications, reduce binding of bilirubin to albumin and may interfere with its transport to the liver.¹²³ Decreased conjugation of bilirubin is seen in neonatal hypoglycemia and hypothyroidism. Decreased excretion occurs with certain infections (e.g., transplacental infections, bacterial sepsis, urinary tract infections), genetic enzymatic defects (e.g., Dubin–Johnson), biliary atresia, cystic fibrosis, galactosemia, and with prolonged use of parenteral nutrition.

All term infants should be examined periodically for the presence of jaundice.¹²⁴ Recently, a risk index or score has been developed to predict which infants will develop a serum bilirubin > 25 g/dL.¹²⁵ Some authors advocate a system-based approach to prevent kernicterus by performing universal screening and plotting the results on an hour-specific nomogram to guide follow-up (Fig. 68.1).^{126,127} Regardless, the jaundiced infant should be carefully evaluated prior to institution of therapy. A complete blood count (CBC) should be performed looking to ascertain red cell number and morphology. A high reticulocyte count indicates rapid RBC turnover. If the direct fraction of bilirubin is elevated, transplacental viral and

Figure 68.1 Nomogram for designation of risk in well newborns based on the hour-specific serum bilirubin values. From Bhutani VK, Johnson LH, Keren R. Diagnosis and management of hyperbilirubinemia in the term neonate: for a safer first week. *Pediatr Clin North Am* 2004;51:843–861.

parasitic infections should be considered. Blood type determination should be performed on the mother and infant, looking for incompatibility, primarily within the ABO and Rh blood group systems. The presence of an antibody should be sought by performing a Coombs' test. If no etiology is ascertained, a urinalysis and urine culture (urinary tract infection), and possibly a urine-reducing substance test (galactosemia) and a serum T₄ (hypothyroidism) should be performed, even though these etiologies usually present with jaundice either after feedings (lactose) have been introduced or beyond the first several days respectively.¹²⁴

The goal of treatment is to reduce bilirubin encephalopathy, which is the toxicity of an elevated serum bilirubin; this is commonly called kernicterus. However, the term kernicterus refers specifically to bilirubin staining of the basal ganglia, which may be a perimortem or postmortem event.¹²⁸ No "toxic" level of bilirubin has been adequately defined.¹²⁹ Historically, a level of > 20 mg/dL has been associated with an increased risk of central nervous system pathology among term or near-term neonates. However, the basis for this assumption continues to be questioned.¹³⁰ The primary therapies for hyperbilirubinemia have been exchange transfusion and phototherapy. Exchange transfusion has many complications including thrombosis, cardiac arrhythmias, electrolyte disturbances, problems of coagulation, and a potential for infection from the invasive procedure and from the donor blood. The historical mortality is approximately 1%, with morbidity as high as 30–79%, although the majority of adverse events associated with exchange transfusion are laboratory abnormalities and are asymptomatic and treatable.^{131,132} Phototherapy is the mainstay of therapy for hyperbilirubinemia. Phototherapy causes photoisomerization of bilirubin molecules into structural isomers that are excreted through the liver and urine.¹³³ Although phototherapy helps to slow the rate of rise of bilirubin, once it is discontinued, there tends to be a 1–2 mg/dL rebound in the next 12–24 h.

Table 68.11 Adverse effects of phototherapy.

Metabolic

- Increased insensible water loss
- Overheating
- Hypocalcemia (white phototherapy)
- Decreased riboflavin (blue phototherapy)

Gastrointestinal

- Loose, watery stools
- Lactase deficiency

Skin

- Bronzing
- Rashes
- Dark-skinned infants pigment faster

Other

- ? Retinal degeneration
- ? DNA damage
- Electrical shock

Phototherapy has numerous side-effects, which are listed in Table 68.11.^{131,133}

Despite the rising tide of technology in medicine, there is much we presently do not know about the long-range and more subtle types of developmental influences of bilirubin.¹²⁹ Hyperbilirubinemia affects each child on an individual basis, and clinicians must be aware of the possible ramifications that even moderate levels of jaundice may contribute in very subtle ways to developmental disability.

Metabolic problems

Hypoglycemia

At the time of delivery, blood or plasma glucose in the fetus is approximately 80–90% of the maternal concentration. SGA

fetuses may have below normal blood glucose values. This has been attributed primarily to reduced supply across the placenta.¹³⁴ With cord clamping, the neonate is separated from the steady supply of maternal glucose and must resort primarily to mobilization of glycogen stores or an exogenous supply of glucose (feeding, parenteral) to remain normoglycemic. Maintenance of an adequate circulating glucose concentration is critical because it is the principal nutrient used by the neonatal brain, although use of ketone bodies may also provide energy to the brain of the neonate. Gluconeogenesis, mainly through alanine, also contributes to glucose homeostasis after birth.¹³⁵ The processes of glycogen breakdown and gluconeogenesis are influenced by hormones such as glucagon, growth hormone, and cortisol, all of which increase markedly after birth. Epinephrine is not an important regulator of glucose metabolism at birth; however, its concentration increases with hypoglycemia. Glucose homeostasis depends not only on its availability, but also on its rate of use. Imbalances between glucose availability and the rate at which it is removed from the circulation result in either hypoglycemia or hyperglycemia.

The cord blood glucose concentration is influenced by the maternal concentration of glucose during labor and delivery.¹³⁶ Maternal hydration with glucose-containing solutions prior to Cesarean section or during oxytocin induction can result in maternal and fetal hyperglycemia and fetal hyperinsulinemia. This relative insulin excess may precipitate a more rapid or profound decrease in postnatal glucose concentrations.^{137,138} An exaggeration of this mechanism is responsible for the early onset of hypoglycemia in the infants of diabetic mothers.

In normal term neonates delivered vaginally to healthy mothers, there is a rapid fall in plasma glucose to 56 ± 19 mg/dL (mean \pm standard deviation) at 1 h and 70 ± 13 mg/dL at 3 h after birth. Then, plasma glucose values remain fairly stable for the first week after birth.^{139,140} Normal glucose values in preterm infants are slightly less than those in term infants. Although the definition of hypoglycemia remains controversial, adoption of pragmatic threshold blood glucose concentrations when clinical intervention should be considered has been recommended, particularly in the presence of neurological signs suggestive of hypoglycemia.¹⁴¹⁻¹⁴³ Attention must be paid to whether the values represent plasma or whole blood glucose, as the former are usually between 10% and 15% higher. The common use of rapid reagent strips is acceptable for screening and follow-up of blood glucose levels well within the normal range. However, low values must be confirmed by laboratory determination of true glucose concentrations.^{144,145} The presence of a high Hct level may interfere with blood glucose determinations using reagent strips.¹⁴⁶

The causes of neonatal hypoglycemia are listed in Table 68.12. An altered endogenous glucose production secondary to lack of glycogen storage is the main reason for the common occurrence of hypoglycemia in preterm and SGA infants. Both these groups are also at risk of complications that may increase peripheral glucose use, such as hypoxia, cold stress,

Table 68.12 Common causes of neonatal hypoglycemia.

I. Altered glucose production:
A. Lack of glycogen stores
Prematurity
Small for gestational age
B. Failure of glucose mobilization
Endocrine disorders
Panhypopituitarism
Cortisol deficiency
Glucagon deficiency
Metabolic disorders
Galactosemia
Glycogen storage disease, type 1
Hereditary fructose intolerance
Tyrosinemia
II. Excess glucose utilization:
A. Hyperinsulinism
Infant of diabetic mother
Excess glucose administration during labor/delivery
Erythroblastosis fetalis
Beckwith-Wiedemann syndrome
Beta-cell hyperplasia/nesidioblastosis
Malposition of umbilical arterial catheter (T11-L1)
Leucine sensitivity
Maternal drugs (thiazides, beta-adrenergic tocolytics)
B. Increased peripheral demands
Hypoxia
Cold stress
Infection
Polycythemia/hyperviscosity

and infection. Hypoglycemia may also result from endocrine or metabolic disorders that lead to decreased hepatic glucose output. As a group, these disorders are uncommon; however, hypoglycemia is sometimes the presenting manifestation. Infants with panhypopituitarism are of normal weight and length at birth, but the finding of hypoplastic genitalia in male infants (small phallus and scrotum, undescended testis) may suggest this diagnosis. Hepatomegaly, jaundice, and metabolic acidosis are all findings suggestive of a metabolic disorder.

Hypoglycemia due to an insulin excess is most often a result of maternal diabetes. Excessive maternal glucose administration during labor and delivery may produce a transient neonatal hyperinsulinemia and rapid fall in glucose. However, persistently low glucose values should be interpreted as secondary to other causes of hypoglycemia. Infants of diabetic mothers can be large for gestational age, mostly on the basis of weight, but have a head circumference within normal limits. They may exhibit mild degrees of organomegaly and signs of plethora. They are also at high risk of having other metabolic abnormalities (hypocalcemia, hypomagnesemia), respiratory distress, and congenital anomalies most commonly involving the central nervous and cardiovascular systems. Infants of diabetic mothers may develop hypoglycemia soon after birth, and they often remain asymptomatic despite very low glucose

values. Organomegaly and other anomalies (e.g., macroglossia, omphalocele, hemihypertrophy, and abnormal ear lobe grooves) are suggestive of Beckwith–Wiedemann syndrome. Hyperplasia of islet cells has been demonstrated in infants with this syndrome and in those with erythroblastosis fetalis. In erythroblastosis fetalis, it has been postulated that the massive hemolysis results in the release of glutathione and inhibition of circulating insulin, with compensatory islet cell hyperplasia. Hypoglycemia secondary to any form of beta-cell hyperplasia may be severe and can persist for several weeks to months. Increased peripheral use of glucose can be seen with hypoxia, cold stress, infection, and polycythemia, despite the presence of adequate glycogen storage and normal insulin levels.

The management of hypoglycemia begins with recognition of the factors that place the neonate at high risk of this condition, so that early glucose screening can be instituted. Attempts to avoid maternal hyperglycemia during labor and delivery must be stressed. The treatment of neonatal hypoglycemia depends on its severity and the availability of the enteral route. In infants with borderline low values detected by reagent strip and no contraindication for feedings, a confirmatory blood or plasma glucose test must be made followed by feeding of 5% dextrose or formula. The latter provides other nutritional sources for energy and gluconeogenesis besides carbohydrates. If correction to euglycemic levels is observed with this intervention, feedings should be advanced as tolerated, and close monitoring of glucose must be continued for at least 24–48 h. Failure to correct glucose levels with this approach or an inability to use the enteral route are indications for parenteral glucose administration. Correction of very low glucose values (< 20–25 mg/dL) is best accomplished by intravenous administration of a minibolus of 200 mg/kg of glucose followed by a constant glucose infusion of 6–8 mg/kg/min.¹⁴⁷ The use of boluses of 25–50% dextrose can result in significant hyperglycemia and rebound hypoglycemia, and should therefore be avoided. A peripheral vein is the preferred route for parenteral glucose administration. The umbilical vein can be used for short-term glucose infusion; however, concerns about infection make it a less desirable route for long-term use. Glucose administration through umbilical arterial catheters placed between T11 and L1 can result in high rates of glucose delivered to the pancreatic vessels and reactive hyperinsulinemia, which resolves after withdrawal of the catheter tip to a lower position. The rate of glucose infusion should be adjusted to maintain normoglycemia. Feedings should be given concomitantly with parenteral glucose whenever possible, unless they constitute the etiology of the hypoglycemia (i.e., galactosemia, tyrosinemia). A high glucose requirement to maintain normoglycemia is suggestive of hyperinsulinism and excess glucose use. If rates in excess of 12–15 mg/kg/min glucose are required, additional therapy is indicated. Corticosteroids (hydrocortisone, 5 mg/kg/day, or prednisone, 2 mg/kg/day), glucagon (300 µg/kg), diazoxide (10–15 mg/kg/day), and epinephrine have been used for the

control of hypoglycemia. Corticosteroids act primarily by enhancing gluconeogenesis, whereas glucagon and epinephrine increase glycogen breakdown. Epinephrine also has a powerful anti-insulin effect. Diazoxide suppresses pancreatic insulin secretion. Also, the hormone somatostatin has been used for control of hypoglycemia when hyperinsulinism is suspected.¹⁴¹

The prognosis for infants with neonatal hypoglycemia depends on its etiology, the presence of clinical signs and associated conditions, and the duration of hypoglycemia. Neonates with significant seizures secondary to hypoglycemia have a risk of up to 50% of an abnormal neurologic outcome.¹⁴² Abnormal neurologic features observed after neonatal hypoglycemia include low IQ score, seizure disorder, and motor deficits (spasticity, ataxia). These features are the neuropathologic reflection of cortical damage due to the lack of glucose.^{148,149} A still unresolved issue is whether marginal or transient hypoglycemia can lead to or worsen damage. Data from a study in preterm neonates suggested that, contrary to general belief, moderate degrees of hypoglycemia can have a significant effect on long-term neurodevelopmental performance.¹⁵⁰ Whether the same is true for term and postterm neonates is not known. However, until the safety of moderate and usually asymptomatic hypoglycemia is demonstrated, neonates with borderline or mildly decreased glucose levels should be properly identified and treated expeditiously.

Hypocalcemia

During the second half of pregnancy, there is rapid fetal accretion of calcium at rates of 110–150 mg/kg/day. Fetal accretion of phosphorus and magnesium is also high. The concentrations of these minerals are higher in cord blood than in the maternal circulation.¹⁵¹ The cord blood levels of hormones involved in calcium homeostasis are also different from the mother and reflect attempts by the fetus to maximize bone mineralization (Table 68.13). A steady decrease in serum

Table 68.13 Approximate mineral and hormonal levels in maternal and cord blood.

	Maternal	Cord
Minerals (mg/dL)		
Ca	9.2 ± 0.3	10.4 ± 0.5*
iCa	4.5 ± 0.2	5.6 ± 0.3*
P	4.3 ± 1.6	5.8 ± 1.2*
Mg	1.8 ± 0.1	2.0 ± 0.1*
Hormones (% of maternal level)		
Calcitonin	–	180%
Parathormone	–	80–100%
25-OH vitamin D	–	80
1-25 (OH) ₂ vitamin D	–	30–40%

*Significantly different from the maternal value.

calcium and ionized calcium (iCa) is observed after birth, reaching a nadir at approximately 24 h of age and remaining low for 48–72 h.¹⁵² This decrease in circulating calcium is due to interruption of the transplacental supply and the predominance of hypocalcemic hormones such as calcitonin and glucagon. Both these hormones increase after birth in normal term neonates, and even further elevations are seen with neonatal asphyxia.^{153,154} Unlike small preterm infants, term neonates are able to increase parathyroid hormone (PTH) levels in response to decreasing calcium concentrations.¹⁵⁵ The postnatal decrease in serum calcium is also prompted by the transient endogenous phosphorous load secondary to tissue breakdown, which cannot be excreted rapidly by the kidneys.

Neonatal hypocalcemia has been defined as a serum calcium level of $< 7\text{--}8\text{ mg/dL}$.¹⁵⁶ In a large proportion of sick preterm infants, serum calcium levels fall to $< 7\text{ mg/dL}$. Because the physiologically important fraction is the iCa, and its concentration cannot be reliably predicted from total calcium determinations, direct measurement of iCa with new electrodes suitable for this purpose has been advocated.¹⁵² Hypocalcemia has been classified as early, which occurs in the first few days after birth, and late, which presents after day 4 or 5. At term, early neonatal hypocalcemia is most commonly seen in asphyxiated neonates and infants of diabetic mothers. In asphyxia, the pathogenesis of hypocalcemia is related to the large phosphorus load secondary to tissue damage and to exaggerated increases in calcitonin and glucagon. In these infants, hypocalcemia may occur despite increased levels of PTH.¹⁵⁴ In contrast, infants of diabetic mothers can show a decrease in PTH secretion during the first days after birth.¹⁵⁷ This has been attributed to fetal and neonatal magnesium deficiency secondary to the chronic maternal loss of magnesium seen with diabetes. Secretion of PTH depends on magnesium concentrations. Other infants at risk of hypocalcemia are those subjected to rapid changes in serum pH, either by correction of acidosis or by hyperventilation, and those who undergo exchange transfusions with blood containing citrate and phosphate as anticoagulants or buffers, which can bind calcium.¹⁵⁸ Late neonatal hypocalcemia may be secondary to a variety of disorders. Abnormalities of calcium and magnesium absorption may present at this time. These may be due to primary intestinal abnormalities or deficiencies in vitamin D metabolism. Ingestion of large phosphorus loads (e.g., from cow's milk) or deficient renal excretion (renal failure) may cause hyperphosphatemia and secondary hypocalcemia. Parathyroid disorders may also present at this time. Primary hypoparathyroidism is seen in DiGeorge's syndrome, which also features abnormal facies, cardiac anomalies (usually conotruncal or of the aortic arch), and defects in T-cell function because of thymic hypoplasia. Maternal PTH excess usually results in transient suppression of neonatal parathyroid function.¹⁵⁹ Protracted hypocalcemia with varying degrees of hyperphosphatemia is suggestive of this diagnosis even in the absence of a positive maternal history.

Neonatal hypocalcemia is often asymptomatic. The signs

suggestive of hypocalcemia are primarily jitteriness and irritability, although apnea or seizures can sometimes occur. However, they are not specific and can also be elicited by hypoglycemia, hypomagnesemia, narcotic withdrawal, neurologic disorders, or infection. Chvostek's and Trousseau's signs are uncommon. Heart failure has also been described with severe hypocalcemia.¹⁶⁰ Signs of hypocalcemia are generally seen only when the iCa falls to very low levels. Disappearance of the symptomatology with calcium treatment supports the diagnosis of hypocalcemia. Serial determinations of serum calcium should be performed in neonates at high risk of hypocalcemia and those with suggestive signs. Although iCa measurements are ideal for diagnosing hypocalcemia, they may not be widely available. Persistently low serum calcium values constitute an indication for magnesium and phosphorous determinations. Total protein and albumin measurements are also useful because hypoproteinemia is associated with low serum calcium values; however, in these cases, the iCa is normal. Although the QT interval of the electrocardiogram may be prolonged in hypocalcemia, it is generally not useful in the nursery.¹⁶¹ Chest radiography and echocardiography are useful when DiGeorge's syndrome is suspected. Despite the thymic hypoplasia of these infants, their lymphocyte count may be normal soon after birth.

Treatment of hypocalcemia is reserved primarily for symptomatic infants. The therapy consists of intravenous administration of 10% calcium gluconate (9.4 mg of elemental calcium/mL) in doses of 100–200 mg/kg, followed by a continuous infusion of approximately 400–800 mg/kg/day. Intravenous calcium gluconate must be administered slowly and with cardiac monitoring because of the possibility of bradycardia. Bolus infusion of calcium gluconate results in marked and transient elevations in serum calcium and iCa. The patency of the vein must be ascertained because extravasation of calcium salts results in skin necrosis. Whether asymptomatic neonates with low serum calcium ($< 7\text{ mg/dL}$), particularly preterm neonates, should be treated is controversial because serum calcium usually returns to normal values spontaneously after the first 3–4 days after birth. Furthermore, controlled studies to evaluate the treatment of hypocalcemia conducted in sick preterm infants with serum calcium levels of $< 6\text{--}7\text{ mg/dL}$ have failed to show any significant benefit of parenteral calcium administration.^{162,163} These findings suggest that, for a majority of newborns, hypocalcemia primarily represents a biochemical abnormality that only merits treatment in a few of them. If serum calcium remains low beyond 4–5 days after birth, or it is refractory to the usual therapy, further evaluation is necessary. Oral calcium gluconate or vitamin D analogs have been used with very limited success to treat or prevent neonatal hypocalcemia. However, the majority of infants with low serum calcium levels either are too sick to be fed or develop hypocalcemia before feedings are initiated or advanced to substantial volumes. The therapy also depends on the etiology of hypocalcemia (e.g., use of low-phosphorous formula for hypocalcemia secondary to

hyperphosphatemia, administration of vitamin D for its deficiency, or hypoparathyroidism).

The long-term outcome of neonates with hypocalcemia depends primarily on the associated problems (asphyxia, DiGeorge's syndrome) rather than on the presence of symptoms or serum calcium values. If seizures due to late-onset hypocalcemia are recognized and treated appropriately, the prognosis is almost invariably normal.¹⁶⁴

Hypomagnesemia and hypermagnesemia

Fetal serum magnesium as well as magnesium accretion increase during the third trimester of pregnancy. Preterm infants have slightly higher serum magnesium than those born at term, probably as a reflection of lower renal excretion. Magnesium and calcium homeostasis is related primarily through PTH and the exchange of these ions in bone. Acute changes in serum magnesium concentrations are inversely related to PTH secretion, but not to calcitonin secretion.^{165,166} However, a chronic magnesium deficiency with depletion of tissue stores reduces PTH secretion. This mechanism may be largely responsible for the hypomagnesemia and hypocalcemia of infants of diabetic mothers.^{167,168} Magnesium is actively transported across the placenta and, after therapeutic use of magnesium salts in the mother, fetal serum magnesium also increases to approximately 80–90% of the maternal concentration.¹⁶⁹ Under normal circumstances, there is a slow and small increase in serum magnesium after birth.¹⁷⁰ Retrospective evidence had associated prenatal exposure to magnesium sulfate with lower rates of cerebral palsy and intracranial hemorrhage. However, a recent systematic review does not suggest a major role for antenatal administration of magnesium as a useful neuroprotective intervention.¹⁷¹

Neonatal hypomagnesemia is defined as a serum magnesium level of < 1.6 mg/dL.¹⁷⁰ It has been described in 9–38% of infants of diabetic mothers and in SGA infants.^{172,173} Low serum magnesium has been reported in up to 30% of infants with polycythemia; however, a good correlation between Hct and serum magnesium does not exist. Whether birth asphyxia is, *per se*, a risk factor for hypomagnesemia is controversial. Hypocalcemia often coexists in neonates with hypomagnesemia. Hypoparathyroidism, hyperphosphatemia, and exchange transfusions with citrated blood also constitute risk factors for hypomagnesemia.¹⁵⁸ Deficient magnesium absorption leading to low serum magnesium levels has been described as a primary disorder and is also seen in infants with short gut.

The signs of hypomagnesemia are similar to those of hypocalcemia. Signs of hyperexcitability soon after birth often present despite normal serum iCa and glucose.¹⁷³ The treatment of hypomagnesemia consists of administration of magnesium sulfate 50% (50 mg of elemental magnesium/mL) in doses of 0.05–0.25 mL/kg intravenously. Oral supplementation using the same dose can be used in neonates without severe signs such as seizures. Only careful follow-up of serum

magnesium is indicated in asymptomatic infants with normocalcemia but low serum magnesium levels because hypomagnesemia, with few exceptions, is usually transient.

The upper range of serum magnesium in infancy has been reported as 2.8 mg/dL. However, studies have shown that normal term infants usually have serum magnesium below 2.4 mg/dL.¹⁷⁰ Thus, neonatal hypomagnesemia at term is best defined as serum magnesium above 2.5 mg/dL in the first few days after birth. The pathogenesis of neonatal hypermagnesemia is almost invariably the use of magnesium salts in the mother. The adverse neuromuscular effects of magnesium excess derive mostly from its interference with the acetylcholine release at the neuromuscular junction. Clinically, this translates primarily as muscle weakness and lethargy. These signs may interfere with gestational age assessment using neurologic signs.¹⁷⁴ There is no good correlation between serum magnesium and presence of signs of hypermagnesemia. Delayed passage of stools, abdominal distention, and even meconium plug syndrome have also been described in preterm neonates of hypertensive mothers with hypermagnesemia.^{174,175} Term infants with serum magnesium below 4 mg/dL are usually asymptomatic or exhibit mild hypotonia. Respiratory depression and apnea may occur with higher levels, particularly in preterm infants.¹⁷⁶ However, asphyxia is uncommon among term infants born to mothers exposed to the usual doses of magnesium sulfate. Although hypermagnesemia suppresses PTH secretion, a decrease in serum calcium following magnesium sulfate therapy has been observed primarily in the mothers and not in their offspring. Despite the suppression of PTH in the infant, serum calcium remains stable or may even increase as a result of an enhanced exchange of magnesium in the bone surface. The treatment of hypermagnesemia consists of support of the cardiorespiratory and renal function as serum magnesium decreases quickly in 48–72 h to levels not usually associated with symptoms. More aggressive therapy, such as exchange transfusion, is not indicated unless there are signs of cardiovascular collapse and renal failure. In these rare cases, the potential benefits of an exchange transfusion must clearly outweigh those of supportive therapy to justify the use of exchange transfusion.

Sepsis/infection

Sepsis, the common term for any viral, bacterial, or parasitic systemic infection of the newborn, is seen in approximately 32 000 full-term births each year in the United States.¹⁷⁷ The two primary modes of infection in the neonatal period are transplacental infection of the fetus and ascending infection in the perinatal period.¹⁷⁸ The term TORCH was popularized in the mid-1970s to denote the transplacental infections of toxoplasmosis (TO), rubella (R), cytomegalovirus (C), and herpes (H). This acronym is easy to remember but, unfortunately, has diverted the focus from the likelihood and evaluation of specific transplacental infections including those mentioned above

and a variety of other organisms.^{178,179} The neonatal problems observed with infections caused by agents in this group are reviewed in detail in Part V. Infections may have profound effects on development early in the pregnancy, altering the growth of the fetus; in later pregnancy and after birth, they may disrupt the normal formation and function of tissues and organs.

Signs and symptoms of infection may resemble or be disguised by other illnesses of the newborn.¹⁸⁰ Common signs of infection are poor temperature control and apnea; fever is very uncommon in the newborn. Other signs include respiratory distress, poor perfusion, lethargy or irritability, poor feeding tolerance, and hypoglycemia. Irritability may arise from inflammation of the membranes surrounding the brain, but is seen more often with birth asphyxia, drug withdrawal, or central nervous system hemorrhage. Similarly, rather than identifying an infected newborn, hypoglycemia is seen more commonly in the growth-retarded or large for gestational age infant. Physical findings suggesting infection include skin lesions, petechiae, and organomegaly. However, these are generally uncommon.

Neonatal sepsis has been divided into “early onset infections,” which usually present at birth or during the first 48–72 h after delivery, and “late onset infections,” which appear beyond this period. The most common organisms causing either early or late onset bacterial or fungal sepsis in the neonatal period are listed in Table 68.14. The incidence of group B streptococcal (GBS) infection has fallen dramatically (to less than 1 per 1000 live births) over the past 10 years, primarily because of intrapartum antibiotic prophylaxis.¹⁷⁷ This is usually an ascending infection, and the newborn, although colonized at birth, may not be symptomatic for several days. Infections with Gram-negative bacteria are even less common than GBS infection.¹⁸¹ It has been suggested recently that the widespread use of antibiotic prophylaxis to prevent GBS disease with drugs such as ampicillin has led to an increase in the rate of significant neonatal infections by

Gram-negative bacteria.¹⁸² Nosocomial infections usually manifest beyond 5–7 days after birth and are more common among very premature infants.¹⁸³ They are caused most frequently by coagulase-negative *Staphylococcus* species, although other Gram-positive and Gram-negative organisms are detected not infrequently. *Candida* species are most common among extremely low-birthweight infants and generally carry a poor long-term outcome.¹⁸⁴

The treatment of the neonate with a bacterial or fungal infection is relatively simple. If infection is suspected, cultures of blood, spinal fluid, and urine should be taken. Initially, the choice of antibiotics depends on the suspected organisms. Once culture results are available, they can be adjusted to the specific organisms. Viral and protozoan infections are difficult to treat. The antibiotics available to treat them are generally toxic and have very limited application.

Necrotizing enterocolitis

Necrotizing enterocolitis (NEC) is a multifactorial disease.¹⁸⁵ It is the most commonly acquired serious gastrointestinal disease in the neonatal intensive care unit. It affects predominantly premature infants of less than 34 weeks' gestation, with an incidence of 5–15%. It has a wide spectrum of clinical manifestations and may occur in both endemic and epidemic forms. Numerous epidemiologic studies have revealed primarily two associations with NEC: prematurity, with an increased risk of NEC with decreasing gestational age; and feeding, especially with formula.^{186,187} Although intestinal ischemia has been suggested as an etiology, only a small proportion of the reported cases of neonatal NEC can be linked to a known ischemic insult.

Studies in animal models have suggested that NEC begins when undigested carbohydrate and other substrates become available to the intestinal flora.¹⁸⁸ Organic acids produced by carbohydrate fermentation lower the luminal pH. There is an alteration in the mucosal tight junctions, allowing luminal proteins to be exposed to the mast cell. This initiates an inflammatory response that may ultimately lead to bowel necrosis. Also, several proinflammatory mediators have been implicated in the pathogenesis of NEC. For instance, elevated levels of platelet-activating factor (PAF) and decreased activity of the enzyme that inactivates this mediator, PAF-acetylhydrolase, have been described in preterm neonates with NEC.¹⁸⁹ Also, it has been shown that human milk, particularly that of mothers delivering preterm, contains this enzyme.¹⁹⁰ Elevated circulating levels of tumor necrosis factor have also been reported among infants with NEC.¹⁸⁹ Proinflammatory cytokines such as interleukin (IL)-6 and anti-inflammatory cytokines such as IL-8 are also increased during NEC.^{191,192} However, direct causality attributable to these mediators has not been demonstrated conclusively.

Generally, there are two types of NEC. The first, which accounts for approximately 10% or less of infants with NEC,

Table 68.14 Common organisms causing sepsis during the neonatal period.

Early-onset sepsis

Group B streptococcus

is found within the first week of life in critically ill neonates who have not been fed enterally. They usually have multiple organ involvement, including renal dysfunction, central nervous system hemorrhage, and tricuspid regurgitation, along with intestinal injury, which may be distributed anywhere within the gastrointestinal tract. Bacteria are not commonly involved because the intestine is only in the first stages of colonization. The cause of this variety is probably intestinal hypoxia associated with birth asphyxia or polycythemia leading to ischemia–reperfusion injury, although the use of exchange transfusions has also been associated with the development of NEC among polycythemic infants.¹⁹³ This mechanism has also been implicated in those cases of NEC seen among infants with congenital heart disease.¹⁹⁴ The latter presentation of NEC is generally seen in the healthier growing preterm infant who is being fed enterally. In this situation, the intestine is colonized with bacteria, and the disease is often localized primarily to the terminal ileum and proximal colon, although nearly all areas of the gastrointestinal tract can be involved. Occasionally, NEC affects the entire length of the intestinal tract.

The symptoms of NEC include bloody stools, decreased number of stools, abdominal distention, gastric residuals, along with variable signs of systemic involvement such as lethargy, poor perfusion, and metabolic acidosis. Abdominal radiography may reveal pneumatosis intestinalis, air in the hepatic vascular tree, and/or bowel wall edema. Uncommonly, free air in the peritoneal cavity, due to bowel perforation, is the presenting sign. Classification of the stages of NEC using the criteria proposed by Bell et al.¹⁹⁵ is useful to define its severity and potential prognosis (Table 68.15). However, only stages II and III of NEC from this classification are considered “proven” NEC, whereas the presentation of stage I NEC is frequently seen with sepsis (without NEC), feeding intolerance, and other etiologies.

The therapy for NEC has remained relatively unchanged for the last 20 years. Feedings should be stopped and the infant placed on intravenous fluids, while attempts are made to decompress the bowel with the use of low intermittent suction. Broad-spectrum antibiotics should be started after appropriate cultures have been taken, along with general supportive care, including correction of metabolic acidosis. Only about 30–50% of cases of NEC are associated with positive blood culture results, usually for Gram-negative bacteria in the most severe cases.¹⁸⁷ Should the disease progress to the point of intestinal perforation, the necrotic portion of the intestine is removed surgically, usually leaving an intestinal ostomy. Bowel perforation is the main indication for surgical intervention in infants with NEC, although a lack of clinical improvement with medical therapy, the persistence of a fixed loop of bowel on abdominal radiography (suggestive of bowel necrosis), and signs of intestinal obstruction are often the reason for surgical involvement. Feedings may be resumed after several weeks of bowel recovery. The mortality still ranges from 30% to 50% for the most severe forms of NEC, even with aggressive medical and surgical management.¹⁸⁷

Predictors of outcome, for both the intestine and the neonate, relate to the extent and severity of intestinal inflammation and the presence of severe systemic involvement. Neutropenia and thrombocytopenia suggest active consumption in the intestinal and systemic inflammatory process. Those infants who have severe metabolic acidosis refractory to therapy, hypotension, shock, and disseminated intravascular coagulation have the poorest prognosis. Even if the infant survives, he or she will usually have a prolonged hospital course.¹⁹⁶ Long-term complications in infants who recover include strictures, enterocolonic fistulas, malabsorption, and postsurgical short bowel syndrome.¹⁹⁷ There may also be complications of parenteral nutrition, such as infection and cholestasis. Moreover, recent evidence suggests that infants

Table 68.15 Bell’s staging for necrotizing enterocolitis (NEC).

Stage I Suspect	Stage II Definite	Stage III Advanced
Any one or more historical factors producing perinatal stress	Any one or more historical factors	Any one or more historical factors
Systemic manifestations – temperature instability, lethargy, apnea, bradycardia	Signs and symptoms as in Stage I plus persistent occult or gross gastrointestinal bleeding; marked abdominal distention	Signs and symptoms as in Stage II plus deterioration of vital signs, evidence of septic shock, or marked gastrointestinal hemorrhage
Gastrointestinal manifestations – poor feeding, increasing pre-gavage residuals, emesis (may be bilious or test positive for occult blood, which may be present in stool with no fissure)	Abdominal radiographs show significant intestinal distention with ileus; small bowel separation (edema in bowel wall or peritoneal fluid), unchanging or persistent “rigid” bowel loops, pneumatosis intestinalis, portal vein gas	Abdominal radiographs may show pneumoperitoneum in addition to signs listed for Stage II
Exclude other disorders via bacterial cultures, electrolyte analysis, maternal drug history, coagulation studies, and contrast studies		

with severe NEC are also at very high risk of poor long-term neurologic outcome.¹⁹⁸

Retinopathy of prematurity

Retinopathy of prematurity (ROP), formerly called retrolental fibroplasia, is a vasoproliferative retinopathy that occurs almost exclusively in preterm infants. Normal vascularization of the retina begins at the optic disk and advances peripherally between 16 and 44 weeks' gestation. After preterm birth, there may be a cessation of normal vascular growth followed by a period of neovascularization. When this vascular regrowth proliferates out of the plane of the retina and into the vitreous, partial or total retinal detachment can result. The factors that control these processes are currently not well understood.¹⁹⁹ ROP is most common in extremely low-birthweight infants. After adjusting for birthweight and gestational age, black infants are less susceptible to ROP than white infants. Additional factors that have been implicated in its pathogenesis by either association or anecdotal evidence include hypercarbia, multiple transfusions, severe apnea and bradycardia, acidosis, and RDS. In general, infants who are sicker and more unstable seem to be at higher risk. Hyperoxia has long been implicated as a cause of ROP. Current evidence suggests that hyperoxia alone is neither a necessary nor a sufficient cause of ROP.²⁰⁰ Recent speculations that exposure to a bright environmental light might contribute to ROP were not supported by clinical trials of light reduction.²⁰¹

An international classification has been developed for ROP, which allows for assessment of its severity and consistent reporting (Table 68.16).²⁰² Approximately 90% of cases of ROP regress spontaneously. The remaining 10% of cases progress to severe ROP. Based on data from the Cryotherapy Study conducted in the mid-1980s on 4099 infants with birthweights of less than 1251 g, 66% of surviving infants weighing less than 1251 g developed ROP.²⁰³ Approximately

6% of the infants in this study developed severe (threshold) ROP. In infants weighing less than 751 g, 90% developed ROP and 16% developed threshold ROP. It is unclear whether the increased use of surfactant or corticosteroids has changed the incidence of ROP over the past decade. Laser surgery is now the treatment of choice for threshold or severe ROP. The risk of blindness with threshold ROP has been reduced substantially with laser or cryotherapy treatment.^{203,204} Once retinal detachment has occurred, there is little likelihood of restoring vision. Even in infants with mild or regressed ROP, the incidence of myopia, strabismus, and amblyopia is more common than in infants without ROP.²⁰⁵

Overall mortality and morbidity of the preterm infant

Over the past 15 years, the survival of preterm infants has been increasing at the lowest end of gestational age, that is around 23–26 weeks (Fig. 68.2).²⁰⁶ However, clinicians generally underestimate the chances of survival and overestimate the chances of serious morbidity.²⁰⁷ This may lead clinicians to restrict potentially beneficial or life-saving therapies.²⁰⁸

In preterm infants, decreasing birthweight and gestational age are the most important determinants of mortality and morbidity (Table 68.17).²⁰⁹ At a given birthweight, infants who are more mature have a lower mortality. Similarly, at a given gestational age, infants with higher birthweight have a lower mortality. For reasons that are not fully understood, even after adjustment for birthweight and gestational age, black and female infants have a lower mortality than white and male infants respectively.²⁰⁹ Higher national neonatal mortality for black infants, compared with white infants, is largely due to the higher proportion of black infants born prematurely and/or with low birthweight.

Acute morbidities increase with decreasing birthweight as shown in Table 68.18. There is also substantial variability

Table 68.16 International classification for ROP.*

Zones	Zone 1 From the center of the optic nerve to twice the distance from the optic nerve to the macula in a circle Zone 2 Circle surrounding the zone 1 circle with the nasal ora serrata as its nasal border Zone 3 Crescent of the circle of zone 2 that did not encompass temporally
Stages	Stage 0 Immature retinal vasculature Stage I Mildly abnormal blood vessel growth. A line is present between the vascular and avascular region Stage II Moderately abnormal blood vessel growth. A ridge is present between the vascular and avascular region Stage III Severely abnormal blood vessels growing toward the center of the eye on or over the ridge Stage IV Partially detached retina Stage V Completely detached retina
Plus disease	Dilation and tortuosity of the peripheral retinal vessels, part of the subclassification given to the above stages

Figure 68.2 Survival by year from 1986 to 2000 for patients with gestational ages of 23–26 weeks. From Hoekstra RE, Ferrera TB, Couser RJ, et al. Survival and long-term neurodevelopmental outcome of extremely premature infants born at 23–26 weeks' gestational age at a tertiary center. *Pediatrics* 2004;113:e1–6.

between centers in the frequency of these complications. The long-term morbidities associated with preterm birth include cerebral palsy, neurodevelopmental delay, chronic lung disease, short bowel syndrome, poor growth, and visual and hearing deficits.

Newborn intensive care is very expensive. The cost is

roughly proportional to the length of hospital stay, which is inversely proportional to gestational age.²¹⁰ For these reasons, the costs of neonatal care have been increasing for extremely low-birthweight infants. Although these costs are quite high, the cost per life-year gained is quite favorable when compared with adult medical interventions.²¹¹

Key points

- 1 The best approach to the management of asphyxia is prevention and anticipation. Although asphyxia occurs primarily in high-risk pregnancies, a sizeable proportion of asphyxiated neonates still present without warning. For this reason, personnel skilled in initiating resuscitation must be present at all deliveries.
- 2 A good response to neonatal resuscitation is primarily indicated by rapid increases in heart rate, although improvements in color and initiation of spontaneous respiratory efforts are also indicators of a positive response.
- 3 The most important risk factor for the development of respiratory distress syndrome (RDS) is preterm birth. The incidence of RDS varies inversely with gestational age and can be as high as 60–70% among infants less than 28–29 weeks of gestation. Conversely, RDS is seldom seen beyond 38 weeks of gestation.
- 4 Administration of exogenous surfactant has become the standard of therapy for infants with RDS who are intubated. Whether used as prophylaxis or rescue therapy, it results in decreases in neonatal mortality and air leaks. However, the occurrence of complications such as intraventricular hemorrhage and bronchopulmonary dysplasia (BPD) is not decreased with surfactant therapy.
- 5 The incidence of BPD is inversely proportional to gestational age. As the survival of very low-birthweight infants has increased, a “new BPD” is now seen in very small infants who did not have RDS or pneumonia in the first week after birth. This seems to be more the consequence of chronic inflammation, deleterious effects of cytokines and other mediators, and an arrest of the process of normal lung development.
- 6 The best approach for term infants born through meconium-stained amniotic fluid who have initiated vigorous respiratory efforts is probably just observation, regardless of the characteristics of the meconium. Direct visualization of the larynx and tracheal suctioning are now reserved primarily for infants in need of resuscitation. Thorough endotracheal suctioning will not prevent all cases of meconium aspiration syndrome (MAS).
- 7 Delivery by Cesarean section without labor constitutes a risk factor for transient tachypnea of the newborn (TTN). Some infants who develop TTN have also been shown to have borderline lung maturity on prenatal amniotic fluid analysis. Additional risk factors are maternal diabetes, prolonged labor, male sex, macrosomia, and asphyxia.

- 8 Anemia, defined as a Hb below 13 g/dL in term infants, can be the result of hemorrhage, hemolysis, or decreased red cell production. It is uncommon to see anemia secondary to combinations of these factors.
- 9 Anemia secondary to acute hemorrhage presents with signs of hypovolemia including lethargy, poor capillary refill, tachycardia, weak pulses, hypotension, or pallor. Chronic blood loss over a period of days or weeks permits substantial hemodynamic compensation, so that the main presenting sign is pallor.
- 10 Hemolytic anemias usually manifest with pallor and early onset of jaundice, but without signs of hypovolemia. ABO or Rh incompatibility and infection are the most common causes of hemolytic anemia in the newborn.
- 11 Rh isoimmunization frequently results in more significant degrees of anemia and hyperbilirubinemia than ABO incompatibility. The severity of the hemolysis increases with subsequent pregnancies of Rh-positive fetuses.
- 12 Although there are no generally accepted criteria for the treatment of polycythemia, most centers will intervene on all infants with central venous hematocrit (Hct) above 70% or those with Hct above 65% if they are symptomatic. Treatment consists of a partial exchange transfusion to lower the Hct to a range at which blood viscosity will also be much lower, usually around 50–55%. However, the long-term benefits of partial exchange transfusion have not been clearly demonstrated.
- 13 All newborns should be examined periodically for the presence of jaundice. The jaundiced infant should be carefully evaluated prior to the institution of therapy.
- 14 Although the definition of hypoglycemia remains controversial, adoption of pragmatic threshold blood glucose concentrations when clinical intervention should be considered is recommended, particularly in the presence of neurological signs suggestive of hypoglycemia.
- 15 Correction of very low glucose values ($< 20\text{--}25\text{ mg/dL}$) is best accomplished by intravenous administration of a minibolus of 200 mg/kg of glucose followed by a constant glucose infusion of 6–8 mg/kg/min. The use of boluses of 25–50% dextrose can result in significant hyperglycemia and rebound hypoglycemia, and should therefore be avoided.
- 16 Neonatal hypocalcemia is often asymptomatic. The signs suggestive of hypocalcemia are primarily jitteriness and irritability, although apnea or seizures can sometimes occur. However, they are not specific and can also be elicited by hypoglycemia, hypomagnesemia, narcotic withdrawal, neurologic disorders, or infection.
- 17 Signs and symptoms of infection may resemble or be disguised by other illnesses of the newborn. Common signs of infection are poor temperature control and apnea; fever is very uncommon in the newborn. Other signs include respiratory distress, poor perfusion, lethargy or irritability, poor feeding tolerance, and hypoglycemia.
- 18 Necrotizing enterocolitis (NEC) is the most commonly acquired serious gastrointestinal disease in the neonatal intensive care unit. It affects predominantly premature infants of less than 34 weeks' gestation, with an incidence of 5–15%.
- 19 Hyperoxia has long been implicated as a cause of retinopathy of prematurity (ROP). Current evidence suggests that hyperoxia alone is neither a necessary nor a sufficient cause of ROP. Additional factors that have been implicated in its pathogenesis by either association or anecdotal evidence include hypercarbia, multiple transfusions, severe apnea and bradycardia, acidosis, infection, and RDS.
- 20 In preterm infants, decreasing birthweight and gestational age are the most important determinants of mortality and morbidity. At a given birthweight, infants who are more mature have a lower mortality. Similarly, at a given gestational age, infants with higher birthweight have a lower mortality. Acute morbidities increase with decreasing birthweight.
