First- and second-trimester prenatal diagnosis

John C. Hobbins

The recent emphasis on noninvasive prenatal diagnosis has evolved over a time when the average age of pregnant patients has crept upward. For example, in 1985, 5.6% of pregnant patients were 35 years of age or older in the United States.¹ This group of advanced maternal age (AMA) patients comprised 12.5% of the overall pregnant population in 2002 and, today, it is estimated that those aged 35 years or older comprise 20% of the pregnant population.

The older pregnant patient today is different from yesterday's AMA woman. She is often a nullipara with a career who, while postponing pregnancy well into her thirties, is inclined to want as much diagnostic information as possible before deciding upon whether or not to have an invasive procedure. In fact, at the University of Connecticut, the percentage of AMA patients having invasive testing decreased by 68% between 1991 and 2002. Interestingly, the number of invasive procedures per diagnosis of Down syndrome (DS; trisomy 21) dropped from 1:43 to 1:14 over a time when the number of detected cases of DS rose by 33%.²

With the trend toward fewer invasive procedures, Egan et al.³ postulated that, if every patient over 34 years of age with a reassuring second-trimester biochemical screen were to forego amniocentesis, 1971 fetuses in the United States would be saved from procedure-related loss.

In this chapter, the rapidly changing panoply of noninvasive first- and second-trimester techniques will be summarized, along with a description of how these tests can be used in combination to provide a reasonably accurate adjusted risk of trisomy 18 and trisomy 21 for every patient. In addition, the latest information on invasive diagnostic procedures will be discussed.

Invasive procedures

Amniocentesis – second trimester

The labeling of a woman of 35 years of age as being AMA stemmed from the concept that her age-related risk for DS of 1:270 was about the same as the procedure-related risk of

amniocentesis. It is interesting that this very arbitrary allocation has been so well ingrained that an individual of 34 years 11 months at the time of delivery would be considered “low risk” and a woman 2 months older would be designated as “high risk.”

The risk of amniocentesis most often quoted is 1:200, and this seems to have come from a vintage National Institutes of Child Health and Human Development (NICHD) study⁴ published in 1976, in which some of the amniocenteses were performed without ultrasound. Nevertheless, from the data presented below, this has become a very reasonable estimate of the procedure-related risk.

In order to arrive at a procedure-related risk, one has to determine what the chances are of a spontaneous fetal loss up until at least 24 weeks, when an ultrasound evaluation at the time of the amniocentesis shows a normal appearing fetus. In a study from Denmark,⁵ 4066 women who were 34 years of age or younger were recruited. After an ultrasound examination suggested that their fetuses were normal, half were randomly allocated to have amniocenteses, and the other half were designated as control subjects. The patients were compulsively followed until 26 weeks. The loss rate in the control group was 7 per 1000 and in the amniocentesis group was 17 per 1000. The derived 1% procedure-related loss rate took some by surprise, but the study has stood up to heavy scrutiny because the numbers were reasonable, the operators were very experienced, and the procedures were all performed under ultrasound direction.

Several uncontrolled early studies (prior to 1992) have yielded loss rates after second-trimester amniocentesis that range from 1.9% to 4.9%. To evaluate the procedure-related loss rate from contemporary midtrimester amniocenteses, Seeds⁶ analyzed data from 29 studies, each including more than 1000 patients having midtrimester amniocenteses. In this sampling, there were five controlled studies (two matched and three unmatched), totaling 8607 patients having amniocenteses and 6457 control patients. The difference in loss rate until 28 weeks between the amniocentesis group and the control group was 0.6%. In the entire sample of 33 795 patients

having a second-trimester ultrasound-guided amniocentesis, the loss rate was 2.1% until 28 weeks, and the loss rate in the above 6457 control subjects was 1.4%, giving a procedure-related risk of 0.7%.

Given the lack of randomized data, it is difficult to precisely quote a risk for amniocentesis, but it is clear that:

- Experience plays a role in procedure-related losses.⁷
- With the exception of data from one large nonrandomized study⁸ suggesting a lower amniocentesis risk, available published information points toward a procedure-related risk of about 1 in 200.
- There is a fixed spontaneous second-trimester loss rate of about 0.5%.

Early amniocentesis

When chorionic villus sampling (CVS) emerged as an option for early prenatal diagnosis, only a few operators were trained in this invasive technique. However, many were trained in amniocentesis. In order to comply with their patients' requests for earlier diagnostic information, some clinicians began offering amniocentesis between 11 and 14 weeks.

Many studies have shown that early amniocentesis is not a safe option. In a Canadian randomized trial, the Canadian Early and Mid-trimester Amniotic Fluid Trial (CEMAT),⁹ the postprocedure loss rate for early amniocentesis was 2.9% versus 1.0% for the standard amniocentesis group. The most recent multicenter study, the Early Amniocentesis versus Transabdominal CVS (EATA) study,¹⁰ showed a loss rate up to 20 weeks of 1.5% in the early amniocentesis group versus 0.8% after CVS. Also, Sundberg et al.¹¹ showed an unacceptable rate of clubfoot with early amniocentesis versus CVS (1.7% versus 0%), and the Canadian (CEMAT) study had a rate of clubbing of 1.3% compared with traditional second-trimester amniocentesis, which yielded a rate of 0.1%.

As the amnion and chorion are often not apposed between 12 and 14 weeks, the separated needle holes will allow fluid to track extramembranously to and through the cervix, as noted in 3.5% and 4% of cases in the Canadian and Sundberg studies respectively.

Because of a higher loss rate with early amniocentesis compared with standard amniocentesis or CVS, and as there is a higher rate of amniotic fluid leakage, respiratory distress syndrome (RDS), and clubbing of the extremities, this technique has been virtually abandoned.

Chorionic villus sampling (CVS)

Investigators in China and Russia first reported on the concept of sampling placental tissue in the first trimester for diagnostic purposes. Brambati et al.¹² were the first to exploit this idea by threading a catheter through the cervix and directing the tip under ultrasound guidance into the placenta. This extramembranous technique allowed small samples of chorionic villi to be obtained for karyotyping with seemingly modest risk.

The transabdominal method of CVS emerged to allow easier access to predominantly anterior placentas. Some investigators, however, have now chosen to use the transabdominal approach exclusively, while others select the approach that gains easiest access to the placenta.

Spontaneous loss rates in apparently normal pregnancies are about 15% at 5–6 menstrual weeks, about 2% at 11 weeks, and slightly less than 1% at 16 weeks. Raw loss rates after CVS have varied between 1.6% and 3.4% in five experienced centers in the United States (R. J. Wapner, personal communication) (Table 27.1).

There is no doubt that the more insertions, the greater the risk of the procedure, and the greater the experience of the operator, the less the need for multiple needle insertions. For example, Saura et al.¹⁴ showed that the spontaneous loss rate was 6.6% in the first 200 cases carried out. This rate dropped to 3.4% in the next 300 cases and leveled off at 1.2% after 1000 cases.

CVS, which became a very popular option for AMA patients in the 1980s, was dealt a blow when a study¹⁵ emerged citing an intolerably high rate of limb reduction defects with CVS (about 2%). When it was clear that this study had a heavy sampling of patients having very early CVS (≤ 9 weeks), an international registry of CVS (WHO CVS Registry)¹⁶ involving 208 682 patients was accessed. This showed the rate of limb reduction defects to be 5.9 per 10000, close to the incidence in the overall population of 6 per 10000 (British Columbia birth statistics). Brambati et al.¹² reviewed their own data and found that, at 6–7 weeks, CVS was associated with a 1.6% incidence of limb reduction defects and, at 9–12 weeks, the incidence was 0.6%. From this, it is clear that CVS prior to 10 weeks should be avoided.

We have been quoting to our patients a procedure-related loss rate of CVS, performed at 10–13 weeks, of about 1%, and, realizing that the paucity of randomized data does not allow us to provide more precise information, we have indicated that this risk is slightly higher than that of amnio-

centesis, as concluded by the authors of a review of the Cochrane Database.¹⁸

Fetal blood sampling

Attempts to sample the fetal circulation emerged when it became clear that many fetal conditions could not be diagnosed by amniotic fluid analysis. The condition that catalyzed the first attempts at fetal blood sampling was beta-thalassemia, a devastating problem that could be identified by globin chain synthesis analysis.

In 1974, Hobbins et al.¹⁹ reported their ability to obtain fetal blood endoscopically from the surface vessels coursing along the chorionic plate of the placenta. In 1979, Rodeck and Campbell²⁰ moved their endoscopic focus to the umbilical cord, which enabled them to sample blood directly from the umbilical vein.

The fetoscopic approach to blood sampling became instantly obsolete when, in 1983, Daffos et al.²¹ demonstrated the capability to enter the umbilical vein percutaneously under ultrasound direction with less maternal and fetal morbidity.

However, through the 1990s, the need for blood sampling procedures diminished because more diagnoses could be made through new methods in the investigation of amniotic fluid, such as polymerase chain reaction (PCR) in cases of infection and fluorescent *in situ* hybridization (FISH) for rapid karyotyping, at less risk.

The risk of fetal blood sampling has varied widely between investigators. For example, in 1993, Ghidini et al.²² pulled together data from the literature from various centers. The fetal loss rate was inversely proportional to the size of the series and was as high as 12% in studies with small numbers. With pooled data from centers with the greatest experience, the risk of fetal loss was 1.4% prior to 28 weeks and 1.4% after 28 weeks. This seemed like a very reasonable risk for some high-risk patients. However, one author who had an extremely low loss rate contributed almost half the cases. If these cases were removed, then data from the remaining centers indicated a 7.2% fetal loss rate for all patients and 3% for low-risk patients.²³

Now, fetal blood sampling has been relegated to only a few indications, such as alloimmune thrombocytopenia (AIT) and fetal anemia. Even in rhesus (Rh) disease, fetal blood sampling has been largely supplanted by Doppler waveform analysis of the middle cerebral arteries, with cordocentesis being saved for those needing intrauterine transfusions.

Noninvasive prenatal diagnosis

AMA patients entering the first or second trimester come in three types:

1 Those who want to know with 100% accuracy whether their fetuses have a chromosomal abnormality or a major congenital anomaly.

2 Those who do not want invasive testing because termination of pregnancy would not be an option for them and the risk of the test would not be worth the reassurance it might provide.

3 Those who want the most accurate noninvasive information available regarding their risk of fetal aneuploidy, before deciding whether or not to undergo invasive testing.

As noted above, as more noninvasive diagnostic combinations have become available, the number of patients in the third category has increased substantially over the last 5 years, while the numbers of those in the first category have decreased.

This portion of the chapter will deal with noninvasive diagnostic options, most of which have only become available over the last few years, and basically involve two modalities: ultrasound and maternal serum biochemistry.

First trimester

In 1992, Nicolaides et al.²⁴ reported on the association between an enlarged nuchal translucency (NT) and fetal chromosome abnormalities. The measurement represented the distance between the inner portion of the nuchal membrane and the underlying tissue (Fig. 27.1). After compulsively organizing a multicenter screening program, which involved careful standardization of the methods and regimented operator training, the group reported their results in a prospective study involving 96 127 patients (Table 27.2).²⁵ The calculation of fetal DS risk was based on the patient's age, the fetal crown-rump length, and the NT measurement. At a false-positive rate of 5%, the detection rate for trisomy 21 was 77%, a sensitivity that exceeded that of the then widely used second-trimester triple screen.

Although the sensitivity figure was questioned initially because spontaneously aborting screen-negative trisomy 21 fetuses were not accounted for in the calculated results,²⁶ the detection rates from other centers, also involving large numbers of patients, have validated the results of Nicolaides and Snijders. The data from the First Trimester Maternal Serum Biochemistry and Fetal Nuchal Translucency Screening (BUN) study²⁷ involving 8514 patients and showing a 69% sensitivity at a 5% false-positive rate, and the results from the

Data from Fetal Medicine Foundation, London, UK.

First And Second Trimester Evaluation for Risk (FASTER) trial²⁸ involving 35 000 patients, bear out the concept that the screening test can be used in a US population.

It has been demonstrated that the accuracy of NT screening drops to nonefficacious levels when less experienced sonographers and sonologists are involved in the process. Therefore, properly trained individuals and carefully standardized protocols for performing the ultrasound examination are necessary for any NT screening program to be effective.

First-trimester biochemistry

As second-trimester biochemical combinations were the first to be used in screening for aneuploidy with obvious success, investigators began testing various analytes in the first trimester and, at the time of writing, the two that have seemed most effective are pregnancy-associated plasma protein A (PAPP-A), a product of the placenta that is a protease for insulin-like growth factor (IGF) binding protein, and the beta subunit of human chorionic gonadotropin (β hCG), another placental product.

In DS, the average PAPP-A is 0.39 multiples of the median (MoM) and β hCG is 1.83 MoM.²⁹ If these two analytes are used together, a risk for a given patient can be fashioned by adding the variables of the patient's age and the estimated gestational age. Based on this model, PAPP-A, by itself, has a sensitivity for trisomy 21 of 42% at a 5% screen-positive rate, and β hCG has a sensitivity of 24% at a screen-positive rate of 5%. However, together, they have a sensitivity of 62% at a 5% screen-positive rate.²⁷

NT and biochemistry in combination

As adding a new testing variable to any of the screening protocols seems to enhance the testing sensitivity, it was a natural next step to combine NT with first-trimester biochemistry in a diagnostic algorithm ("combined test"). This combination

has yielded sensitivities of between 62% and 90% with varying screen-positive rates. Malone and D'Alton³⁰ combined data from seven studies involving 85 482 patients in which the sensitivity of this combined approach was 82% at a screen-positive rate of 5% (Table 27.3).

Nasal bone

In 1866, Langdon Down noted that infants with a particular syndrome, ultimately named after him, had noses that were quite small. This stimulated Cicero et al.³¹ to investigate the possibility that this observation could be used as an adjunctive diagnostic tool in the first trimester. The endpoint was quite simple – the presence or absence of a nasal bone. In their first publication,³¹ they found that 73% of fetuses with DS had absent nasal bones, compared with only 0.5% of the normal fetal population. The updated experience of this group³² was published in 2003 and involved 3788 patients. They found that:

- 1 They could adequately evaluate the nasal bones in 98.9% of cases.
- 2 Some 67% of DS fetuses had absent nasal bones.
- 3 There were ethnic variations in the results.
- 4 The nasal bone findings were independent of NT. In fact, the addition of nasal bone evaluation increased the sensitivity of the combined test from 89% to 97% with a screen-positive rate of 5%.

Recent data from Malone et al.³³ do not concur with the excellent results from Cicero and other authors,^{34,35} although this could represent a difference in technique.

Second-trimester biochemistry

In 1984, Merkatz et al.³⁶ serendipitously noticed that pregnancies complicated with fetal DS were sometimes associated with low levels of maternal serum alpha-fetoprotein (MSAFP). Since then, it was found that adding total hCG, which tends to be elevated, and unconjugated estriol, which is generally

Table 27.3 First-trimester screening for trisomy 21 using nuchal translucency (NT), pregnancy-associated plasma protein A (PAPP-A), and free beta-human chorionic gonadotropin (β hCG) at 10–13 weeks' gestation.

low, to MSAFP improved the screening sensitivity for DS from about 33% to 65%. Although many other analytes have been investigated, the additional analyte most commonly used to take the above “triple” screen to a “quad” screen is inhibin A, contributed by the placenta.

If one were to plot the individual analytes against gestational age and incorporate the patient’s age into the calculation, the newest data from the BUN study²⁷ indicate a triple-screen sensitivity for DS of 67.2% at a screen-positive rate of 5%. This represents a substantial increase in diagnostic yield from using the patient’s age and second-trimester MSAFP alone. In patients above 35 years of age, the triple-screen sensitivity can exceed 85% (but at a 14% screen-positive rate). Unpublished FASTER trial results show an even higher sensitivity with the quad screen than expected.

Prenatal diagnostic combination options

From the above-mentioned trials, sufficient data have emerged to fashion three different approaches to prenatal diagnosis using first-trimester ultrasound and first- and second-trimester biochemical information. As the titles for these programs below are descriptive and concepts are just now evolving, these names may well change.

Integrated (basic) screen

This represents the protocol pursued in the FASTER trial. It consists of a first-trimester NT and PAPP-A screen and a second-trimester quad screen. The controversial part of this scheme is that the patient is not informed of the first-trimester results until all the information is in; she gets one answer a few days after the second-trimester blood is drawn. Through analysis of existing data, this method gives a 96% sensitivity at a 5% screen-positive rate.

Independent sequential screen

This consists of a combined screen of NT, PAPP-A, and β hCG, which is performed in the first trimester with the patient being apprised of the results immediately. The result of second-trimester biochemistry is then given to the patient, which is independent of the first-trimester result and based on a pretest risk of age alone. The reported sensitivity of this technique in the BUN study³⁷ using a triple screen was 98% at an overall screen-positive rate of 17%. However, when using extrapolated data to give parallel results, this technique would have resulted in a sensitivity of 87% at a screen-positive rate of 5%. With a quad screen, the sensitivity figure would be higher.

Dependent sequential

In this case, risk is derived from the combined first-trimester test (NT and PAPP-A, with or without hCG), which is given

to the patient. She then goes into her second-trimester quad screen with a new pretest risk that is not based on her age but on the result of the first-trimester test. The second result would then yield a lower false-positive rate than the independent screen described above. With modeling from FASTER data, this would yield a sensitivity of 95% at a total screen-positive rate of 5%.

A variation on the above dependent sequential theme is a “contingency” approach, in which a preset first-trimester numerical risk would be used as a threshold below which no further testing would be required.³⁸ This would make sense from a cost standpoint and could diminish patient angst.

Increased nuchal translucency in euploid fetuses

Fetuses with NT measurements that are above the 95th percentile need further diagnostic attention even if invasive procedures indicate a normal karyotype. A number of fetal abnormalities that are too long to list have been reported to be associated with an increased NT. Basic anomaly categories are noted in Table 27.4 along with the prevalence of each in the face of a normal fetal karyotype.³⁹

The common denominator in many of these generally rare anomaly syndromes is a cardiac abnormality. One of the theories for increased NT is that nuchal fluid accumulates secondary to cardiac dysfunction, which is then accompanied by tricuspid regurgitation and an increase in ductus venosus backflow during atrial contraction, often noted in first-trimester fetuses with DS. In 1999, Hyett et al.⁴⁰ quantified the risk of a structural cardiac abnormality based on the size of the NT. The highest prevalence has been noted in abnormalities of the left heart, such as aortic stenosis, hypoplastic left heart syndrome, and coarctation of the aorta. Souka et al.³⁹ have put together data that will help in counseling patients whose euploid fetuses have increased NTs (Table 27.5).

The anomalies most commonly associated with this combination of NT and euploidy are diaphragmatic hernia, exomphalos, body stalk abnormality, skeletal dysplasia, and various syndromes such as fetal akinesia, Noonan syndrome, Smith–Lemli–Opitz syndrome, and spinal muscular atrophy. Those

Table 27.5 Relation between nuchal translucency thickness and prevalence of chromosomal defects, miscarriage, or fetal death and major fetal abnormalities.

Nuchal translucency	Chromosomal defects (%)	Fetal death (%)	Major fetal abnormalities (%)	Alive and well (%)
< 95th percentile	0.2	1.3	1.6	97
95th–99th percentile	3.7	1.3	2.5	93
3.5–4.4 mm	21.1	2.7	10.0	70
4.5–5.4 mm	33.3	3.4	18.5	50
5.5–6.4 mm	50.5	10.1	24.2	30
> 6.5 mm	64.5	19.0	46.2	15

From Souka AP, Von Kaisenberg CS, Hyett JA, et al. Increased nuchal translucency with normal karyotype. *Am J Obstet Gynecol* 2005;192:1005–1021.

not seemingly associated with increased NT and euploidy are neural tube defects, holoprosencephaly, gastroschisis, and renal anomalies.

Our approach to fetuses with large NTs and normal karyotypes is to do a very detailed ultrasound in the second trimester (after ruling out any obvious first-trimester structural abnormalities by transvaginal ultrasound) and to add a detailed fetal echocardiogram at about 20 weeks. If these examinations are negative, then the risk of fetal anomalies drops to almost baseline levels.

The genetic sonogram

In 1985, Benacerraf et al.⁴¹ reported that about 40% of fetuses with DS had increased nuchal skinfold thickness (NSFT) in the second trimester and, around that time, she and others published an observed tendency toward shorter femurs in these fetuses when compared with the biparietal diameter⁴² or the expected femur length.⁴³ This started a search for many other ultrasound-derived “soft” markers for DS that is still continuing. To date, at least 12 different soft markers have been investigated alone, in combination with other markers, or incorporated into a scoring system to adjust the risk of fetal DS for a given patient. Some markers are clearly superior performers, while others are not or are so new that their efficacy has not been adequately tested with large enough numbers. The most commonly used markers are summarized in Table 27.6.

Interestingly, the heart, which is a source of potent information about aneuploidy, has not been adequately investigated. For example, about 30% of DS infants have structural abnormalities at birth, but undoubtedly more have ventricular septal defects in the second trimester that close over later. Also, many more will have at least a transient functional right heart predominance that results in a larger right atrium with a deviated interatrial septum along with tricuspid regurgitation. By thoroughly scrutinizing the fetal heart, DeVore⁴⁴ has increased the sensitivity of the genetic sonogram to over 90%.

The concept with this noninvasive form of testing is to calculate a likelihood ratio based on an ultrasound examination that would allow a far more accurate adjusted risk for DS

Table 27.6 Soft markers.

Nuchal skinfold thickness

Pyelectasis
Mild ventriculomegaly
Biometry: femur length (vs. biparietal diameter or against expected femur length for gestational age)

from an individual patient than with age alone. The idea is very workable but is dependent upon the predictive accuracy of the providers offering the genetic sonogram, which consists of: (1) ruling out major structural abnormalities by performing a standard fetal survey according to guidelines published by the American Institute of Ultrasound in Medicine and the American College of Radiology; (2) measuring femur and humerus length; and (3) looking for soft markers for DS. Although there are standards in place for the investigations of (1) and (2), there is no consensus regarding which soft markers to evaluate, with the exception of the NSFT, the best performer to date.

The most commonly investigated markers, in addition to the NSFT, are:

- 1 An echogenic intracardiac focus in the heart (EIF), which is noted in about 18% of fetuses with DS.⁴⁵
- 2 An echogenic bowel, seen in about 13% of fetuses with DS.⁴⁶
- 3 Modest pyelectasis, noted in about 20% of fetuses with DS.⁴⁷

Other less commonly utilized markers are:

- 1 Fetal ear length⁴³ (sometimes small in DS).
- 2 Iliac angle⁴⁹ (often widened in DS).
- 3 Indirect measurements of the frontal lobe⁵⁰ (most often small in DS).

Table 27.7 The genetic sonogram experience.

Study	No. of patients	Sensitivity (%)	FPR (%)	LR (+)	LR (–)

Vergagni	22	59	5.3	11.1	0.43

4 The middle phalanx of the fifth digit⁵¹ (sometimes absent or very small in DS).

The newest marker on the scene is fetal nasal bone length, which represents an extension of the observation noted in the first trimester mentioned above. Early investigation suggests that this marker may well be the best performer in the second trimester if measured compulsively and compared against a commonly used standard, the biparietal diameter. Bromley et al.⁵² have demonstrated that, if using a nasal bone/biparietal cutoff of 10, 81% of fetuses with DS would be detected with a screen-positive rate of 11%. The addition of this marker to the genetic sonogram, although not yet tested prospectively, should enhance the sensitivity of the genetic sonogram well above the figures in the literature, which are summarized in Table 27.7.

The finding of a marker for DS can raise the risk, but much depends upon which marker is found and whether or not it is in isolation. For example, an enlarged NSFT increases the risk at least 11 times,⁵³ even in isolation, while minor markers, such as the fetal ear, middle bone of the fifth digit, and femur length, have a very modest effect on the adjustment of risk when isolated.

Choroid plexus cysts are clearly markers for trisomy 18, but it is unclear whether they are markers for DS. Bromley et al.⁵² and unpublished FASTER data show no greater association with DS, whereas some smaller studies suggest a higher prevalence of this finding in DS than in the control populations studied.

At the time of writing, it seems reasonable not to change a pre-ultrasound risk for an isolated marker that most studies have shown to have likelihood ratios of ≤ 2.0 , and to adjust the risk upward only when likelihood ratios are high, such as for NSFT, short humerus, and small nasal bone. However, once more than one marker is found, this catapults the risk upward. For example, Nyberg et al.⁵³ have shown that, with each additional “minor” marker found, the likelihood of DS goes up exponentially (Table 27.8).

The beauty of the genetic sonogram is that, if the carefully performed examination fails to reveal any fetal anomalies,

Table 27.8 Comparison of the number of markers in fetuses with Down syndrome (DS) and control fetuses.

Markers (%)	DS (%) Nyberg <i>n</i> = 186	Normal (%) Nyberg <i>n</i> = 8728	LR Nyberg
0	31.2	86.7	0.36
1	22.6	11.3	2.0
2	15.1	1.6	9.7
3+	14.5	0.1	115.2
Majority	16.7	0.6	27.5

short limbs, or markers for DS, the risk can be adjusted downward. An eight-center study⁵⁴ pooling data from experienced diagnostic centers in the United States had an average sensitivity of 71.6% with a range of 63.6–80%. Also, this study, along with others,^{55–57} showed that the genetic sonogram performed as well in those with an elevated biochemical risk for DS as in those of AMA, suggesting that the genetic sonogram and second-trimester biochemistry had independent diagnostic values.

At present, current results in the literature suggest that centers with large patient numbers and accurate outcome data can calculate their own likelihood ratios. Then, using Bayes’ theorem, an adjusted risk can be estimated for a given patient after a negative genetic sonogram. For example, a 35-year-old woman with a pretest value of 1:280 having a reassuring sonogram in a center generating a likelihood ratio of 0.3 would be adjusted downward to a risk of 1:840 (0.3×280).

Programs yet to establish their own sensitivity and specificity values but following a carefully standardized protocol for a genetic sonogram could add a conservative “cushion” by simply adjusting the pretest risk downward by half after a negative genetic sonogram. The FASTER trial⁵⁸ has shown that the few trisomy 21 fetuses not screened in with the integrated test were picked up in over 8000 patients in the study having

a genetic sonogram, giving a 100% sensitivity for DS when the ultrasound was added to the integrated testing scheme.

Trisomy 18

While the thrust of prenatal diagnosis has been directed toward DS because of its frequency, especially in AMA patients, progress in the noninvasive investigation of trisomy 18 has quietly moved forward to a point where the diagnosis can be made with ultrasound and biochemistry in the first and second trimesters in virtually every affected fetus. For example, the BUN study²⁷ showed a sensitivity for trisomy 18 of 91% at a 2% screen-positive rate using the “combined” first-trimester screen approach. One hundred percent of trisomy 18 fetuses were identified in those patients over 35 years old with a screen-positive rate of 2.6%.

With second-trimester biochemistry alone, the sensitivity quoted by most laboratories is around 65%. However, for some reason, this figure has been calculated for a screen-positive rate of 0.5%. If the screen-positive rate is raised to 5%, sensitivity would far exceed 90%.

As fetuses with trisomy 18, an ultimately lethal perinatal abnormality, are almost always phenotypically abnormal and usually have a cardiac defect (90%), very few fetuses with this condition will slip through a genetic sonogram unnoticed. Table 27.9 outlines the various markers known to be associated with trisomy 18.

Controversy still exists about whether or not to employ invasive sampling when common markers of trisomy 18, choroid plexus cysts, are found in isolation. First, it is important to be assured that the finding is truly in isolation by compulsively excluding every one of the markers in Table 27.9. If this is the case, and the biochemistry is reassuring, the chance of a fetus having trisomy 18 is close to zero and certainly far less than the risk of amniocentesis.

Table 27.9 Ultrasound signs for trisomy 18.

Symmetrical intrauterine growth retardation (IUGR)
Polyhydramnios
Cardiac anomaly (over 90%)
Other major anomalies
“Strawberry”-shaped calvarium
Small frontal lobe
Small and deformed ears
Small transcerebellar diameter
Large cisterna magna
Small mandible
Single umbilical artery
Overlapping fingers
“Rocker bottom” foot

Screening for fetal anomalies with ultrasound

About 28 per 1000 fetuses will have a major congenital anomaly, and many of these fetuses will have findings that can be identified with ultrasound. In the literature, there is a huge variation in the identification rates for fetal anomalies. As a standard (basic) fetal ultrasound survey is designed to screen for most anomalies, it is surprising how low the overall identification rate has generally been.

The RADIUS study,⁵⁹ published in 1994, was launched to assess the value of routine screening with ultrasound in the second and third trimesters. After excluding about half the patients who were enrolled in the study to concentrate on purely low-risk patients, 7685 patients were randomly assigned to have two ultrasound evaluations, and 7596 control subjects were designated not to have an ultrasound unless a clinical indication arose.

The study had virtually complete ascertainment; 6.5% of anomalies were diagnosed in the control group, and 15% were diagnosed in the ultrasound group before 24 weeks. Although it was heartening that three times more anomalies were identified when ultrasound was used routinely, the fact that 85% of major anomalies were missed was not. A similar randomized control trial (RCT) originating in Helsinki⁶⁰ showed an identification rate of 40%.

When simply evaluating the sensitivity of ultrasound in the identification of fetal anomalies, an RCT is not required. The largest of the observational studies is the multicenter Eurofetus study.⁶¹ In pooled data from > 200 000 patients, the sensitivity for major anomalies was 73.7% and for minor anomalies was 45.7%. Prior to 24 weeks, the sensitivity was 55% for major anomalies, more than three times that of the RADIUS trial.

There are many variables that affect the efficacy of a fetal anatomic survey. For example, operator experience plays an important role. The RADIUS trial showed a sensitivity in identifying fetal anomalies at all gestational ages of 38% in tertiary centers, compared with 16% in the hands of local practitioners. The Helsinki study generated a sensitivity of 77% and 36% for the above categories respectively.

Results also vary according to the degree of risk assigned to patients being evaluated. If the risk is high, the practitioner might be more alert to subtle findings than when there is a lessened pre-examination chance of an anomaly.

Fetal cells in the maternal circulation

The placenta is an almost perfect gatekeeper with regard to restricting components of the fetal circulation from traversing into the maternal circulation. However, about one cell per 10 million maternal cells is fetal in origin but, in some patients,

such as those destined to have preeclampsia, more fetal cells seem to get across the placenta. The concept of capturing these fetal cells is compelling as it would represent the ideal form of noninvasive diagnosis, requiring a simple blood draw. However, scientists have struggled for more than 10 years to isolate these cells of fetal origin.

In 1969, Walknowska et al.⁶² first found lymphocytes carrying the Y chromosome in maternal blood. In 1990, Bianchi et al.⁶³ identified fetal nucleated red cells in the maternal circulation. Since then, many techniques have been employed for cell separation including magnetic-activated cell separation (MACS) and fluorescence-activated cell sorting (FACS). The chromosome analysis has been largely accomplished through FISH methodology.

Since 1990, such investigations have been in full swing but, to date, the largest study published is the NICHD Fetal Cell Isolation Study (NIFTY),⁶⁴ involving almost 3000 patients. In this study, the accuracy of predicting a male karyotype was 41% and, in the 60 samples from aneuploidy pregnancies, 79% were identified at a false-positive rate of 4.1%.

Until now, the process suffers from technical difficulties inherent in the job of finding the one cell per 10 million that contains the key to the fetal karyotype and from the cost of employing a very expensive, labor-intensive process with, thus far, disappointing results.

The investigation has turned up some ancillary, potentially useful information.

1 More fetal cells and fetal DNA are noted in the blood of mothers who later develop preeclampsia.

2 More fetal cells and DNA are found in patients with aneuploid fetuses.

3 Fetal free cell DNA has a short half-life compared with fetal cells that can remain in the maternal circulation into the next pregnancy (with obvious negative diagnostic implications).

At the time of writing, the ability to isolate free DNA from maternal serum has exciting potential. It can be found in the maternal plasma by 7 weeks of gestation, and levels increase as pregnancy progresses. It has a 16-min half-life.

In 1998, Lo et al.⁶⁵ published their ability to diagnose fetal RhD status by molecular analysis of maternal plasma and, in 2000, Lo et al.⁶⁶ and Zhang et al.⁶⁷ reported being able to determine fetal sex by DNA analysis using PCR. Then, these groups published their success in determining fetal Rh status with a sensitivity and specificity of 94% and 100%, respectively, in the first trimester, and 92% and 100%, respectively, in the second trimester.

At the moment, this approach to fetal diagnosis is passing through an embryonic stage in investigation. However, there is reason to believe that, with technical breakthroughs and expanded clinical investigation, coupled with strategies to cut costs, these methods could contribute hugely to large-scale screening for aneuploidy, X-linked conditions, and blood group disorders.

Conclusions

Progress in prenatal diagnosis has been exponential over the last decade, and there is reason to believe that the “dots” of progress will continue to be connected along the same pathway in the next decade. Ultrasound technology is exploding, as evidenced by the recent advent of three- and four-dimensional methods, investigators are better trained, and “bench” science is becoming more automated. Soon, invasive

techniques will be needed for patients who are only at the very highest risk for severe fetal abnormalities.

Acknowledgment

It is with deep appreciation that I acknowledge the substantial efforts contributed by Jane Berg in the preparation of this manuscript, as well as in many other endeavors over the past 7 years.

Key points

- 1 There is now a major emphasis on noninvasive prenatal diagnosis stimulated by patient desire for the best information with which to make decisions regarding invasive testing.
- 2 Standard second-trimester amniocentesis has a procedure-related risk that is difficult to pinpoint precisely but, according to the literature, is about 1 in 200.
- 3 The risk of CVS varies among investigators, but seems to be slightly higher than if a patient waits until the second trimester for an amniocentesis. However, with the emergence of first-trimester noninvasive testing, the need for CVS will increase in patients at high risk for fetal aneuploidy.
- 4 The risks of early amniocentesis (11–14 weeks) are generally not acceptable.
- 5 First-trimester nuchal translucency assessment, along with biochemistry, has a reasonable sensitivity in the adjustment of risk of trisomy 21 and trisomy 18.
- 6 The emergence of second-trimester biochemistry (triple screen and quad screen) has significant diagnostic benefit by itself but, when used adjunctively with first-trimester tests, has a very high predictive value.
- 7 Various combinations of first- and second-trimester ultrasound methods and biochemistry have sensitivities for Down syndrome that exceed 95% at a 5% screen-positive rate.
- 8 The genetic sonogram has an average sensitivity for trisomy 21 of about 75% in major centers and, when negative, can be used to adjust the risk of Down syndrome downward by at least 50%.
- 9 The accuracy of a second-trimester ultrasound examination for the identification of fetal anomalies had initially been a disappointment, but it now has the capability of diagnosing over 50% of major abnormalities.
- 10 During the last decade, little major progress has been made in the isolation of fetal cells in the maternal circulation. However, very recent inroads into the separation and analysis of fetal DNA in the maternal circulation have tremendous diagnostic potential in fetal aneuploidy, X-linked conditions, and blood group disorders.
- 11 The number of pregnant patients who are of advanced maternal age has soared steadily over the last decade to a point where it exceeds 20%.
- 12 Loss rates from second-trimester amniocentesis and CVS seem to be dependent upon the experience of the investigator.
- 13 Fetuses with increased nuchal translucency but with a normal karyotype have increased risks for various anomaly syndromes.
- 14 Once ultrasound rules out a major structural anomaly and a fetal echocardiogram has ruled out the presence of a major cardiac abnormality, fetuses with increased nuchal translucency and normal karyotypes do not have an increased risk for an adverse pregnancy outcome.
- 15 A genetic sonogram consists of a search for major anomalies and markers for DS in addition to assessing femur and humeral lengths.
- 16 With the exception of an increase in nuchal skinfold thickness, small nasal bone, or short humerus, it is unclear how to precisely adjust the risk for DS in a given patient who has other ultrasound markers in isolation.
- 17 Initial studies from the United States have shown a low sensitivity for ultrasound in the diagnosis of major congenital anomalies in the second trimester. However, European studies have shown a marked improvement in detection rates over the last 10 years.
- 18 The identification of anomalies is now dependent upon an enhanced ability to diagnose cardiac anomalies (perhaps through three- and four-dimensional technologies).
- 19 With more investigation in prenatal diagnosis techniques, patients will be able to make better informed decisions, which in turn should translate into fewer unnecessary invasive procedures.

First- and second-trimester screening for open neural tube defects and Down syndrome

James E. Haddow, Glenn E. Palomaki, and Ronald J. Wapner

Biochemical testing for fetal disorders dates from the discovery that amniotic fluid alpha-fetoprotein (AFP) levels are elevated in the presence of open neural tube defects (NTDs; open spina bifida and anencephaly) during the early second trimester.¹ This finding led to diagnostic testing for open NTDs in pregnant women with a previous affected pregnancy. An important limitation of the public health impact of such testing was that fewer than 5% of the annual births affected by open NTDs occurred among women known to be at high risk. Subsequently, maternal serum AFP (MSAFP) levels were also documented to be elevated in the presence of open NTDs, and such measurements were offered to all pregnant women for screening purposes. Women with elevated serum AFP levels were offered diagnostic amniotic fluid AFP (AFAFP) testing. Initially, the presence of open spina bifida could be confirmed only by ultrasound examination of the fetal spine; however, this was technically difficult. This has now been supplemented by more reliable and technically easier ultrasound observations of the fetal cranium and brain (the “lemon” and “banana” signs).^{2,3}

Data accumulated during the early years of screening for open NTDs set the stage for the discovery that MSAFP levels were lower in the presence of Down syndrome. A combination of maternal age and AFP levels resulted in an improved prediction of Down syndrome risk, with amniotic fluid chromosome analysis offered to high-risk women. The subsequent discovery of other biochemical markers for Down syndrome greatly improved the efficiency of second-trimester screening. A further important breakthrough occurred with the identification of both biochemical [pregnancy-associated plasma protein A (PAPP-A); free beta subunit of human chorionic gonadotropin (β hCG)] and ultrasound (nuchal translucency, NT) markers for Down syndrome in the first trimester. When used together, these markers perform better than second-trimester screening and have the added advantage of early detection. At present, several strategies that combine first- and second-trimester biochemical measurements (with and without NT measurements) are being evaluated as a way of

maximizing the rate of detection and minimizing the rate of false-positives.

Diagnostic testing for open NTDs in amniotic fluid

In 1956, Bergstrand and Czar⁴ described a protein in fetal serum, located in the α 1 region on electrophoresis [subsequently labeled α 1-fetoprotein (AFP)], that was not present in adult serum. It is this unique fetal protein that serves as a marker for leakage of fetal serum into the amniotic fluid and which is therefore helpful in diagnosing open fetal lesions. The molecular weight and structure of AFP is similar to that of albumin (about 69 kDa),⁵ but antibodies raised against AFP have virtually no cross-reactivity. This characteristic was critical in allowing the development of a variety of antibody-based assays for reliably measuring AFP in amniotic fluid and maternal serum. The bulk of amniotic fluid protein is now known to be maternally derived,^{6,7} and AFP is the only marker that has been found to be helpful in identifying open NTDs.

Figure 28.1 illustrates the relationship between AFAFP values in unaffected pregnancies and AFAFP values in pregnancies affected with open spina bifida; there is a small degree of overlap. Most of that overlap, leading to false-positives in amniotic fluid, can be traced to procedure-related fetal blood contamination. Sometimes, before samples are sent for AFP analysis, they are centrifuged and the red cells are removed. In such cases, hemoglobin F can often be detected in the supernatant, leading to a heightened suspicion of a false-positive result. Once fetal blood contamination has been excluded, the likelihood of obtaining a false-positive result is considerably reduced.

Acetylcholinesterase (AChE) is a neuronally derived protein. Measurements of AChE in amniotic fluid⁸ are also used to significantly improve the ability to distinguish between affected and unaffected pregnancies. This gel-electrophoretic approach has not only proved to be highly sensitive at detecting open NTDs (99% of anencephaly cases and 98% of open spina bifida cases with positive AFP results), but also yielded

Figure 28.1 Amniotic fluid AFP distributions in singleton, unaffected pregnancies (solid line) and pregnancies affected by open spina bifida (dashed line) during the second trimester. AFP measurements are expressed as multiples of the unaffected population median (MoM) on a logarithmic scale. Distributions of AFP values are logarithmic Gaussian for both of the populations and a small degree of overlap is present. This forms the basis for defining detection and false-positive rates at various amniotic fluid AFP cut-off levels. The odds of being affected, given a positive AFP measurement, can also be estimated using these distributions and the population prevalence of open spina bifida.

negative results in 9 out of 10 cases when the AFAFP measurement was falsely elevated.⁹

Other fetal disorders are also associated with elevated AFAFP levels, including open ventral wall defects (omphalocele and gastroschisis), congenital nephrosis, and the presence of a severely distressed or recently dead fetus.¹⁰ In the USA, open ventral wall defects are the second most common open fetal malformations identified by elevated AFAFP levels during the second trimester, occurring at a rate of three per 10 000 pregnancies.¹¹ These lesions may also be associated with the presence of AChE in amniotic fluid, probably secondary to leakage from intestinal nerve plexuses. Congenital nephrosis, an autosomal recessive disorder, is rare in most of the world but occurs frequently in Finland.¹²

Experienced laboratories can utilize the band densities of AChE to help distinguish between open ventral wall defects and open NTDs.¹³ This distinction has previously been helpful in guiding follow-up sonographic studies in cases when a lesion is difficult to visualize. Presently, however, ultrasound imaging can almost always differentiate between these defects. Fetal death is frequently associated with both elevated AFP levels and the presence of AChE in amniotic fluid.¹⁴ Gel electrophoresis of AChE in such cases often shows a characteristic smeared pattern. Small amounts of fetal calf serum, when accidentally introduced into an amniotic fluid sample prior to analysis, can produce a visible AChE band.¹⁴ When this is suspected, testing for bovine serum albumin can identify the cause of the false-positive result.

Maternal serum screening for open NTDs in the second trimester

In 1974, it was discovered that, during the second trimester, AFP levels in maternal serum were, on average, higher when anencephaly or open spina bifida was present in the fetus.^{15,16} A multicenter study in the UK¹⁷ tested the feasibility of using MSAFP measurements for second-trimester screening purposes; pregnancies identified as high risk would then become candidates for diagnostic procedures, including amniocentesis and high-resolution ultrasound.

MSAFP concentrations rise by approximately 15% per week during the second trimester in unaffected singleton pregnancies, and it was therefore necessary to take this into account when establishing normative data. In addition, it was important to take into account any potential differences in assay standards among centers. For example, an MSAFP level measured as 40 ng/mL in one center might be measured as 75 ng/mL in a second center. Both of these measurements would be correct in relation to other measurements within the respective population, but it would be impossible to compare them without establishing a common currency. In analyzing data from the UK collaborative study, Wald and colleagues¹⁷ began by converting data from each of the centers into multiples of the unaffected population's median. The median is the most stable and reliable measure of any given population's midpoint, and serves as the point of reference against which all other measurements can be expressed as multiples of the median (MoM). This conversion of the data allowed the different within-laboratory mass unit values for each gestational week to be taken into account, and made it possible to compare the median MSAFP values for pregnancies affected with open spina bifida (3.8 MoM) or anencephaly (7.7 MoM) with values from unaffected singleton pregnancies (1.0 MoM). Figure 28.2 demonstrates the distributions of MSAFP values in unaffected singleton pregnancies and in pregnancies affected by open spina bifida. Defining the distributions of MSAFP values in MoM also allowed the extent of overlap between unaffected and affected populations to be analyzed. With this information, both the individual and the collective odds that a pregnancy would be affected with a given fetal disorder could be estimated (Fig. 28.3).

The ability to estimate the individual and collective odds for open spina bifida provided a rational basis for deciding on a reasonable cut-off level for high-risk classification. For example, 3.4% of screened pregnancies from the general population and 75% of open spina bifida pregnancies were associated with MSAFP values of 2.5 MoM or above. At that time, the prevalence of open spina bifida in the UK was approximately two cases per 1000 births. Therefore, for every 10 000 pregnancies screened, 340 would initially be placed in the high-risk category and 17 of those (1 out of 20) would be affected with open spina bifida. In the USA, where the prevalence of open spina bifida was lower (one case per 1000

Figure 28.2 Maternal serum AFP distributions in singleton, unaffected pregnancies (solid line) and in pregnancies affected by open spina bifida (dashed line) during the second trimester. AFP measurements are expressed as multiples of the unaffected population median (MoM) on a logarithmic scale. Distributions of AFP values are logarithmic Gaussian for both of the populations and a moderate degree of overlap is present. These distributions form the basis for estimating both collective and individual odds for being affected with open spina bifida, once the maternal serum AFP value and the population prevalence are known.

Figure 28.3 Estimation, during the second trimester, of a pregnant woman's individual odds of carrying a fetus affected by open spina bifida once her maternal serum AFP value has been determined. In this example, the woman's AFP level is 2.0 MoM, and the measurements from that point on the baseline to the intersection with the unaffected (H_{UA}) and affected (H_{OSB}) curves are approximately 4 units (solid vertical line) and 8 units (dashed vertical line) respectively, producing a likelihood ratio of 2. Based on her AFP level, the woman's individual odds of having a pregnancy affected by open spina bifida are now two times higher than those of the general population.

births), 1 out of 40 of the pregnancies in the high-risk category would be affected by open spina bifida. It also became possible to assign individual risk estimates for open spina bifida based on the initial MSAFP value. If pregnancies are dated by ultrasound measurement before screening, the overall screening performance is improved in that the rate of detection is increased and the false-positive rate is reduced. Improved MSAFP assay performance also influences the odds estimates. In contrast to the mid-1970s when coefficients of variation ranged from 8% to 25%, assays now have figures that are below 5%. This improvement substantially lowers the false-positive rate. Some believe that faulty assay performance is largely responsible for the less than complete detection of open lesions and that improvement in the assay will lead to better detection rates. This perception is incorrect as commercially available assays now perform very satisfactorily.¹⁸ Detection is limited because the distribution of MSAFP levels in various open fetal lesions overlaps to varying degrees with that of the unaffected population. This characteristic needs to be understood by physicians, office personnel, and patients, so that expectations do not exceed the capacity of the screening test.

The original estimates for both detection rates and false-positive rates of MSAFP screening for open NTDs were based upon the date of the last menstrual period (LMP).¹⁷ Even when LMP dates are carefully obtained, they are incorrect by more than 2 weeks in about 20% of cases.¹⁹ Furthermore, there is a tendency to think that a pregnancy is further advanced than it really is, and this diminishes detection because normative data are based on a known rise in MSAFP measurements of about 15% per week during the second trimester. In 1980, the average biparietal diameter (BPD) of fetuses with spina bifida was found to be smaller than that of unaffected fetuses at any given gestational week in the second trimester.²⁰ Other ultrasound measurements did not differ. If BPD measurements were to be used routinely for dating in MSAFP screening, the MSAFP measurements would appear to be higher for pregnancies with open spina bifida, and sensitivity for detecting the lesion would be increased, possibly to above 90%. An abbreviated ultrasound study involving fetal biometry would correct the dates of pregnancies that are further advanced than predicted by LMP and would also identify twins, thereby reducing false-positive screening results. Cases of anencephaly would also be identified at this point. Systematically carrying out fetal biometry and dating pregnancies by BPD measurements would reduce screening program costs and increase screening performance, thereby avoiding unnecessary anxiety for many women.

As AFP screening became more widely used, factors were identified that influence the analyte level, the risks of open NTDs, or both. One of these factors is maternal weight. Heavier women tend to have lower concentrations of serum markers because of their increased blood volume. This factor has added significance in that very heavy women are reported to have a higher risk of having a fetus affected with open spina

bifida.^{21–28} Adjusting for a woman's weight has the overall effect of increasing detection while decreasing false-positives; the false-positive rate becomes similar for both lighter and heavier women. A second influencing factor is maternal race.²⁹ Among black women, MSAFP levels are about 10–15% higher than among white women.³⁰ If this is not taken into account, an inappropriately high proportion of black women will be identified as having positive screening results and will be sent for further diagnostic procedures. The inappropriateness of this action is compounded by the fact that black women have a lower risk (by about one-half) of open NTDs. A 16-center US collaborative study³¹ confirmed the feasibility of adjusting the MSAFP values to reflect a more appropriate proportion of black women with positive screening results. A third influencing factor is maternal insulin-dependent diabetes, which is associated with a 20% lower MSAFP value than unaffected singleton pregnancies.^{32,33} Women with insulin-dependent diabetes also have a higher risk of having a pregnancy affected by open NTDs. At present, a re-evaluation is in progress to determine whether the level of diabetic control, as measured by hemoglobin A_{1c}, influences the MSAFP concentration^{34,35} but this issue is not yet completely resolved.

Use of ultrasound in the identification of open NTDs

Ultrasound is an invaluable complement to AFP measurements in the evaluation of NTDs. Advances in imaging now allow the diagnosis of all cases of anencephaly as early as 12 weeks' gestation, and the diagnosis of over 95% of fetuses with spina bifida in the second trimester. In addition, many other causes of elevated MSAFP levels are discernable by ultrasound. Accordingly, ultrasound can be used both in the definitive diagnosis of open NTDs in high-risk patients and as part of an AFP screening program.

Use of ultrasound as a component of open NTD screening

The efficacy of using MSAFP levels in screening for open NTDs is well documented^{36,37} and has stood as a routine obstetrical test for almost 30 years. As physicians have become more skilled in the identification of fetal structural anomalies using ultrasound, and the resolution of the equipment has improved, experts have questioned whether AFP screening could be replaced by ultrasound. In expert centers this may be feasible. Wald and colleagues,^{38,39} as well as others, have demonstrated that ultrasound evaluation of the fetal spine and head rivals MSAFP screening when performed in a high-risk population by experienced perinatal sonographers. However, there is little to suggest that ultrasound will perform as well in a general low-risk pregnant population, when the availability of sonographers with extensive experience of identify-

ing open NTDs is limited. Detection rates in this population are approximately 60–80%. Therefore, MSAFP screening between 15 and 20 weeks' gestation (ideally between 16 and 18 weeks) remains the primary approach to open NTD screening.

Because only about 2% of women with an initially elevated MSAFP screen have a fetus with an open NTD, the initial step in the subsequent evaluation is the performance of a fetal ultrasound to rapidly identify other causes of the elevated screen. These include incorrect dating (see section on maternal serum screening for open NTDs in the second trimester, above), the presence of twins, oligohydramnios, fetal demise, and other more easily identifiable fetal anomalies such as omphalocele and gastroschisis. In up to 50% of cases, incorrect dating will be identified and subsequent adjustment of the MSAFP value will resolve the issue. If the cause of the elevation remains unknown after the initial scan, genetic counseling and additional testing by either ultrasound or amniocentesis will be required.

Until recently, the standard diagnostic test for high-risk patients (i.e., those with unexplained elevated MSAFP levels, those having a previously affected child, and those taking medications known to increase the risk of open NTDs) was amniocentesis with an evaluation of AFAFP and AChE levels. Measurement of this combination of amniotic fluid analytes has a greater than 99% detection rate for anencephaly and an approximately 95–99% detection rate for spina bifida with a 0.4% false-positive rate.^{40–42} Recently, advances in high-resolution ultrasound have led to similar detection rates without the potential risk of an invasive procedure.^{43,44} In the hands of the most experienced sonographers, targeted sonographic evaluation of high-risk cases has a sensitivity of 97–100% with 100% specificity.

Ultrasound detection of a meningocele is frequently based on the finding of a small cystic mass protruding from the fetal lumbosacral or thoracic area. On other occasions, the findings may be more subtle and may only present as a widening of the posterior processes of the vertebral bodies. Although many open NTDs will be seen in the coronal or sagittal planes, others may not. The definitive views to identify or exclude spina bifida are transverse images of each individual vertebral body (Fig. 28.4).

The ultrasound diagnosis of open NTDs has been greatly enhanced by the recognition of associated anomalies of the fetal skull and brain,^{2,45} which are present in over 95% of cases of spina bifida imaged in the second trimester. These findings include ventriculomegaly, microcephaly, frontal bone scalloping ("lemon" sign), and obliteration of the cisterna magna with either an absent or abnormal anterior curvature of the cerebellar hemisphere ("banana" sign). These last two findings are secondary to the presence of an Arnold–Chiari malformation and their appearance is related to gestational age. The lemon sign appears in approximately 90–98% of pregnancies with spina bifida imaged before 24 weeks' gestation but in significantly fewer of those imaged at a more advanced

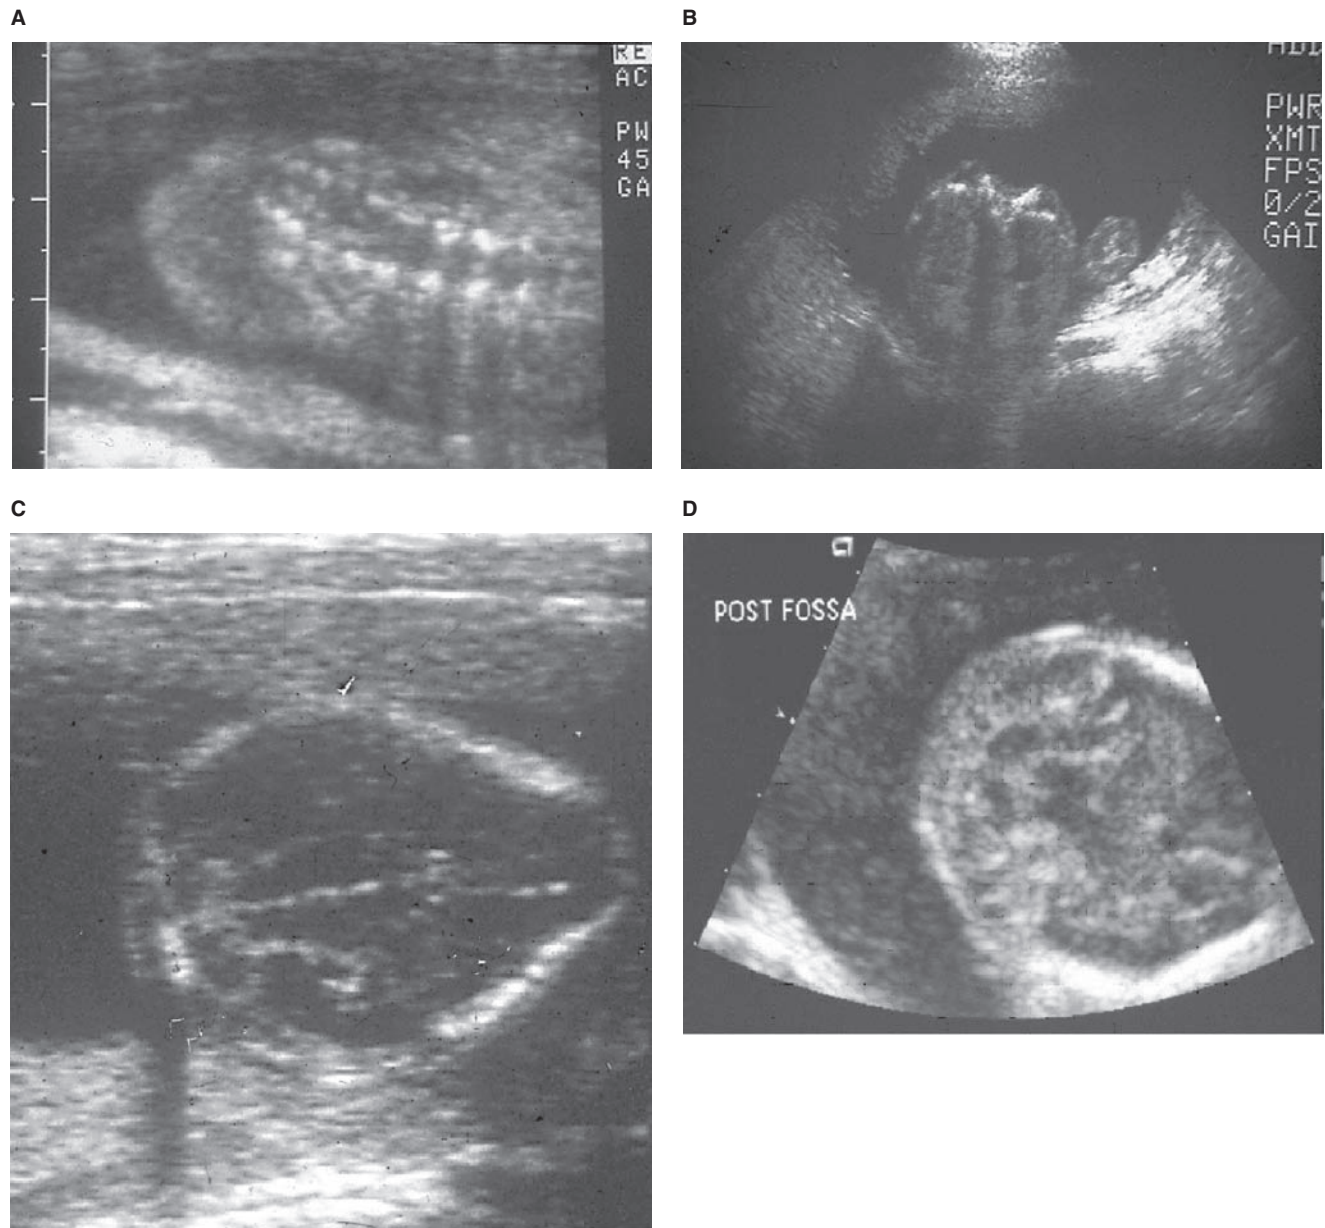

Figure 28.4 Ultrasound prenatal diagnosis of spina bifida. (A) Coronal view of lower lumbar spine demonstrating widening of the posterior processes and disruption of the vertebra; (B) a transverse view of a meningocele (note that in this case the spinal defect

is seen as an indentation with no sac); (C) head view of a fetus with spina bifida demonstrating the “lemon” sign secondary to frontal bone scalloping; and (D) typical “banana” sign, showing downward displacement of the cerebellum.

gestational age. Cerebellar abnormalities are present in 95% of fetuses irrespective of gestational age; however, they appear as the banana sign most frequently before 24 weeks and as cerebellar absence after 24 weeks.^{3,45}

The cranial signs associated with spina bifida are frequently more easily attainable than the detailed transverse scans required to identify the specific spinal lesion. It is reassuring that the sacral lesions that are the most difficult to visualize appear to be the ones most frequently accompanied by cranial

and cerebellar findings. In the series reported by Van den Hof³ and Nyberg and colleagues,⁴⁵ all sacral lesions were accompanied by abnormalities of the head, whereas only lumbar lesions were associated with normally shaped heads.

Two schools of thought continue to exist as to whether ultrasound scanning alone is sufficient for high-risk patients or whether amniocentesis should continue to be the primary diagnostic procedure. Recent studies have confirmed that, with the addition of the cranial signs, centers with specialized

expertise in fetal imaging show excellent specificity and sensitivity for the detection of open NTDs.^{43,46} In less experienced hands, however, where both false-positive and false-negative results are obtained, ultrasound must still be considered a screening rather than a diagnostic procedure.⁴⁷⁻⁴⁹

Even in centers with expertise in sonography there may be additional value in performing an amniocentesis. In addition to the close to 100% detection rate reported with AFAFP and AChE measurements,⁵⁰ invasive testing has the additional advantage of enabling the fetal karyotype to be evaluated. Several studies suggest that elevated MSAFP levels independently increase the risk of fetal aneuploidy.⁵¹ In pregnancies complicated by an elevated MSAFP, the incidence of fetal aneuploidy is 0.61% in fetuses with a normal ultrasound and 16% in those with an abnormal ultrasound.^{52,53} One additional advantage is knowing that the AFAFP level is differentiating between cases that have an elevated MSAFP level secondary to placental leakage and those that also have an elevated AFAFP level. Those with only elevated maternal serum values have an increased risk of placental problems, including fetal growth retardation, stillbirth, and preeclampsia. Those with elevated amniotic fluid levels should be further evaluated for fetal anomalies. In the evaluation of a very high MSAFP level, amniocentesis may be of particular value because there is a direct relationship between the degree of MSAFP elevation and the occurrence of anomalies.^{54,55} With an MSAFP of 2.5 MoM, there is a 3.4% risk of anomalies, whereas at 7 MoM, the risk increases to 40.3%.⁵⁵

Although many of the congenital anomalies associated with elevated AFAFP levels are easily diagnosed with ultrasound (e.g., omphalocele, gastroschisis, bladder extrophy, and some cases of sacrococcygeal teratoma), other equally severe fetal problems may have no ultrasound findings. For example, fetal skin lesions such as epidermolysis bullosa may leak serum and be associated with elevated levels of both MSAFP and AFAFP. Very high levels of both MSAFP and AFAFP are also seen in congenital nephrosis,⁵⁶ frequently without any abnormalities identified on second-trimester ultrasound.

At present, the ideal management of an elevated MSAFP level should include both ultrasound and amniocentesis. If a high-quality ultrasound fails to identify a fetal defect, the risks and benefits of both amniocentesis and a specialized ultrasound examination should be discussed with the patient. The decision can then be based on the degree of AFP elevation, the patient's history, the quality and findings of the ultrasound examination, and the patient's age.

An elevated MSAFP level in which both the ultrasound scan and AFAFP and AChE levels are normal retains an increased risk of adverse pregnancy outcome; there is a 20–58% risk of poor pregnancy outcome with an unexplained raised MSAFP level.⁵⁷⁻⁵⁹ Risks include low birthweight, growth restriction, placental abruption, fetal or neonatal death, and preeclampsia. Crandall and colleagues⁶⁰ studied 1002 women with MSAFP values greater than 2.5 MoM and stratified them

according to the degree of elevation. In those with a normal ultrasound and amniocentesis, the risk of an adverse outcome was 27% overall but varied with the degree of elevation. An adverse outcome occurred in 16% of cases when the MSAFP was 2.5–2.9 MoM, 29% when the MSAFP was 3.0–5.0 MoM, and 70% when it was greater than 5.0 MoM. Wailer and co-workers⁶¹ evaluated the predictive value of a high MSAFP level compared with a low level in 51 008 women screened for MSAFP. The risk of delivery before 28 weeks was 0.4% for those with low MSAFP values (< 0.81 MoM) and 3.2% for those with high values (> 2.5 MoM), an eightfold difference.⁶¹⁻⁶³ The rates of delivery before 37 weeks were 2.6% for the low MSAFP group and 24.3% for the high MSAFP group. Notably, women with MSAFP values greater than 2.5 MoM had a 10.5-fold increased risk of preeclampsia and a 10-fold increased risk of placental complications, suggesting that an elevated value in the absence of an anomaly may derive from a fetal–maternal hemorrhage of sufficient volume to have clinical significance. To date, no management protocol has been demonstrated to improve outcome in these cases. Despite this, such patients should be followed throughout the pregnancy, with serial testing of fetal growth and well-being.

Maternal serum screening for Down syndrome in the second trimester using AFP measurements

A new and unexpected association between low MSAFP levels and certain autosomal trisomies (Down syndrome, trisomy 18) was reported in 1984.⁶⁴ This discovery was rapidly confirmed and a method was proposed that would enable a patient-specific risk for Down syndrome to be obtained by combining a woman's age-related risk with the increase (or decrease) in risk as defined by her serum AFP level.⁶⁵ The additional information provided by MSAFP measurements had the potential to identify a subgroup of younger pregnant women whose individual risk of a Down syndrome-affected pregnancy was similar to that of women aged 35 and older.

An eight-center collaborative field trial was initiated in 1985 to determine the efficacy of applying MSAFP screening routinely to the pregnant population.⁶⁶ A total of 77 273 pregnancies were screened; 4.7% were initially classified as being at high risk for Down syndrome, and 2.7% remained at high risk after gestational dates had been confirmed. Of these high-risk women, 66% elected to have amniocentesis, and 18 fetuses with Down syndrome and four fetuses with trisomy 18 were identified. One case of Down syndrome was identified per 89 amniocenteses performed (among unscreened women aged 35 and older, the rate is approximately one case per 150 second-trimester pregnancies), and an additional three Down syndrome births were identified from among the women who refused amniocentesis. Thus, approximately 25% of the fetal Down syndrome cases were identified in pregnant women

under 35, and the study concluded that this type of screening was feasible. A survey of screening centers carried out in 1988 in the USA reported that more than one million pregnancies were being screened for Down syndrome by MSAFP testing.⁶⁷

Maternal serum screening for Down syndrome in the second trimester using multiple markers

In the late 1980s, the levels of hCG and unconjugated estriol (uE_3) in a pregnant woman's blood were found to be useful screening markers for Down syndrome during the second trimester.^{68–71} Levels of uE_3 and AFP are lower in the presence of Down syndrome, whereas hCG levels are higher. These three markers in combination raised the detection rate for Down syndrome to approximately 60%, while keeping the false-positive rate at 5%. In the early 1990s, several successful trials were undertaken in Europe and the USA to determine the efficacy of multiple-marker screening under everyday conditions. The first trial, reported from the USA, was carried out by two centers in New England.⁷² In this study, a risk cutoff of 1:190 was selected with the aim of initially identifying about 5% of the screened pregnancies as being at high risk for Down syndrome (i.e., a positive screening result was defined as being a risk of at least 1 in 190). Among the 25 207 women who were screened, 6.6% were initially classified as being at high risk. The revised positive rate was 3.8% after follow-up and reclassification of LMP dates by ultrasound. These women were offered amniocentesis and chromosome studies; 79% accepted. In this group of 720 women, 20 fetuses with Down syndrome (one per 38 amniocenteses) and seven fetuses with other chromosomal disorders were identified. It was determined from follow-up information that the Down syndrome detection rate was 58%, which was close to the expected rate.⁷¹

In the mid-1990s, dimeric inhibin-A (DIA) was discovered to be a useful second-trimester marker for Down syndrome.⁷³ The median DIA level in maternal serum of affected pregnancies was twice that of unaffected pregnancies. A consensus estimate of performance data from eight case-control studies showed a univariate detection rate for Down syndrome of 41%, with a 5% false-positive rate.⁷³ An independent dataset that was reported in conjunction with this consensus analysis concluded that adding DIA to the three-marker screening panel would raise the detection rate for Down syndrome to 78% at a 5% false-positive rate (using ultrasound dating), a substantial improvement. This performance estimate has been confirmed in a recent multicenter study, which found an 81% detection rate with the same 5% false-positive rate.⁷⁴ DIA is now commonly included with AFP, uE_3 , and hCG as part of routine second-trimester screening. Figure 28.5 provides overlapping distributions of these four second-trimester markers on a common scale to allow for direct comparisons.

Figure 28.5 Overlapping distributions of second-trimester maternal serum AFP, uE_3 , hCG, and DIA measurements in unaffected (solid line) and Down syndrome (dashed line) pregnancies. The four figures are drawn on the same scale. For AFP and uE_3 measurements, Down syndrome pregnancies have lower values, whereas hCG and DIA measurements are higher. These overlapping distributions show the relative frequencies, so those with less variability (i.e., smaller standard deviation) are higher. Overall, AFP is the least effective of the four screening markers for Down syndrome.

Adding trisomy 18 interpretations to second-trimester maternal serum screening

Trisomy 18 (Edwards syndrome) is a lethal chromosome disorder.⁷⁵ The birth prevalence of trisomy 18 increases with maternal age, similar to Down syndrome. In the general pregnant population, the second-trimester prevalence of trisomy 18 is approximately one out of 2400 pregnancies, whereas the birth prevalence is one out of 8000; this is because of a third-trimester spontaneous fetal loss rate of 70%.⁷⁶ More than one-half of the liveborn infants will die by the age of 10 days and over 90% by 100 days.⁷⁵ Prenatal detection can be medically and economically justified when performed in conjunction with Down syndrome screening if a high proportion of women offered amniocentesis have an affected fetus. Fetuses with trisomy 18 are growth retarded and this, along with a high rate of fetal loss in the third trimester, leads to a Cesarean section rate of 50% or higher when the condition is undiagnosed.⁷⁷ Approximately 25% of fetuses with trisomy 18 also have spina bifida or omphalocele.

Second-trimester maternal serum levels of AFP, uE_3 , and hCG are all lower, on average, in the presence of trisomy 18. This pattern is not associated with incorrect gestational dating (unlike the pattern for Down syndrome) and, therefore, is rarely seen in unaffected pregnancies. Optimal screening performance requires a risk-based algorithm that treats the

analyte measurements as continuous variables and includes maternal age, similar to the approach used for Down syndrome screening described earlier in this chapter. This algorithm was developed using data provided by nine prenatal screening centers in North America and Europe, which retrospectively provided maternal serum AFP, uE₃, and hCG measurements (expressed as MoM) and relevant pregnancy-related information on a total of 94 second-trimester trisomy 18 pregnancies.⁷⁸ In the 89 pregnancies without an accompanying open NTD, the median levels for AFP, uE₃, and hCG were 0.65, 0.43, and 0.36 MoM, respectively. Overall, 70% of uE₃ MoM values, 54% of hCG values, and 44% of AFP values from trisomy 18 pregnancies were equal to or less than those of the 5th percentile of unaffected pregnancies. At a risk cutoff level of 1:100, a combination of AFP, uE₃, and hCG measurements detected 60% of the trisomy 18 pregnancies with a false-positive rate of about 0.2%; one in every nine amniocenteses identified a fetus with trisomy 18. The risk-based screening protocol is now the preferred approach to screening for trisomy 18.

Abnormal analyte levels with normal karyotype

The association of elevated AFP levels with poor pregnancy outcome is discussed above. Similarly, there are clinical consequences of altered levels of the other analytes used in aneuploid screening.

Unexplained elevated hCG levels

The risk of an adverse pregnancy outcome with elevated hCG levels appears to be independent of the risks associated with elevated AFP levels. Studies have shown that an unexplained elevated hCG level is associated with an increased risk of preeclampsia, preterm birth, low birthweight, fetal demise, and possibly hypertension.⁷⁹ It appears that the higher the level of hCG, the greater the risk.

Elevated hCG and AFP levels

The combination of elevated MSAFP and hCG levels occurs rarely but may have an overall pregnancy complication rate exceeding 50%. A study of 66 singleton and 33 multiple pregnancies with an MSAFP of more than 2 MoM and an hCG of more than 3.0 MoM found that 60% of singletons and 81% of twins had at least one obstetric complication; these included preeclampsia, preterm birth, growth restriction, placental abnormalities, and fetal death.⁸⁰ Confined placental mosaicism for chromosome 16 has been reported to be associated with extremely high levels of both analytes and to have a very poor prognosis.^{81,82}

Low second-trimester maternal serum uE₃ levels

Low maternal serum uE₃ levels have been linked to adverse pregnancy outcomes.^{83,84} Very low or absent uE₃ levels of 0.0–0.15 MoM suggest biochemical abnormalities of the fetus or placenta, including placental steroid sulfatase deficiency, Smith–Lemli–Opitz syndrome, congenital adrenal hypoplasia, adrenocorticotropin deficiency, hypothalamic corticotropin deficiency, and anencephaly.

Smith–Lemli–Opitz syndrome is an autosomal recessive disorder secondary to a defect in 3-hydroxysteroid-7-reductase, which alters cholesterol synthesis and results in low cholesterol levels and the accumulation of the cholesterol precursor 7-dehydrocholesterol in blood and amniotic fluid. Because cholesterol is a precursor of E₃, the defect results in reduced or undetectable levels of E₃ in maternal serum and amniotic fluid. Smith–Lemli–Opitz syndrome is characterized by low birthweight, failure to thrive, and moderate to severe mental retardation. It is associated with multiple structural anomalies, including syndactyly of the second and third toes, microcephaly, ptosis, and typical-appearing facies.^{85–87}

Bradley and colleagues⁸⁸ summarized findings in 33 women who delivered infants with Smith–Lemli–Opitz syndrome. Out of the 26 women whose second-trimester uE₃ values were determined, 24 had levels that were below the 5th percentile (< 0.5 MoM). The median level in this group was 0.23 MoM (below the 1st percentile). A risk assessment based on maternal serum uE₃ levels in combination with AFP and hCG has been suggested⁸⁹ and subsequently used prospectively in a cohort of 1079301 pregnancies.⁹⁰ Reliable and inexpensive prenatal diagnostic testing for Smith–Lemli–Opitz syndrome is available based on amniotic fluid cholesterol or 7-dehydrocholesterol levels.⁹¹

Placental steroid sulfatase deficiency is an X-linked recessive disorder resulting from deletion of Xp22.3. This enzyme deficiency prevents removal of the sulfate molecule from fetal estrogen precursors, preventing their conversion to E₃. The fetal phenotype depends on the extent of the deletion, with over 90% of cases presenting as X-linked ichthyosis that can be treated with topical keratolytic agents. However, in about 5% of cases, there can be a deletion of contiguous genes, causing mental retardation. The deletion can extend, on occasion, to cause Kallmann syndrome or chondrodysplasia punctata. The lack of estrogen biosynthesis may result in delayed onset of labor, prolonged labor, or stillbirth.

Prenatal diagnosis of the deletion that leads to placental sulfatase deficiency and congenital ichthyosis can be performed by karyotyping or fluorescence *in situ* hybridization.^{92–94} Although very low uE₃ levels, usually below the level of detection, can detect males at risk for this disorder, testing in these cases is not routinely offered because the phenotype is usually mild. However, the rarer more serious cases of extensive deletions will be missed.⁹⁵

Ultrasound in second-trimester aneuploid screening

Second-trimester ultrasound markers for Down syndrome

There are no single physical characteristics that are diagnostic for Down syndrome, rather the diagnosis is suspected when a combination of associated features (e.g., Simian crease, epicanthal folds, increased nuchal skinfold) are present. Similarly, the *in utero* probability of Down syndrome is increased when ultrasound imaging demonstrates anomalies or physical features that occur more frequently in Down syndrome fetuses than in the general population. Some of these are distinct congenital anomalies such as atrioventricular canal or duodenal atresia, which strongly suggest the possibility of Down syndrome and are independent indications to offer invasive testing. None of these occurs frequently enough, however, to be valuable in routine screening of a low-risk population. For example, although 40% of fetuses with duodenal atresia have Down syndrome, it is seen in only 8% of affected fetuses. More valuable for routine screening are the “soft markers,” which are variations of normal that occur more commonly in fetuses with Down syndrome than in unaffected fetuses. By comparing the prevalence of these markers in Down syndrome fetuses with their prevalence in the unaffected population, a likelihood ratio can be calculated that can be used to modify the *a priori* age or serum-screen risk.

For a marker to be useful for screening, it should be present in a high proportion of Down syndrome pregnancies, infrequently seen in normal fetuses, easily imaged during routine sonographic examination, and present early enough in the second trimester that subsequent diagnostic testing by amniocentesis can be performed with results available when pregnancy termination remains an option. Markers commonly used to assess the risk of Down syndrome include the following:

- An *increased nuchal fold* is the most distinctive second-trimester marker. To obtain the correct image, the fetal head is scanned in a transverse plane similar to that used in measuring the BPD. The thalami and upper portion of the cerebellum should be in the plane of the image. The distance between the external surface of the occipital bone and the external surface of the skin is measured. About 35% of Down syndrome fetuses have a nuchal skinfold measurement that is greater than 6 mm compared with only 0.7% of unaffected fetuses. When fetuses with more than one marker are included, a measurement of greater than 6 mm yields a likelihood ratio for Down syndrome of 50. When an increased nuchal fold is an isolated finding, the likelihood ratio for Down syndrome is 20. Thus, the presence of an increased nuchal fold alone is an indication to offer invasive testing.^{96–101}
- In the second trimester, Down syndrome fetuses may have *short proximal extremities*. An observed–expected ratio of less than 0.91 or a BPD–femur ratio of more than 1.5 has a reported likelihood ratio for Down syndrome of 1.5–2.7 when

present as an isolated finding. A short humerus is more strongly related to Down syndrome than a short femur, with reported likelihood ratios ranging from 2.5 to 7.5.¹⁰²

- *Echogenic intracardiac foci* are secondary to mineralization within the papillary muscle and occur in up to 5% of normal pregnancies and in approximately 13–18% of Down syndrome pregnancies.¹⁰³ When an echogenic focus is present as an isolated marker, the likelihood ratio for Down syndrome is approximately 2. The risk does not seem to vary if the focus is in the right or left ventricle or if it is unilateral or bilateral.
- *Increased echogenicity of the fetal bowel*, when brighter than the surrounding bone, has a likelihood ratio for Down syndrome of 5.5–6.7.^{104–106} This finding can also be seen with fetal cystic fibrosis, congenital cytomegalovirus infection, swallowed bloody amniotic fluid, and severe intrauterine growth restriction. Therefore, if amniocentesis is performed for karyotype analysis in these cases, testing for other potential etiologies should be considered.
- *Mild fetal pyelectasis* (a renal anterior–posterior diameter of greater than 4 mm) has been suggested as a potential marker for Down syndrome. As an isolated marker, the likelihood ratio ranges from 1.5 to 1.9. More recently, Snijders and co-workers¹⁰⁷ did not find a significant increase in mild fetal pyelectasis in Down syndrome pregnancies compared with normal pregnancies, and its value in Down syndrome screening is questionable.
- Other markers that have been described include a hypoplastic fifth middle phalanx of the hand,¹⁰⁸ short ears, a sandal gap between the first and second toes,^{109,110} an abnormal iliac wing angle,¹¹¹ an altered foot–femur ratio,¹¹² and a short or absent nasal bone.¹¹³ These markers are inconsistently used because of the time and expertise required to obtain them.

Use of ultrasound to estimate the risk of Down syndrome

As with other screening modalities, second-trimester ultrasound can be used to alter the *a priori* risk in either direction. A benign second-trimester scan that finds none of the known markers and no anomalies has been suggested to have a likelihood ratio for Down syndrome of 0.4, assuming the image quality is satisfactory.¹¹⁴ Nyberg and colleagues used this approach to calculate an age-adjusted ultrasound risk assessment for Down syndrome in 8914 pregnancies (186 fetuses with Down syndrome, 8728 control subjects). Some type of sonographic finding (major abnormality, minor marker, or both) was observed in 68.8% of fetuses with trisomy 21 compared with 13.6% of control fetuses ($P < 0.001$); about one-third of fetuses with Down syndrome have neither a marker nor an anomaly.

A positive finding on ultrasound can also be used to modify the risk of aneuploidy. The magnitude of the increase depends on the marker(s) or anomalies seen. Nyberg and colleagues^{114,115} reviewed their own data and the data of others¹¹⁶ to estimate a likelihood ratio for each marker when it is present as an isolated finding (see Table 28.1).

Combined ultrasound and multiple marker risk assessment in the second trimester

Ultrasound markers can be combined with serum markers, but a relatively small correlation between the two approaches needs to be taken into consideration if a quantitative approach is used.¹¹⁷ Bahado-Singh and colleagues¹¹⁸ combined ultrasound markers with maternal analytes, including urinary hyperglycosylated hCG and urinary β -core fragment of hCG. In a sample of 585 pregnancies, the sensitivity of this combined screening approach for trisomy 21 was 93.7%, with a false-positive rate of 5%.

Table 28.1 Likelihood ratios (LR) and 95% confidence intervals (CI) for isolated markers in three studies.

Sonographic marker	LR*	LR (95% CI)†	LR (95% CI)‡
Nuchal thickening	18.6	11 (5.2–22)	17 (8–38)
Hyperechoic bowel	5.5	6.7 (2.7–16.8)	6.1 (3–12.6)
Short humerus	2.5	5.1 (1.6–16.5)	7.5 (4.7–12)
Short femur	2.2	1.5 (0.8–2.8)	2.7 (1.2–6)
EIF	2	1.8 (1.0–3)	2.8 (1.5–5.5)

Ultrasound screening for other chromosomal abnormalities

Fetal aneuploidy other than Down syndrome can be suspected based on the finding of specific ultrasound abnormalities. Table 28.2 demonstrates the association of specific ultrasound findings and chromosomal abnormalities.

Choroid plexus cysts deserve specific mention because they occur relatively frequently. They are seen in approximately 1% of fetuses between 16 and 24 weeks' gestation and have been associated with trisomy 18. About 30–35% of fetuses with trisomy 18 will have choroid plexus cysts. Alternatively, among fetuses with a choroid plexus cyst, about 3% will have trisomy 18, and most (65–90%) will also have other ultrasound findings. Early studies suggested that an isolated choroid plexus cyst might result in a probability of trisomy 18 of as high as 1 in 150. However, many of these series contained a high proportion of older women, resulting in the risk being overstated. Snijders and co-workers¹¹⁹ more recently calculated that an isolated choroid plexus cyst has a likelihood ratio for trisomy 18 of 1.5. The size, location, or persistence of the cyst does not alter the risk.^{120–124}

Maternal serum screening for Down syndrome in the first trimester

Within a few years of the 1984 report of the association between reduced AFP levels in the second trimester and Down syndrome,⁶⁴ researchers reported measurements of AFP and other second-trimester markers earlier in pregnancy.^{125,126} The

*Renal anomalies defined as mild hydro, moderate hydro, severe hydro, multicystic kidney, obstruction, or renal agenesis

levels of AFP and uE₃ were found to differ only slightly between affected and unaffected pregnancies in the late first trimester.⁷¹ Measurements of hCG and particularly its free β -subunit were found to have some utility; however, the serum marker PAPP-A was found to be the best single marker.^{127–129} One factor leading to some early confusion in reported studies is that the strength of association of all of the known first-trimester markers changes week by week.¹³⁰ For example, PAPP-A measurements alone are a much better marker at 10 weeks' gestation (58% detection with a 5% false-positive rate) than at 13 weeks' gestation (27% detection with a 5% false-positive rate). This has required screening programs to have the ability to compute week-specific Down syndrome risks.¹³¹ According to the SURUSS report,¹³¹ the combination of maternal age, PAPP-A, and hCG (or the free β -subunit) at 12 weeks' gestation has a detection rate of about 63% with a 5% false-positive rate (less than the 81% found using quadruple markers in the second trimester). This led to a general agreement that stand-alone first-trimester biochemical screening should not be made available clinically. At present, few, if any, laboratories in the USA routinely provide Down syndrome risks based only on first-trimester biochemistry.

First-trimester ultrasound findings in Down syndrome pregnancies

In his initial description of the syndrome that bears his name, Langdon Down described skin which was so deficient in elasticity that it appeared to be too large for the body. This was particularly evident in the neck area of newborns. Since that time it has been clearly demonstrated that, as early as 10 weeks' gestation, the fetal neck area is expanded in Down syndrome. Although all fetuses demonstrate a small amount of fluid in the posterior nuchal area (called nuchal translucency, NT) at between 10 and 13 weeks' gestation (Fig. 28.6), fetuses with Down syndrome will, on average, have a larger amount. This difference allows measurement of NT to be converted to a likelihood ratio and used to modify the *a priori* maternal age risk of trisomy 21.

NT is defined as the maximum fluid-filled space between the skin of the posterior fetal neck area and the underlying structures. This area can be measured by transabdominal ultrasound in over 95% of cases and with transvaginal scanning in the remaining cases. Because the amount of fluid in euploid pregnancies increases with gestational age, no absolute "normal" value exists (Fig. 28.7); rather, the measurement is converted to either multiples of the gestational age median or the absolute deviation from the median (called delta NT) before conversion to a likelihood ratio. This manipulation is similar to that routinely used for gestational age standardization of biochemical analytes.

The performance of NT combined with maternal and gestational age in Down syndrome risk assessment has been well studied. In more than 100 000 pregnancies, NT measurements were greater than the 95th percentile in over 70% of fetuses

Figure 28.6 Correct measurement of NT in the first trimester.

Figure 28.7 Median, 5th, and 95th percentile of NT by crown-rump length.

with trisomy 21.¹³² Using a cutoff risk of 1:300, 82% of trisomy 21 pregnancies were screen positive with a total screen-positive rate of 8.3%. When a screen-positive rate of 5% was chosen, the sensitivity of screening was 77%. Subsequent studies have demonstrated similar rates of between 70% and 75%.^{133,134}

Although NT appears to be a powerful first-trimester Down syndrome screening analyte, it will be efficacious only if all operators measure it in a standard fashion. To encourage this, the Fetal Medicine Foundation in London, UK, developed detailed guidelines for taking NT measurements, which include the following:

- 1 The crown-rump length should be between 45 mm and 84 mm.
- 2 Either transabdominal or transcervical scanning can be used. Transabdominal is successful in most cases and should

be the primary approach in order to minimize the time and expense.

3 A true sagittal scan of the fetus is required.

4 The image must be magnified so that the fetus occupies 75% of the image. This insures that each increment in the distance between calipers will be approximately 0.1 mm. It has been demonstrated that ultrasound measurements can be accurate to the nearest 0.1 or 0.2 mm.¹³⁵

5 The fetal skin must be clearly separated from the amnion. When the fetus is lying directly on the amnion, separation can be accomplished either by waiting for fetal movement or by facilitating this (asking the mother to cough or tapping on her lower abdomen).

6 The maximum thickness of the subcutaneous translucency between the skin and the soft tissue overlying the cervical spine should be measured by placing the calipers as in Fig. 28.8. The

Figure 28.8 Appropriate placement of calipers for measuring NT. The arrow represents correct caliper location.

measurement should be taken three times, and the maximum one used for the risk calculation

7 The NT should be measured with the fetal head in the neutral position. Hyperextension will increase the measurement by as much as 0.6 mm, and excessive flexion will decrease it by 0.4 mm.¹³⁶

Although the above criteria assist in standardizing the technique used for measuring NT, consistently reliable results require sonographer training, image review, and ongoing quality management. In the USA, the Society of Maternal Fetal Medicine has developed a program of education and image review which leads to certification and indicates that individuals have mastered the technique (www.ntqr.org). Once sonographers and sonologists have completed this process, their clinical measurements are monitored and compared with expected standards. Centers or individuals demonstrating a deviation from the norm are alerted and remediation provided. This process is similar to those used by laboratories to ensure consistent values for biochemical analytes. A similar program is provided by the Fetal Medicine Foundation in London. Studies have demonstrated the efficacy of NT monitoring programs in assuring accurate results.¹³⁷

Combining NT and biochemical markers to screen for Down syndrome in the first trimester

If first-trimester biochemical and NT measurements at 10–13 weeks' gestation are combined, the performance is at least as good as or better than the second-trimester quadruple test. Table 28.3 shows the expected Down syndrome detection rate at 11–13 weeks' gestation for a 'combined' first-trimester screening test (maternal age, ultrasound NT measurements, and maternal serum measurements of PAPP-A and the free β -

Table 28.3 Comparing the Down syndrome detection rate (DR) and false-positive rate (FPR) for first-trimester combined testing (by week of gestation) with second-trimester quadruple marker testing.

§Modeled for first trimester.

¶OAPR: the odds of being affected given a positive result.

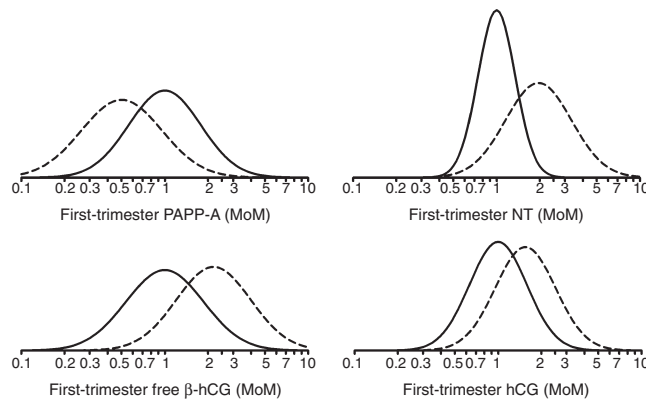

Figure 28.9 Overlapping distributions of first-trimester Down syndrome markers, including maternal serum PAPP-A, NT, free β -subunit of hCG, and hCG. These distributions vary by gestational week. The distributions correspond to the twelfth completed week, and the scales are the same as for Fig. 28.5 to allow for direct comparison. NT and PAPP-A measurements are more effective screening markers than hCG and free β hCG.

subunit of hCG). For comparison, the quadruple test performance is also provided. Either the free β -subunit of hCG or total hCG can be used as the fourth marker. Because PAPP-A and NT are the best discriminators, programs can choose, with minimal impact on performance, which form of hCG to use based on other factors, such as availability and cost of reagents.¹³⁸ Figure 28.9 provides overlapping distributions for NT measurements and for the three biochemical markers used for first-trimester screening.

Other first-trimester ultrasound markers

Individuals with Down syndrome are known to have midfacial flattening and hypoplasia of the nasal bridge, which most likely results from altered collagen formation. Pathologic studies of Down syndrome fetuses demonstrate this finding as early as the end of the first trimester.¹³⁹ Recently, Cicero and colleagues¹¹³ reported that ultrasound can identify this abnormality in a high proportion of Down syndrome fetuses in the first trimester. This finding is present in approximately 65% of Down syndrome fetuses and only 2.5% of the unaffected population, which results in a Down syndrome likelihood ratio of approximately 30 when the nasal bone is absent and 0.3 when it is present.¹⁴⁰

Although the initial reports on nasal bone imaging suggest that it may have an important role in Down syndrome risk assessment, many caveats remain before it can be recommended for routine use. It is difficult to routinely image, the frequency of absence varies depending on the patient's ethnic group (e.g., there is a much higher frequency in patients of African origin¹⁴¹), visualization is gestational-age dependent, and measurements of the nasal bone are not independent of the NT thickness. For these reasons, at the present time, the

use of nasal bone imaging in a Down syndrome risk algorithm is not recommended as part of primary screening. Nicholaides and colleagues¹⁴² have demonstrated its potential for secondary evaluation of patients initially identified as being at risk by more standard procedures. In his analysis, a first-trimester screening approach using NT, biochemical analytes, and nasal bone evaluation had a detection rate of 92% with a false-positive rate of 2.5%.¹⁴²

Other first-trimester ultrasound findings have also been suggested to have a role in Down syndrome risk assessment. These include altered flow through the ductus venosus and the presence of tricuspid regurgitation.^{143,144} At the present time, reports of these findings come from only a limited number of centers and their use for screening is still being investigated.

Integrating first- and second-trimester screening strategies for Down syndrome

Choosing an overall screening strategy for Down syndrome is complicated by the need to consider not only the performance of each strategy but also the ancillary issues of program implementation. This includes the timing and availability of diagnostic tests, adherence to risk cutoffs, concern about holding first-trimester test results until the second trimester, acceptability to women and healthcare providers, financial costs, medical costs, and second-trimester serum testing for open NTDs. Although there are clinical and programmatic advantages to screening in either the first or the second trimesters, the concept of combining markers from both trimesters into a single integrated interpretation provides the most accurate estimate of Down syndrome risk yet available.¹⁴⁵ Integrated screening calls for the holding of first-trimester information until the second-trimester results are also available. A single risk is then provided to the woman, and a single risk cutoff level is used to define screen-positive results (e.g., $\geq 1:200$). Figure 28.10 demonstrates that integrated screening performs more effectively than any of the strategies applied in the first or second trimesters. However, it requires that information is withheld from patients until at least 16 weeks' gestation.

The potential advantages of a first-trimester diagnosis have led to the creation of screening strategies that combine the high performance of integrated screening with a high detection rate of Down syndrome pregnancies in the first trimester.¹⁴⁶ Two of these strategies, sequential screening and contingent screening, are reviewed below; both include NT measurements.

- Sequential screening¹⁴⁷ initially offers counseling and diagnostic testing to all women with a first-trimester risk at or above an initial risk cutoff level (e.g., $\geq 1:50$); the remaining women are given a quadruple test (AFP, uE₃, hCG, and DIA) in the second trimester that is interpreted as an "integrated" test, using information from both trimesters. Those with a Down syndrome risk above a final second-trimester risk

Figure 28.10 Comparative performance of several Down syndrome screening strategies. Numbers in the individual bar graphs indicate detection rates at a 5% false-positive rate. Maternal age alone results in a 25% detection rate, and each strategy after that is associated with successively higher detection rates. The highest detection rate is achieved with full integrated screening, followed by serum integrated screening.

cut-off level (e.g., $\geq 1:270$) are also offered counseling and second-trimester diagnostic testing.

- Contingent screening^{148,149} differs from sequential screening by having not only a high-risk cutoff level defined in the first trimester but also a low-risk cutoff level (e.g., $\geq 1:50$ and $< 1:1500$). Women with Down syndrome risks below the low cutoff level are informed that they do not require further testing, as they are unlikely to become screen positive.

Given that integrated screening uses all of the informative markers before assigning a risk and determining who should be offered diagnostic testing, the other two strategies will, of necessity, be less efficient, as defined by detection and false-positive rates. This is because both sequential and contingent screening strategies assign an interim risk and make the offer

of diagnostic testing in the first trimester based on only a subset of informative markers. Thus, the early detection of some affected pregnancies and the reduced need for second-trimester screening (contingent testing) must logically be “paid for” by having either a somewhat lower detection rate or more false-positives. Modeling these strategies shows that sequential and contingent screening performances can approach that of integrated screening if the proportion of women offered diagnostic testing in the first trimester is kept well below the proportion offered diagnostic testing in the second trimester. Both perform more effectively than either the first-trimester combined strategy or second-trimester stand-alone screening.¹⁵⁰

Speculation

In the near future, Down syndrome screening programs will increasingly combine information from both trimesters as a way of reducing false-positives while simultaneously improving detection. Although NT measurements have been shown to be reliable in the research setting, it is not yet clear whether such testing can be reliably offered as a routine screening test.¹³⁴ Other improvements, such as repeated measures of biochemical markers,^{149,151} are being investigated as ways of increasing performance even further, even when NT measurements are not available. Also, methods using multiple contingent policies are being promulgated.¹⁵² Routinely available screening strategies, including those based on maternal serum alone, may soon be able to detect over 90% of Down syndrome pregnancies with only a 1–2% false-positive rate by combining information from first- and second-trimester screening tests. Research is also continuing in the area of collecting and testing individual fetal cells (or fetal DNA) in the maternal circulation as either a screening or a diagnostic test.¹⁵³

Key points

- In 1956, a fetal-specific protein (alpha-fetoprotein or AFP) was discovered in fetal serum.
- Elevated AFP in second-trimester amniotic fluid is a strong indicator of the presence of a fetal open neural tube defect (NTD).
- AFP levels in maternal serum can be used as a screening (but not diagnostic) test for open NTDs in the second trimester.
- AFP measurements in both amniotic fluid and maternal serum vary with gestation. They are routinely expressed as a multiple of the median (MoM) AFP value found in unaffected pregnancies of the same gestational age.
- In expert hands, ultrasound markers in the fetal brain at 18–21 weeks' gestation are diagnostic of open NTDs.
- Beginning in the 1970s, a woman's age was used as a determinant in screening for Down syndrome, with those aged 35 and older being offered amniocentesis and karyotyping.
- In 1984, reduced levels of maternal serum AFP in the second trimester were reported in Down syndrome pregnancies.
- Combining maternal age and serum AFP measurements allowed diagnostic testing to be offered to younger women; this combination had a detection rate of 25%.

(with a 5% false-positive rate) among women aged under 35 years.

- 9 Down syndrome risk, as defined by screening marker levels in combination with maternal age, is now used as the prime screening variable, and cutoff levels to determine detection and false-positive rates are based on risk.
- 10 Adding second-trimester serum markers (unconjugated estriol, uE₃; human chorionic gonadotropin, hCG; and dimeric inhibin-A, DIA) improved detection to 60–70% (with a 5% false-positive rate).
- 11 Second-trimester multiple marker screening is also able to identify 60% of trisomy 18 pregnancies (with a false-positive rate of less than 1%).
- 12 In the second trimester, significant ultrasound abnormalities can be seen in about three-fourths of all trisomy 18 pregnancies.
- 13 In the mid-1980s, pregnancy-associated plasma protein-A (PAPP-A) and free β hCG were found to be useful as Down syndrome markers in the late first trimester, but performance was not as good as second-trimester serum testing.
- 14 At about the same time, ultrasound measurements of nuchal translucency (NT) thickness (at between 11 and 13 completed gestational weeks) were found to be the best single marker for Down syndrome.
- 15 Combining NT measurements with biochemical markers (combined testing) in the first trimester yields equivalent performance to second-trimester quadruple marker testing.
- 16 Obtaining reliable NT measurements requires specific training, high-quality sonographic equipment, and participation in ongoing quality assurance.
- 17 In about 60% of Down syndrome fetuses and 1% of unaffected fetuses, it is not possible to visualize a nasal bone, but such measurements are difficult to achieve in routine screening.
- 18 Integrated testing fuses both first-trimester combined and second-trimester quadruple testing into a single second-trimester risk.
- 19 Integrated screening can have a detection rate of 90%, with a false-positive rate of less than 2%, depending on the gestational age at first-trimester sampling and the combination of markers used.
- 20 Sequential and contingent screening strategies are modifications of integrated screening that aim to preserve the high performance of integrated screening, and have the ability to diagnose a proportion of Down syndrome cases in the first trimester.

Methods of Evaluation of Fetal Development and Well-being

Prenatal diagnosis of deviant fetal growth

E. Albert Reece and Zion J. Hagay

Fetal growth is a fundamental characteristic of the continuity of life and fetal well-being. Cell divisions, cell hyperplasia, and cell hypertrophy are the cornerstones of fetal growth. Winick¹ has suggested that, early in pregnancy, growth of fetal organs takes place first by cell hyperplasia or cell division, then by hyperplasia and cell hypertrophy and, finally, by the cessation of hyperplasia, after which growth continues by cellular hypertrophy alone. Despite this apparent orderly sequence of events, fetuses grow at different rates, become different sizes, and have different shapes. It has been observed in sheep that, up until 130 days' gestation, growth seems to be very similar between fetuses but, after this point, varying patterns of growth may be recognized.

In this chapter, we discuss the two extreme types of deviant fetal growth – accelerated (macrosomia) and diminished [intrauterine growth restriction (IUGR)]. In addition, prenatal diagnosis of these conditions is discussed.

Intrauterine growth restriction

Etiology and definition

IUGR is an abnormality of fetal growth and development that affects 3–7% of all deliveries, depending on the diagnostic criteria used.^{2–4} The growth-restricted fetus is at greater risk for mortality and morbidity. It is estimated that perinatal mortality is 5–10 times higher in the growth-restricted neonate than in the neonate who is sized appropriately for gestational age.⁵ Several associated morbid conditions of serious concern occurring after different periods of growth failure *in utero* include birth asphyxia, neonatal hypoglycemia, hypocalcemia, polycythemia, meconium aspiration, and persistent fetal circulation. Investigators have reported poorer neurodevelopmental outcome in small-for-gestational-age (SGA) infants, particularly when there is also associated prematurity.^{6–8} The incidence of major neurologic handicaps in preterm SGA infants may be 35%.⁹

There are several causes of IUGR. These may be conceptually divided into three main categories: maternal, fetal, and

uteroplacental (Table 29.1). It should be stressed, however, that in almost half the cases of IUGR, the etiology is unknown. Furthermore, it has been found that the single most important maternal clinical risk factor is a previous history of IUGR.¹⁰ Therefore, suspicion of IUGR should not be based only on the existence of clinical risk factors during the index pregnancy.

One point of confusion and disagreement is the criteria that are used to define IUGR. IUGR has been defined variously as an infant whose birthweight is below the 3rd,¹¹ 5th,¹² and 10th¹³ percentiles for gestational age or whose birthweight is more than two standard deviations below the mean for gestational age.^{14,15} The ponderal index is determined in the neonate by the following formula:

$$\text{Ponderal index} = [\text{birthweight (g)} \times 100] / [\text{crown-heel length (cm)}]^3$$

The ponderal index may identify a neonate who has a small amount of soft tissue clinically evident by loss of subcutaneous tissue and muscle mass, even though the birthweight is normal for gestational age. Neonates with a ponderal index below the 10th percentile for gestational age are probably suffering from malnutrition *in utero*. For example, a fetus of 2900 g born at 38 weeks' gestation would have been larger (e.g., 3500 g) under normal nutritional conditions. Such an infant may be identified as having IUGR only when using the ponderal index definition for this condition.

In an interesting study by Weiner and Robinson,¹⁶ the results of sonographic diagnoses of IUGR were compared with the postnatal ponderal indices. The study showed that 40% of SGA infants identified by birthweight percentiles were not growth restricted according to their ponderal index. In contrast, 53% of the neonates diagnosed as IUGR by postnatal ponderal index were average for gestational age according to their birthweight percentile. Because the importance of antenatal diagnosis of IUGR is to identify those infants at high risk for intrapartum and neonatal complications, the ponderal index is more closely related to perinatal morbidity and mortality than the birthweight percentile.¹⁷ Therefore, it would be useful to be able to employ the ponderal index in attempting

Table 29.1 Risk factors of intrauterine growth restriction.**Maternal risk factors**

 Placenta previa
 Focal abruption
 Marginal insertion of the cord

to diagnose IUGR *in utero*. Unfortunately, there is presently no practical method to evaluate ponderal index *in utero*. Hence, the most commonly used definition of IUGR is a fetal weight below the 10th percentile for gestational age.

Another index, the crown–heel length, has been used to evaluate neonatal size. Prediction from the femur length (FL) measurement, however, has been found to be too imprecise to be useful.¹⁸

One unresolved problem concerns which growth curve to use. Goldenberg and colleagues¹⁹ have shown that the 10th percentile birthweights at each gestational age differ substantially among published charts, occasionally by more than 500 g. One of the most widely used birthweight curves is that of Battaglia and Lubchenco,² which was derived from 5635 liveborn white and Hispanic people living at approximately 8000 feet above sea level in Denver, CO, USA. Obviously, this growth curve cannot be applied to a different ethnic and geographic population.

It has been suggested that much of the confusion that presently surrounds IUGR would be eliminated, at least in the United States, if we used a clearly defined American population to derive the percentiles for defining IUGR.¹⁹ In fact, discrepancies between different birthweight charts from different geographic areas underscore the need for generating birthweight curves from the population to which they will be applied.

Classification of intrauterine growth restriction

Clinically, three categories of IUGR may be recognized. Each reflects the time of onset of the pathologic process (Fig. 29.1).^{20–23}

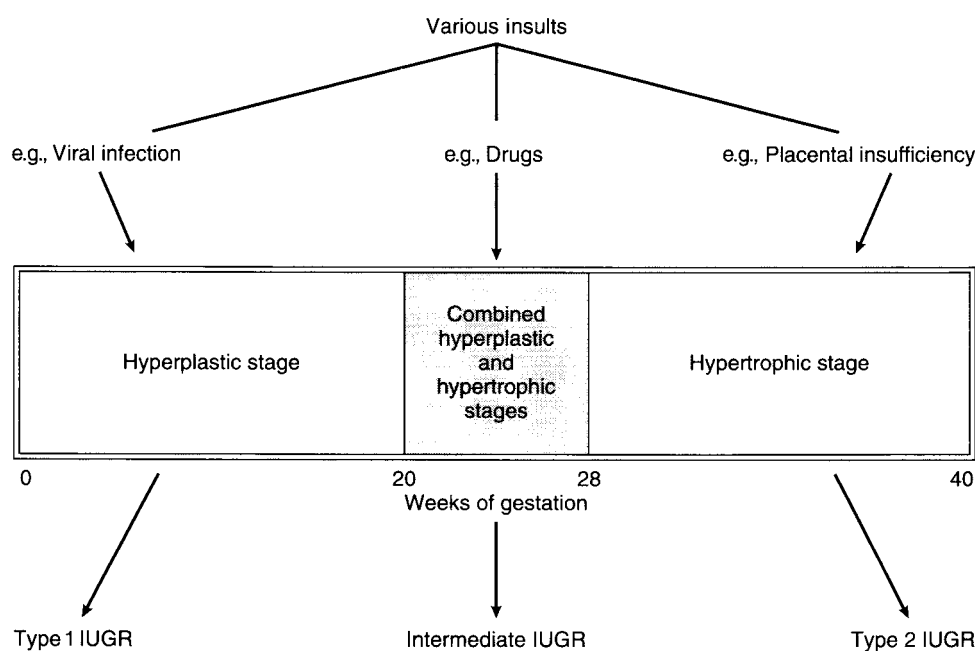

Figure 29.1 A schematic illustration of possible insults during the three stages of embryonic–fetal development and the corresponding intrauterine growth restriction (IUGR) that may develop.

Type 1, or symmetric, IUGR

Type 1 IUGR refers to the infant with decreased growth potential. This type of IUGR begins early in gestation, and the entire fetus is proportionally SGA.

Head and abdominal circumferences, length, and weight are all below the 10th percentile for gestational age. However, those infants have a normal ponderal index.

Type 1 IUGR is a result of growth inhibition early in gestation. This early stage of embryonic–fetal development is characterized by active mitosis from 4 to 20 weeks' gestation and is called the hyperplastic stage.^{24–26} Any pathologic process during this stage may lead to a reduced number of cells in the fetus.

Symmetric IUGR accounts for 20–30% of growth-restricted fetuses.^{22,27} This condition may result from the inhibition of mitosis, as is seen in intrauterine infection (e.g., herpes simplex, rubella, cytomegalovirus, toxoplasmosis), chromosomal disorders, and congenital malformations. It should be remembered, however, that symmetrically small fetuses may be constitutionally small and suffer from no abnormality at all.²⁰

In general, type 1 IUGR is associated with a poor prognosis: this is in direct relation to the pathologic condition that causes it. Weiner and Williamson²⁸ showed that, in the absence of an identifiable maternal factor and sonographically detected abnormality, approximately 25% of fetuses evaluated for severe, early-onset growth restriction have aneuploidy. Therefore, the performance of percutaneous umbilical blood sampling is strongly recommended to search for karyotypic abnormality.

Type 2, or asymmetric, IUGR

Type 2, or asymmetric, IUGR refers to the neonate with restricted growth and is most frequently due to uteroplacental insufficiency.^{21,29}

Type 2 IUGR is a result of a later growth insult than type 1 and usually occurs after 28 weeks' gestation. As has been shown by Vorherr,²⁶ in the late second trimester, normal fetal growth is characterized by a process of hypertrophy. In this hypertrophic stage, there is a rapid increase in cell size and the formation of fat, muscle, bone, and other tissues. In this phase, the process of hyperplasia is decreased (Fig. 29.2).

Symmetrically growth-restricted fetuses have a near normal total number of cells, but these cells are decreased in size. Asymmetric IUGR fetuses have low ponderal indices with below average infant weight but normal head circumference (HC) and fetal length. In these cases of asymmetric IUGR, fetal growth is normal until late in the second trimester or early in the third, when head growth remains normal, whereas abdominal growth slows ("brain-sparing effect"). This asymmetry is a result of a fetal compensatory mechanism that responds to a state of poor placental perfusion. Redistribution of fetal cardiac output occurs with increased flow to the brain, heart,

Figure 29.2 Cell number and rate of mitosis in relation to embryonic–fetal growth. Embryonic weight gain is slow (small initial cell number) even though the rate of mitosis is very high. At approximately weeks 16 to 20 of gestation, a substantial fetal cell mass is reached. Thereafter, however, mitosis is slowed (organ differentiation and function). Even though slowed, division of a large number of fetal cells produces a rapid fetal weight gain. (Redrawn from ref. 26.)

and adrenals and decreased glycogen storage and liver mass.³⁰ However, if placental insufficiency is aggravated during late pregnancy, the head growth may be flattened, and its size may drop below the normal growth curve.

It is estimated that 70–80% of growth-restricted fetuses are type 2 IUGR.³¹ This form of IUGR is frequently associated with maternal diseases such as chronic hypertension, renal disease, diabetes mellitus with vasculopathy, and others (see Table 29.1).

Intermediate IUGR

Intermediate IUGR refers to growth restriction that is a combination of types 1 and 2 IUGR. The insult to fetal growth in intermediate IUGR most probably occurs during the middle phase of fetal growth – that of hyperplasia and hypertrophy (see Figs 29.1 and 29.2) – which corresponds to 20–28 weeks' gestation. At this stage, there is a decrease in mitotic rate and a progressive overall increase in cell size.

This form of IUGR is less common than types 1 and 2; it is estimated as being responsible for 5–10% of all growth-restricted fetuses. Chronic hypertension, lupus nephritis, or other maternal vascular diseases that are severe and begin early in the second trimester may result in an intermediate

IUGR with symmetric growth and no significant brain-sparing effect.

Ultrasonic measurements used in the diagnosis of IUGR

The intrauterine detection of restricted fetal growth by clinical means is possible in approximately 30% of affected pregnancies.³² Ultrasonography offers an objective, reliable, and effective means of identifying restricted intrauterine fetal growth. However, to make a proper diagnosis and appropriately manage the growth-restricted fetus, it is crucial to determine the gestational age as accurately as possible.

Pregnancy dating has traditionally been based on historical and clinical clues. The certain date of a patient's last menstrual period had been regarded as the most reliable method of estimating a fetus' gestational age.³³ However, it has been reported that 20–40% of pregnant women fail to recall the exact date of their last menstrual period.³⁴

Therefore, ultrasonography may be of help in dating a pregnancy. In the first trimester, crown–rump length measurement allows for an estimation of gestational age with a range of 4.7 days at the 95% confidence level. Between 12 and 24 weeks' gestation, the biparietal diameter (BPD) measurement provides reliable estimates comparable with that of the crown–rump measurement performed in the first trimester of pregnancy. Beyond 28–30 weeks' gestation, there is a progressive increase in BPD variations, and the establishment of accurate gestational age is less satisfactory.

The FL correlates with gestational age, particularly during 14–22 weeks' gestation, with a range of 6–7 days at the 95% confidence level.³⁵

Accurate antenatal diagnosis of IUGR may prevent the high perinatal morbidity and mortality associated with this condition and permit appropriate management and obstetric intervention when fetal compromise is evident. Most authorities believe that, whenever IUGR is diagnosed after 37 weeks' gestation, delivery is indicated to decrease the risk of fetal death.³⁶

Several sonographic parameters may be used in the diagnosis of IUGR. These parameters are critically reviewed in the following sections.

Biparietal diameter

Nomograms of BPD or HC are available to provide calculated estimates of weekly increments for the size of the fetal head (Tables 29.2–29.4).³⁷ Hence, when comparing the observed increase in BPD with the expected rate of growth, the physician should be able to identify growth-restricted fetuses when the head is affected in the growth curtailment. In fact, the BPD was the first ultrasonic parameter used for detection of IUGR.^{23,38} The detection rates of IUGR with single and serial BPD measurements alone have been reported to be of poor value by most authors.^{39,40–42} Reported accuracy rates have ranged from 43% to 82%.^{40,43–47} Rosendahl and Kivinen⁴⁸

studied the efficiency of a single BPD measurement at 34 weeks' gestation to identify infants with birthweights below the 10th percentile. Single BPD measurements at 34 weeks' gestation detected only 26.9% of the SGA infants, with a positive predictive value of 30.9%, which means that 69% of the fetuses with restricted BPD actually proved to be normally grown. The study by Warsof and colleagues⁴⁹ indicates that a single BPD measurement in the third trimester is a poor predictor of IUGR.

Others studies used serial BPD determinations in the hope of improving accuracy; however, their results were equally disappointing. Kurjak and colleagues⁴³ have shown that only 48% of fetuses with a small BPD (below the 10th percentile) had birthweights below the 10th percentile and actually resulted in delivery of SGA infants.

From the previously mentioned data, it is clear that BPD alone cannot be used as a good predictor of IUGR. This is not surprising, because almost two-thirds of IUGR cases are of the asymmetric or late-flattening type, which have normal growth of the head until late in pregnancy as a consequence of the brain-sparing process. Therefore, BPD in asymmetric IUGR may be normal until late in gestation. Another reason for the low sensitivity of BPD measurements in detecting IUGR is the distortion of the fetal head shape that may occur, for example in dolichocephaly, or may be seen in cases of breech presentation when the BPD may be falsely small.

BPD determinations, when used singly, fail to identify approximately 20–50% of IUGR infants and, therefore, cannot be used as the only parameter in screening for IUGR.³⁹

Transverse cerebellar diameter

The cerebellum can be easily visualized as early as the first trimester as a butterfly-shaped figure in the posterior fossa of the fetal head, behind the thalami and in front of the echolucent area (cisterna magna) (Fig. 29.3). The transverse cerebellar diameter (TCD) in millimeters has been shown to correlate with gestational age in weeks up to 24 weeks. After 24 weeks' gestation, the growth curves turn upward, and this uniform correlation no longer exists. Goldstein and colleagues⁵⁰ have constructed a nomogram of the TCD throughout pregnancy (Table 29.5).

Reece and colleagues⁵¹ subsequently evaluated the TCD measurement in IUGR fetuses. They reported that the TCD measurement was not significantly affected by restricted fetal growth and, therefore, the TCD could be used as a reliable predictor of gestational age even in cases of IUGR. This parameter is particularly useful because it is a standard against which other parameters can be compared. Duchatel and colleagues⁵² have corroborated these findings in their report of 12 cases of IUGR below the 3rd percentile in which the TCD remained unaltered. Other investigators have provided additional support for the usefulness of the TCD by constructing a nomogram of the ratio between TCD and abdominal circumference (AC).⁵³ In a small series, these investigators have

HC, head circumference.

shown that this ratio permits the identification of IUGR by demonstrating the fairly consistent growth of the TCD relative to the decrease in AC in cases of IUGR. In yet another study by Hill and colleagues,⁵⁴ the TCD was found to be within two standard deviations in only 40% of IUGR cases and, in 60% of cases, the TCD was more than two standard deviations below the mean. The results of this paper are at variance with the three reports discussed earlier. Nevertheless, the majority of data available would suggest that the use of the TCD when gestational age is unknown or IUGR is suspected is extremely valuable. The accuracy of the TCD can be enhanced by using biometric ratios, especially FL:AC, as well as amniotic fluid volume and the presence or absence of fetal ossification centers.

Abdominal circumference

The AC has been reported to be the best fetal biometric parameter that correlates with fetal weight and is the most

sensitive parameter for detecting IUGR.⁵⁵ Warsof and colleagues⁴⁹ studied the effectiveness of three ultrasonic growth parameters – BPD, HC, and AC – in detecting IUGR in a large group of obstetric patients. They demonstrated that AC measurements are more predictive of IUGR than BPD or HC, singly or in combination. In this study, it was shown that screening at 34 weeks' gestation for IUGR results in a sensitivity of approximately 70% and a positive predictive value of 50%. However, the authors used the 25th rather than the 10th percentile measurement to determine a positive result to maximize sensitivity of the screening test.

It is noteworthy that the sensitivity and true positive rates are influenced by the incidence of IUGR in the population studied. This is demonstrated in the studies by Geirsson and colleagues,^{56,57} who have shown that measuring the abdominal area at 36 weeks' gestation to detect fetuses below the 10th percentile for weight resulted in a sensitivity of 72% in a high-risk group, but only 56% when the entire obstetric population was screened. The positive predictive values were

68% in the high-risk group and 50% in the unselected group.

Others have found results that further demonstrate that AC is the single best predictor of IUGR, with an accuracy that may reach 96% of cases.^{43,58} In fact, in contrast to the BPD measurement, AC is smaller in both symmetric and asymmetric types of IUGR, and therefore its measurement has a higher sensitivity. Animal studies have shown that the liver is the most affected organ in IUGR. Because the liver is the largest intra-abdominal organ, assessment of the AC at the level of the liver is actually an indirect indication of the nutritional status of the fetus.

Unfortunately, AC has more intraobserver and interobserver variation than either BPD or FL.³⁶ Furthermore, AC variability may result from fetal breathing movements, compression, or position of the fetus. To obtain the proper AC, the section should be round and at the level of the fetal stomach and the portal umbilical vein (or the bifurcation of the main portal vein into the right and left branches). Normal values of AC are presented in Table 29.6.⁵⁹

Long bones

The FL is another important parameter in evaluating fetal growth (Table 29.7). Long bones other than the femur can be

equally useful in the assessment of gestational age (Tables 29.8 and 29.9). It has been demonstrated by several authors that there is a linear relationship between FL specifically and long bones in general and crown-heel length of a newborn.^{18,60} These long bones are generally decreased in symmetrically growth-restricted fetuses, but may be of normal length in asymmetric IUGR. In fact, the fetal head and long-bone length in asymmetric IUGR tend to be affected late in gestation.⁶⁰ Because the measurement of most long bones is relatively simple, they become a useful means of estimating gestational age on a routine basis. Like most other biometric parameters, the standard deviation tends to expand with increasing gestational age. Hence, accuracy is greatest in early gestation.

Total intrauterine volume

The rationale for measuring total intrauterine volume derives from the fact that, in IUGR, intrauterine content is reduced (fetal, placental mass, and the amount of amniotic fluid). Gohari and colleagues⁶¹ calculated total intrauterine volume using the formula of an ellipsoid volume. Although these results were encouraging because 75% of IUGR were correctly diagnosed, this method has been abandoned by most centers because of the widespread use of real-time ultrasonography and the fact that a static scanner is needed to measure total intrauterine volume.

Amniotic fluid volume assessment

In the growth-restricted fetus, decreased amounts of amniotic fluids may be observed. This is a direct result of decreased renal perfusion and reduced urine production. Manning and colleagues⁶² have shown that oligohydramnios, determined by ultrasound as the absence of a pocket of amniotic fluid greater than 1 cm in its largest diameter, may predict with high accuracy that the fetus is growth restricted. Their study group included patients at high risk for IUGR. In this group, oligohydramnios was found to be highly sensitive (84% and 97%), with a predictive value approaching 90%. Unfortunately, progressive growth curtailment usually occurs without evidence of significant amniotic fluid reduction. Hence, this parameter is not very sensitive to evolving IUGR. As shown previously, its utility is greatest in diagnosing frank IUGR.

When amniotic fluid volume evaluation was tested as a screening method in the detection of IUGR in the general obstetric population, the results were quite disappointing. Philipson and colleagues⁶³ studied 2453 pregnant patients and found the oligohydramnios test to be poorly sensitive (16%); in other words, in 84% of IUGR infants, there was no evidence of oligohydramnios and therefore the problem would have been missed by this test. In summary, it seems that this ultrasonic method of detecting fetal growth restriction is unsatisfactory because of low accuracy.

Table 29.5 Nomogram of the transverse cerebellar diameter, biparietal diameter, and head circumference according to percentile distribution.

Placental growth

Grannum and colleagues⁶⁴ were the first to present an ultrasonic classification of placental maturity. This classification grades placentas from 0 to 3 according to specific ultrasonic findings at the basal and chorionic plates, as well as within substances of the organ itself (Table 29.10). It is noteworthy that placentas do not all necessarily go through the full maturation process during pregnancy. This is demonstrated by the fact that, in normal pregnancies at term, only 20% of placentas are classified as grade 3.⁶⁵ Furthermore, ultrasound examination of placental maturation, or examination after 42 weeks'

gestation, shows that 45% of placentas are of grade 3 and all the others are grade 2.⁶⁶ Therefore, it has been assumed that the appearance of a grade 3 placenta before 35 weeks' gestation should alert the physician to the possibility of the presence or subsequent development of IUGR. However, there are still no substantial data to support this assumption. Kazzi and colleagues⁶⁷ studied the value of placental grading in the diagnosis of IUGR in a high-risk group of patients. They have shown that grade 3 placentas accurately diagnose IUGR in 62% of cases, with a positive predictive value of 59%. Therefore, the prenatal diagnosis of IUGR using placental grading is rather limited.

In fact, placental grading in general has been supplanted by more sensitive tests that are consequently used in clinical practice.

Body proportionality

Investigators examined the possibility that the use of fetal body proportionality might improve ultrasonic accuracy in the diagnosis of IUGR. Indices of body proportionality that have been studied and found clinically useful include the HC/AC ratio (Table 29.11) and the FL/AC ratio.

Head circumference (HC)–abdominal circumference (AC) ratio

The use of the ratio of HC to AC in determining IUGR was proposed by Campbell and Thoms in 1977.³⁷ The rationale for this was based on the observation that type 2 IUGR may have a disturbed HC/AC ratio as a result of the brain-sparing effect. Although this method has been shown to have a sensitivity of approximately 70% in detecting asymmetric IUGR, its use is limited by its high false-positive rate in screening a general population.^{37,68}

Further limitations of this technique are its inability to detect asymmetric growth restriction and the need for accurate knowledge of gestational age to make the diagnosis of IUGR. It is therefore believed that the value of the HC/AC ratio lies in the assessment of proportionality, and thus it may assist the clinician in classifying IUGR as symmetric or asymmetric. Obviously, an elevated ratio suggests symmetric IUGR (see Table 29.11).

Femur length (FL)–abdominal circumference (AC) ratio

The ratio of FL to AC is the equivalent of the postnatal ponderal index and has been proposed as a useful method of detecting asymmetric IUGR.⁶⁹ This ratio has the advantage of being age independent and thus may help in the diagnosis of IUGR when gestational age is unknown. In fact, FL/AC ratios have a constant value of $22 \pm 2\%$ after 21 weeks' gestation. Hadlock and colleagues⁶⁹ evaluated this method in the diagnosis of IUGR and reported that 63% of growth-restricted fetuses were accurately diagnosed when a ratio of more than 23.5% was considered abnormal. However, these authors and others have indicated the poor predictive value of less than 25% of a positive test result.⁷⁰ In spite of this, the FL/AC ratio still has its merits, because it is the only ultrasonic technique that enables the physician to identify IUGR when gestational age is unknown.

Estimated fetal weight

Several formulas that use multiple ultrasonic parameters are used to estimate fetal weight.^{71–73} The most widely used formula is that of Shepard and colleagues,⁷⁴ in which estimated fetal weight (EFW) is derived from the BPD and AC. This equation predicts fetal weight with an accuracy of 15–20%.⁷⁵ Hadlock and colleagues⁷⁶ and Warsof and colleagues⁷⁷ have also introduced equations to estimate fetal weight using combinations of BPD, AC, and FL.

Ott and Doyle⁷⁸ reported accurate predictions of IUGR in 90% of cases in a high-risk population when EFW was determined by BPD and AC. The use of this formula may introduce errors that are related to the variations in BPD that usually occur as a result of changes in head shape in the last weeks of pregnancy, in malpresentation, and in pregnancies complicated by spontaneous rupture of membranes.^{79,80} BPD may be inaccurate if there is dolichocephaly or brachycephaly. We therefore strongly recommend that the physician calculates

Table 29.10 Summary of placental grading.

	Grade 0	Grade 1	Grade 2	Grade 3
<i>Chorionic plate</i>	Straight and well-defined	Subtle undulations	Indentations extending to, but not into, the basal layer	Indentations communicating with the basal layer
<i>Placental substance</i>	Homogeneous	Few scattered echogenic areas	Linear echogenic densities (comma-like densities)	Circular densities with echospared areas in center, large irregular densities that cast acoustic shadowing
<i>Basal layer</i>	No densities	No densities	Lineal arrangement of small echogenic areas (basal stippling)	Large and somewhat confluent basal echogenic areas can create acoustic shadows

the cephalic index in each case. If the cephalic index is abnormal (< 75% or > 80%), one should not rely on estimated weight formulas that include the BPD.

Weiner and colleagues⁸¹ have proposed the use of another formula for the prediction of fetal birthweight that incorporates HC and FL to avoid errors related to changes in head shape. The authors suggest that the prediction of IUGR fetuses may be more accurate using this formula.

In an effort to further increase the accuracy of ultrasonic estimation of fetal weight, Hadlock and colleagues⁷⁶ advocate the use of HC, AC, and FL measurements in combination. They have shown that the prediction of fetal weight has a standard deviation of $\pm 15\%$ (two standard deviations). However, the accuracy in predicting fetal weight decreases in small fetuses (< 1500g), and the error may approach $\pm 20\%$.

Various ultrasound methods are used to estimate fetal weight with essentially equal accuracy when low-risk obstetric populations are studied. It is thought that as many as 80% of IUGR fetuses can be detected; however, there is still a relatively low positive predictive value that approaches only 40%. Therefore, 60% of fetuses suspected of IUGR because of low EFW will actually be normally grown.

Doppler in IUGR

Maternal arterial uterine blood flow increases from 50mL/min early in pregnancy to about 700mL/min at term. The increase is secondary to a gradual decrease in vessel resistance to blood flow throughout the pregnancy. Doppler ultrasound gives us information on the vascular resistance and, indirectly, on the blood flow. Three indices are considered to be related to the vascular resistance: S/D ratio (systolic/diastolic ratio), resistance index (RI = systolic velocity–diastolic velocity/systolic velocity), and pulsatility index (systolic velocity–diastolic velocity/mean velocity). Doppler velocimetry uses ultrasound to measure peak-systolic and end-diastolic blood flow through the umbilical artery. As the pregnancy progresses, diastolic flow increases, and the systolic/diastolic ratio

should gradually decrease. In a large number of IUGR pregnancies, an alteration in placental blood flow occurs. As a result, researchers have correlated an increased systolic/diastolic ratio with IUGR. The ratio is increased in about 80% of cases of IUGR diagnosed by ultrasound examination.⁸² An average systolic/diastolic ratio of greater than three at 30 or more weeks of gestation has a sensitivity of 78% and a specificity of 85% in predicting IUGR.⁸³

Doppler velocimetry, previously argued as a diagnostic technique for IUGR, has not found a place in routine antenatal surveillance. Nowadays, Doppler ultrasound has been shown to be useful in the assessment of growth-restricted fetuses.⁸⁴ It has helped physicians to understand the pathophysiology of IUGR with regard to diminished blood flow. The results of this procedure correlate with increased fetal morbidity and mortality: an absent or reversed end-diastolic umbilical flow is an ominous finding and may need intervention.^{85–87} As a screening test, however, the procedure appears to be lacking in benefit; some studies⁸⁸ have shown that 40–60% of infants with IUGR had normal Doppler velocimetry results just before birth. However, normal umbilical flow is rarely associated with significant morbidity.⁸⁹

Doppler velocimetry has been shown to reduce interventions and improve fetal outcome in pregnancies at risk for IUGR.⁹⁰ Randomized controlled trials have demonstrated that monitoring with Doppler velocimetry reduces the risk of perinatal morbidity.⁹⁰ Moreover, the IUGR fetuses seem to be at even greater risk of impending demise when Doppler abnormalities are observed in the venous circulation.⁹¹

Uterine circulation

The main uterine artery is the most commonly analyzed vessel. In normal pregnancy, the S/D ratio or RI values decrease significantly with advancing gestation until 24–26 weeks. In the absence of this physiologic decrease, a higher incidence of hypertensive diseases and/or IUGR has been widely documented. Chien and colleagues⁹² published an overview of the

efficacy of uterine artery Doppler as a predictor of preeclampsia, IUGR, and perinatal death. In low-risk women, an abnormal uterine artery Doppler result gave a likelihood ratio (LR) of developing IUGR of 3.6 (95% confidence interval (CI) 3.2–4.0), while a normal test reduced the risk to below background, with a LR of 0.8 (95% CI 0.08–0.09). For high-risk women, an abnormal test gave a LR of 2.7 (95% CI 2.1–3.4), while a normal result reduced the risk of LR to 0.7 (95% CI 0.6–0.9) (Fig. 29.4).

Umbilical artery

In the normal fetus, the pulsatility index decreases with advancing gestation. This reflects a decrease in the placental vascular resistance. In fetuses with IUGR, there is an increase in the pulsatility index secondary to the decrease, absence, or reversal of end-diastolic flow. The changes in these waveforms are thought to be indicative of increased placental resistance. The absent or reversed end-diastolic flows are strongly associated with an abnormal course of pregnancy and a higher incidence of perinatal complications, when compared with fetuses with IUGR but characterized by the presence of end-diastolic flow (Fig. 29.5).^{93,94}

Fetal cerebral circulation

The middle cerebral artery is the vessel of choice to assess the fetal cerebral circulation because it is easy to identify, has a high reproducibility, and provides information on the brain-sparing effect. The circulation in the brain is normally high impedance. The middle cerebral artery (MCA) in the fetal brain carries more than 80% of cerebral flow.⁹⁵ When a fetus does not acquire enough oxygen, central redistribution of blood flow occurs, resulting in a preferentially increased blood flow to protect the brain, heart, and adrenals. This increase in blood flow can be evidenced by Doppler ultrasound of the MCA. This effect has been called the brain-sparing effect and is demonstrated by a lower value of the pulsatility index (Fig. 29.6).⁹⁵ In IUGR fetuses with a pulsatility index below the

Figure 29.4 Uterine artery Doppler waveform showing normal (left) and abnormal (right) flow.

Figure 29.5 Abnormal umbilical artery Doppler waveform showing absent (left) and reversed (right) end-diastolic flow.

Figure 29.6 Doppler waveform of middle cerebral artery showing normal (left) and abnormal (right) flow.

normal range, there is a greater incidence of adverse perinatal outcome.⁹⁰ The brain-sparing effect may be transient, as reported during prolonged hypoxemia. The disappearance of the brain-sparing effect is a very critical event for the fetus, and appears to precede fetal death.^{97,98}

Fetal venous Doppler

Doppler flow of the fetal inferior vena cava (IVC) and ductus venosus is practical and provides information about right ventricular preload, myocardial compliance, and right ventricular end-diastolic pressure.^{99,100} Chronic fetal hypoxemia leads to decreased preload, decreased cardiac compliance, and elevated end-diastolic pressure in the right ventricle.¹⁰⁰ These changes raise central venous pressure in the chronically hypoxemic fetus, which shows up as an increased reverse flow in Doppler waveforms of the IVC and the ductus venosus during late diastole (Fig. 29.7). Changes in the fetal central venous circulation are associated with an advanced stage of fetal hypoxemia.

At this late stage of fetal adaptation to hypoxemia, cardiac decompensation is often noted with myocardial dysfunction.¹⁰¹ The presence of reversed flow in the ductus venosus is an ominous sign. Indeed, fetal metabolic acidemia is often present in association with Doppler waveform abnormalities of the IVC and ductus venosus.¹⁰²

Macrosomia

The etiology of fetal macrosomia is believed to be multifactorial. Although this condition is often associated with diabetes mellitus in pregnancy, especially in women without vasculopathy, macrosomia may also occur in nondiabetics. Fetal macrosomia is defined as either an EFW of > 4000g at term or an EFW of more than that of the 90th percentile for gestational age.

Macrosomic infants and their mothers are at increased risk for intrapartum injury, and perinatal mortality is more

Figure 29.7 Adaptation for progressive fetal hypoxia.

common among these fetuses. The principal causes of injury include shoulder dystocia, fractures, and neurologic damage.^{103–106}

Accurate prenatal diagnosis of fetal macrosomia would permit fetuses to be delivered by Cesarean section, thus obviating these complications. On the other hand, liberal Cesarean section may expose the mother to unnecessary operative risks.

Prenatal diagnosis of macrosomic fetuses is often difficult because less than 40% of such infants are born to mothers with identifiable risk factors for macrosomia.¹⁰⁷ A number of sonographic parameters have been used in an attempt to diagnose altered fetal growth, including the BPD, HC, HC/AC, or HC to thoracic circumference ratio, the macrosomic index, and the EFW. Miller and colleagues¹⁰⁸ conducted a study of 382 patients with singleton pregnancies whose infants were born outside 1 week of the ultrasound examination. Of the 382 pregnancies, 58 delivered macrosomic infants (> 4500g). Ultrasonically determined BPD, FL, AC, and EFW were analyzed for their ability to predict the macrosomic newborn. EFW was found to be superior to BPD or FL in the prenatal diagnosis of fetal macrosomia. Elliott and colleagues¹⁰⁹ calculated a macrosomic index for 70 diabetic pregnancies by subtracting the BPD from the chest diameter. Thirty-three macrosomic infants (weighing more than 4500g) were delivered. In this study, 20 of 23 (87%) infants weighing more than 4500g had a chest BPD of more than 0.4cm. The authors reported four cases of shoulder dystocia among 15 infants with macrosomic indices of more than 0.4cm. They recommended Cesarean section for all fetuses with a chest BPD of more than 0.4cm because this approach would decrease the incidence of traumatic morbidity from 27% to 9%.

In yet another study, Tamura and colleagues¹¹⁰ showed that the EFW determined by Shepard and colleagues,⁷⁴ when greater than the 90th percentile, correctly predicted macrosomia at birth in 74% of cases.

When both the AC and the EFW exceeded the 90th percentiles, macrosomia was correctly diagnosed in 88.8% of pregnant women with diabetes mellitus. The BPD and HC percentiles were significantly less predictive of macrosomia.

Summary

Although the etiology of IUGR is variable, prenatal diagnosis is possible using a variety of biometric parameters. When the gestational age is certain, IUGR is diagnosed if sonographic predictors of gestational age reflect an age significantly reduced from the expected, or an EFW less than the 10th percentile. Adjunctive indices that can enhance the prenatal diagnosis include reduced amniotic fluid volume, early third trimester grade 3 placenta, abnormal Doppler waveform analysis, and abnormal biometric ratios.

When the gestational age is unknown or uncertain, it is necessary to differentiate between the IUGR fetus and the normally grown fetus identified at an inaccurate gestational age. The TCD is a useful parameter for estimating gestational age even in IUGR fetuses and can be a parameter against which other biometric indices are compared. Biometric ratios, especially FL/AC, may also be useful adjuncts in the prenatal diagnosis of IUGR.

The prenatal diagnosis of macrosomia is best accomplished by the use of EFW. However, a certain amount of caution should be exercised in light of the fact that a margin of error exists with this method of weight estimation. EFW is reported to be accurate to within 10% of the actual birthweight 85% of the time. In the remaining 15% of cases, EFW is less accurate, and the error can range from 15% to 20% of the actual birthweight.

Key points

- 1 Definition: IUGR is defined as a fetus that weighs less than the 10th percentile for its gestational age.
- 2 Symmetric IUGR (intrinsic): normal head circumference/abdominal circumference ratio caused by genetic disease or fetal infection; poor prognosis.
- 3 Asymmetric IUGR (extrinsic): increased head circumference/abdominal circumference ratio caused by placental insufficiency; good prognosis with appropriate treatment.
- 4 Risk factors are multiple and include: chronic maternal disease including chronic maternal hypertension, pregnancy-induced hypertension, diabetes, cyanotic heart disease, collagen vascular disease, severe maternal anemia, renal disease, multifetal pregnancy, etc.; fetal genetic disorders or fetal malformations; intrauterine infections such as rubella, herpes, toxoplasmosis, syphilis, cytomegalovirus; previous history of small-for-gestational-age baby, smoking, drug, or alcohol abuse; and abnormalities of the placenta or placental blood flow.
- 5 Diagnosis: One should be suspicious when the fundal height does not exhibit the predicted 1 cm/week growth between 20 and 36 weeks of gestation. A lag in fundal height by 4 cm mandates ultrasonographic evaluation; otherwise, consider ultrasound on a clinical basis. Serial ultrasonic scanning may confirm the diagnosis.
- 6 Evaluation: Clinical indicators of IUGR are poor maternal weight gain (most sensitive indicator for IUGR) and fundal height less than expected for gestational age. Consider environmental and comorbid factors such as tobacco abuse (most significant individual risk), poor nutrition, illicit drug use, alcohol abuse, minimal to no prenatal care, traumatic stress.
- 7 Fetal assessment consists of following fetal movement counts, nonstress test, serial obstetric ultrasounds for growth, and biophysical profile.
- 8 Monitoring. Nonstress testing every week. Biophysical profile every week. This test uses ultrasound and a series of measurements to determine the health status of the developing fetus. Pregnancy ultrasound every 10–14 days.
- 9 Peripartum risks of IUGR include meconium aspiration, intrauterine asphyxia, polycythemia, hypoglycemia.
- 10 Long-term effects in the fetus before or during delivery include the following: premature delivery, poor tolerance of labor, increased rates of Cesarean section, increased risk of birth defects, asphyxia at birth, temperature instability, hypoglycemia, infections, death.
- 11 Management. The development of IUGR makes the pregnancy high risk. Stillbirth, oligohydramnios, and intrapartum fetal acidosis are common antepartum complications. Close antepartum surveillance is required, and the decision about when to deliver the infant is complex. Neonatal complications include persistent fetal circulation, meconium aspiration syndrome, hypoxic ischemic encephalopathy, hypoglycemia, hypocalcemia, hyperviscosity, and defective temperature regulation.
- 12 A perinatologist should manage these pregnancies.
- 13 Address risk factors: tobacco cessation, eliminate other negative habits, ensure adequate maternal weight gain, maximize prenatal care, reduce environmental stressors.
- 14 Perinatology consultation indications: poor nonstress test, decreasing biparietal diameter, oligohydramnios, abdominal circumference 4 weeks less than biparietal diameter.
- 15 Prognosis. Babies who suffer from IUGR are at an increased risk for death, hypoglycemia, hypothermia, and abnormal development of the nervous system. These risks increase with the severity of the growth restriction.
- 16 The growth that occurs after birth cannot be predicted with certainty based on the size of the baby when it is born. Infants with asymmetrical IUGR are more likely to catch up in growth after birth than infants who suffer from prolonged symmetrical IUGR.

Three- and four-dimensional ultrasound and magnetic resonance imaging in pregnancy

Teresita L. Angtuaco

Tremendous innovations in technology have propelled the field of medicine into a new dimension not imaginable 20 years ago. Ultrasound remains the mainstay of prenatal imaging, and the refinement in both hardware and software has led to the demonstration of fetal anatomy in exquisite detail beyond the imagination of ultrasound pioneers many years ago. Yet, in spite of the vast improvements in our ability to visualize the fetus, technology has not stopped evolving with regard to fetal imaging. Of all the new developments in technology applicable to obstetric imaging, three-dimensional/four-dimensional (3D/4D) ultrasound and magnetic resonance imaging (MRI) have benefited the most from the computer revolution. New horizons have been opened by the 3D/4D capabilities of ultrasound, and MRI is fast becoming an acceptable method in fetal diagnosis.¹⁻⁴ In most medical centers, ultrasound is performed as the initial examination, and MRI is performed as a complementary problem-solving tool. When both are performed to delineate a fetal anomaly, the MRI examination is often interpreted in conjunction with an ultrasound examination done just prior to the MRI study. As this practice becomes more and more widely accepted, it is becoming imperative that those who deal in prenatal diagnosis become familiar with these tools, as they increasingly gain acceptance as part of the routine armamentarium in fetal imaging.

Three-dimensional (3D) and four-dimensional (4D) ultrasound

Technique

Three-dimensional ultrasound provides a method of storing complete sets of volume data in a computer memory so that they can be accessed to reconstruct any desired image plane. To accomplish this, four steps have to be taken: data acquisition, 3D visualization, volume/image processing, and storage of images.⁵ The acquisition of images in state-of-the-art machines uses internal integrated systems that are built into

the ultrasound system. This calls for specialized 3D transducers that perform high-precision automated volume acquisition with the touch of a button. The transducer element is automatically swept in a fan-shaped pattern at a specified angle. After signal processing and quantification, the acquired planes are stored digitally at correlative sites in an electronic volume memory. Once stored, the acquisition planes are retrieved from the volume memory and displayed as multiplanar sections. This is usually accomplished by simultaneous display on the monitor of the three standard orthogonal planes (coronal, axial, and sagittal) (Fig. 30.1). As one plane is rotated or shifted, the changes are simultaneously displayed in the other two planes. This simultaneous display has the distinct advantage of allowing the anatomy in question to be viewed in several planes, thus making the diagnosis of an anomaly more certain. It is a well-known phenomenon in ultrasound that artifacts of scanning can produce suspicious images that can suggest anomalies where there are none (Fig. 30.2). When processing the images in three planes, the distinction between real findings and artifacts becomes obvious. In instances when volumetric determinations become necessary, the ability to determine the largest dimension of an object in all three planes results in more accurate volume calculations.

Four-dimensional imaging is a relatively recent addition to the tools of fetal imaging. It is 3D ultrasound with a dynamic display of rendered images rapidly updated over time (real-time 3D). Because of rapid acquisition rates, it is possible to capture all the acquired volumes sequentially. This results in the ability to document entire sequences of fetal movement, which can be stored with digital image quality. These volumes can then be retrieved sequentially from memory similar to cine loops in 2D ultrasound. With this technique, it is possible to view specific 3D movement phases and obtain remarkable "snapshot movements" (Fig. 30.3). These 3D surface images can therefore be demonstrated as separate images on the monitor or as animated displays on cine loops. Thus, digital video clips of fetal movements can be stored and shown repeatedly as isolated "images" without the need for video tapes, which used to be the mainstay of data storage.

Figure 30.1 The fetal spine is shown in three orthogonal planes as well as a 3D-rendered coronal view. Upper left image, sagittal; lower left, coronal; upper right, axial.

Clinical impact

The advent of 3D ultrasound has taken away some of the “mystique” held by ultrasound over the years. For a very long time, only the sonologists and sonographers could recognize structures on the screen, leaving the patient and other nonexperts in ultrasound to wonder how anyone could make “head or tail” out of “weather maps” and come up with a determination regarding the presence or absence of fetal anomalies. Now, both the patient and the accompanying family and friends can actually relate to what the sonographer is seeing⁶ (Fig. 30.4). This sudden familiarity is partly the reason behind the explosion of businesses offering ultrasound examinations for entertainment. Although an argument can be made for 3D ultrasound facilitating the “bonding experience,” the Food and Drug Administration and the American Institute of Ultrasound in Medicine have jointly issued a statement discourag-

ing the practice of performing 3D ultrasound solely for entertainment purposes.

Detection of fetal anomalies

When 3D ultrasound was first introduced, there was much anticipation of perceived improvements in the delineation of complex anomalies such as facial and limb deformities (Fig. 30.5). There have been several reports in the literature showing the feasibility and benefit of 3D ultrasound in demonstrating anomalies of the face and extremities^{7–11} (Fig. 30.6). In addition, its use in the skull and brain has been explored, but with limited success^{12,13} (Fig. 30.7). The fetal spine is among those structures more frequently imaged on 3D ultrasound because the three orthogonal planes of imaging can often follow the curvature of the spine even when the fetus is in a suboptimal lie^{14,15} (Fig. 30.8). In the face, there is

B

Figure 30.5 Unilateral cleft lip. 3D rendering (B) of the defect in the upper lip was guided by precise localization of the abnormality in three orthogonal planes (A).

Figure 30.6 2D-image (A) and 3D-rendered images (B and C) of a fetus with trisomy 18 and micrognathia.

undoubtedly a distinct advantage in being able to see the extent of a complex midline anomaly, which may have a limited view on regular 2D images (Fig. 30.9). In a rotated and contorted limb, the confusing orientation of the whole extremity can be easier to appreciate on 3D ultrasound^{16–20} (Fig. 30.10). In the past, this could only be appreciated on direct scanning as the mind processes the hundreds of real-time frames generated during the actual examination. With 3D

surface rendering, the finding becomes obvious and easily documented by the sonographer when the sonologist is not physically present during the examination, as is often the case. However, as in any new advancement in imaging, many problems remain to be solved before 3D imaging of can fulfill its potential in producing these results in a constant, reproducible manner. Among these are oligohydramnios, shadowing from adjacent fetal parts, deep position of the head

A

in the pelvis, very early gestation, and maternal body habitus. In oligohydramnios, the anatomy of interest could very easily be obscured by the adjacent placenta or uterine wall owing to the inability of the images to demonstrate a true plane of separation between these structures. Although it is possible to electronically “cut away” certain structures with an “electronic scalpel” and still obtain a 3D image on these occasions, it often leaves a suboptimal image (Fig. 30.11). This emphasizes the fact that the quality of 3D rendering is critically dependent upon the quality of the 2D image.²¹ Similarly, an early gestational age tends to provide less prominent features for fetal imaging. The earlier the gestational age, the higher the chances of fetal motion, which can create motion artifacts. This can lead to images that simulate fetal defects. Also, the low resolution of the features of an embryo or fetus in the first trimester makes the rendered image suboptimal. In spite of these setbacks, a number of publications have documented the feasibility of performing 3D ultrasound in the first trimester, not only to demonstrate known embryologic events but also to diagnose anomalies resulting from faulty fetal development^{22–26} (Fig. 30.12). As the fetus ages, surface rendering

Figure 30.11 A close-up of a fetal profile using the “electronic scalpel” to eliminate other parts of the image.

A

B

Figure 30.12 First-trimester 3D ultrasound. At 8 weeks (A), physiologic bowel herniation is seen at the cord insertion (arrow), which disappears by 12 weeks (B).

becomes less and less of a problem, and 3D ultrasound images obtained late in the third trimester become more impressive. It is in this scenario that 3D ultrasound has been employed in the chest^{27–29} and the abdomen^{30–32} (Figs 30.13 and 30.14). Although the results have been promising, these applications need to be validated by future studies that can convincingly show an improvement in visualization of the abnormalities on 3D ultrasound.

Detection of fetal cardiac anomalies has become possible with the development of the STIC technique (spatiotemporal image correlation) (Fig. 30.15). This allows the performance of 4D fetal echocardiography in B-mode without the use of external triggering devices.^{33,34} Data acquired in one cardiac cycle are rearranged by correlation of their temporal and spatial domain. This can then be processed offline in a cine loop. This triplanar demonstration of the heart has allowed the assessment of both the cardiac chambers and the great vessels (Fig. 30.16). The possibility of reslicing the heart in all three dimensions and viewing these in different degrees of rotation has made possible the diagnosis of previously difficult anomalies.^{35,36} The latest experience of cardiac 4D imaging has shown the detection of anomalies such as ventricular septal defects, tricuspid atresia, transposition of the great vessels, pulmonary atresia, and interruption of the inferior vena cava with azygous venous return. Although this experience is currently limited to a few referral centers, it is promising in that it provides another dimension in diagnosing complex cardiac defects that are typically difficult to see on conventional 2D ultrasound.^{37–39} Faster computer processing has allowed this innovation to happen, but any further significant advances in 4D ultrasound depend upon the implementation of faster computer processing for imaging and the development of active matrix array transducers with further enhanced capabilities over those of the current machines.

Comparison of 3D/4D ultrasound over 2D ultrasound

The advantages of 3D ultrasound over conventional 2D ultrasound lie in its ability to store and retrieve complete volumes of data, its multiplanar display, surface rendering, and 4D display of fetal movements.⁵ Because of its ability to store and retrieve volumes of data, the examiner can navigate precisely through fetal anatomy in three orthogonal planes simultaneously. Digital storage of complete sets of volumes allows us to manipulate the data even in the absence of the patient. This is a distinct advantage for sonologists and sonographers as it enables them to scrutinize equivocal findings in an unhurried fashion. This has tremendous implications in terms of time saved in actual scanning time, thus increasing patient turnover in a busy service. Consultations with peers and referring physicians can be conducted at mutually convenient times, and the need for additional images does not necessarily require return clinic visits. Retrospective analysis of the stored volume data is possible years later as the digital volume is stored without

data loss. The same data can be copied and viewed by many examiners independently or used for training purposes. The multiplanar display allows for visualization of the anatomy in planes not possible during conventional 2D imaging, identification of the precise location of the imaged anatomic plane, and collection of more accurate volumetric measurements. Surface rendering allows the examiner a more vivid depiction of the fetal structures from various angles, increased confidence in the diagnosis of complex malformations, and the exclusion of anomalies in otherwise equivocal studies. For the parents, it is claimed to enhance the parental bonding experience owing to a more photorealistic depiction of fetal structures, better appreciation of any anomaly, and more reassurance in excluding fetal anomalies. In the acute clinical setting where an anomaly is discovered for the first time, the ability to display images that are easily recognized by the patient and her relatives becomes invaluable for counseling purposes.

Among the disadvantages of 3D ultrasound are: larger probes, motion artifacts (Fig. 30.17), production of iatrogenic structural defects by faulty electronic settings, the possibility of orientation problems in the stored volume, and the inability to perform surface rendering in the presence of oligohydramnios. Among these, only the problems related to oligohydramnios remain difficult to resolve (Fig. 30.18). The others should improve with experience and rapidly advancing technology. Another challenge facing any attempts at making 3D/4D ultrasound routine in obstetric imaging is the need for tremendous storage capacity for the acquired data. Each volume set can require 3–18 MB of memory depending upon the area of interest, and this could tax an overburdened common archiving device. With the widespread use of picture archiving and communication systems (PACS) workstations, this problem can only escalate with time as more and more people learn how to manipulate stored data. However, it is hoped that, as media storage becomes less and less expensive, this will not prove to be an impediment to a very promising diagnostic tool.

Magnetic resonance imaging (MRI)

General considerations

The applications of MRI in clinical medicine have spanned the whole human anatomy from head to foot. Over the past 10 years, there has been an increasing number of medical centers around the world embracing MRI as a primary diagnostic test. In obstetrics however, its applications are predominantly complementary to ultrasound and mainly as a problem-solving tool when ultrasound is inadequate for diagnosis.^{40–42} Its use has been limited to the late second and third trimesters of pregnancy, mainly because of the uncertainty that bioeffects may eventually be proven in the fetus.⁴³ To date, no untoward incidents or fetal sequelae have been reported.^{44,45} However, it is customary to obtain informed consent prior to

A

the examination so that the patient is aware of the nonroutine nature of the examination and its potential for causing unforeseen bioeffects in the future. It is best to reassure the patient that there is no conclusive evidence supporting the direct relationship between short-term exposure to electromagnetic fields and any hazard to the developing fetus and that there are no documented ill-effects to either the mother or the fetus. In instances where MRI is indicated, it is always important to emphasize that the potential benefits obtained from the scan may outweigh any potential risks that exist.

MRI technique

It is suggested that patients be placed feet first into the magnet to minimize any possibility of claustrophobia. A pillow is placed under the knees for comfort, and the patient is scanned in the supine position. However, those who cannot tolerate this position for prolonged periods are scanned on their side.⁴⁶ It is important to monitor the examination as changes in fetal position can lead to alterations in any preplanned protocol.⁴⁷ It is routine to use the set of images from one sequence to decide on the next series of images. It is also best to correlate the images obtained on MRI with an ultrasound study preferably done immediately before the MRI or within a few days of the examination. This will tremendously facilitate the interpretation of the MRI examination and direct the conduct of the remainder of the study. The imaging sequences used in MRI vary depending upon the manufacturer-specific recommendations. The most popular is the half-Fourier single-shot turbo spin echo sequence that gives T2-weighted images of sufficient anatomic detail for both maternal and fetal structures^{48,49} (Figs 30.19 and 30.20). This sequence comes under

two proprietary technical names, HASTE (Half-Fourier Acquisition Single Shot Turbo Spin Echo) and SSFSE (Single Shot Fast Spin Echo). Another technique is the T1-weighted imaging sequence usually using gradient echo techniques (Fig. 30.21). This technique results in superb anatomic images that can be obtained in short periods of time that even allow for breath-holding sequences.⁵⁰ This becomes valuable especially in cases where there is suspected hemorrhage or fatty masses.

Excessive motion artifacts generated by the fetus early in pregnancy have likewise limited the early acceptance of MRI in fetal diagnosis (Fig. 30.22). In the early days of fetal MRI imaging, it was necessary to immobilize the fetus with an intramuscular dose of pancuronium because of the long imaging times.⁵¹ This required percutaneous introduction of the drug into the fetal muscle (usually the thigh). The associated complications were similar to those of amniocentesis, compounded by the danger of inadvertently administering the drug partially to the mother, thus causing some respiratory problems. With current technological advances, whole imaging sequences can now be performed in seconds instead of the minutes that it used to take. This has eliminated the need for pancuronium and its potential complications. In occasional circumstances in which fetal motion compromises the study, diazepam or meperidine may be given to the mother to help lessen fetal motion artifacts. Another question raised about MRI was the possibility of using contrast agents such as gadolinium to enhance visualization of fetal organs. This has not been advocated in pregnancy, not only because gadolinium is known to cross the placental barrier, but also because it has not been needed in making the diagnosis of fetal abnormalities.

Figure 30.19 Sagittal MRI showing the fetal head and chest using the HASTE sequence of MRI data acquisition.

Figure 30.20 SSFSE sequence. A sagittal view of the maternal abdomen shows a normal axial image of the fetal brain surrounded by high-signal amniotic fluid.

Fetal anomalies

There is a potential for misdiagnosis on ultrasound in spite of experienced specialists (Figs 30.23 and 30.24). This is especially true when technical problems exist owing to maternal body habitus, suboptimal fetal lie, or oligohydramnios. What may seem like a simple diagnosis may actually be more complex and therefore need to be delineated prenatally for counseling purposes.^{52,53} It is in circumstances such as these that the majority of fetal MRI studies are done, as a complement to a complete obstetric ultrasound that has already been performed. Often, an abnormality seen on ultrasound needs to be confirmed with certainty prior to the more invasive procedures necessary to correct the defect. This is especially true when specialists have been consulted prenatally to perform immediate neonatal intervention.⁵⁴ Examples are fetal abnormalities that may necessitate immediate invasive procedures at delivery because of airway obstruction. Entities such as lung masses or epignathus may benefit from an *ex utero* intrapartum treatment (EXIT) procedure in which the fetus is partially delivered and the airway is secured prior to clamping of the cord (Fig. 30.25). In these instances, it is critical to know the precise location and extent of the tumor so that management planning can be facilitated at the time of delivery.

The strength of MRI has been proven in the diagnoses of central nervous system (CNS) abnormalities where ultrasound

may be inadequate^{55–69}. However, there are instances when the etiology of the abnormality cannot be determined, even with better definition of anatomic structures on the MRI images. (Fig. 30.26). In brain anomalies associated with ventriculomegaly, the decision to shunt sometimes hinges on very subtle findings such as the presence or absence of a cerebral mantle in the high convexities (Fig. 30.27). This becomes crucial in the differentiation of hydrocephaly from hydranencephaly when the cerebral mantle is so compressed as to be almost invisible on ultrasound (Fig. 30.28). Similarly, the level of obstruction can be clearly defined on MRI, whereas it may only be determined on ultrasound by the process of exclusion (Fig. 30.29). Another example would be unilateral hydrocephalus due to an obstructing suprasellar arachnoid cyst. On ultrasound, the wall separating the body of the lateral ventricle from the cyst may not be obvious, and rare entities such as unilateral obstruction of the foramen of Monro may be entertained. MRI can clearly show the delineation between the dilated lateral ventricle and the large arachnoid cyst (Fig. 30.30). Other associated anomalies (such as agenesis of the corpus callosum) become clear on MRI. Future trends in diagnosis are geared toward earlier diagnosis of intracranial processes before they can produce detectable changes on ultrasound. One such possibility is the demonstration of subependymal tubers in tuberous sclerosis, which have been demonstrated as early as 21 weeks by MRI but not on ultrasound.⁷⁰

Figure 30.21 T1-weighted sagittal image of the fetus is distinguished by the low signal in the surrounding amniotic fluid and the high-intensity signal in the fetal and maternal subcutaneous fat.

Figure 30.22 Fetal motion artifact has produced low-signal bands (arrow) in the middle of the fetal face, making the image uninterpretable.

The utility of MRI in other areas of the body has not been as successful as in the head or spine.^{71–74} To a large extent, this is because of the many potential artifacts that can compromise imaging of the remainder of the fetus. Maternal bulk motion can be minimized by breath-holding techniques (Fig. 30.31). Fluid motion secondary to fetal respiration, urination, or swallowing can mimic masses, which can only be seen on a few images. This is usually not consistently imaged on multiple sequences. Many other technical artifacts are known to compromise the image such as aliasing, radiofrequency interference, susceptibility artifacts, and partial volume artifacts (Fig. 30.32). However, in spite of these, the indications for MRI of the fetal chest and abdomen are increasing.^{75–81} These range from genitourinary abnormalities to unusual gastrointestinal abnormalities and a range of case reports in which MRI contributed significantly in making a diagnosis.^{82–87}

Nonfetal complications of pregnancy

Nonfetal abnormalities can also be diagnosed with confidence on MRI whereas ultrasound can be doubtful.^{88–90} At times, this could be crucial if an invasive procedure becomes indicated prior to term. A case in point would be the diagnosis of an abdominal pregnancy (Fig. 30.33). As this hinges on the demonstration of an empty uterus separate from the fetus, it is imperative that this be documented on prenatal ultrasound. A uterine leiomyoma can easily mimic the empty uterus, and MRI easily differentiates between the two entities (Fig. 30.34).

A large adnexal mass may be difficult to demonstrate and characterize on ultrasound, not only because of its size but also because of its position. A large teratoma, for instance, can mimic a demised twin on account of its heterogeneous contents (Fig. 30.35). MRI can be definitive in characterizing these masses from their typical features and tissue content. Specifically, the identification of fat within the mass clinches the diagnosis (Fig. 30.36). In the case of uterine anomalies, the ultrasound picture can be very confusing. A uterus didelphys with a normal pregnancy in one of the uterine cavities can be associated with hematometra when the other cavity is obstructed (Fig. 30.37). A unicornuate uterus can be a difficult diagnosis even with MRI. In these cases, the abnormal orientation of the pregnancy can be a clue to the uterine anomaly (Fig. 30.38).

Clinical considerations

A significant factor driving the need for prenatal MRI is the level of comfort that the specialist has regarding ultrasound. Most neurosurgeons, who use MRI on almost every adult patient prior to intervention, sometimes require prenatal MRI before the initial consultation. This is increasingly true in spite of some excellent anatomical delineation that may already have been provided by the ultrasound examination. Similarly, with patients becoming more involved in management decisions regarding their pregnancy, the Internet has become their

Figure 30.23 Cystic hygroma. 2D image of the fetal brain (A) suggested a mass arising from the occiput (arrow), perhaps a cephalocele. MRI (B) clearly shows that the cystic mass is in the neck (arrow), with no connection to the intracranial structure.

Figure 30.24 Suprasellar arachnoid cyst. A septated fluid collection (arrow) was seen on ultrasound (A and B) that extended to the parietal convexity. MRI (C–E) showed this to be a huge suprasellar cyst (arrow) that replaced part of the parietal cerebral cortex.

E

Figure 30.24 *Continued*

A

B

C

Figure 30.25 Epignathus. A large teratoma is seen protruding outside the oral cavity on ultrasound (A). MRI image (B) shows no intracranial extension. An EXIT procedure allowed maintenance of the airway during delivery (C).

Figure 30.26 Moderate hydrocephalus. Both ultrasound (A) and MRI (B–D) failed to demonstrate an anatomical reason for the symmetric ventriculomegaly.

Figure 30.27 Asymmetric hydrocephalus. The ultrasound examination (A) did not find an etiology. MRI showed absence of cerebral cortex in the occipital region especially on the left. This is well demonstrated on coronal (B), sagittal (C), and axial (D) views.

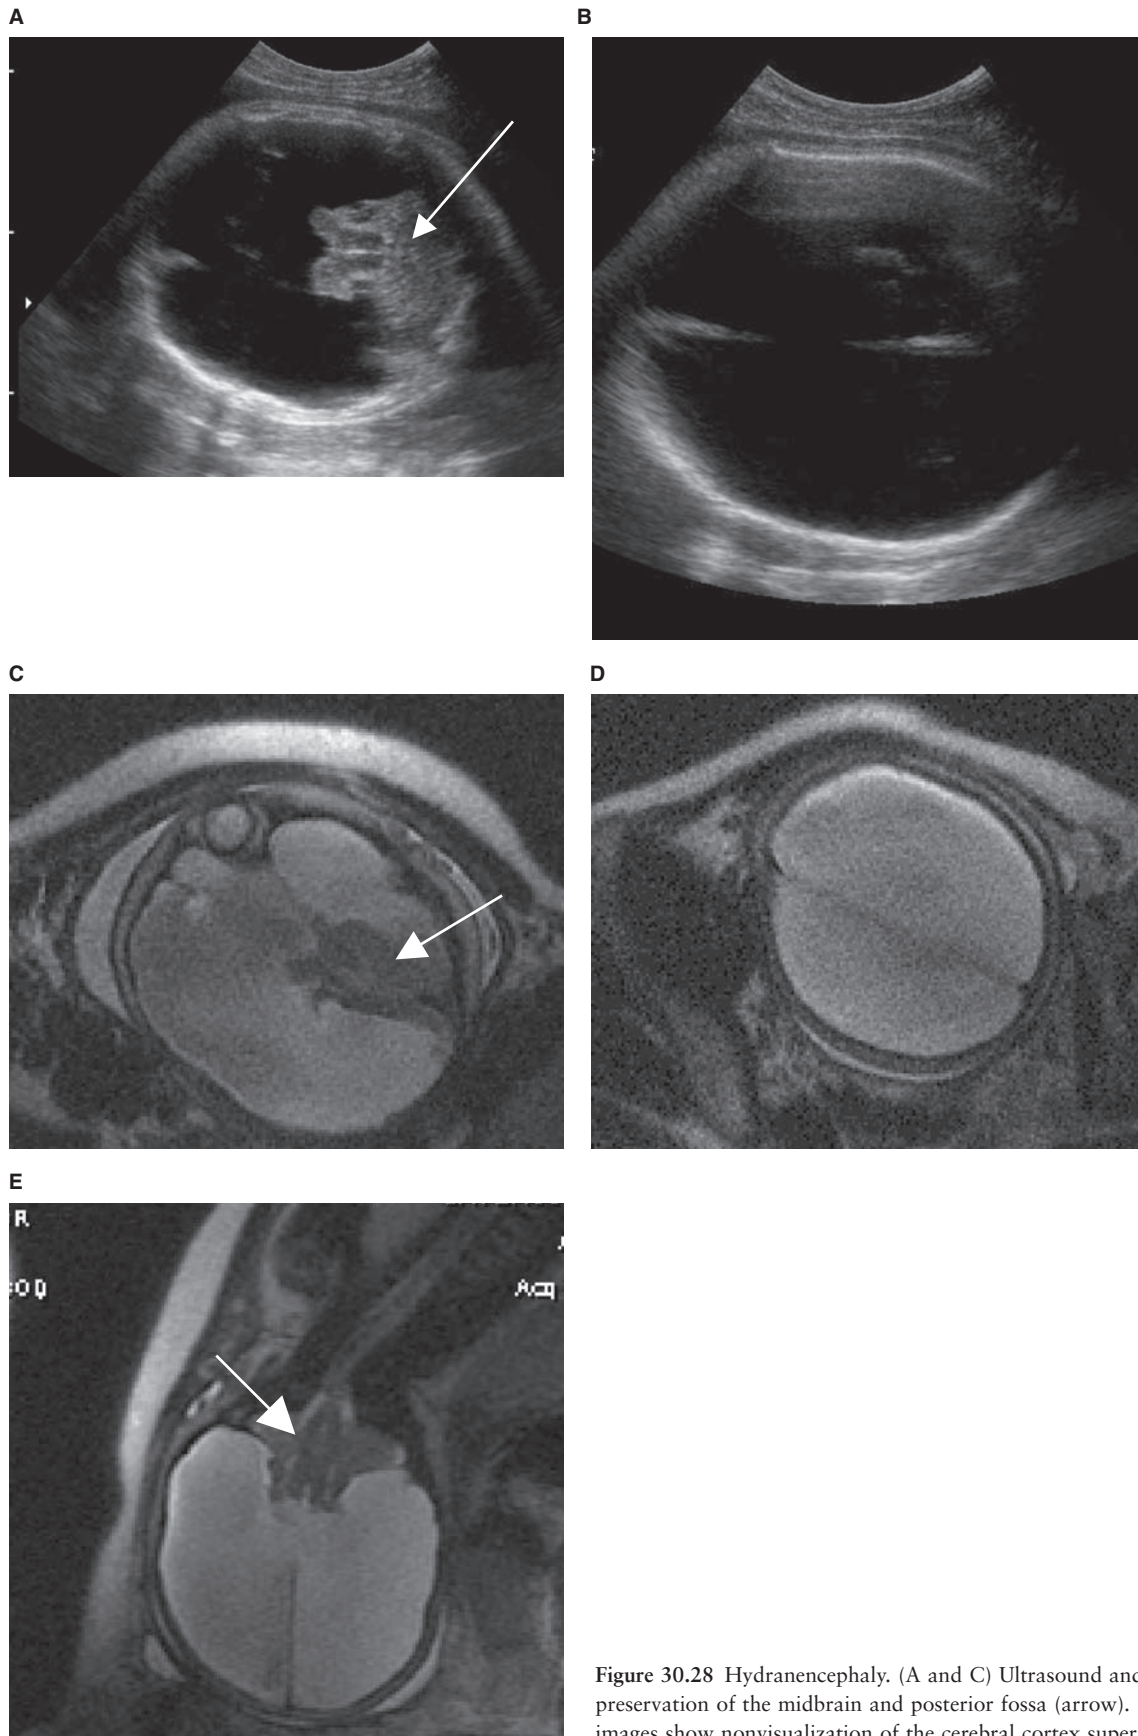

Figure 30.28 Hydranencephaly. (A and C) Ultrasound and MRI showed preservation of the midbrain and posterior fossa (arrow). (B and D) These images show nonvisualization of the cerebral cortex superiorly.

Figure 30.29 Aqueductal stenosis. Both ultrasound (A) and MRI (B and C) images show massive hydrocephalus with enlargement of the third ventricle (arrow). The cerebral mantle is very thin but preserved in all of the images.

A

Figure 30.30 Agenesis of the corpus callosum with an interhemispheric cyst. The ultrasound image (A) suggested unilateral hydrocephalus. MRI (B–E) showed that the lateral ventricle (long arrow) is separate from the large interhemispheric cyst that has occupied the majority of the left side of the brain. There is no corpus callosum identified on MRI. The parallel orientation of the frontal horn (short arrow) and its wide separation from the midline is consistent with this diagnosis on both ultrasound and MRI.

C

D

E

Figure 30.31 Maternal breathing motion has degraded MRI resolution of fetal anatomy.

Figure 30.32 Inappropriate field of view settings can create wrap artifacts that superimpose on the region of interest.

most powerful resource. The numerous publications regarding the merits of prenatal MRI have often been brought up by patients during consultation. The obstetrician therefore becomes a gatekeeper in the determination of the need for MRI under a variety of instances.

In complicated cases, the MRI examination should be interpreted in consultation with a multispecialty team. The perspectives of a maternal-fetal medicine specialist, radiologist, or pediatrician can complement one another in a complex case and provide the best set of differential diagnoses. In CNS anomalies, for instance, neuroradiologists can provide a wider range of possible diagnoses than those who do not deal with these cases on an everyday basis. As always, the ultrasound findings need to come into play in the performance and interpretation of any MRI examination. In many instances, the

findings on ultrasound determine the best planes to start an MRI examination. Frequent references to the ultrasound study can clarify any confusion brought about by fetal change in position or artifacts of scanning. In most instances, the MRI study is tailored to the area of concern on ultrasound. If the abnormality is within the brain, MRI of the fetal chest and abdomen are de-emphasized, and the planes of imaging are centered on those that will best demonstrate the brain abnormality. This focus will not only decrease the time required to keep the mother in the magnet, but will also simplify an examination that could otherwise not only take time but also produce hundreds of images for interpretation. When these factors are taken into consideration, the power of ultrasound and MRI together can increase the accuracy of diagnosis by several degrees of magnitude.

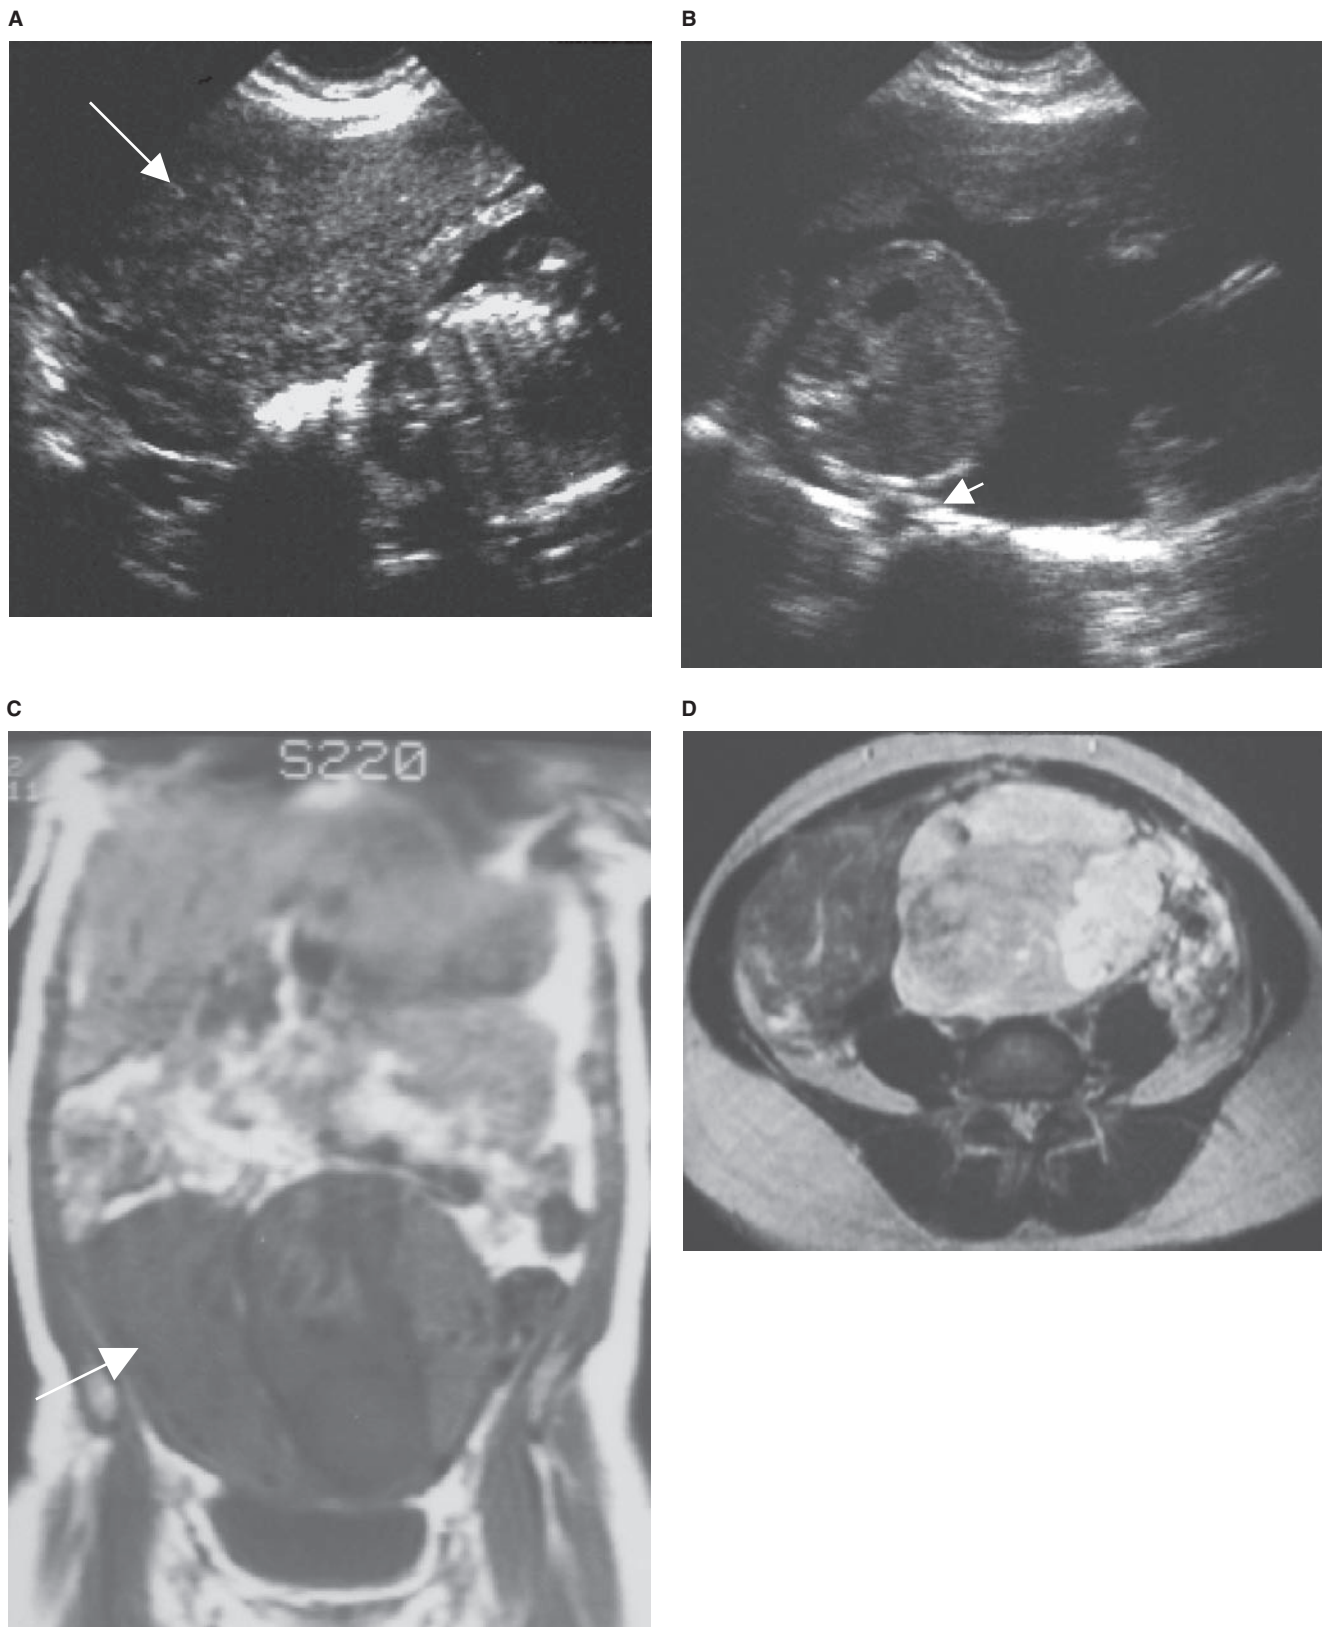

Figure 30.33 Abdominal pregnancy. Ultrasound images show the empty uterus (long arrow) anterior to the fetus (A). There is no myometrium posterior to the fetus separating the body from the common iliac artery (short arrow) (B). MRI confirmation images (C) and (D) show the uterus (long arrow) separate from the fetus on the coronal T1-weighted image (C). T2-weighted axial image (D) shows the typical high signal arising from the endometrium.

Figure 30.34 Uterine leiomyoma. An anterior myoma (arrow) raised the suspicion of an empty uterus in an abdominal pregnancy in ultrasound (A). MRI showed the normal gestational sac and the anterior myoma (B).

Figure 30.35 Teratoma. A large teratoma was mistaken for a demised twin on ultrasound (A and B). MRI shows a typical fat signal on T1-weighted image (C) and high-signal fluid component on T2-weighted image (D).

Figure 30.35 *Continued*

Figure 30.36 Teratoma. A mass associated with a first-trimester gestation showed typical MRI characteristics: on fat suppression, the fat-containing elements (arrow) decrease in signal relative to the fluid component (C). (A) The normal first-trimester fetus with a crown-rump length measurement corresponding to 11 weeks' gestation. (B) An endovaginal image of the dermoid showing better the cystic and solid components. Note the non-layering debris in the mass corresponding to a mixture of liquid and fat.

Figure 30.37 MRI images of uterus didelphys with normal pregnancy in the left uterine cavity and hematometra in the obstructed right uterine cavity (arrow) (B–D). This presented on ultrasound as a vaginal mass with heterogeneous echoes (A).

Figure 30.38 Unicornuate uterus. Severe oligohydramnios was seen on ultrasound (A and B) limiting fetal evaluation. MRI (C) shows the pregnancy in the unicornuate uterus, which was only diagnosed at Cesarean section.

Key points

- 1 Prenatal diagnosis expertise requires familiarity with 3D/4D ultrasound and MRI to remain at the cutting edge of technology.
- 2 3D ultrasound provides data storage that can be accessed to reconstruct any desired image plane.
- 3 Stored volumetric data can be reviewed by multiple examiners long after the examination has ended.
- 4 Digital storage of data allows for consultation among specialists at different locations.
- 5 4D ultrasound is 3D ultrasound with dynamic display of rendered images in real time.
- 6 The use of 3D/4D ultrasound solely for entertainment purposes is not a prudent use of medical technology and is discouraged.
- 7 3D/4D ultrasound has been promoted as a technique that enhances bonding between the fetus and its parents.
- 8 Detection of fetal anomalies with the use of 3D ultrasound has been proven useful in the demonstration of complex facial anomalies.
- 9 Complicated limb abnormalities are clearly shown on 3D imaging.
- 10 The application of 3D/4D ultrasound in the abdomen has seen limited use at this time.
- 11 Electronic artifacts can be generated by motion, oligohydramnios, and faulty electronic settings.
- 12 MRI applications in obstetrics have been proven in the second half of pregnancy, but have limited use in the first trimester.
- 13 Rapid scanning sequences available in modern MRI equipment have obviated the use of paralyzing agents for the fetus.
- 14 Artifacts can be generated on MRI images by both fetal motion and maternal motion.
- 15 The use of MRI should always be correlated with a recently performed ultrasound examination to facilitate the performance of the examination and the diagnosis of fetal abnormalities.
- 16 The greatest application of MRI in the fetus to date has been in the CNS, with increasing applications in the chest and abdomen.
- 17 Abnormalities detected but not conclusive on ultrasound should be pursued with an MRI examination.
- 18 Nonfetal complications of pregnancy such as adnexal masses and uterine anomalies are best evaluated with MRI.
- 19 The diagnosis of complicated fetal anomalies should be approached by a multidisciplinary team to maximize the diagnostic power of the examination.
- 20 The combination of ultrasound and MRI increases the accuracy of fetal diagnosis more than either modality alone.

Doppler ultrasonography and fetal well-being

Brian J. Trudinger

Doppler ultrasound has provided a noninvasive clinical tool to assess blood flow in pregnancy in the circulations, previously precluded from direct study because of risk to the fetus from invasive procedures. The desire of obstetricians to measure blood flow, particularly to the placenta, has been achieved. Diagnoses such as “placental insufficiency” were created to express a hypothetical reduction in blood flow almost without any actual basis. The scope of Doppler studies has now extended from the placenta to many fetal vascular beds and a great variety of disorders of pregnancy. The information obtained from such studies has expanded our knowledge of the physiology of pregnancy and the pathophysiology of a variety of disorders, and provided a diagnostic tool for evaluation of the welfare of the fetus.

Doppler instrumentation

Doppler equipment used in obstetric practice ranges from the simplest fetal heart detectors through the fetal heart rate (FHR) monitors to the most sophisticated high-level ultrasound imaging systems. Common to all is the incorporation of the Doppler effect. When there is movement between a wave source and a reflecting target, there is a change in frequency of the reflected wave relative to the transmitted wave, and that change in frequency is proportional to movement velocity. The Doppler equation is:

$$F_D = F_1 - F_0 = (-2v \cos \theta \times F_0)/c$$

where F_0 is the transmitted frequency, F_1 the received frequency, c the velocity of sound in tissue, v the velocity of movement, and θ the angle between the ultrasound beam and the direction of flow. When an ultrasound beam strikes a blood vessel, the moving column of red blood cells scatters and reflects the ultrasound beam with a new frequency. The change in frequency or Doppler frequency shift (incident frequency minus reflected frequency) is proportional to the velocity of the red blood cell scatterers or blood flow velocity

because the other terms are constants in the Doppler equation. This change in frequency may be displayed and used to calculate blood flow.

The ultrasound transducer of the Doppler used for flow studies can act as both the emitting source of the ultrasound beam and the receiver of the reflected signal. In continuous wave systems, there are separate crystals for each role, usually mounted side by side, whereas in a pulsed system, the single crystal emits an ultrasound pulse and then functions as a receiver. Activation of the crystal causes the conversion of electrical energy to an ultrasound beam during emission, and the returning ultrasound signal reverses this process. The weak returning signals are amplified and fed to the Doppler shift detector, which filters out unwanted frequencies (including the original ultrasound frequency) so that the Doppler frequency shift remains. This information is nondirectional. To separate the Doppler signals produced by flow toward and away from the transducer (forward and reverse flow), phase domain processing is commonly used. This requires two detectors with their reference inputs differing in phase by 90°. The filtered output signals are referred to as quadrature Doppler shift signals. Two types of Doppler systems are in use – continuous wave and pulsed. They differ in a number of ways. Continuous wave systems are continuously emitting from one crystal and receiving through another. They are relatively simple, cheap, and portable. The reflected echoes from any moving structure within the ultrasound beam are detected, so that there is no spatial resolution. Positioning the transducer and line of sight of the ultrasound beam is readily done. This system is used in simple fetal heart detectors. In the pulsed system, a short burst of the ultrasound wave is transmitted, and the crystal then acts as a receiver. A range gate circuit allows recording only at a specified time after the pulse emission, so the Doppler shift detected originates from a fixed depth. This type of processing may be referred to as setting the sample volume to a known depth. These Doppler velocimeters may exist as stand-alone items, but are now commonly built into ultrasound imaging systems. Integration with an imaging facility provides the ability to steer the ultrasound

beam and, for pulsed Doppler systems, to locate the sample volume precisely over the vessel to be studied. In addition, the dimensions of the vessel under study may be measured.

The chosen frequency of the ultrasound beam is a compromise based on a number of considerations.¹ In general, the highest frequency producing a reliable signal is used. The depth of penetration (tissue attenuation) is inversely proportional to the square of the frequency. The degree of scattering is proportional to the fourth power of the frequency. The higher the transmitting frequency, the greater the Doppler frequency shift. With pulsed Doppler systems, there must be sufficient time to characterize the Doppler shift frequency before the next pulse is emitted. The laws of signal processing state that any Doppler signal with a frequency greater than the “Nyquist limit” (equal to half the pulse repetition rate) will be grossly distorted, suffering “frequency aliasing” and so appearing with quite different frequencies.

With medical equipment and vascular studies, the Doppler shift frequency usually falls in the audible range; therefore, the simplest display of the Doppler frequency shift is an audio signal. The method of choice is spectral analysis. If the vessel is totally insonated, the frequency spectrum represents all the different velocities across its lumen. The process of spectral analysis is carried out by a spectrum analyzer and is therefore also subject to the possibility of frequency aliasing if too fast a sampling rate is required. Equipment usually carries out the spectral analysis sufficiently quickly (less than 10 ms/spectrum) so that it is available in real time. It is also possible to display the frequency and direction of blood flow by color coding superimposed on the real-time ultrasound two-dimensional image (“color flow mapping”). This facility is particularly useful for locating vessels containing blood flow and determining the direction of flow of blood within a vessel. If the power of the frequency-shifted signals is displayed (rather than the frequency), then a power flow image is obtained. This facility is also a feature of ultrasound imaging systems now. Power imaging does not provide directional information.

Because blood flow velocity is directly proportional to the Doppler frequency shift, the information made available to the clinician by the Doppler instrumentation is a blood flow velocity waveform (FVW). The envelope of this wave is the maximum flow velocity. Beneath this is a frequency distribution, representing the various velocities of blood flow in the vessel under study. Both instantaneous and temporal mean flow velocities can be determined from this. If the angle between the ultrasound beam and the vessel is known, then the absolute velocity can be calculated. This requires the use of pulsed Doppler systems. Volume blood flow may be determined as the product of mean velocity and vessel area.

The blood flow velocity waveform

Blood flow is pulsatile. With each contraction of the heart, a pressure pulse or wave propagates down the aorta and its

branches with an initial wave speed of 5 m/s. This creates a time-varying pressure gradient between neighboring points along the arterial tree. Blood flows ahead of this pressure gradient from high to low pressure. The blood flow is also pulsatile – the FVW. Doppler ultrasound systems record this FVW. Early in systole, the pressure and flow waveforms are in phase, but this breaks down later in systole because of the arrival of waves reflected from points of branching along the arterial tree and the periphery. The FVW travels more slowly than the pressure wave, and its amplitude decreases as it moves away from the heart. In the ascending aorta, following the opening of the aortic valve, blood flow velocity increases to a peak and then falls. After closure of the aortic valve, the blood is close to stationary for the remainder of the cardiac cycle.

The pressure and flow waveforms are influenced by cardiac contraction, the physical properties of the arterial walls and the blood within, and outflow impedance from the arterial tree. Traditionally, blood flow is described in terms of pressure and flow. Resistance has been defined as the ratio of mean pressure difference (or pressure head) across a vascular bed to mean flow through it. Resistance may also be conceptualized as how difficult it is to force blood through the circulation or the energy dissipation required for blood flow.² It is an artificial concept insofar as blood flow is not steady but pulsatile. Changes in resistance in clinical physiology are more often than not due to changes in the caliber of small blood vessels, but resistance is not necessarily only an index of arteriolar caliber. It also depends on the dispensability of the arterial walls (and transmural pressure) and blood viscosity.³ The term impedance is introduced to take into consideration the pulsatile nature of blood flow, being the ratio of pulsatile pressure to pulsatile flow.⁴ A consequence of pulsatile blood flow in comparison with steady flow is the requirement for more energy to move a given volume of blood, and much of this extra energy is used to distend the large arteries. The mean term resistance depends much more on arteriolar caliber than on large artery distention. Various indices derived from the FVW pattern have been defined to assess “resistance.” They would appear to depend most on the size of the peripheral vascular bed.

When a blood vessel is interrogated with an ultrasound beam, not one but a spectrum of Doppler frequencies is found. This corresponds to all the different velocities across the flowing stream of blood. Each point across the vessel may be represented by a velocity vector, and a line through the tips of these vectors creates the velocity profile (Fig. 31.1). The variations in velocity result from the nonviscous and inhomogeneous nature of blood. The velocity profile also varies through the cardiac cycle and, in some circumstances, flow may not always be forward or in the same direction. Color flow mapping may demonstrate this.

If the lumen of the blood vessel has been totally insonated, all this information is available in the Doppler FVW. In order to recreate the exact velocity profile, it would be necessary to

Figure 31.1 The blood flow velocity profile across a vessel. U_0 , center line velocity; u , velocity at radial position r (modified from ref. 3, p. 47).

use a pulsed Doppler system and sample from each point across the vessel. If the vessel is uniformly insonated, the mean Doppler frequency shift is proportional to the mean velocity, and this fact is used in the calculation of volume flow.⁵ In a blood vessel with an established flow, the “boundary layer” is the region of flow in which velocity is increasing with distance from the wall. Here, viscosity is important, because there is shear between adjacent flow lamina. In the central stream, the movement is “en masse” and inertia is more important. If the disturbances of local geometry are ignored, then in large arterial vessels, inertial forces dominate blood flow, whereas in small vessels, viscous forces are more important. Reynold’s number expresses the relative importance of these two forces.³

The Doppler FVW has been analyzed in a variety of different ways. In clinical applications, inferences about the cardiovascular system are made using empirical indices. The connection between an empirical index and a physiological variable may be based on a statistical association or evidence from an experimental model. In many situations, only the maximum velocity waveform (or the waveform envelope) is used. This is the easiest waveform to locate and is relatively error free. It does ignore all the information about the velocity profile contained within the frequency spectrum. The problems of analysis of the maximum mean and first moment of the velocity waveform in the fetal circulation have been reviewed.^{6,7} The shape of the waveform envelope can be considered a characteristic of the vascular site. Waveforms recorded from arteries supplying low-impedance vascular beds (e.g., internal carotid, umbilical, and uterine artery in pregnancy) exhibit relatively high forward velocities throughout diastole. A triphasic waveform shape, where there is a period of reverse flow in diastole, is characteristic of sites with high distal impedance. The peripheral impedance, vessel wall elasticity, the degree and geometry of any proximal stenoses, and the condition of the upstream pump all affect the waveform. All these factors are important, all can be affected in the disease state being investigated, and none can be independently eliminated or controlled in clinical practice. Even in normal, presumably healthy subjects, blood flow patterns at a site with complicated geometry such as the carotid bifurcation are very complex.

The fetal circulation is uniquely suited to Doppler waveform

Pulsatility index	$= \frac{A - B}{\text{Mean}}$
Pourcelot ratio	$= \frac{A - B}{A}$
Systolic–diastolic ratio	$= A/B$

Figure 31.2 The three indices of downstream resistance in common clinical use for the analysis of arterial flow velocity waveforms.

analysis by simple empirical indices. This is because of the absence of degenerative arterial disease. The umbilical circulation was the first to be studied, and the indices used for this fetal circulation have been directed toward assessing downstream resistance. Three are in common usage (Fig. 31.2). All of these are highly correlated. Coefficients in excess of 0.9 have been demonstrated when the indices are compared.^{6,8} This means that the indices are all providing the same information about the same physiological variables. Choice of index, then, is a matter of convenience relative to the investigational task. The systolic:diastolic ratio is easiest to calculate. Abnormally high values, when there is little or no diastolic value, tend to infinity and become meaningless. The pulsatility index has a precise mathematical definition. It requires determination of the mean velocity, and this is usually an inaccurate estimate. The resistance index (Pourcelot ratio) is the only one normally distributed and has the advantage that the maximum value attainable is one. It has an extra arithmetic step in comparison with the systolic–diastolic ratio. All these indices, when used to interpret the maximum velocity waveform, should be seen as simple descriptors of the waveform pattern. They are not precisely estimatable quantities. There is an inherent systematic error of 10–20% in their calculation.⁸ The same indices have been used to assess vasodilation in the

cerebral circulation (brain-sparing effect) in fetal compromise. The peak velocity of the FVW envelope has been correlated with volume flow⁹ in animal studies, and this parameter has been used as an index in the cerebral circulation. In fetal anemia (e.g., rhesus alloimmunization), cerebral blood flow is increased. It has also been used in the aorta. In the central fetal veins (inferior vena cava and ductus venosus), the FVW pattern reflects the central venous pressure waveform, and different indices have been used (see below). In studying the maternal uterine artery FVW, the presence of a diastolic notch at the end of systole, which is created by reflected waves, is noted. In summary, there are a variety of empirical indices that have been developed to reflect changes in the pattern of blood flow, which are the result of the pathophysiology of the disorder under study.

The umbilical circulation

The umbilical cord, linking the fetus and placenta, is long and suspended in amniotic fluid, and so is ideal for Doppler studies. The two umbilical arteries travel along this without branching or changes in lumen diameter. The radius of curvature of the loops of cord is large in comparison with the diameter of the umbilical arteries, and so is unlikely to significantly influence flow patterns. However, this spiraling course means that it is not possible to image a sufficient length of artery or vein to permit determination of the angle between the ultrasound beam and vessel, and so it is not possible to make Doppler volume flow measurements. Studies of the umbilical artery FVW using the indices of resistance have been carried out to assess the downstream vascular bed – the fetal placenta. The umbilical arteries can be readily studied with simple continuous wave Doppler ultrasound systems. They have been studied extensively, and these studies have been subjected to much critical appraisal.

Normal pregnancy

Blood flow through the umbilical circulation increases throughout pregnancy and represents some 40% of the combined ventricular output of the fetus.¹⁰ The actual flow in the fetal lamb has been measured at 180–200 mL/min/kg fetus;¹¹ in human pregnancy, it is less, 100–110 mL/min/kg fetus.^{12,13} The umbilical placental vascular bed is not innervated, and indeed is refractory to such circulating vasoconstrictors as epinephrine and norepinephrine.¹¹ Blood flow to the placenta appears to be the result of the balance between resistance to other fetal vascular beds and the placenta.¹⁰ Almost certainly, there are local controls of placental blood flow that regulate the perfusion to keep a balance between the fetal and maternal placental flows.¹⁴ It has been pointed out that the fetus does not need to regulate umbilical blood flow finely, because it has the capacity to vary tissue oxygen extraction ratios and, consequently, oxygen uptake.¹⁵ The fetus requires oxygenated

Figure 31.3 The changing form of the umbilical artery FVW recorded from one patient at varying periods of gestation.

blood from the placenta for distribution to the fetal tissues, where uptake and delivery may be regulated.

The umbilical circulation is a low-resistance vascular bed, which is reflected in the pattern of the umbilical artery FVW (Fig. 31.3). Throughout pregnancy, the increase in umbilical blood flow is achieved by a decrease in resistance rather than an increase in driving pressure, although this also occurs in the last part of pregnancy.¹¹

Gestational age is an important influence in determining the normality of the umbilical FVW (Fig. 31.3). The indices of resistance decrease as the placenta grows and expands its vascular bed. In early pregnancy, diastolic flow velocities may be absent. The range of variation in waveform pattern is much greater in early pregnancy. This is clearly apparent in the normal ranges of the various indices of resistance used to describe the umbilical waveform pattern (Fig. 31.4).

There has been debate about the influence of fetal heart rate (FHR) on the umbilical FVW. Two careful studies observed a weak relationship between FHR and waveform index over the physiological range of heart rates.^{6,16} Others have reported

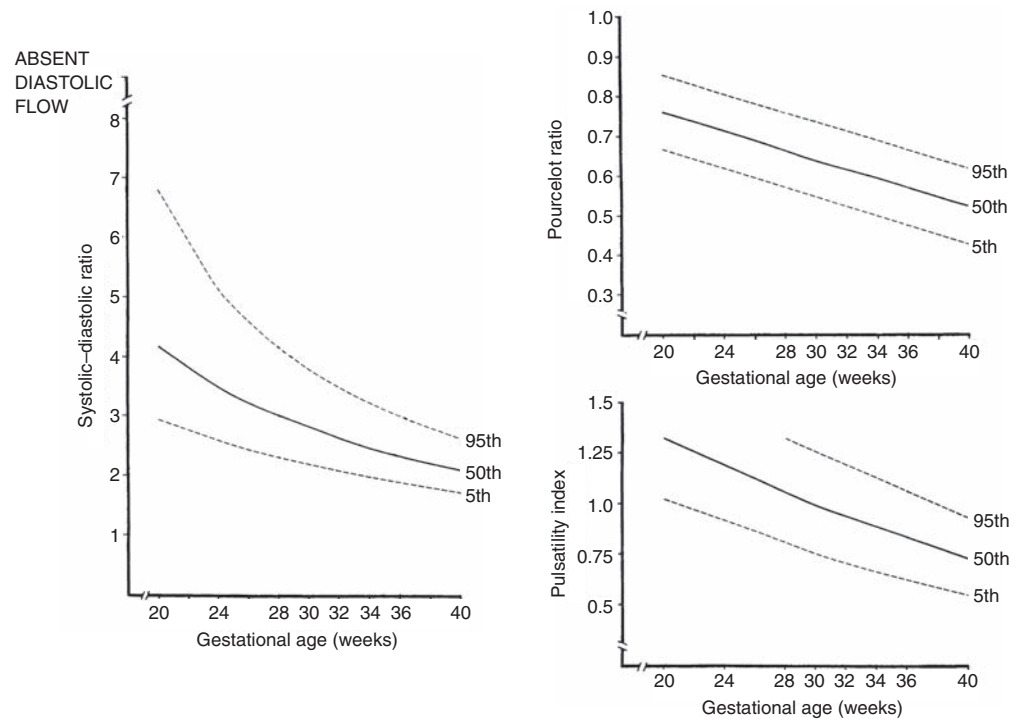

Figure 31.4 The normal range of values for the umbilical artery downstream resistance indices (from ref. 8).

strong associations, but included values outside the normal range, especially below 100 beats per minute (b.p.m.). Over the normal range of FHR, the correction suggested is less than the systematic error present in calculation of the various indices and very small in comparison with the difference between normal and abnormal waveform patterns. The suggestion that a correction factor is necessary is based in part on the assumption that the decay in the diastolic component of the maximum velocity is passive. This assumption is unfounded.

Fetal breathing movements do alter the FVW. During "inspiration," both peak systolic and least diastolic values are decreased, so that the systolic:diastolic ratio is increased (Fig. 31.5). It is interesting to speculate on the reason for this change. During inspiration, more of the right ventricular output has been directed through the pulmonary circulation and less bypasses this through the ductus arteriosus to the aorta and umbilical circulation. This implies that fetal breathing is associated with opening of the fetal pulmonary circulation.

Behavioral states do not influence the FVW pattern or indices of resistance in the umbilical circulation. This is in contrast to the aortic waveform.¹⁷ Such an observation is not unexpected, because the aortic waveform is influenced by flow to various fetal organs under autonomic control, whereas the placenta is not so regulated.

There has been debate about variations in the umbilical FVW along the length of the cord. Close to the fetus, a higher value may be obtained for the systolic:diastolic ratio.¹⁸ There is a transition from the typical aortic to umbilical waveform. At the placental end, the resistance indices have been reported

Figure 31.5 The influence of fetal breathing movements on the FVW of the umbilical artery (upper trace) and umbilical vein (lower trace).

to be lower than the values recorded from free-floating loops of cord. This difference is very small in comparison with differences between normal and abnormal pregnancy.

In recording the umbilical FVW, it is necessary to review a sequence of 10–20 cycles to confirm that variations due to fetal activity are absent. Ideally, at least five waveforms should be measured and averaged. To minimize errors, the measured waveforms should be those displaying the maximum obtainable peak systolic and least diastolic flow velocities. This requires that the angle between the ultrasound beam and the vessel is small, and an ideal image can be sought by small movements of the transducer. Simultaneous display of flow in the umbilical artery and vein allows confirmation of the origin of the signal from the umbilical cord by the characteristic

pattern, and eliminates the possibility of superimposition of signals from the vein and artery, giving a false value for the diastolic velocity.

Experimental studies of the umbilical circulation relevant to FVW interpretation

The placental vasculature has been modeled as a lumped electrical circuit equivalent,^{19,20} an approach widely used in other circulations. Thompson and Stevens¹⁹ developed a computer-based model recreating the branching structure of the villus tree with each arterial vessel represented by a resistor and a capacitor in parallel. The validity of this approach was confirmed by substituting physiologically realistic values for vessel size, resistance, capacitance, and pressure, and demonstrating that calculated and clinically measured umbilical flow were similar. Using this model, it can be shown that the pulsatility index (PI) of the FVW is proportional to the pulsatility of the pressure waveform

and the resistance of the umbilical placental villus vascular tree.²¹

Assuming a diffuse vascular pathology, it can be shown that the FVW index of resistance increases as the fraction (q) of terminal arterial vessels obliterated increases. This increase is not linear (Fig. 31.6). It is not until some 50–60% of the vessels have been obliterated that the PI is increased beyond the “normal range.” Thereafter, it rises rapidly. It highlights the presence of extensive disease before Doppler detection is possible, and emphasizes the reserve capacity of the placenta. The model also showed a difference between the response of a large and a small placental vascular bed to superimposed vascular obliteration. The same fraction of obliteration (q) produced a much greater increase in PI when the placenta was small. It follows from this prediction that a large, late third-trimester placental vascular bed can accommodate a considerably greater degree of obliteration with minimal change in resistance index in comparison with a smaller, second-trimester placenta. This parallels clinical reports indicating

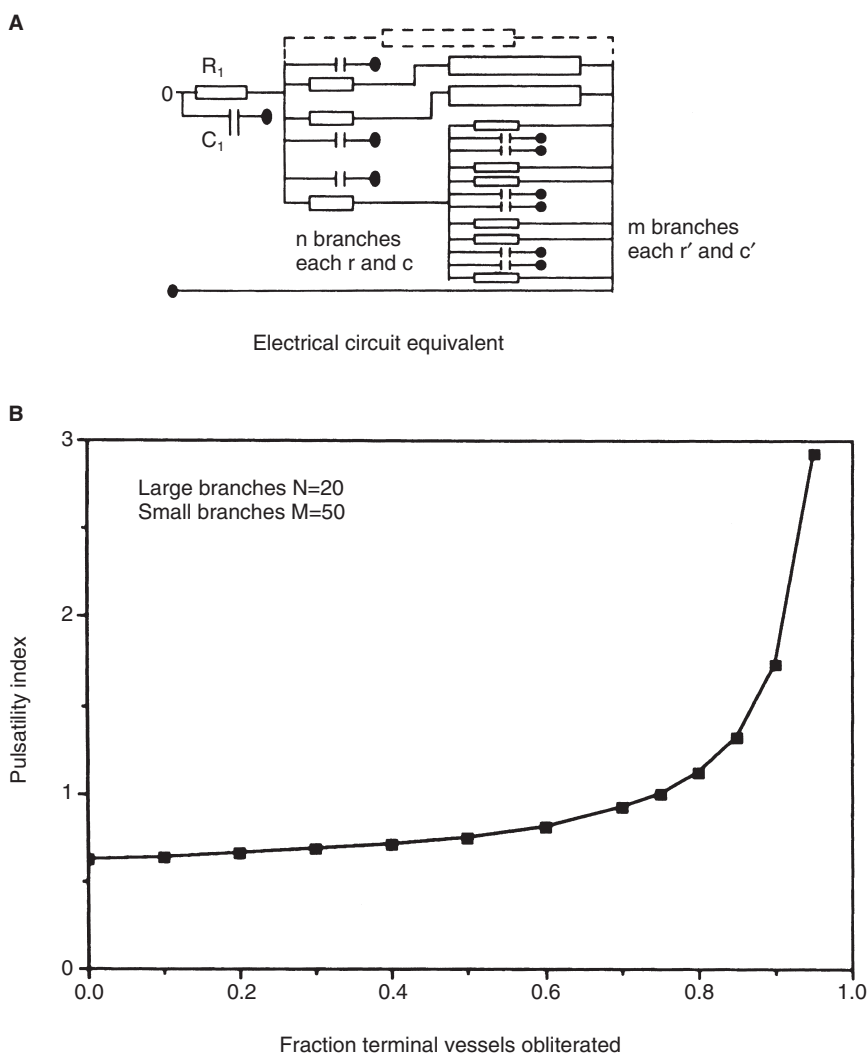

Figure 31.6 Using a mathematical model of the umbilical circulation, based on a lumped electrical circuit equivalent (A) [r = resistance, c = capacitance, of individual proximal branches (n) or distal branches (m)], the change in the umbilical artery pulsatility index was calculated in the presence of an increasing fraction (q) of the umbilical placental vascular bed (B). N is the total number of large (n) branches each having M small (m) branches chosen to be representative of a placenta at 30 weeks (from ref. 21, with permission).

that Doppler studies have a low sensitivity in predicting fetal compromise in postdate pregnancies.^{22,23} Doppler umbilical studies are a far more sensitive test for the detection of placental vascular pathology earlier in pregnancy.

This model also demonstrated that variations in blood pressure will alter the PI, but this variation is small.²¹ Over the physiological range of blood pressures, the very high values of PI seen in fetal compromise could not be obtained by variations in blood pressure. The PI was demonstrated independent of heart rate over the range 100–180 b.p.m. The effect of a fetal response (by increase in blood pressure) following placental vascular bed obliteration was examined using this mathematical model. If terminal vessels in the placenta were obliterated, the placental resistance increased, as did the PI, while umbilical volume flow decreased. However, a small, physiologically realistic increase in systolic pressure was sufficient to maintain umbilical flow until approximately 80% of the terminal arterial vessels were obliterated. Beyond this point, the pressure increase required was unrealistic (outside the physiological range).

The umbilical circulation in the fetal lamb has been studied with Doppler ultrasound. In ovine pregnancy, it is possible to demonstrate the same decrease in the FVW indices of resistance seen in human pregnancy.²⁴ The Doppler indices have been demonstrated to be a measure of resistance in the umbilical circulation in the fetal lamb. Embolization of the umbilical cotyledon circulation with microspheres was carried out to increase the resistance of the peripheral vascular bed.^{25,26} This caused a rise in the umbilical systolic:diastolic ratio and a rise in calculated vascular resistance.

Pathophysiology of abnormal umbilical Doppler FVW

In normal pregnancy, placental growth continues throughout, as demonstrated by the progressive increase in the weight of the placenta. The overall increase in placental size is associated with an increase in the number of tertiary stem villi and, therefore, total small arterial channels. The continuing expansion of the umbilical placental vascular tree matches the decreasing vascular resistance measured directly in fetal lambs.¹¹ The decrease in the umbilical artery FVW indices of resistance seen in normal pregnancy is consistent with this. The abnormal umbilical Doppler FVW is characterized by a change in the opposite direction, with decreasing diastolic flow velocities relative to the systolic peak and, in extreme cases, by absence or even reversal of blood flow in diastole. This is a high resistance pattern and contrasts with the normal FVW discussed and illustrated above.

A histological study to correlate the umbilical artery FVW pattern with the “resistance” vessels in the umbilical placental vascular tree has been carried out.²⁷ Because the major drop in arterial pressure across the umbilical placental vascular bed occurs in the small arteries and arterioles of the ter-

ary villi, these are the “resistance” vessels. When these placental vessels were examined after delivery in pregnancies classified according to whether the antenatal umbilical Doppler studies were normal or abnormal, significant differences were found. The modal tertiary villus small arterial vessel count was significantly less in the group with the abnormal umbilical artery FVW (1–2 arteries/high-power field) in comparison with the normal group (7–8 arteries/field). This work has been confirmed by others.^{28,29} Change in the walls of these resistance vessels was also recognized.³⁰ This placental lesion of vascular sclerosis, with obliteration of the small muscular arteries of the tertiary stem villi, could be expected to cause an increase in flow resistance in the umbilical placenta. This lesion in the fetal placenta could best be described as “umbilical placental insufficiency.”

Placental pathologists have recently focused attention on vascular changes in the umbilical placental circulation. It is noteworthy that this has followed the Doppler definition of a changing vascular resistance in the fetal placenta. A large group of severe placental fetal vascular lesions (fetal thrombotic vasculopathy, chronic villitis with obliterative fetal vasculopathy, chorioamnionitis with severe vasculitis, and meconium-associated fetal vascular necrosis) have been identified and associated with neurological impairment.^{31,32} Avascular villi are a common feature. However, it does not appear that the chronic inflammatory or vaso-occlusive histological patterns are specific.³³

Studies of the fetal circulation and endothelium of the vessels of the placental villi have shed light on the pathogenic pathway. The umbilical artery Doppler high-resistance FVW pattern is associated with fetal platelet activation³⁴ and consumption.³⁵ The endothelium is activated,³⁶ and this is a likely cause. There is proinflammatory cytokine [interleukin (IL)-6 and IL-8] production by the endothelium.³⁷ These findings link the inflammatory change and thrombosis. The cause of this remains uncertain. The similarity of this to atherosclerosis in later life has been noted.³⁶ Fetuses with these findings also have an atherogenic lipoprotein profile.³⁸

Clinical correlates of abnormal umbilical Doppler FVW in high-risk pregnancy

The abnormal umbilical artery Doppler FVW is characterized by a pattern of reduced, absent, or even reversed diastolic flow velocities relative to the systolic peak velocity (Fig. 31.7). In this situation, the indices of resistance are increased. A review of the normal ranges for these measures (see Fig. 31.4) illustrates the importance of knowledge of gestational age before an index is called abnormal. Before 18 weeks, absent diastolic flow may be seen in normal pregnancies. Particularly in early pregnancy, serial studies are necessary to determine whether the normal growth of the placental vascular tree is occurring, because the normal range is wide.

Before considering the clinical correlates of the abnormal

Figure 31.7 Examples of (A) a normal umbilical artery waveform, (B) a waveform in which the systolic:diastolic ratio is high, and (C) an extremely abnormal waveform, in which the diastolic flow velocities are reversed.

umbilical FVW, it is worth restating that analyzing the umbilical artery FVW with the various indices of resistance does not indicate a fetal condition, but rather the presence of a vascular lesion in the placenta – umbilical placental insufficiency. It is believed that this Doppler-defined umbilical placental insufficiency precedes the fetal deprivation. The fetal effects consequent upon this vascular lesion are the clinical correlates. Poor fetal outcome, particularly in terms of the birth of an infant small for gestational age (SGA), is the major clinical association reported. This has been the consistent finding in many reports of the results of Doppler studies in high-risk pregnancy.^{39–41} However, what matters most to the obstetrician is not the recognition of the small fetus, but rather the fetus at risk of death *in utero*, distress in labor, and neonatal morbidity. Evidence that umbilical artery Doppler gives this information is provided by reviewing the results of a large study from a single laboratory⁴² and collected studies from several centers.⁴³ The most abnormal studies (highest systolic:diastolic ratio group) had the greatest incidence of fetal

Table 31.1 Results of the last study before delivery in the group of 53 SGA fetuses.

	Umbilical artery waveforms	
	Normal	Abnormal
Number of fetuses	19	34
Mean gestational age at delivery (weeks)	37.6	34.6
Admission to neonatal intensive care	3	23
Neonatal deaths	0	7

Data from ref. 46.

growth failure, as indexed by the percentile birthweight. Both fetal and neonatal deaths were highest in this group.

There has been considerable discussion about the group of patients that show an umbilical FVW pattern with absent diastolic flow velocities. Statements about the poor pregnancy outcome of this group and the need for delivery appear in the literature. It has been suggested that this constitutes a watershed for fetal risk. The outcome of patients with this finding has been reviewed in published reports.⁴⁴ In a collected review of 785 cases, there was an 84% incidence of birthweight less than the 10th percentile. Morbidity and mortality were high in this group. Careful anatomical ultrasound study is warranted as there is a 5–10% incidence of major anomalies including aneuploidy.⁴⁴ Absent diastolic flow is a part of the spectrum of FVW change from normal to extremely abnormal. It is not a level at which fetal morbidity starts to appear. It is the opinion of the author that absent end-diastolic flow velocities should not be the reason for delivery. Rather, it recognizes a severe vascular lesion in the placenta. Specific evidence of fetal effect should be sought as delivery may be warranted. Absent diastolic flow may be a feature of normal pregnancy before 18 weeks. This finding may occasionally result from error of technique. The greater incidence of hypoxemia in this group of fetuses is not surprising, but a number have normal gas tensions.⁴⁵ Caesarean delivery is usual.

Among a group of SGA fetuses, an abnormal Doppler umbilical study predicted those who were more likely to require early delivery and neonatal intensive care and those with the highest mortality (Table 31.1).⁴⁶

The trend of umbilical Doppler results proved a very useful measure of neonatal morbidity in those patients with serial studies. This was analyzed among 794 high-risk pregnancies with three or more umbilical Doppler studies available.⁴² A decreasing systolic:diastolic ratio was associated with a good outcome, even if the values were outside the normal range (Table 31.2). Such a result suggests continuing placental growth. This trend in serial studies will identify the single false-positive result. Serial studies are also helpful in determining the response to therapy.

Table 31.2 Pregnancy outcome in relation to trend in serial umbilical artery flow studies.

Outcome parameter	Pattern of serial Doppler studies		
	Normal	Abnormal/improving	Abnormal/deteriorating
Total number of cases	567	117	110
Gestational age at delivery	38.5	37.5*	34.5†
Birthweight (mean g)	3164	2708†	1906†
Percentile birthweight (mean)	43.8	26.5†	12.4†
Small for gestational age (< 10th percentile): number (%)	97 (17%)	47 (40%)†	78 (71%)†
Admission to NICU: number (%)	101 (18%)	27 (23%)†	65 (59%)†
Duration of stay in NICU (mean days)	6.1	11.1	34†

Umbilical Doppler FVW and specific pregnancy complications

Hypertensive disease of pregnancy

A high resistance pattern in the umbilical artery Doppler FVW is not present in all cases of pregnancy hypertension. It does appear that it predicts fetal mortality and morbidity.^{47,48} It is not related to the severity or duration of the hypertension.

Diabetes mellitus

Umbilical artery FVWs have also been used in the management of diabetic pregnancies.^{49,50} Umbilical artery resistance indices are not different from those found in nondiabetic pregnancy. Glycemic control does not appear to affect these indices. The expected relationship between abnormal umbilical artery FVWs and both antenatal fetal compromise and birthweight has been noted.⁵⁰ However, in diabetic pregnancy, abnormal nonstress FHR monitoring and biophysical profile have been noted in the presence of a normal umbilical artery FVW. Fetal death has also been reported. Two cases drawn from the author's experience provide further understanding of this problem. Illustrated in Fig. 31.8 is the development of a high-resistance pattern in the umbilical artery FVW in a macrosomic fetus. Diabetic control had been poor and, earlier in pregnancy, fetal growth was excessive. Late in pregnancy, growth was restricted as vascular pathology developed in the placenta. In Fig. 31.9 is the FHR tracing of a mother admitted with hyperglycemia and ketoacidosis in whom the umbilical Doppler result was normal. Good control was re-established, and the FHR tracing became normal. It is likely that many of the cases of unexpected fetal deterioration or demise in diabetes relate to swings in glycemic control, and this is not predicted by the umbilical artery FVW.

Multiple pregnancy

Premature labor, preeclampsia, and fetal growth restriction all contribute to high perinatal mortality and morbidity rates in twin pregnancies. Doppler umbilical studies are especially useful. Care with assignment of umbilical cord recording to the correct fetus is necessary.⁵¹

The great value of Doppler studies in twin pregnancy management lies in the early recognition of the fetus at risk. Two groups of twin pregnancy problems should be distinguished. In dizygotic twins, discordancy of fetal growth may occur, and this is typically associated with a high-resistance pattern in the umbilical artery Doppler in the small fetus. Such a finding then warrants close fetal surveillance. A recent randomized controlled trial showed no benefit from the use of Doppler⁵² when all other fetal surveillance tests were available. Unexplained fetal deaths were reduced however. In contrast to this, an old study of historical data collected soon after the introduction of Doppler⁵³ into obstetrics showed benefits. Perinatal mortality and, in particular, fetal deaths were significantly reduced. The perinatal mortality was reduced from 58/1000 to 18/1000 ($P < 0.05$). This suggested that a program of intensive fetal surveillance improves outcome.

A consistent Doppler picture in the case of twin-twin transfusion syndrome has been disputed. Discordance in ultrasound measures of fetal size, cord diameter, amniotic fluid volume, and the urinary bladder between the members of the twin pair form the basis of grading.⁵⁴ The finding of absent or reversed end-diastolic flow velocities in the umbilical artery FVW indicates a poor prognosis, and this is a consistent observation in several published studies.⁵⁵ Interestingly, this finding may be intermittent. This is a subject of much controversy. Recent research has also focused on the possibility that it is pressure rather than volume overload that is the key factor in pathogenesis.⁵⁶

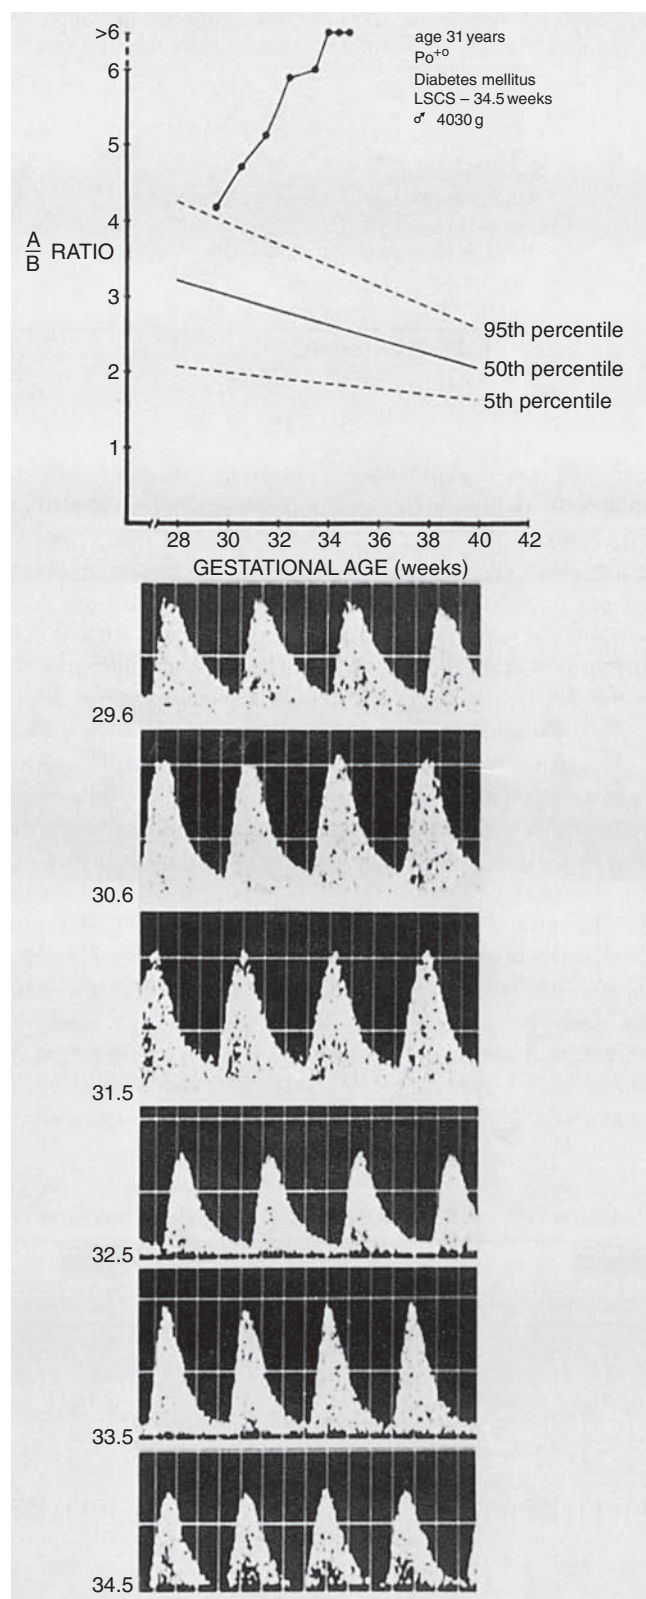

Figure 31.8 Sequential studies of the umbilical artery FVW in one patient with poorly controlled diabetes mellitus. Although the fetus was large, there was evidence of ultrasound fetal growth failure at the end of the pregnancy (from ref. 39).

Figure 31.9 In one diabetic mother, with an episode of hyperglycemia and acidosis, the FHR monitoring trace was abnormal (A), although the umbilical artery Doppler FVW appeared normal (C). After correction for the metabolic problem, the FHR monitoring was normal (B).

Doppler studies have also been reported to be useful in fetal assessment of triplet pregnancies.⁵⁷ In triplet pregnancy, umbilical artery FVW studies may also be used to delineate those pregnancies requiring more intensive fetal surveillance.

Maternal thrombophilia

A high incidence of both early and late pregnancy fetal wastage and maternal hypertension and placental hemorrhage is seen in a variety of prothrombotic states collectively referred to as maternal thrombophilia. The antiphospholipid syndrome with or without systemic lupus erythematosus (SLE) or other autoimmune phenomena is the best known of these. However,

also included are mothers with Factor V Leiden, hyperhomocysteinemia, protein S, protein C, or antithrombin (AT) III deficiency, or prothrombin mutations. Fetal deterioration is predicted by the development of an abnormal umbilical artery waveform, and these studies have aided the management of such pregnancies as this is a common sequelae. Frequent studies, at least weekly in the third trimester, are recommended because fetal demise may occur over a short time. Many of these are hereditary conditions, and there has been recent attention paid to the presence of the prothrombotic state of the fetus. This could be expected because thrombosis is a component of the umbilical placental pathology. Adverse long-term neurological outcome has also been related to fetal thrombophilia.

Major fetal anomaly

Major fetal anomaly is not consistently associated with an abnormal umbilical artery waveform, although such a finding is more common in this group.⁵⁸ The systolic–diastolic ratio has been reported to be high in fetuses with trisomy 13, 18, and 21.^{58,59} Care should be taken before extrapolating these findings to a total population, because the reported cases studied by Doppler had come to the attention of the clinician before the Doppler study, and the reported findings may be the result of this selection bias. An incidence of abnormal karyotype of 16% has been reported in a series of profoundly growth-restricted fetuses confirmed by ultrasound scan (abdominal circumference less than the third percentile). Most of these fetuses had an abnormal Doppler study.⁶⁰

Postdate pregnancy

It appears that the Doppler studies of the umbilical artery FVW do not predict fetal compromise in postdate pregnancy.^{22,23} This may be due to the fact that the mechanism of fetal demise in this group differs from that operating before term. However, as noted above, mathematical modeling of the placental vascular tree has shown that the larger the placental size, the greater the fraction of the vascular tree that needs to be obliterated to cause a detectable increase in the systolic:diastolic ratio.²¹ This, combined with a greater susceptibility of the mature fetus to the effects of hypoxemia, could account for the poor predictive value of the Doppler study. Doppler umbilical study as a method of surveillance is not recommended for postdate pregnancies.

The relationship of umbilical Doppler to fetal welfare tests

Tests of fetal welfare exist to identify the potentially compromised fetus (sometimes termed the “at-risk” fetus) and to quantitate fetal condition. The recognition of imminent fetal demise (i.e., the fetus in a terminal state) may be too late to prevent damage or loss of potential. It has been stated above that the umbilical Doppler study recognizes a vascular pathology in the fetal placenta that may lead to a fetal effect. Eval-

uation of umbilical Doppler studies against other fetal tests supports the fact that the umbilical studies better predict the potentially compromised pregnancy.

Antenatal nonstressed FHR monitoring is widely used in fetal surveillance protocols for high-risk pregnancy. Several comparative studies have demonstrated a greater sensitivity (the proportion of abnormal outcomes identified by the test) of umbilical Doppler in comparison with nonstressed FHR monitoring in recognizing the SGA fetus and a similar sensitivity in predicting adverse outcome.^{61,62} The association of an abnormal nonstress FHR test with an abnormal Doppler study selects a group with a very high risk of morbidity. In a randomized trial, the umbilical Doppler was shown to allow antenatal monitoring and obstetric intervention to be aimed more precisely.⁶³

The relationship between umbilical Doppler and ultrasonic estimation of fetal size has been examined.^{64,65} Sonographic biometry is a more sensitive technique for identifying the small fetus. In a study of 179 fetuses identified by ultrasound measurements of having a small abdominal circumference, an abnormal umbilical Doppler result was shown to predict the need for preterm delivery and the risk of fetal distress in labor.⁶⁶ The authors of that study raised the question “is intrauterine growth retardation with normal umbilical artery blood flow a benign condition?” A Swedish study of all small fetuses identified from a total obstetric population, screened for ultrasound weight estimation at 32 weeks, reported operative delivery for fetal distress to be more likely in the group also exhibiting an abnormal Doppler study.^{67,68} Serial umbilical Doppler studies in the genetically small, low growth potential fetus which is growing should reveal the normal decrease in systolic:diastolic ratio as the placenta grows even if the placenta is small and the initial Doppler index of resistance is high.

Because fetal compromise is not confined to the SGA fetus, larger fetuses in whom growth has stopped may also be identified by umbilical Doppler, although the ultrasonic measurements of fetal size are not small. Serial ultrasound measurements could be expected to reveal the growth failure in these fetuses, but this requires a delay of at least 2 weeks.⁶⁵

The biophysical profile has not been widely compared with umbilical Doppler studies.

Screening of all pregnancies by umbilical Doppler studies

The possible use of umbilical Doppler studies to screen all pregnancies or low-risk pregnancy has been investigated by several groups. Results have been disappointing. The largest patient group examined was 2097, and these patients were seen at 28, 34, and 38 weeks.⁶⁹ There was a significant association between abnormal Doppler results and low percentile birthweight, but the authors suggested from receiver operating curves that this lacked sufficient sensitivity for clinical usage. The most important result was the presence of an

Figure 31.10 The FVW recorded from the umbilical vein to show venous pulsations. This may be seen normally in early pregnancy. In late pregnancy, it is a feature associated with high umbilical placental flow resistance.

abnormal waveform in all three of the unexplained stillbirths and one of two fetal deaths associated with placental abruption. This was emphasized in correspondence subsequent to the original report.⁷⁰ Other studies of smaller numbers from unselected low-risk pregnancy groups reported poor prediction of SGA infants and adverse perinatal outcomes.⁷¹ The statistical power of these reports was low, because adverse outcome is infrequent in an unselected pregnancy population.

Fetal umbilical vein studies

The umbilical vein in the cord is readily imaged and a FVW recorded. Pulsations in the umbilical vein (Fig. 31.10) have been described in association with fetal compromise and fetal growth restriction.⁷² They have been associated with the most profound fetal compromise. Two possible mechanisms have been advanced to explain the occurrence of this phenomenon. In fetal compromise with placental insufficiency, there is obliteration and so reduction in small arterial channels in the placenta. This results in a decrease in capacitance in the umbilical placental vascular bed so that compliance (its inverse) is changed. In this circumstance, arterial pulsation can be transmitted through to the venous circulation. This is predicted by placental model studies.²⁰ The alternative explanation is the retrograde transmission of the giant A waves backwards along the venous system. The validity of this observation has been challenged as pulsations may be seen in normal pregnancy.⁷³

Doppler ultrasound measurement of volume flow in the umbilical circulation is possible by recording from the umbilical vein as it traverses the fetal liver.⁵ The dimensions of the vessel need to be measured at the same time, and flow calculated as the product of average velocity and of vessel lumen. In normal pregnancy, flow in the umbilical vein increases with gestation. Flow per unit of fetal weight is relatively constant at 110 mL/min/kg fetus.¹²

Studies in high-risk pregnancy suggested that a reduced umbilical vein volume flow was associated with growth restriction, but only 40% of fetuses with a low flow had a

birthweight below the 10th percentile.⁷⁴ The relationship between umbilical artery FVW and umbilical vein volume flow measurements has been examined.⁷⁵ The FVW was more sensitive and recognized more SGA fetuses. It had a higher predictive value and similar specificity. The ratio of umbilical vein flow to aortic flow was also measured in this series. In the normal fetuses, this was 39%; in those fetuses with an abnormal umbilical artery FVW systolic:diastolic ratio, it was 25%. This result suggests that the fetus is able to maintain umbilical placental circulation at least initially by an increase in cardiac output. The same observation has been made in experimental growth restriction in fetal lambs.⁷⁶ Thus, there is experimental and clinical evidence to suggest that the umbilical artery FVW will detect the compromised fetus earlier than volume flow measurements. A high umbilical vein volume flow has been seen in association with fetal hydrops associated with fetal anemia.⁷⁷

The high umbilical vein volume flow has been reduced in rhesus isoimmunization by fetal transfusion.

The application of measures of umbilical vein volume flow to obstetric practice has been limited by the need for a detailed technique, measurement errors, and complex equipment.

Fetal arterial Doppler studies

Within the fetal body, arterial flow in the aortic and cerebral circulations has been most studied in the vascular trees, although reports of FVW in the renal, splanchnic, and external iliac arteries have been made.⁷⁸ Blood flow has been recorded from the fetal coronary arteries.⁷⁹

Fetal aorta

Recordings from the fetal aorta (Fig. 31.11) are readily achieved using the duplex of a Doppler system integrated with real-time imaging.^{80,81} The shape of the flow waveform varies along the aorta and, for reproducibility, most studies have concentrated on the midthoracic aorta, which is free of large branches. The fetal aortic blood FVW has been analyzed using

Figure 31.11 The normal FVW recorded from the aorta and inferior vena cava (IVC) in the lower thorax in the third trimester.

the same indices of downstream resistance as used for the umbilical circulation. Volume blood flow has been calculated from mean blood flow velocity and vessel area, but the pulsatile nature of the flow means that measuring diameter from a single frozen image has an error estimated to be 6%.

Normal pregnancy

The PI of the maximum velocity waveform in the thoracic aorta (1.68 ± 0.28) does not change with gestation⁸² in the second half of pregnancy. Forward flow velocities are present throughout diastole. This index is significantly affected by changes in FHR. Within the normal FHR range, there is a small negative correlation with the PI. This index is also affected by behavioral state.¹⁷ These observations are not surprising, because 60% of aortic blood is distributed to non-placental fetal vascular beds in which the vasomotor tone will be regulated according to fetal behavioral and metabolic states. However, the variation due to FHR is small in comparison with the differences between normal and compromised pregnancy. The same influence of FHR and behavioral state has been reported in the growth-restricted fetus.⁸³ Fetal breathing movements affect the aortic flow waveform, and studies should be carried out during fetal apnea to ensure reproducible results.

Volume blood flow measurement in the fetal descending thoracic aorta increases with gestation up to 36–37 weeks, when a plateau is attained, whereas flow per unit fetal weight decreases during the third trimester.⁸⁴

High-risk pregnancy

Studies of aortic FVW have been used to assess fetal condition in the presence of growth restriction and/or an abnormal fetal heart rate monitoring. Two approaches have been taken to analysis in this situation. Downstream resistance has been assessed by measuring the PI,^{74,75,85} and the waveform pattern

classified by the presence or absence of forward flow velocities in diastole.⁷⁶ Both methods predict perinatal morbidity and fetal growth restriction. Two factors are likely explanations for this. As so much of the blood flow down the aorta is directed to the placenta, the increase in downstream flow resistance in the placenta will dominate. In addition, an increase in resistance as part of the redistribution of blood flow away from the viscera and carcass to vital cerebral, coronary, and adrenal circulations will effect the aortic resistance. It has been reported that the ratio of the PI of the descending thoracic aorta and the middle cerebral artery (MCA) is the best Doppler predictor of fetal acidosis.⁷⁷ Fetuses that display absence of diastolic flow velocities in the fetal aorta have been shown to have more developmental disability at age 7 years in comparison with normal.⁸⁶

A second approach to analysis of the aortic FVW has focused on the measurement of the peak mean velocity of the aortic waveform. Correlation with hypoxemia, hypercarbia, hyperlactemia, and acidemia, as determined from fetal blood obtained at cordocentesis,⁸⁷ has been demonstrated. These endpoints were used to compare the various methods of analysis of the FVW from aortic, cerebral, and umbilical fetal circulations. Again, the peak mean velocity of the aortic waveform was the most sensitive.⁷⁷ In fetal lamb studies, direct measurements of volume flow and the FVW from the fetal aorta have shown a strong correlation between peak and mean velocity of the aortic FVW and volume flow.⁹ The correlation between the aortic FVW and blood gas analysis can therefore be explained by appreciating that those fetuses with abnormal blood gas results had depressed myocardial function and ventricular output. Many growth-restricted infants do not show these changes in blood gas analysis. They are present when the fetus is severely compromised. This highlights the different information that is provided by different Doppler studies. There is a distinction between the prediction of risk of fetal compromise and the identification of severe compromise.

Fetal cerebral circulation

The fetal intracranial arteries are readily visualized using a combined B-mode imaging ultrasound system and pulsed Doppler. The recording of FVWs from the fetal internal carotid artery and the individual arteries of the human fetal cerebral circulation spreading out from the circle of Willis is easily achieved. The internal carotid artery is best located at the level of its bifurcation into the middle and anterior cerebral artery.⁸⁸ This particular point can be readily identified on a transverse cross-section of the fetal cerebrum. The standard plane for measuring the biparietal diameter, which includes the thalamus and the cavum of the septum pellucidum, is visualized. The MCA can be seen pulsating at the level of the insula. If the transducer is now moved in a parallel fashion toward the base of the skull, a plane is reached that demonstrates a heart-shaped cross-section of the brain stem with the anterior

Figure 31.12 Color flow imaging of the circle of Willis of the fetal cerebral circulation. The FVW from the MCA is shown at the bottom.

lobes representing the cerebral peduncles. Anterior to this heart-shaped structure, on either side of the midline, is an oblique cross-section of the internal carotid artery as it divides into its middle and anterior cerebral branches. The MCA has become the standard vessel to image for recording cerebral FVWs. It sweeps out laterally from the internal carotid bifurcation, and a good straight length is usually seen in the transverse plane. It is usually possible to place the transducer so that the line of sight and sampling box is along this length of the vessel. The cosine θ term in the Doppler equation is then 1, and the maximum and peak velocity of the FVW do not need angle correction. Studies from right and left arteries yield similar FVWs, and only one needs to be recorded. Color Doppler imaging facilitates vessel identification (Fig. 31.12).

Normal pregnancy

The waveform of the fetal internal carotid and MCA is not unlike the umbilical artery in shape with forward flow through diastole. The indices of resistance have a higher value than those of the umbilical artery in normal pregnancy. With advancing gestation through the third trimester, this waveform reveals a small decrease in resistance. A normal range for the PI of the fetal internal carotid and MCA FVW has been reported.⁸⁹ In the third trimester, a value below 1.1 for the PI at 34 weeks (systolic–diastolic ratio below 2.5, resistance index above 0.67) is regarded as low – less than the fifth percentile value. Fetal breathing movements can cause fluctuations in the FVW which can be seen. Behavioral state also

affects the FVW.¹⁵ For clinical studies, the fetus should be inactive and apneic. Monitoring of the cerebral artery FVW waveform during labor⁹⁰ has not developed.

High-risk pregnancy

Intrauterine fetal growth restriction may be associated with a fetal cerebral artery FVW PI that is lower than normal.^{91–93} Only some growth-restricted fetuses with a high-resistance pattern on umbilical artery Doppler show this low MCA PI. When a normal fetal MCA FVW was associated with a high-resistance umbilical FVW, it was suggested that normal cerebral blood flow was continuing. Later, when fetal condition deteriorates, cerebral vasodilation occurs, and there is an increase in flow. The cerebral FVW shows a lower PI. Whether this effect is adaptive to maintain cerebral oxygen supply or consequent to the occurrence of fetal hypoxia and hypercarbia is not known at present. Studies of the MCA indices of resistance have been related to the results of fetal blood sampling in SGA fetuses.⁹⁴ It was shown that the maximum reduction in PI was associated with a fetal PO_2 two to four standard deviations below the mean. In the most extreme cases with an oxygen deficit greater than this, the PI has been observed to rise, and it was suggested that this indicated developing brain edema.⁹⁵ The term “centralization of flow” was introduced to describe the situation with a low cerebral flow resistance. The suggested explanation was the redistribution of cardiac output to maintain blood flow to vital organs by the profoundly compromised fetus. Others have used the term “brain sparing” to describe this preservation of brain blood flow. The finding in the cerebral circulation is in contrast to the aorta.

Although the MCA indices of resistance are low in association with fetal compromise, the values overlap with the lower part of the normal range in many small fetuses. To improve discrimination and recognize a deteriorating situation, it has been suggested that the ratio of cerebral to umbilical index of resistance be used to identify the fetuses in whom the placental insufficiency is associated with altered cerebral blood flow. This ratio has been evaluated.⁹⁶ A group of fetuses with severe neonatal morbidity can be identified by a ratio of less than 1.0.

Fetal anemia, rhesus alloimmunization

The measurement of maximum velocity in the MCA FVW has become the standard method for assessment of fetal anemia in rhesus alloimmunization. It has obvious advantages over invasive testing. It can, of course, be used in any circumstance in which fetal anemia may occur, e.g., parvovirus infection, hemoglobinopathy. A detailed account is provided in Chapter 49.

Other fetal arterial circulations

In the fetal external iliac and femoral arteries, the resistance index was found to increase with gestation.⁹⁷ In fetal growth restriction, there was a small increase in the resistance index.

In the fetal brachial artery, the PI in the right and left arms was seen to be similar in normal pregnancy. In association with severe growth retardation and abnormal umbilical Doppler, the PI in the left arm was higher.⁹⁸

Blood flow in the arteries of the fetal abdomen has been studied in normal and compromised fetuses. SGA fetuses have been identified as having decreased resistance in the splenic artery.⁹⁹

Renal artery PI is reportedly increased in growth-restricted fetuses.¹⁰⁰

In the coronary circulation, vasodilation has been reported in association with profound fetal compromise.⁷⁹ This has been referred to as the “heart-sparing effect.” The coronary arteries can be imaged at an earlier gestation in profound fetal growth restriction, and this is a likely sign of dilation as a result of the circulatory redistribution to maintain this vital vascular bed. The FVW pattern is of low resistance in comparison with normal.

These studies in other vascular beds are not part of current clinical management protocols, but provide insight into pathophysiology and are an investigational tool.

Fetal venous Doppler studies

The studies of FVWs in fetal vessels have extended from the arterial circulation to the great veins. The ductus venosus, the inferior vena cava, and the umbilical vein have been the subject of most studies. The FVWs in the central fetal veins are influenced in form by the central venous pressure, and this in turn is a reflection of cardiac function. The form of the flow velocity wave is best understood by reviewing the shape of the central venous pressure waveform (Fig. 31.13). Four waves are identified on this. The A crest is associated with atrial contraction. The X trough occurs with atrial relaxation in early

systole. The V crest is the result of rising central venous and atrial pressure as forward blood flow is obstructed while the atrioventricular valves are closed during ventricular systole. The Y trough begins as soon as the atrioventricular valves open at the end of isovolumetric ventricular relaxation. The pulsatile changes in the inferior vena cava reflect the same events of the cardiac cycle and are illustrated (Fig. 31.14). To understand the origin and interpretation of the changes in venous FVW pattern seen with fetal compromise, it is important to remember the differences in blood flow through the heart before and after birth. In the fetus, the pulmonary circulation is small, and systemic venous return passes to the left heart through the foremen ovale as well as through the right heart. Blood returning from the placenta is predominantly directed to the left heart. Ventricular outflow from the right heart enters the systemic circulation through the ductus arteriosus. Conceptually, there exists a combined ventricular output directed into the systemic circulation so that the afterload for both ventricles is systemic vascular resistance. However, blood from the left ventricle is directed to the head and upper body, whereas from the right, it is directed to the lower body and placenta. As 40% of the combined ventricular output is directed to the placenta, this is a major determinant of right ventricular afterload. Already in this chapter, changes in the arterial circulation in fetal growth restriction have been discussed. These have a profound effect on afterload, preload, and cardiac contractility. Umbilical placental resistance is high, so that a high right ventricular afterload is present. Resistance in the cerebral circulation is low, reducing the left ventricle afterload in the most compromised fetus. As the fetus becomes significantly hypoxemic, contractility and output from the heart fall. These are major changes in fetal cardiovascular hemodynamics and explain why venous Doppler has become widely incorporated in management protocols to define fetal condition.

Figure 31.13 A fetal central venous pressure waveform with the “A”, “X”, “V”, and “Y” components marked (see text) to show the associated events of the cardiac cycle (reprinted from ref. 107, with permission). ECG, electrocardiogram; IVC, inferior vena cava.

Figure 31.14 The FVW recorded from the fetal inferior vena cava in normal pregnancy at 34 weeks. The component A, X, V, and Y waves (see text) are shown.

Figure 31.15 The FVW recorded from the fetal ductus venosus in normal pregnancy at 35 weeks. The component A, X, V, and Y waves (see text) are shown.

Fetal ductus venosus and inferior vena cava

The umbilical vein returns blood from the placenta. After entering the fetal abdomen, it is directed to the porta hepatis and into the liver. It is directed initially upwards and backwards and, at the point where it joins the portal vein to the right, it divides so that a thicker walled ductus venosus continues upwards to the sinus venosus entry to the right atrium. Although here the ductus venosus and inferior vena cava are a single sinus in open fetal lamb surgery, it is fascinating to see the two streams separately distinguished by differing color consequent upon the different degrees of oxygenation. This anatomy is relevant to the imaging of these vessels. The ductus venosus can be identified in a transverse plane directed upwards and backwards to include the region at which the umbilical vein joins the portal sinus. The inferior vena cava is best seen in a sagittal plane, which includes the region where it enters the right atrium. The ductus venosus may also be seen in this plane, but hepatic veins can confuse. The FVW patterns are, however, quite distinct, and the color Doppler imaging demonstrates the higher flow velocities¹⁰¹ in the ductus venosus. A peak systolic velocity of 80 cm/s may be seen in the ductus venosus waveform in the third trimester of pregnancy in contrast to the inferior vena cava peak of 40 cm/s. Fetal breathing movements especially and fetal state affect these waveform patterns, and recordings should be made during quiet sleep.¹⁰²

A large number of parameters have been calculated from the Doppler flow waveform of the inferior vena cava (Fig.

31.14) and ductus venosus (Fig. 31.15). These figures should be contrasted with the central venous pressure wave (Fig. 31.13) as a different set of symbols has been used in fetal medicine. The “A” wave of atrial contraction is identified as the trough “A” because pressure and flow are inversely related. However, the “S” and “D” peaks in the FVW correspond to the “X” and “Y” troughs on the central venous pressure wave. This allows the events of the cardiac cycle to be timed. In two recent comprehensive studies,^{103,104} these parameters (Fig. 31.16) have been related to fetal blood gas status and especially fetal hypoxemia. Normal ranges were reported for all parameters.¹⁰³ Among a group of growth-restricted fetuses (ultrasound estimate of weight less than the 5th percentile), all indices were abnormal. Fetal hypoxemia was associated with an increase in the percentage time of the cardiac period when there was reverse flow present and an increase in the preload index of the inferior vena cava.¹⁰⁵ For the ductus venosus, the systolic to atrial contraction peak velocity ratio and preload index were increased.¹⁰¹ The dominant feature in growth-restricted fetuses was a reduction in the velocities during atrial contraction. Some workers have found better associations between fetal condition and parameters derived from the ductus venosus. Others prefer inferior vena cava parameters. The ductus venosus is the most widely used because of its unique pattern. The inferior vena cava FVW is very similar to the hepatic vein FVW, and this makes vessel identification more problematic. The underlying hemodynamic disturbance affecting both great veins is likely to be an increase in right ventricular end-diastolic pressure consequent to an increase in right ventricular afterload and reduction in cardiac contractility. Both of these are a consequence of the placental lesion (defined by the umbilical Doppler study).

In fetal anemia attributable to rhesus alloimmunization, a change in the waveform with an increase in the “S” peak and a decrease in the “A” trough has been noted. This is consistent with an increase in cardiac output and end-venous return.¹⁰⁶

Recently, a technique to record the fetal central venous pressure waveform has been described.¹⁰⁷ Studies in normal and growth-restricted pregnancy demonstrate changes consistent with high right ventricular afterload (giant A waves) and, at a later stage, depressed myocardial function. Doppler FVWs of the central fetal vein are used as a surrogate for the central

Figure 31.16 Various indices have been used to assess the FVWs from the fetal inferior vena cava and ductus venosus. This diagram shows these indices. The S and D peaks correspond to the X and Y troughs on the central venous pressure waveform (from ref. 103).

venous pressure wave to reflect changes in cardiac function, and these studies confirm such changes.

Fetal pulmonary veins

The pulmonary veins entering the left atrium are readily imaged with power Doppler or color flow mapping. The FVW is similar to the ductus venosus.¹⁰⁸ The hope that an alteration in pattern would identify pulmonary hypoplasia has not been achieved.¹⁰⁹

Clinical strategies in Doppler and fetal compromise

The approach of the obstetrician to fetal compromise progresses through a sequence of steps, which can be summarized as:

- 1 Recognition of high-risk pregnancy on the basis of clinical history and examination, supported by the ancillary aids of maternal–fetal movement counting and fundal height measurement. (Is it a high-risk pregnancy?)
- 2 Confirmation of fetal risk by identifying the placental vascular lesion with Doppler ultrasound studies of the umbilical artery FVW. (Is there a placental pathology threatening the fetus?)
- 3 Determination of the extent to which the fetus is affected using the direct fetal assessments of biophysical profile, ultrasound growth, and FHR monitoring and direct fetal Doppler studies. This is relevant to the timing of delivery. (How sick is the fetus?)
- 4 Therapy aimed at improving the intrauterine environment by treating mother or fetus, and delivery if the risks to the fetus of intrauterine death or damage exceed that of delivery.

Included in this approach is the use of Doppler studies at two points. Umbilical Doppler studies are interposed between the clinical identification of the high-risk pregnancy and full fetal surveillance testing to quantitate the degree to which the fetus is affected. Umbilical Doppler is a doorway test confirming the potential for fetal compromise and so leading to intensive fetal testing. Direct fetal Doppler assessments are then used to quantify how sick the fetus is. These will be discussed.

The use of umbilical artery Doppler assumes that the placental vascular lesion identified by umbilical Doppler underlies all fetal compromise. Although this is common in the “chronic” situation, it is not always the case. Acute fetal deterioration (e.g., abruption) is not recognized. Fetal anemia, whether due to isoimmunization or other causes such as fetomaternal hemorrhage, is also not identified. However, chronic “placental insufficiency” is operating in the majority of cases, and these are identified. The one-quarter to one-third of SGA infants with normal umbilical Doppler studies have a good outcome (see above) and include cases of low growth potential where the growth velocity of the small fetus is normal and there is no placental constraint.⁴² The concept of identification of umbilical placental insufficiency by umbilical Doppler studies also implies that the various clinical situations in which this is present operate through a final, common pathological pathway. This is recognized by the abnormal umbilical FVW.

The above scheme involves the use of the Doppler umbilical waveform study as a discriminator or doorway test to determine which fetuses are truly at risk and in need of intensive fetal surveillance. The relationship of the various direct fetal assessments to the umbilical FVW has been described above.

It cannot be stated too frequently that the Doppler umbilical

artery waveform provides a guide to the presence of a placental pathology that is important in terms of the equation:

placental lesion → fetal effect

It is not a direct fetal test and should not in itself be used as a measure of fetal condition, but rather as an indication of the need for detailed assessment of fetal welfare.

The use of umbilical Doppler in clinical practice has been evaluated by several randomized controlled trials. Indeed, umbilical Doppler studies have been subjected to more rigorous and extensive assessment than any previous test of fetal health or fetoplacental function. Meta-analysis¹⁰⁹ has established that women with high-fetal-risk pregnancies should have access to Doppler studies of the umbilical artery FVW. Meta-analysis of the umbilical Doppler trials demonstrated a reduction in the odds of a perinatal death by 38% (odds ratio 0.62, 95% confidence interval 0.45–0.85) (Fig. 31.17). This result was significant at the 1% level when umbilical studies were available to influence management. In the Doppler group, there was a significant reduction in the number of antenatal admissions, inductions of labor, and Cesarean section for fetal distress. The reviewers¹¹⁰ noted that the results were consistent across all trials. The author¹¹¹ in the first published trial claimed that monitoring with umbilical Doppler led to more selective and appropriate elective delivery.

Direct fetal Doppler is increasingly used to quantify fetal condition and so determine the time of delivery. In the circumstance of fetal compromise, delivery is the definitive treatment. This is effected when the prospects for survival are better than the risk of remaining *in utero*. In late pregnancy, this is not so critical as delivery usually results in good fetal

outcome. The clinical challenge at this gestational age lies in the identification of the potential for adverse outcome. At earlier gestations, this problem is not so simple. There are risks to the fetus from both prematurity and from continuing in the uterus in a situation of inadequate supply of oxygen and nutrients. It is the aim of management to prolong the pregnancy for as long as possible and deliver when there is a belief that fetal damage is occurring. Testing to define fetal condition is necessary. Of the nonDoppler flow tests, FHR monitoring relates to higher central nervous system (CNS) control of cardioregulation and biophysical profile to CNS behavior determination. Both therefore imply a CNS effect. Fetal Doppler adds new dimensions to testing. Cerebral Doppler defines the redistribution of cardiac output. Central venous Doppler defines changes in cardiac loading and contractility. There has been a search for evidence that they better predict the risk of fetal damage and, in particular, long-term neurological handicaps. There have been several recent studies aimed at defining longitudinally the sequence of change in these tests.^{112–114} Unfortunately, a uniform pattern has not been documented, and it remains uncertain whether changes in cerebral or venous Doppler, FHR, or biophysical profile should guide the timing of delivery.¹¹⁵ One randomized trial questioned the benefit of this precise definition using such testing and outcomes were comparable among early and late delivery groups.¹¹⁶ More evaluation is needed, particularly with long-term neurological performance as an endpoint.

Doppler umbilical studies have also been used to guide specific therapies aimed at reversing the placental lesion. The demonstrated placental vascular obliteration²⁷ and fetal platelet consumption³⁵ suggested a role for thromboxane activity in the fetal placenta. It was the rationale for the

Figure 31.17 Meta-analysis of 12 randomized controlled trials demonstrated a significant benefit in reducing the number of fetal and neonatal deaths associated with the use of umbilical Doppler (from ref. 110).

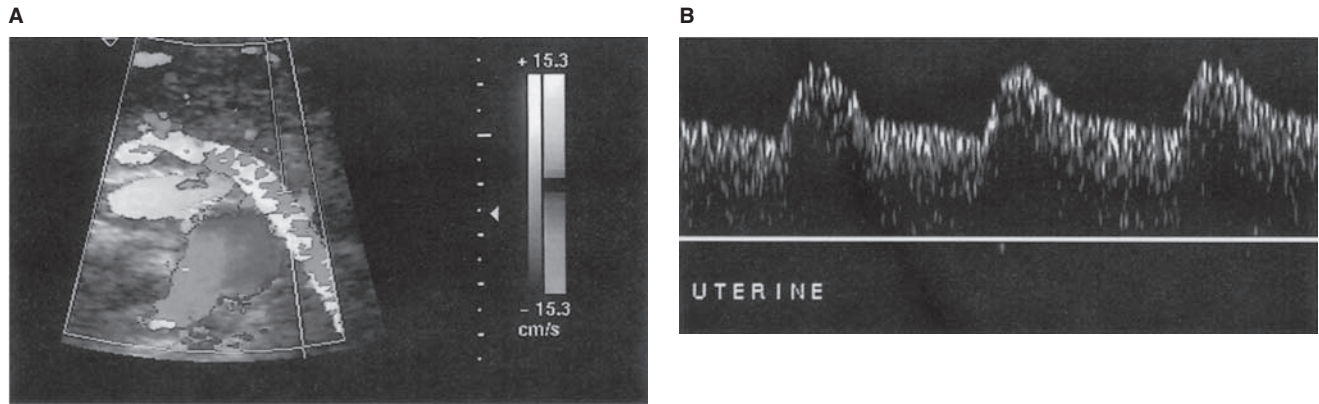

Figure 31.18 The uterine artery can be seen appearing to cross the external iliac vessels in this color Doppler mapping superimposed on a B-mode ultrasound image (A). The FVW in (B) is a normal uterine artery pattern with high diastolic flow velocities.

evaluation of low-dose aspirin as a therapy.¹¹⁷ In a randomized clinical trial, soluble aspirin (150 mg/day) was administered to mothers with pregnancies identified by an umbilical artery waveform systolic:diastolic ratio above the 95th percentile. The treated pregnancies yielded infants with a 25% greater birthweight. There was an increase in head circumference. The placentas from the treated pregnancies showed the same proportional increase in size. This improvement was not seen in pregnancies in which the umbilical Doppler study was extremely abnormal, with absent diastolic flow velocities. Low-dose aspirin may provide a means of treatment of placental insufficiency if the Doppler diagnosis can be made early and before marked fetal effect. This study has not been repeated. The disappointing results obtained in using aspirin to prevent preeclampsia in large unselected groups have been allowed to overshadow the benefits demonstrated in small, highly selected studies.

Maternal uterine circulation

Both pulsed¹¹⁸ and continuous wave¹¹⁹ ultrasound have been used to record FVWs from the uterine circulation. The early problems of vessel identification in the study of uteroplacental circulation with continuous wave Doppler systems were overcome by the introduction of color Doppler and power Doppler imaging, which permit more precise localization of the uterine artery and its radial, arcuate, and spiral branches.¹²⁰ Color Doppler systems enable the main uterine artery to be studied¹²¹ and identified, usually in the supracervical region after it is seen to cross the iliac veins (Fig. 31.18). The signal recorded from the side of placental implantation may have a lower resistance pattern in comparison with the nonplacental side.¹²²

The same indices of downstream resistance that are described in the assessment of umbilical artery FVWs are used to assess FVWs of uteroplacental arteries. High diastolic flow velocities indicate low downstream resistance. Attention has

also been focused on the presence or absence of an early diastolic “notch,” which has been attributed to an increased downstream resistance.⁴⁷ The explanation for this is speculative. The distance between the main uterine artery and the vascular bed it feeds is short in comparison with the umbilical artery in the long umbilical cord. Reflected waves have little influence on the shape of the umbilical waveform, and no diastolic notch is seen. In the uterine circulation, reflected waves from a high-resistance periphery can be expected (Fig. 31.19). The subjective yes–no present–absent use of a notch to identify a high-resistance pattern has been shown to be reproducible.¹²³

Normal pregnancy

The process of trophoblast invasion of the spiral arteries of the decidual and inner third of the myometrium occurs during the first 20 weeks of gestation. Endovascular trophoblasts replace the endothelium of the spiral arteries in the placental bed, and the trophoblasts infiltrate into the musculoelastic coat. It is widely believed that this lowers the resistance to blood flow in the uterine artery branches opening into the intervillous space. A decrease in resistance in uterine artery branches causes higher end-diastolic flow velocities, and this can be detected in early pregnancy. This invasion extends from the decidua to the intramyometrial portion of the spiral arteries during the first half of pregnancy. After 20 weeks of gestation, there is little change in the waveform of the uteroplacental arteries throughout the remainder of the pregnancy. A pattern of low pulsatility and high end-diastolic velocity relative to peak systolic velocity is seen (Fig. 31.19).¹¹⁹ After 20 weeks, the uterine artery S/D ratio is less than 2.0,¹¹⁹ and the PI less than 1.5¹²¹ in normal pregnancy. The early diastolic “notch” of the uteroplacental FVW has been reported in normal pregnancy until approximately 26 weeks’ gestation. However, on the side of the uterus of the placental bed, it has been reported to be rarely found after 20 weeks’ gestation.¹²¹ The evidence linking the trophoblast invasion to the changing

Figure 31.19 A uterine artery FVW from a pregnancy with preeclampsia. A diastolic notch is present. Diastolic flow velocities are low. This is a high-resistance uterine artery pattern.

FVW pattern is the temporal relationship of these two processes. There has been much debate about the occurrence of intervillous blood flow in the first trimester as a result of Doppler studies. The inability to image intervillous flow until 10–12 weeks¹²⁴ is in conflict with the observation of a low-resistance flow pattern in the spiral arteries from very early in pregnancy,^{125,126} and is probably attributable to limitations of the equipment.

High-risk pregnancy

Both severe fetal growth restriction and maternal hypertension may be associated with uteroplacental waveforms demonstrating a high systolic–diastolic ratio (Fig. 31.19). Among patients with pregnancies complicated by hypertension or intrauterine growth restriction, there were two patterns of results: those with FVWs similar to the normal population and those who had evidence of a high impedance to flow.¹¹⁸ In this second group, there was a higher incidence of proteinuric hypertension, the time of delivery was significantly shorter, and the birthweight ratio of the infants (actual birthweight/mean birthweight for gestational age corrected for sex and parity) was lower. In women with hypertensive disorders of pregnancy of varying degrees, patients with an abnormal uterine waveform may be identified. This group has a significantly higher maternal uric acid level, shorter gestational period, higher Cesarean section rate for fetal distress, and lower infant birthweight than the patients with normal waveforms. Furthermore, in the pathologic group, there was a significantly higher incidence of SGA babies and a significant increase in stillbirths.⁴⁷ Whether the reduction in uteroplacental circulation is the cause or effect of pregnancy hypertension remains an open question. Others have not been able to demonstrate consistently abnormal studies in hypertension of pregnancy.¹²⁷

Screening normal pregnancy

Based on the hypothesis that trophoblast invasion of the spiral arteries causes the change in the uterine waveforms during the first half of pregnancy, and that this invasion is less developed in pregnancy hypertension, uterine waveform studies have also been evaluated for screening in early pregnancy.¹²⁸ The test demonstrated a high sensitivity for prediction of preeclampsia

and fetal growth restriction, but there was a high false-positive rate. The results of one study from a well-regarded center are illustrative of this.¹²⁹ From 1326 pregnancies, 214 women were identified at 19–21 weeks. Abnormal Doppler findings were still present in 110 of these women at 24 weeks. Three-quarters (77%) of the cases of preeclampsia and one-third of the SGA babies (32%) were found in this group of 110. The predictive value of 31% and 38% from the 24-week result appears good, but the denominator for this calculation should be the number identified at 19–21 weeks. This would halve the positive predictive value. Comment has been made that an incidence of 44 cases of proteinuric pregnancy hypertension out of 1326 pregnancies is high, suggesting that this was a high-risk population of low socioeconomic status. The performance of uterine Doppler in a truly low-risk population is debated. No adequate randomized controlled trials are available to settle this issue at the present time. A recent authoritative review¹³⁰ concluded that screening was not effective. This assessment was based on a collective total of 13 000 pregnancies screened. The authors noted a sixfold greater risk of preeclampsia if the Doppler findings were abnormal; however, the sensitivity in the reported studies was 20–60%, and the positive predictive value was 6–40%.

Relationship of umbilical and uterine flow studies

Study of umbilical and uterine waveforms allows classification into four groups, depending on whether these waveforms are normal or abnormal.^{46,131,132} The two subgroups characterized by normal umbilical waveforms exhibit little fetal morbidity, irrespective of whether the uterine waveforms are normal or not. If the umbilical waveforms are abnormal, fetal morbidity is present. In patients with a normal uterine artery pattern, it has been suggested that the primary defect is on the fetal side of the placenta. Although the uterine waveform is normal, indicating normal resistance in that branch of the uterine artery, the total uterine flow may be low if the size of the uteroplacental bed (and number of branches of the uterine artery feeding it) is not extensive. In patients with both abnormal umbilical and uterine waveforms, disease may exist in the maternal uteroplacental vascular bed, and it is this that produces the constraint of the fetal–placental circulation. This result has been confirmed by others.^{127,128}

Early pregnancy uterine flow studies

The advent of color Doppler ultrasound leading to precise vessel identification has permitted studies of the early first-trimester changes in the uterine artery FVWs. The waveform pattern and the various indices of resistance decrease between

6 and 16 weeks of gestation.¹²⁴ In early pregnancy failure (missed abortion, anembryonic pregnancy), there was no difference in these indices of resistance.¹³³ This finding is interesting as it suggests that early pregnancy failure does not result from failure of visualization.

Key points

- 1 The difference in frequency between incident and reflected waves produced when an ultrasound beam strikes a moving column of blood is proportional to the velocity of the blood flow. This is the Doppler principle.
- 2 The flow velocity waveform (FVW) is the collection of frequency differences produced by insonating a vessel over a time base. The maximum velocity or envelope is the most widely used feature of this waveform in Doppler clinical studies, and a variety of empirical indices have been used to describe the waveform pattern; some reflect physiological hemodynamic quantities such as resistance and volume flow.
- 3 Blood flow in the umbilical artery in the umbilical cord can be recorded using Doppler ultrasound equipment.
- 4 Throughout pregnancy, there is a progressive decrease in resistance to blood flow to the placenta in the umbilical arteries as the placenta grows, and this is reflected by the changing pattern of the umbilical artery FVW.
- 5 Mathematical modeling studies confirm that in excess of 50% of small arteries and arterioles (resistance vessels) need to be obliterated before the umbilical artery Doppler FVW shows an abnormal (high-resistance) pattern.
- 6 Correlation studies of umbilical artery FVW pattern and placental villous histology confirm vascular disease with loss of small arterial channels in fetal villi when a high-resistance pattern is present.
- 7 The high-resistance pattern of the umbilical artery FVW is characterized by reduced, absent, or reversed diastolic flow relative to the systolic peak velocity.
- 8 The presence of a high-resistance pattern in the umbilical artery FVW is associated with an increased risk of intrauterine growth restriction, fetal distress *in utero*, fetal distress in labor, and need for early delivery.
- 9 Some 60–70% of small-for-gestational-age (SGA) fetuses have a high-resistance umbilical FVW.
- 10 In dizygotic twin pregnancy with discordant growth, a high-resistance pattern FVW is seen with a small fetus.
- 11 The use of umbilical artery Doppler FVWs to study high-risk pregnancy has been shown by meta-analysis of randomized controlled trials to be associated with a 32% reduction in perinatal mortality.
- 12 Volume flow in the umbilical circulation may remain normal when the FVW pattern is one of high resistance, presumably because there is an increase in fetal blood pressure, at least in the early phases.
- 13 FVW patterns can be recorded from the fetal aorta. The peak velocity of maximum or mean aortic FVW correlates with the degree of fetal hypoxemia and reflects depressed ventricular output.
- 14 FVW patterns can be recorded from the cerebral arteries. In the middle cerebral artery FVW, a pattern of low resistance predicts fetal hypoxemia.
- 15 In fetal anemia, the peak velocity of the middle cerebral artery FVW can be used as an index of the degree of anemia and requirement for fetal intravascular transfusion.
- 16 Changes in the FVWs from the central fetal veins (ductus venosus, inferior vena cava) are produced in fetal compromise by a high central venous pressure, in turn reflecting changes in afterload, cardiac outflow, and ventricular end-diastolic pressure.
- 17 Retardation of flow velocity in the ductus venosus waveform at the time of atrial systole indicates developing fetal hypoxemia. A variety of indices measure this.
- 18 The uterine artery FVW shows a low-resistance pattern in normal pregnancy from 8 weeks onwards.
- 19 A high-resistance pattern in the uterine artery FVW is signaled by low diastolic flow velocities and the appearance of an early diastolic notch. This predicts pregnancy at risk of preeclampsia and fetal growth restriction.
- 20 Abnormality in the umbilical artery FVW signals developing placental vascular pathology, which may lead to fetal hypoxemia and acidosis. Changes in the fetal aortic, middle cerebral artery, and ductus venosus waveforms correlate with the degree of fetal hypoxemia and fetal condition. The information from Doppler studies of different fetal vessels is complementary.

Antepartum and intrapartum surveillance of the fetus and the amniotic fluid

Lami Yeo, Michael G. Ross, and Anthony M. Vintzileos

Introduction

The challenge of assessing the intrauterine fetus as a patient lies in the inability to perform a truly direct examination. Instead, one must rely on current indirect modalities such as dynamic, high-resolution ultrasonography, fetal heart rate (FHR) monitoring via the nonstress test (NST) and contraction stress test (CST), and vibroacoustic stimulation (VAS), to name some examples. Fortunately, technological and scientific advances over the years have permitted more specific examinations of the fetus and its behavior. It is clear that one of the most important goals of perinatal medicine is to recognize fetal disease states, optimize fetal outcome, and prevent perinatal mortality. Therefore, surveillance of the fetus during the antepartum and intrapartum periods is an important component of this process, which has the intent of detecting fetal asphyxia so that appropriate and timely interventions can be made. It is also clear that, because fetal compromise has a diverse etiology, forms of testing must be able to survey both acute fetal asphyxia and more chronic disease states. In the past, both the method and the frequency of antepartum testing have been arbitrary and generalized. However, it is apparent that tailoring testing to each disease-specific state is not only practical, but also more appropriate. Surveillance of the amniotic fluid volume (AFV) is also crucial, as fluid disorders may not only represent but also lead to fetal disease states. By utilizing the information from fetal surveillance, conservative management may be possible and may allow continued maturation *in utero*, while reducing the potential of neonatal prematurity complications. This chapter will discuss the current techniques available to survey the fetus and amniotic fluid during both antepartum and intrapartum periods.

Antepartum surveillance techniques (fetus and amniotic fluid)

Currently, there are multiple maternal and fetal indications to perform antepartum surveillance (Table 32.1), although

these are not absolute. The common basis for selecting these patients are those who are at increased risk of perinatal mortality, uteroplacental insufficiency, and fetal asphyxia. Many surveillance methods rely on natural fetal behavior. While the mechanisms controlling sleep and activity cycles in the fetus are not well understood, it is imperative that knowledge of this behavior is available to appropriately interpret FHR monitoring and fetal biophysical profile (BPP) activities. In the near-term fetus, there are four behavioral states (occurring repeatedly and stable over time) that have been described: quiet sleep, active sleep, quiet awake, and active awake.¹ Quiet sleep is characterized by absent eye or breathing movements, infrequent startle-type body movements, reduced FHR variability, and no accelerations. Active sleep is characterized by frequent gross body movements, rapid eye movements, breathing, normal FHR variability, and accelerations. The fetus predominantly spends its time in either a quiet or an active sleep state.²

Fetal movement monitoring

This method of surveillance (also known as “fetal kick counts”) by the mother is advantageous because it lacks contraindications, is simple, inexpensive, noninvasive, and understandable to patients. In general, because the presence of good fetal movement is a sign of fetal well-being and an indirect measure of normal fetal acid–base status, it is a viable modality. However, a decrease in fetal movements often (but not invariably) precedes fetal death, in some cases by several days.³ Around 16–18 weeks’ gestation, most women become cognizant of fetal activity, and this perception appears to be at its maximum by 28–32 weeks.⁴ However, awareness of fetal movements will vary from patient to patient, and is also affected by other maternal, fetal, and uterine factors (Table 32.2). In general, patients perceive about 80% of ultrasonographically visualized fetal movements.⁵

While several protocols have been utilized, neither the ideal duration for counting movements nor the optimal number of movements has been defined. Accordingly, there are many reported techniques that are acceptable, all of which rely on

Table 32.1 Selected indications for antepartum surveillance (fetus and amniotic fluid).

Indications
Diabetes mellitus
Hypertensive disorders (chronic hypertension, preeclampsia)
Renal disease
Collagen vascular disorders
Maternal thyrotoxicosis
Severe anemia or maternal hemoglobinopathies
Isoimmunization
Prior unexplained fetal demise
Third-trimester vaginal bleeding
Premature rupture of membranes
Maternal perception of decreased fetal movements
Postdate pregnancy (>41 weeks)
Elevated maternal serum AFP (normal amniotic fluid AFP)
Abnormal or irregular fetal heart rate on auscultation
Selected fetal anomalies (e.g., gastroschisis)
Multiple gestation
Intrauterine growth restriction
Amniotic fluid abnormalities (oligohydramnios or polyhydramnios)

AFP, alpha-fetoprotein.

Table 32.2 Fetal movement monitoring.

Factors influencing maternally perceived fetal movements
<i>Maternal</i>
Activity
Obesity
Ingestion of medications or drugs that depress (e.g., methadone) or increase (e.g., cocaine) fetal movements
<i>Fetal</i>
Behavioral states
Gestational age
Congenital anomalies (e.g., neuromuscular disorders, fetal akinesia syndrome)
Duration of fetal movements
<i>Uterine</i>
Placental location
Amniotic fluid volume

maternal compliance. A popular approach is to have the patient lie on her left side and count distinct fetal movements.⁶ Counting 10 movements in a period of up to 2 h is felt to be reassuring. If the count is nonreassuring or decreased, further assessment is recommended (such as NST with AFV assessment or BPP), and the physician should be contacted immediately.

The relationship between decreased fetal activity and poor perinatal outcome has been well established.^{7,8} Leader et al.⁸

found that, among high-risk pregnancies, 15% perceived an inactive fetus; among these, 46% had a poor perinatal outcome (stillbirths or poor neonatal condition at birth). Rayburn⁷ examined high-risk patients and found that patients with inactive fetuses were more likely to have a stillborn or do poorly during labor and the immediate neonatal period (abnormal labor FHR patterns, Cesarean for fetal distress, 5-min Apgar scores ≤ 6). In addition, in the inactive group, the incidence of severe fetal growth restriction was almost 10 times higher than that of the active group, and the overall risk of stillbirth was 35% (versus 0.6% in the active group).

While fetal movement monitoring is beneficial in high-risk pregnancies, it may also be useful in low-risk populations in reducing fetal mortality. In one large prospective study, during a 7-month control period (patients were not advised in formal fetal movement assessment), the fetal mortality rate was 8.7/1000 births.⁶ However, in a subsequent study period, when a fetal movement screening program was instituted, this rate dropped to 2.1/1000 births. It should be noted that there was a 13% increase in the number of NSTs performed for “decreased fetal movement,” and the intervention rate for fetal distress was 2.6 times higher (versus control subjects).

Contraction stress test (CST)

Designed to detect uteroplacental insufficiency before fetal compromise, this test is based on the response of the FHR to uterine contractions. It relies on the premise that fetal oxygenation will be transiently worsened by contractions. In the suboptimally oxygenated fetus, the resultant intermittent worsening in oxygenation will, in turn, lead to the FHR pattern of late decelerations.⁹

Lying in a lateral recumbent position, the patient has an external fetal monitor record both the FHR and uterine contractions simultaneously for a 20- to 30-min interval. If the patient is spontaneously contracting, and the frequency is ≥ 3 contractions/10 min, and the duration of each contraction is ≥ 45 s, then uterine stimulation is not required. However, if these criteria are not met, then either nipple stimulation or exogenous oxytocin can be used to elicit contractions. Once adequate contractions are achieved, the oxytocin infusion is discontinued. The CST should be avoided when there is a contraindication to labor. Examples include prior myomectomy or classical Cesarean section scar, placenta previa or placental abruption, premature rupture of membranes (PROM), current preterm labor, multiple gestations, and incompetent cervix.

Freeman's criteria (Table 32.3) are used by most to interpret CST results.¹⁰ The most common result is a negative CST, which indicates adequate fetal oxygenation in the presence of contractions.^{10–12} It has also been consistently associated with a good fetal outcome. One group reviewed data from their institution along with the literature, and found that the incidence of antepartum fetal death (within 1 week of a negative CST) was 0.2–0.7%.¹¹ Lagrew and colleagues¹³ evaluated antepartum test results in 614 diabetic women. Only one

Table 32.3 Interpretation of the contraction stress test.

Interpretation	Criteria
Nonreactive	No acceleration of at least 15 b.p.m. in amplitude or of 15-s duration during test
Reactive	Any acceleration \geq 15 b.p.m. for \geq 15 s during test
Negative	No late deceleration, with at least three contractions/10 min
Positive	Consistent, persistent late decelerations, regardless of contraction frequency, in the absence of uterine hyperstimulation
Equivocal:	
Suspicious	Nonpersistent ($< 50\%$ of the contractions) late decelerations
Hyperstimulation	FHR deceleration in the presence of uterine contractions exceeding five/10 min or lasting \geq 90 s
Unsatisfactory	Insufficient FHR tracing or inability to achieve appropriate uterine contractions

FHR, fetal heart rate; b.p.m., beats per minute.

patient had an intrauterine demise within 1 week of a negative CST. Thus, the literature suggests that there is a low incidence ($< 1\%$) of antepartum fetal death within 1 week of testing. However, this test will not predict acute fetal compromise unrelated to placental insufficiency, such as cord prolapse. In addition, the fetal deaths that have been reported after a negative CST are often attributed to abruption, congenital malformations, and poor glucose control in diabetic women.¹¹ Fetal outcome is controversial when a negative, nonreactive CST is seen. Druzin et al.¹⁴ have reported an increased likelihood of fetal death. Others have not found an increase in perinatal mortality or in low Apgar scores in this group; however, 12% of these fetuses had congenital anomalies.¹⁵ Also, 18% of the mothers were on sedatives and 45% were hypertensive. Thus, it has been recommended that investigation into possible causes of nonreactivity (prematurity, medications, congenital anomalies) should be done, along with repeat testing within 24 h.¹²

In general, a positive CST implies uteroplacental insufficiency and has been associated with adverse perinatal outcome and an increased incidence of intrauterine demise.¹⁰ However, an important drawback is the high incidence of false-positive CSTs. In fact, the false-positive rate has been reported to be $> 50\%$, depending on which perinatal outcome is defined.¹⁶ This may lead to intervention, which can be significant for the preterm fetus. The most ominous FHR pattern seen in this testing is when the CST is positive and nonreactive. In fact, the corrected perinatal mortality rate has been found to be as high as 17% in this group; nonreassuring FHR patterns have been found to occur during labor, and up to 25% of the cases demonstrate fetal growth restriction.^{10,17} Thus, this type of CST result usually necessitates delivery, and Cesarean section

should be considered. Another possible occurrence is the positive, reactive CST. Devoe¹⁸ found that, in those with positive CSTs but accelerations, there were lower rates of perinatal mortality, intrapartum fetal distress, low 5-min Apgar scores, primary Cesarean sections, and neonatal morbidity (versus positive, nonreactive CSTs). Another group found that 70% of patients with a positive CST (and accelerations) could tolerate labor without distress.¹⁷ Having this finding does not require abdominal delivery, and labor induction is acceptable. In addition, if the fetus is preterm, further alternative testing is a reasonable option.¹²

Varying results have been reported with the suspicious CST.^{19,20} A retrospective evaluation of CST results found that 2.3% were suspicious; 26% of these went on to have a positive CST or subsequent perinatal death.¹⁹ Conversely, Staisch and colleagues²⁰ performed 435 CSTs on 217 high-risk patients. A suspicious CST occurred in 24% of patients, and they found no association between this finding and neonatal morbidity or mortality. Thus, it is recommended that patients with a suspicious CST should have a repeat CST within 24 h or be evaluated with another form of antepartum testing. Equivocal tests resulting from uterine hyperstimulation or an inability to obtain a satisfactory FHR tracing should also be followed up similarly. Various causes of unsatisfactory CSTs include obesity, excessive fetal activity, and polyhydramnios.

Nonstress test (NST)

This testing modality is based on the premise that the heart rate of the fetus that is not acidemic or neurologically depressed will temporarily accelerate with fetal movement. FHR reactivity is felt to be a good indicator of normal fetal autonomic function and well-being; it depends on normal neurological development and normal integration of the central nervous system (CNS) control of FHR. In contrast, loss of reactivity is most commonly associated with a sleep cycle (an important point to remember), but can result from any cause of CNS depression (including fetal acidemia). The purpose of the NST is to identify both normal fetuses (who can remain *in utero*) and those with asphyxia/hypoxia (so that timely intervention can improve outcome). Fortunately, the NST (compared with the CST) has the advantages of time, easier interpretability, and lack of contraindications.²¹

The FHR is monitored with a Doppler ultrasound transducer, while a tocodynamometer may be used to record uterine contractions, if any. Fetal activity is also recorded with the results displayed on the strip; however, the patient does not need to document fetal movement for the test to be interpreted. Less than 1% of NSTs provide unsatisfactory results owing to inadequate recording of the FHR tracing.²² Technical difficulties that may be encountered include obesity, fetal hiccups, excessive fetal activity, and polyhydramnios.¹⁶

The tracing is categorized as reactive (normal) or nonreactive. While various definitions of reactivity have been used, the most common is ≥ 2 FHR accelerations [which peak, but

do not necessarily remain, at least 15 beats per minute (b.p.m.) in amplitude above the baseline, and last 15 s from baseline to baseline] within a 10- or 20-min period, with or without fetal movement.²³ It may be necessary to continue the tracing for 40 min to account for variations in the fetal sleep–wake cycle, because it may take this long for a healthy term fetus to display two FHR accelerations.²⁴ If, after 40 min (from the start of testing), the criteria are still not met, the test is considered nonreactive. On initial testing, almost 85% of high-risk patients show a reactive NST, and the remaining 15% are nonreactive.²² Other factors (besides fetal hypoxia, asphyxia, behavioral states, gestational age) can lead to a nonreactive NST, such as depressants (narcotics, phenobarbital), beta-blockers (propranolol), and smoking (decreased NST reactivity).^{25–27} It is also important to realize that variable decelerations can be observed in up to 50% of NSTs.²⁸ If they are not repetitive and brief (< 30 s), they likely indicate neither fetal compromise nor the need for obstetric intervention. However, repetitive variable decelerations (at least three in 20 min) even if mild, have been associated with an increased risk of Cesarean section for a nonreassuring intrapartum FHR pattern.²⁹

Routine NST interpretation does not take gestational age into account; however, this is an important consideration, as preterm fetuses are less likely to have FHR accelerations in association with fetal movements. Navot et al.³⁰ found a linear increase in the incidence of FHR accelerations in association with fetal movements, from 20% (25 weeks) to 65% (40 weeks). The amplitude of accelerations also appears to be related to gestational age, as accelerations of > 15 b.p.m. are responsible for only 20% of the total number of accelerations at early gestations (24–26 weeks).³¹ Gagnon et al.³² described the normal maturation of the FHR pattern from 26 weeks to term: decrease in basal FHR, increase in amplitude of accelerations, and increase in long-term variability. All these changes evolved by 30 weeks, and no further significant changes developed later until term. As the gestational age increases, a higher percentage of reactive NSTs is found.³³ For instance, the percentage of reactive NSTs was 16.7%, 65.6%, 90.5%, and 94.4% at 23–27, 28–32, 33–37, and 38–42 weeks respectively.³³ This also implies that the lower the gestational age, the higher the percentage of nonreactive NSTs. This concept should be kept in mind, as fetuses may undergo antepartum surveillance at < 32 weeks. Preterm fetuses may also normally exhibit decelerations between 20 and 30 weeks.³⁴ They become less common as the gestation advances, and are more frequent at < 30 weeks. However, while it is clear that gestational age should always be considered when interpreting NSTs, nonreassuring FHR patterns in the preterm fetus should not be automatically and improperly attributed to prematurity.

Lavery³⁵ reviewed perinatal mortality among patients in whom the NST was the main method of fetal assessment. In nine separate studies (7759 patients), a gross perinatal mortality of 12.5/1000 was found. The predictive value of a negative

NST (normal outcome associated with a reactive NST) is very high. The reactive NST predicts good perinatal outcome in about 95% of cases.³⁶ Accordingly, false-negative NSTs are infrequent. Within 1 week of a reactive NST, the perinatal mortality rate is about 3–5/1000.^{10,22} In addition, Devoe³⁷ found that, compared with nonreactive tests, patients with reactive NSTs were less likely (5% versus 22%) to experience perinatal morbidity (intrapartum fetal distress, low Apgar scores, neonatal complications, intrauterine growth restriction). Barss et al.³⁸ found the antepartum stillbirth rate (within 7 days of a reactive test) was 2.7/1000 and 2.8/1000 for the general high-risk population and postdate pregnancies respectively. For the two groups, the mean interval between a reactive test and stillbirth was 3.8 and 3.5 days. Accordingly, some have recommended that increasing the testing frequency to twice per week could prevent some of these fetal deaths. Boehm et al.³⁹ found a reduction in the stillbirth rate in a high-risk population (6.1/1000 to 1.9/1000) when the NST frequency was increased from weekly to twice a week. In a review of 1000 patients with diabetes or fetal growth restriction, one group suggested that weekly testing was not effective, and that twice-weekly testing should be established.⁴⁰ However, the American College of Obstetricians and Gynecologists (ACOG) states that NSTs are typically repeated at weekly intervals (although certain high-risk conditions may warrant twice-weekly testing).⁹

While there is excellent specificity with a reactive NST, the predictive value of a positive test is low (in most large studies, it is < 40%).⁴¹ The false-positive rate of a nonreactive NST is also very high. A literature review found false-positive rates of 57–100% for perinatal mortality, and 44–92% with softer outcome measures of perinatal morbidity.¹⁶ Therefore, given this fact, when a nonreactive NST is seen, one can either extend the time of the NST or proceed with other forms of testing (such as the BPP). Studies have shown that a reactive FHR (even after a prolonged NST) may still be consistent with good fetal outcome. However, persistent absence of reactivity (without an obvious cause such as medication, prematurity, congenital anomalies) may be associated with fetal compromise in most cases. Devoe et al.⁴² found that all tracings that became reactive did so by the end of 70 min. Those fetuses that remained nonreactive (after 90 min) had 67% and 93.3% perinatal mortality and morbidity rates respectively.

In summary, while a reactive NST is usually associated with good outcomes, most fetuses who do not show accelerations during an NST are also not compromised. We believe that, if the NST is used for fetal surveillance, once per week testing may not offer the most optimal outcome; one may consider the use of biweekly testing. As will be discussed later, indication-specific testing with a more individualized approach may be more appropriate.

Vibroacoustic stimulation (VAS)

Because the majority of nonreactive NSTs occur in healthy fetuses in a physiologically normal sleep state, some have tried

to improve NST efficacy by “stimulating” the fetus, in the hope of distinguishing normal fetal sleep from asphyxia. This method may elicit FHR accelerations by utilizing an artificial larynx (positioned on the maternal abdomen over the fetal vertex) with a stimulus of 1–2 s being applied. This may be repeated up to three times (at 1-min intervals) for progressively longer durations (of up to 3 s) to elicit accelerations. The normal fetal response to VAS includes not only FHR accelerations, but also increases in long-term FHR variability and gross body movements. VAS has been conclusively demonstrated to be effective in achieving fetal arousal, is reasonably safe, and improves the efficiency of antepartum FHR testing. Utilizing this on the nonacidemic fetus may elicit accelerations that appear to be valid in predicting fetal well-being. It offers the advantage of safely reducing testing time, without compromising detection of the acidemic fetus.⁴³ While VAS produces increases in intrauterine sound, and although these sound pressure levels are elevated, they are thought to be safe and harmless to the fetus.

Trudinger and Boylan⁴⁴ found that using VAS with NST (versus NST alone) had a higher sensitivity in detecting abnormal outcomes (66% versus 39%). Those fetuses with an abnormal response (who remained nonreactive after VAS) demonstrated increased rates of intrapartum fetal distress, fetal growth restriction, and low Apgar scores.⁴⁴ Gestational age appears to affect the FHR response to VAS, with a maturational response as gestation advances. Gagnon et al.⁴⁵ found that in 26- to 28-week fetuses, the maximum amplitude of the first acceleration was lower, and in 75% of these fetuses, was < 15 b.p.m. In contrast, after 36 weeks, all the initial accelerations were > 15 b.p.m. Another study evaluated FHR responses to VAS in fetuses < 36 weeks and ≥ 36 weeks.⁴⁶ Baseline changes in FHR, as well as tachycardia in response to VAS, were common findings in both groups. Baseline changes in FHRs of ≥ 10 b.p.m. were observed in 46% and 70% of preterm and term fetuses respectively. Unusual FHR patterns (including prolonged tachycardia) were seen after VAS in some

preterm fetuses. The authors cautioned that these unusual FHR patterns must be properly recognized to adequately interpret the FHR tracings in response to VAS.

In summary, VAS is an effective technique to improve the efficiency of antepartum FHR testing. It may decrease the time needed to perform NSTs, as well as the number of false-positive results. This is accomplished without changing the predictive reliability of a reactive NST.

Biophysical profile (BPP)

The BPP is performed using real-time ultrasonography to assess multiple fetal biophysical activities, as well as AFV. The observation is continued until either normal activity is seen or 30 consecutive minutes of scanning have elapsed. The BPP is unique in that it assesses both acute (FHR reactivity, fetal breathing movements, fetal movements, fetal tone) and chronic markers (AFV) of fetal condition. An understanding of the fetal biophysical response to hypoxemia and acidemia is essential to interpret the BPP score. The fetus will respond to central hypoxemia/acidemia by altering its movement, tone, breathing, and heart rate pattern. The corollary is also true that, in the presence of normal biophysical activities, CNS tissue is functional and is not significantly hypoxic.

Manning et al.⁴⁷ introduced the BPP score in 1980. It provides an estimate of the risk of fetal death in the immediate future, with the risk being low when a normal score is present. Scoring systems assign a numeric value (usually 0 or 2) to each of the biophysical components (Table 32.4). An advantage of the BPP is that observations of fetal movement and breathing (or their absence) are unequivocal, and there are no interobserver discrepancies in interpretation which, in contrast, exist with the NST. Fetal hiccups are interpreted as a variant of normal fetal breathing. Presently, the rate and pattern of the breathing movements are not considered clinically significant, except in extreme cases. Notably, each BPP

Table 32.4 Biophysical profile scoring: technique and interpretation.

Biophysical variable	Normal (score = 2)	Abnormal (score = 0)
Fetal breathing movements	≥ 1 episode of ≥ 30 s in 30 min	Absent or no episode of ≥ 30 s in 30 min
Gross body movements	≥ 3 discrete body limb movements in 30 min (episodes of active continuous movement considered)	≤ 2 episodes of body limb movements in 30 min as single movement
Fetal tone	≥ 1 episode of active extension with return to flexion of fetal limb(s) or trunk Opening and closing of hand considered normal tone	Either slow extension with return to partial flexion movement of limb in full extension or absent fetal movement
Reactive fetal heart rate	≥ 2 episodes of acceleration of ≥ 15 b.p.m. and of ≥ 15 s associated with fetal movement in 20 min	< 2 episodes of acceleration of fetal heart rate or acceleration of < 15 b.p.m. in 20 min
Qualitative amniotic fluid volume	≥ 1 pocket of fluid measuring 2 cm in vertical axis	Either no pockets or largest pocket < 2 cm in vertical axis

b.p.m., beats per minute.

parameter reflects a normally functioning area of the CNS, evolves *in utero* at predictable gestational ages, and is based on fetal neurophysiology. Vintzileos et al.⁴⁸ proposed the gradual hypoxia concept, which states that the biophysical activities developed last *in utero* are also the first to become abnormal in the presence of fetal acidemia or infection. At about 7.5 weeks, the CNS center controlling fetal tone is the first to develop, followed by development of body movement at 8.5–9.5 weeks. The center controlling regular breathing movements develops after 20–21 weeks, and the center controlling FHR reactivity functions by the end of the second/beginning of the third trimester. Therefore, in accordance with the gradual hypoxia concept, early stages of compromise are revealed by abnormalities in FHR reactivity and breathing, while movement and tone are not abolished until much later stages of compromise.

Absence of a particular activity may be due to diurnal variation, maternal drugs, short-term periodicity, acute fetal asphyxia, or fetal infection. The sequential loss of BPP variables serves as a marker of the degree of placental dysfunction. A BPP score of 8 or more is considered reassuring. In fact, if all four sonographic components are normal, the NST may be omitted without compromising the validity of the test results.⁴⁹ When the score is < 8, however, analyzing which individual components of the BPP are abnormal can assist in determining true fetal status and minimize false-positive examinations. The BPP score should also be interpreted within the overall clinical context. In general, a score of 6 is considered equivocal, and a score of ≤ 4 is abnormal. In the mature fetus, a BPP of 6/10 may indicate compromise and may be an indication for delivery; however, in the immature fetus, repeat testing or use of Doppler velocimetry may be in order before intervention is recommended. Also, regardless of the total score, in the presence of oligohydramnios (largest vertical pocket of AFV ≤ 2 cm), further evaluation is warranted.⁵⁰ Manning believes that oligohydramnios (in the presence of a normal fetus, functioning renal tissue, intact membranes) is always considered an indication for induction, despite the presence of normal FHR reactivity, breathing, movement, and tone. He bases this approach on an extensive review of the relationship between ultrasound-defined oligohydramnios and perinatal mortality,⁵¹ and a subsequent prospective study indicating that intervention for oligohydramnios can improve perinatal outcome.⁵² However, more recent data would advocate the use of Doppler velocimetry (umbilical artery, middle cerebral artery, ductus venosus) to assist in management.

The data strongly suggest that the application of BPP to the high-risk pregnant population results in a dramatic improvement in perinatal mortality rates. The corrected perinatal mortality rate for two large series (16 804 high-risk referred patients) was 2.2/1000.^{53,54} Manning et al.⁵³ contrasted perinatal mortality among 12 620 high-risk tested patients with 65 979 nontested historical control subjects. The control population (the majority were low risk) yielded a gross perinatal mortality rate of 14.3/1000 (versus 7.37/1000 in the tested

Figure 32.1 The relationship between perinatal mortality (either total or corrected for major anomaly) and the last biophysical profile scoring result. This relationship is exponential, yielding a highly significant inverse correlation using log 10 conversion. PNM, perinatal mortality.

population) for a decrease in mortality of 48.5%. In this study, the corrected stillbirth rate among tested patients was 1.18/1000 (versus 6.35/1000 among historical control subjects), a decrease of 81%. A normal BPP conveys a low risk of stillbirth; the false-negative rate of the BPP (fetal death within 1 week of a last normal test result) ranges from 0.645 to 7.000 per 1000.^{53,55} Figure 32.1 shows an inverse and exponential relationship (highly significant correlation) between last BPP score and perinatal mortality. There is also a strong relationship between the last BPP score and perinatal morbidity variables.^{54,56} Figure 32.2 shows a highly significant inverse linear correlation between last BPP score and perinatal morbidity (fetal distress, admission to neonatal intensive care unit, intrauterine growth restriction, 5-min Apgar score ≤ 7 , and cord pH < 7.20). Combinations of these variables also showed the same highly significant inverse linear correlation with BPP score. The interval of BPP testing frequency (1–2/week) is arbitrary, however, and is often a matter of individual judgment, training, preferences, and experience.

Vintzileos et al.⁵⁷ examined the relationship between BPP components and cord pH in 124 patients undergoing Cesarean birth (prior to labor onset). An umbilical arterial pH of < 7.20 was used to define fetal acidemia. At pH < 7.20, inhibition of fetal breathing and FHR nonreactivity occurred; however, a pH < 7.10 was needed before movements and tone

Figure 32.2 The relationship between last biophysical test score before delivery and individual perinatal morbidity variables: presence of fetal distress, admission to neonatal intensive care unit (NICU), intrauterine growth restriction (IUGR), 5-min Apgar score ≤ 7 , and umbilical vein pH < 7.20 , either alone or in any combination. BPS, biophysical profile score.

were abolished. Importantly, none of the fetuses with a reactive NST, or breathing, or both, had a pH < 7.20 . By analyzing the individual components of the BPP (versus score), the sensitivity, specificity, positive and negative predictive values in predicting fetal acidemia were 100%, 92%, 71%, and 100% respectively. Vintzileos and colleagues⁵⁸ later examined the relationship between the absence of fetal biophysical activities and umbilical artery blood gas values (pH, PO_2 , PCO_2 , HCO_3 , and base excess levels), thus confirming the gradual hypoxia concept.

The modified BPP is composed of the NST (an acute indicator of fetal acid-base status) and AFV (indicator of chronic uteroplacental function). It is used by many centers as a primary mode of surveillance. The amniotic fluid index (AFI) is the sum of measurements (cm) of the deepest cord-free amniotic fluid pocket in each of the maternal abdominal quadrants. Because an AFI > 5 cm is generally considered to be an adequate volume,⁵⁹ a normal modified BPP exists when the NST is reactive and the AFI is > 5 cm.⁹ An abnormal test

occurs if either the NST is nonreactive or the AFI is 5 cm or less. The advantage of using this modality is that the perinatal morbidity/mortality using this scheme compares favorably with previous studies (which use the entire BPP). Figure 32.3 shows our suggested protocol for the modified BPP. By using this protocol in 17211 tests, we had only four deaths of normal fetuses, for a false-negative rate of 0.02%.⁶⁰ Another study compared the outcomes of high-risk patients whose last antepartum assessment was a negative CST or negative modified BPP.⁶¹ The incidence of adverse perinatal outcome (after reassuring testing) was significantly less in those managed by the modified BPP than in the CST group (5.1% versus 7.0%).

The BPP has also been useful as a method of assessing fetal well-being and predicting the development of infectious complications in patients with PROM. Vintzileos et al.⁶² examined the effect of PROM on the biophysical components. They found that, in PROM patients (without intrauterine infection), there is an increased likelihood of FHR reactivity and oligohydramnios throughout gestation, adequate fetal breathing is decreased, and the other BPP components are not affected. A review of the literature found that, in most studies, a strong correlation was found between abnormal BPP assessment and the development of infectious outcome (maternal or neonatal) in patients with PROM.⁶³ The authors concluded that correlation between an abnormal BPP and infectious outcome is dependent on time. For instance, the relationship between an abnormal BPP and infection (neonatal, as well as intra-amniotic, as diagnosed by amniocentesis) exists only if the BPP is performed within 24 h of delivery. In contrast, no correlation exists between an abnormal BPP and infectious outcome if the test is performed > 24 h before delivery. It is also vital to remember that the development of maternal clinical chorioamnionitis alone (without neonatal infection) or invasion of the intra-amniotic cavity with *Mycoplasma* species are two conditions that are not necessarily associated with an abnormal BPP. Frequent NSTs or BPPs in patients with preterm PROM are helpful in distinguishing the healthy fetuses that can safely remain *in utero* from those that are either already infected or at high risk of developing neonatal infection.

Amniotic fluid volume (AFV) assessment

Amniotic fluid (AF) is essential to pregnancy, providing a compartment for normal development, growth, and movement of the fetus. AFV is a chronic marker of fetal well-being, and a normal AFV also protects the fetus from cord compression during fetal activity or uterine contractions. This volume changes during pregnancy (Fig. 32.4); at 22 weeks, the average AFV is 630 mL, and this increases to 770 mL at 28 weeks.⁶⁴ Between 29 and 37 weeks, there is little change in volume, which averages 800 mL. Beyond 39 weeks, AFV decreases sharply (averaging 515 mL at 41 weeks). Once a patient becomes postdate, there is a 33% decline in AFV per week,

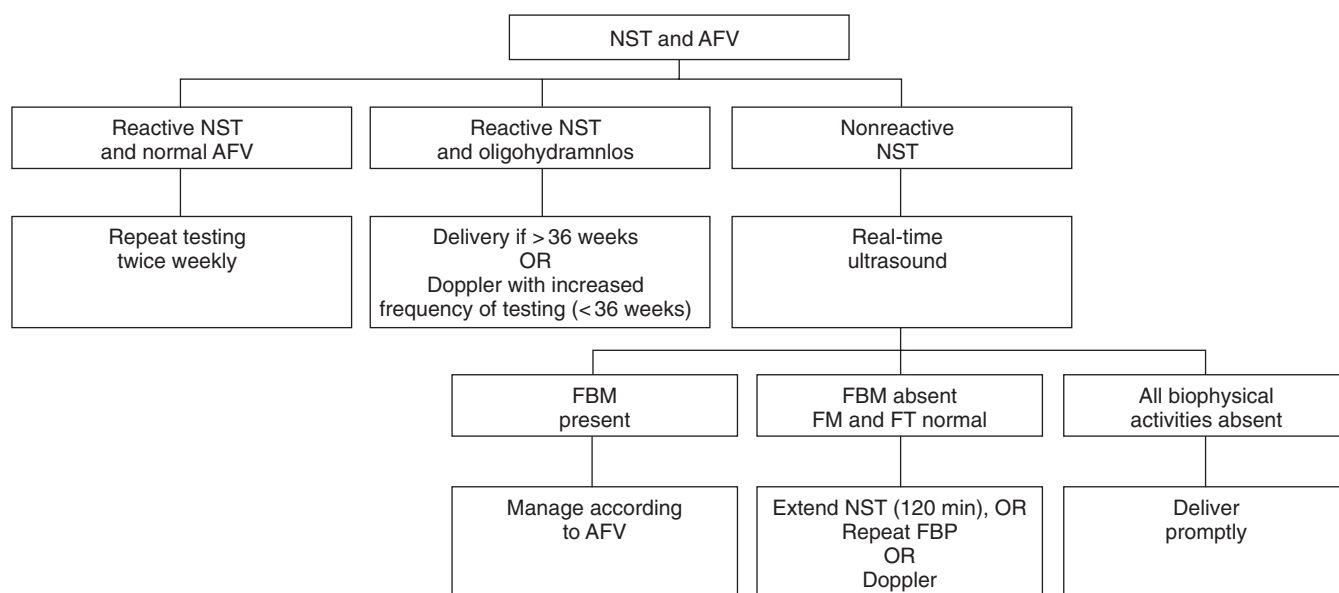

Figure 32.3 Suggested protocol for the modified fetal biophysical profile. AFV, amniotic fluid volume; FBM, fetal breathing movements; FBP, fetal biophysical profile; FM, fetal movements; FT, fetal tone; NST, nonstress test.

Figure 32.4 Mean amniotic fluid volume (AFV) changes during pregnancy.

consistent with clinical observations of an increased incidence of oligohydramnios in post-term gestations.⁶⁵

During embryogenesis, little is known about AF dynamics. With advancing gestational age, the AF composition changes. In the second half of pregnancy, the main sources of AF include fetal urine excretion (especially) and fluid secreted by the fetal lung. However, unlike the role of the kidneys, the fetal lung does not play a role in regulating fetal body fluid homeostasis. Fetal urine production rates appear to be in the range of nearly 1 L/day near term. The primary pathways for fluid removal are fetal swallowing (mainly) and intramembranous absorption into fetal blood perfusing the fetal surface of the placenta. Thus, under pathologic conditions, fetal modulation of sites of fluid secretion (urine and lung liquid) and resorption (swallowing and intramembranous flow) contributes to

the marked AFV changes seen. For example, increases in fetal blood volume (twin–twin transfusion) likely increase urine flow and induce polyhydramnios in the recipient twin. Alternatively, absent fetal swallowing due to gastrointestinal obstruction (e.g., esophageal atresia) or neurological deficits may also cause polyhydramnios. Placental dysfunction may result in decreased fetal renal perfusion, leading to oligohydramnios.

While a variety of techniques have been developed in the past to assess AFV, one of the initial methods involved vertically measuring a single (largest) AF pocket. Chamberlain et al.⁵¹ developed the “2-cm rule”. By using a 2-cm vertical pocket, they could reliably predict which fetuses were at risk of intrauterine growth restriction, oligohydramnios, and perinatal mortality; patients having pockets of > 2 cm were considered to have a normal AFV and were at low risk of these complications. One of the most common methods utilized today is the AFI, which was first described in 1987.⁶⁶ With the uterus “divided” into four quadrants (linea nigra and umbilicus divide the uterus into right/left halves and upper/lower halves respectively), the vertical diameter of the largest pocket in each quadrant (umbilical cord free) is measured. The summation of all four quadrant numbers equals the AFI (in cm) (Fig. 32.5). In low-risk pregnancies, the mean AFI was 16.2 ± 5.3 cm. Notably, the mean AFI is relatively stable from 24 weeks through term. Phelan et al.^{66,67} also established definitions for oligohydramnios (AFI ≤ 5 cm) and polyhydramnios (AFI > 25 cm). In comparing the various techniques that have been described, some believe the AFI appears to be superior to the determinations of single vertical pockets.^{51,59} It has been demonstrated that the AFI is not only simple and easy to perform, but is also reproducible and

Figure 32.5 Prenatal ultrasound of 30-week fetus depicting vertical measurements (cm) of the amniotic fluid in all four quadrants (Q1–Q4) of the maternal abdomen, comprising the amniotic fluid index (14.86cm in this case).

without substantial interobserver and intraobserver differences, which is important.⁶⁸ In addition, the AFI definitions of oligohydramnios and polyhydramnios are highly correlated with fetal outcome. Several limitations exist, however, with the AFI technique. First, prior to 20 weeks, a four-quadrant assessment may not be feasible. Second, a composite AFI does not provide quantitative information relative to each fetus in a twin pregnancy. Finally, the AFI does not correlate with actual AFV throughout gestation.

A recent study found that, during antepartum surveillance, measurement of the single deepest pocket (versus AFI) was associated with a significantly lower rate of suspected oligohydramnios (10% versus 17% respectively).⁶⁹ Another study found that the AFI offered no advantage in detecting adverse outcomes (compared with the single deepest pocket) when performed with the BPP.⁷⁰ In fact, they found that the AFI may cause more interventions by labeling twice as many at-risk pregnancies as having oligohydramnios (than with the single deepest pocket technique).

Preterm PROM affects 6% of all patients and is responsible for 30% of preterm deliveries. Early sonographic evaluation of AFV in patients admitted with preterm PROM is useful in counseling patients as to the chances of early delivery. While not absolute, patients with a normal AFV are four times more likely to be undelivered (after 1 week) than those with reduced fluid.⁷¹ Vintzileos et al.⁷¹ also showed that a normal AFV is associated with a significantly lower rate of Cesarean section, Apgar scores < 7 (1 and 5 min), and perinatal mortality. Assessment of AF either on admission or later can also serve as a predictor of amnionitis.^{72,73} In patients with preterm

Table 32.5 Potential complications associated with polyhydramnios.

Complications

Placental abruption
Puerperal hemorrhage
Perinatal mortality
Maternal respiratory difficulties

PROM, Vintzileos et al.^{72,73} showed that a low AFV or non-reactive FHR pattern is associated with a 67% probability of intrauterine infection, which is six or seven times higher than in patients with normal test results.

The frequency at which AFI evaluations should be repeated in the antepartum period is not well established. Most recommend that follow-up examinations should be tailored individually and, in general, if the AFI is normal, fluid checks can be repeated weekly. However, with marginal or decreased fluid, or in a postdate pregnancy, a shorter test interval should be considered.

Polyhydramnios (pathologic accumulation of AF), which is defined as an AFI > 25 cm, occurs in 0.2–1.6% of the general population.⁷⁴ It is associated with increased maternal and perinatal morbidity and mortality (Table 32.5).^{67–75} The causes of polyhydramnios depend on its severity. For instance, Hill et al.⁷⁴ found the cause to be apparent in only 17% of patients with mild polyhydramnios (idiopathic in the remaining 83%), but in 91% of those with moderate or severe polyhydramnios.

When the cause of polyhydramnios can be found, the diagnosis usually falls into the following categories:⁶⁷ fetal malformations and genetic disorders, diabetes, rhesus (Rh) sensitization, and congenital infections. Fetal swallowing impairment may also result in excess AFV. Once polyhydramnios is diagnosed, a targeted and detailed ultrasound should be performed to examine for fetal abnormalities and movement disorders (e.g., gastroschisis, duodenal atresia, anencephaly). In the absence of a sonographic abnormality, the patient evaluation may include (but not require) screening tests for maternal diabetes, Rh sensitization, and hemoglobinopathies. If a cause is diagnosed, when possible, it should be treated.

In some cases, it may be beneficial to attempt to reduce the risk of obstetric complications with AFV reduction. Techniques that have been used are amniocentesis and maternal administration of prostaglandin synthetase inhibitors (indomethacin), which reduce fetal urine flow.⁷⁶ However, because of continuous production of AF, repeated amniocenteses may be required, which is associated with both maternal and fetal risks. In addition, indomethacin must be administered carefully, as it is associated with potential fetal side-effects (oligohydramnios, premature closure of the ductus arteriosus, and increased incidence of neonatal necrotizing enterocolitis and renal compromise). While patients are on indomethacin, the AFV and, perhaps, fetal ductal flow should be monitored frequently.

Oligohydramnios (reduced AFV) occurs in 5.5–37.8% of pregnancies,^{59,77} and is significant because of its known association with adverse pregnancy outcome (Table 32.6), such as umbilical cord occlusion, fetal distress in labor, meconium aspiration, operative deliveries, and stillbirth.⁷⁷ Some clinical conditions commonly associated with oligohydramnios include intrauterine growth restriction, urinary tract malformations, postdate pregnancies, and ruptured membranes. Decreased fluid may also be a sign of placental insufficiency. Evaluation of oligohydramnios should include a targeted sonogram, which may be difficult owing to the reduced AFV. Generally, second-trimester oligohydramnios is associated with a poor fetal prognosis. For instance, it may impair lung development with resulting neonatal morbidity/mortality.⁷⁸ Mercer and Brown⁷⁹ found that, of 34 pregnancies with second-trimester oligohydramnios (without PROM), 27% had

fetal congenital malformations, 32% of fetuses died *in utero*, and 18% had an entirely normal outcome. However, second-trimester oligohydramnios should not be considered hopeless for patients with either intact or ruptured membranes. As third-trimester oligohydramnios has an increased risk of FHR decelerations and nonreactivity, ultrasound must often be complemented by FHR monitoring. It is important to remember, however, that, regardless of NST results, oligohydramnios in the third trimester (unrelated to PROM) should alert one to the potential for fetal compromise, and these patients should be considered for delivery.

Condition-specific antepartum fetal testing

Evidence-based observations have shown that there are different pathophysiologic processes that can place the fetus at risk; thus, the efficacy of the various fetal tests depends on the underlying pathophysiologic condition.⁸⁰ It also follows that no one test is ideal for all high-risk fetuses. Therefore, multiple parameter assessment or combinations of different tests may often be the optimal fetal strategy, depending on the testing indication. The most recent information in fetal testing reveals that, in order to improve accuracy, condition-specific fetal testing should be utilized. By using this method (at Robert Wood Johnson Medical School) in 12 766 high-risk fetuses, the number of fetal deaths was reduced to 1/3191 (four fetal deaths), which is three times lower than the number of fetal deaths that are seen when the same biophysical assessment tests are applied regardless of the underlying pathophysiologic process (1/1300).^{61,80–82} The pathophysiologic processes that can lead to fetal death/damage include decreased uteroplacental blood flow, decreased gas exchange at the trophoblastic membrane level, metabolic processes, fetal sepsis, fetal anemia, fetal heart failure, and umbilical cord accidents.⁸⁰ Table 32.7 shows the various pathophysiologic processes, examples of maternal/fetal conditions, and the specific surveillance tests that may be the most appropriate.

Intrapartum fetal surveillance techniques

Fetal heart rate (FHR) monitoring

The main surveillance technique for intrapartum fetal evaluation is FHR monitoring, which can be performed either intermittently or continuously. Intermittent FHR monitoring can be performed by either manual counting of the FHR (using a hand-held Doppler ultrasound on the abdomen or DeLee stethoscope) or using a continuous electronic FHR monitor intermittently (recorded on a tracing). In low-risk patients, it is recommended that the FHR should be determined at least every hour, every 30 min, and every 15 min in the latent phase, active phase, and second stages of labor respectively.⁸³ The FHR is generally monitored and recorded during a contraction, and for 30 s afterward. However, there are no studies

Table 32.6 Potential consequences of oligohydramnios.

Consequences

Maternal or neonatal infection

Table 32.7 Condition-specific antepartum fetal testing.

Pathophysiologic condition	Maternal/fetal condition	* Appropriate test(s)
Metabolic abnormalities	Type 1 diabetes	NST, CST, BPP, Doppler in class F–R diabetes, maternal blood glucose (goal is normal)
Decreased uteroplacental blood flow	Hypertensive disorders Collagen, renal, vascular disease Most cases IUGR (< 32–34 weeks)	NST, CST, BPP, AF assessment, Doppler, EFW by US (growth rate)
Decreased gas exchange	Postdate pregnancy Some cases IUGR (> 32–34 weeks)	NST, CST, BPP, AF assessment, first-trimester US (accurate dating), EFW by US
Fetal sepsis	PROM Intra-amniotic infection Maternal fever, primary subclinical intra-amniotic infection	NST, BPP, AF assessment, amniocentesis (rule out infection)
Fetal anemia	Fetomaternal hemorrhage Erythroblastosis fetalis Parvovirus B19 infection	NST (if hydrops present), CST (if hydrops present), BPP (if hydrops present), MCA peak systolic velocity, US to rule out hydrops, fetal liver length, cordocentesis, amniocentesis (> 28 weeks)
Fetal heart failure	Cardiac arrhythmia Nonimmune hydrops Chorioangioma placenta Aneurysm of the vein of Galen	NST or CST (if hydrops present/arrhythmia absent), BPP, Doppler (venous circulation), US to rule out hydrops, continuous FHR monitoring (determine time spent in sinus rhythm), M-mode echo (rule out arrhythmias)
Umbilical cord accident	Umbilical cord entanglement (monoamniotic twins) Velamentous cord insertion/funic presentation Noncoiled umbilical cord Oligohydramnios	Frequent NST, umbilical artery Doppler, color Doppler on US (verify diagnosis)

AF, amniotic fluid; BPP, biophysical profile; CST, contraction stress test; EFW, estimated fetal weight; FHR, fetal heart rate; IUGR, intrauterine growth restriction; MCA, middle cerebral artery; NST, nonstress test; PROM, premature rupture of membranes; US, ultrasound.

*Specific surveillance tests that may be the most appropriate and are suggested guidelines.

providing data on the optimal intervals for monitoring low-risk patients. In high-risk patients, it is recommended that the FHR be determined every 30 min, 15 min, and 5 min during the latent phase, active phase, and second stages of labor respectively.

Continuous electronic FHR monitoring (EFM) determines the FHR on a beat-to-beat basis and displays data continuously. It can be performed either externally or internally. External monitoring is noninvasive, and can be used in every patient by placing a Doppler transducer on the abdomen (overlying the fetal heart); however, signal loss can be a significant problem. In addition, the true beat-to-beat variability of the FHR can be assessed only from a fetal electrocardiogram by determining the R–R interval. This is accomplished via internal monitoring and direct FHR evaluation. Internal FHR monitoring requires ruptured membranes, and the cervix to be dilated ≥ 1 –2 cm. A spiral electrode is applied to the presenting fetal part (either vertex or breech). Signal loss is reduced, and maternal obesity, fetal, and maternal movements should not alter the signal quality. An essential adjuvant component to FHR monitoring is uterine contraction monitoring, which can be accomplished via an external tocodynamometer

(most commonly) on the maternal abdomen. While uterine frequency and duration of contractions are measured with reasonable accuracy, the strength/amplitude of the contractions cannot be determined using this modality. In contrast, another method involves insertion of an intrauterine pressure catheter, which requires cervical dilation and ruptured membranes. With this internal technique, the strength, amplitude, duration, and frequency of contractions can be assessed.

The interpretation of FHR patterns should incorporate knowledge of gestational age, maternal condition, medications, and other factors that could influence FHR components. In 1997, the National Institute of Child Health and Human Development (NICHD) Research Planning Workshop developed standardized definitions for electronic FHR patterns and recommendations for interpreting them.⁸⁴ These definitions are found in Table 32.8. The workshop did not make a distinction between short-term variability (or beat-to-beat variability or R–R wave period differences in the electrocardiogram) and long-term variability, because they felt that, in actual practice, they are visually determined as a unit. Thus, the definition of variability was based visually on the amplitude of the complexes, with exclusion of the regular, smooth

Table 32.8 Fetal heart rate patterns.

Fetal heart rate pattern	Definition	Comments
Baseline FHR	Approximate mean FHR rounded to increments of 5 b.p.m. during a 10-min segment (excluding periodic/episodic changes, periods of marked FHR variability, segments of the baseline that differ by > 25 b.p.m.)	In any 10-min window, the minimum baseline duration must be ≥ 2 min, or the baseline for that period is indeterminate [one may then need to refer to the previous 10-min segment(s) for determination of the baseline]
Bradycardia	Baseline FHR < 110 b.p.m.	
Tachycardia	Baseline FHR > 160 b.p.m.	
Baseline FHR variability	Fluctuations in the baseline FHR of ≥ 2 cycles/min	Fluctuations are irregular in amplitude and frequency; visually quantitated as the amplitude of the peak-to-trough (b.p.m.)
Absent FHR variability	Amplitude range undetectable	
Minimal FHR variability	Amplitude range > undetectable and ≤ 5 b.p.m.	
Moderate FHR variability	Amplitude range 6–25 b.p.m.	
Marked FHR variability	Amplitude range > 25 b.p.m.	
Acceleration	Visually apparent abrupt increase (onset of acceleration to peak in < 30 s) in FHR above baseline. Increase is calculated from most recently determined portion of the baseline	Acme is ≥ 15 b.p.m. above baseline, and acceleration lasts ≥ 15 s and < 2 min from onset to return to baseline. Before 32 weeks, defined as acme ≥ 10 b.p.m. above baseline and duration ≥ 10 s
Prolonged acceleration	Duration ≥ 2 min and < 10 min	Acceleration of ≥ 10 min is a baseline change
Early deceleration	Visually apparent gradual (onset of deceleration to nadir ≥ 30 s) decrease and return to baseline FHR associated with UC	Decrease is calculated from most recently determined portion of baseline. Deceleration is coincident in timing, with nadir occurring at the same time as peak of contraction
Variable deceleration	Visually apparent abrupt decrease (onset of deceleration to beginning of nadir < 30 s) in FHR below baseline	Decrease is calculated from most recently determined portion of baseline. Decrease in FHR below baseline is ≥ 15 b.p.m., lasting ≥ 15 s and < 2 min from onset to return to baseline
Late deceleration	Visually apparent gradual (onset of deceleration to nadir ≥ 30 s) decrease and return to baseline FHR associated with UC	Decrease is calculated from most recently determined portion of baseline. Deceleration is delayed in timing, with nadir occurring after peak of contraction
Prolonged deceleration	Visually apparent decrease in FHR below baseline	Decrease is calculated from most recently determined portion of baseline. Decrease from baseline is ≥ 15 b.p.m., lasting ≥ 2 min, but < 10 min from onset to return to baseline. Prolonged deceleration of ≥ 10 min is a baseline change
Sinusoidal pattern	Smooth, sine wave-like pattern of regular frequency and amplitude	Excluded in the definition of FHR variability

Adapted from ref. 84.

b.p.m., beats per minute; FHR, fetal heart rate; UC, uterine contractions.

sinusoidal pattern. The workshop also stated that the individual components of the FHR patterns that were defined do not occur alone and generally evolve over time. Therefore, they felt that a full description of a FHR tracing requires a qualitative and quantitative description of: baseline rate, baseline FHR variability, presence of accelerations, periodic or episodic decelerations, and changes or trends in FHR patterns over time.⁸⁴

While the baseline FHR normally ranges from 110 to 160 b.p.m. across all gestational ages, rates as low as 90 b.p.m. or as high as 180 b.p.m. are common in healthy fetuses. Such rates are not necessarily abnormal if they are transient and the other FHR parameters are normal. As gestation advances,

there is a gradual slowing of the mean baseline FHR, from 160 b.p.m. (15 weeks) to 140 b.p.m. (term).⁸⁵ Fetal tachycardia has been associated with maternal fever, maternal thyrotoxicosis, atropine, excessive fetal movement, fetal infection, and tachyarrhythmias. Although fetal tachycardia can be associated with compromise, it is not usually associated with acidemia in the setting of normal FHR variability and absence of decelerations.⁸⁶ Fetal bradycardia can be seen with maternal hypotension or hypothermia, MgSO₄ toxicity,³⁵ and congenital heart block. Periodic FHR patterns are those associated with uterine contractions, while episodic patterns are those not associated with uterine contractions. Normal FHR variability is generally described as the most reliable indicator of

fetal well-being, as it reflects intact integration of the CNS and cardiovascular systems. It is associated with fetal well-being despite the concomitant presence of FHR decelerations.^{86–88} Various causes of decreased variability include fetal asphyxia, fetal behavioral states, gestational age, narcotics, and fetal anomalies.³⁵ During labor, extended periods of decreased FHR variability (up to 45 min) can normally be seen.⁸⁹ A clinical rule of thumb is that FHR decelerations reflect the nature of the insult to the fetus, while FHR variability reflects the fetal ability to tolerate the insult. If decreased variability is associated with baseline FHR changes, or is seen with recurrent decelerations, the likelihood of fetal compromise increases.^{86–88}

The presence of FHR accelerations during labor is a sign of fetal well-being and indicates a well-oxygenated fetus.⁹⁰ Four types of decelerations are seen intrapartum, and they are classified as early, variable, late, or prolonged, based on their temporal relationship with contractions, as well as their configuration. The workshop stated that any deceleration is quantitated by the depth of the nadir in b.p.m. below the baseline (excluding transient spikes or electronic artifacts), and the duration is quantitated in minutes and seconds from the beginning to the end of the deceleration.⁸⁴ Accelerations are quantitated similarly. Decelerations are defined as recurrent if they occur with $\geq 50\%$ of uterine contractions in any 20-min segment. Early decelerations are thought to be secondary to an increase in vagal tone due to fetal head compression during the contraction. These decelerations are innocuous, are not associated with fetal hypoxemia or acidemia,^{86,91} can be observed throughout labor (but are seen most often at cervical dilations of 4–8 cm),⁹² and no corrective measures are indicated. Variable decelerations are the most common decelerations seen in labor, are most often seen during the second stage, and indicate umbilical cord compression. Variable decelerations have been graded by some as mild, moderate, and severe based on the duration of the deceleration and the level to which the FHR drops.⁹¹ Mild variable decelerations (in the presence of a normal FHR and variability) are usually of minimal clinical significance. However, prolonged and deep variable decelerations may result in a transient respiratory acidemia. If decelerations are severe, repetitive, and accompanied by decreased variability or changes in FHR baseline, fetal acidemia may be developing.^{86,88} Late decelerations are caused by fetal hypoxia, which is often due to decreased intervillous exchange between mother and fetus (decreased placental perfusion). In advanced stages of fetal acidemia, late decelerations can also be a result of direct myocardial depression. For this pattern to become significant clinically, they must be repetitive. Although decelerations with larger amplitudes may be associated with lower fetal pH, shallow, repetitive, late decelerations with diminished FHR variability are nonreassuring, and there is a high likelihood of fetal acidemia.^{88,92} Clinical situations in which late decelerations are seen include excessive uterine activity, placental abruption, and maternal hypotension. Prolonged decelerations may occur sponta-

neously, or be related to prolapsed cord, excessive uterine activity, maternal hypotension, or fetal manipulation. A sinusoidal FHR differs from variability in that it has a smooth, sine wave-like pattern of regular frequency and amplitude, and is excluded in the definition of FHR variability.⁸⁴ It may be nonreassuring in that it has been associated with severe fetal anemia. A transient “sinusoid-like” pattern may also be seen after maternal administration of some narcotic analgesics.⁹³ However, in this setting, it does not indicate fetal compromise.

Figure 32.6 shows a suggested protocol for managing nonreassuring FHR tracings or fetal heart decelerations in labor. The use of this should aid in detecting the acidemic fetus requiring delivery, and should limit the number of unnecessary interventions for suspected (but not proven) fetal distress. Conservative measures for resuscitation include discontinuation of oxytocin (if used), altering maternal position (left or right lateral, knee–chest), administering O₂, correcting maternal hypotension if present, amnioinfusion (if variable decelerations), tocolysis (if no contraindications), and performing a vaginal examination to rule out cord prolapse.

Introduced in the 1960s with the aim of detecting intrapartum fetal asphyxia and improving neonatal outcomes, EFM is now the main screening method for intrapartum fetal assessment in most developed countries, but has been disappointing on account of its subjective nature, frequency of falsely nonreassuring patterns, and persistent questions regarding efficacy.⁹⁴ Also, the widespread use of EFM does not appear to have reduced cerebral palsy.⁹⁵ Nonreassuring patterns occur in about 15% of labors.⁹⁶ Its diagnostic accuracy in predicting fetal compromise (positive predictive value) is not as good as its accuracy in confirming fetal well-being. Early randomized controlled trials (RCTs) in the 1970s and 1980s comparing intermittent auscultation with continuous monitoring failed to show a consistent improvement in neonatal outcome, despite the associated increase in operative deliveries with continuous EFM.^{97–100} However, many of these early trials suffered from limitations, such as small sample sizes and low overall perinatal mortality rates in the studied populations. The Dublin trial had more than 6000 patients enrolled in each study arm.⁹⁸ The only significant difference found was a twofold higher rate of neonatal seizures and abnormal neurologic examinations in the intermittent auscultation group. However, crossover from one group to the other and the exclusion of many high-risk patients may have obscured any advantages of EFM over auscultation. In 1993, Vintzileos et al.¹⁰¹ conducted a RCT that evaluated intermittent auscultation versus continuous EFM as the primary (and only) surveillance method, and included both low-risk and high-risk patients. No crossover was allowed from one group to the other. This study found a significant reduction in perinatal mortality secondary to hypoxia in those patients managed with continuous EFM. In addition, they found that EFM was superior to intermittent auscultation in detecting fetal acidemia at birth.¹⁰² Our group performed a meta-analysis on the RCTs of monitoring

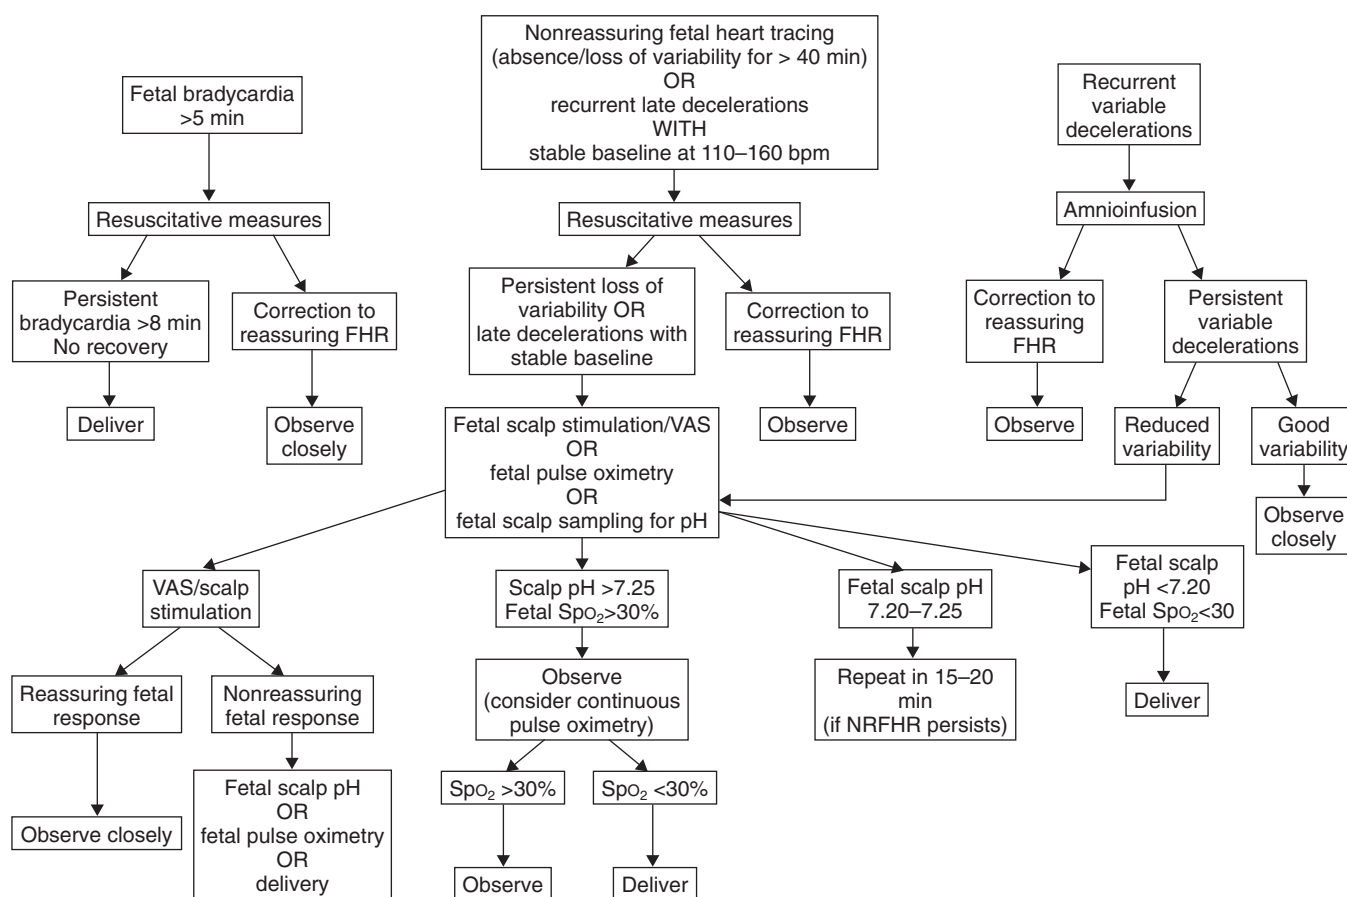

Figure 32.6 Management of nonreassuring fetal heart tracing or fetal heart decelerations in labor. FHR, fetal heart rate; NRFHR, nonreassuring fetal heart rate; SpO₂, arterial oxygen saturation; VAS, vibroacoustic stimulation (from Apuzzio JJ, Vintzileos AM, Iffy L, eds. *Operative obstetrics*, 3rd edn. Abingdon, United Kingdom: Taylor & Francis, 2005, with permission).

techniques.¹⁰³ Although perinatal mortality was no different with the two techniques (continuous versus intermittent), there was a significant reduction (about 40%) in perinatal deaths due to hypoxia in the continuous EFM group. Patients monitored electronically had overall higher rates of Cesarean and operative vaginal deliveries, as well as operative interventions for fetal distress. A recent Cochrane review¹⁰⁴ of nine RCTs concluded that the only clinically significant benefit from the use of routine continuous EFM (versus intermittent auscultation) was the reduction in neonatal seizures [relative risk (RR) 0.51, 95% confidence interval (CI) 0.32–0.82], with an increase in Cesarean and operative vaginal deliveries. There were no significant differences in 1-min Apgar scores below 4 or 7, and the rates of neonatal intensive care unit admissions, perinatal deaths, or cerebral palsy. Thus, although it appears that EFM is associated with reductions in neonatal seizures and perinatal deaths due to hypoxia, the price is a small (but significant) increase in operative deliveries.

Fetal acid–base evaluation

While EFM is mostly satisfactory, there is a clear need for an adjunctive method of intrapartum fetal surveillance when concerns arise about the EFM pattern. Fetal scalp capillary blood sampling was developed in the 1960s and is complementary to the FHR, by evaluating fetal acid–base status during labor. It has been used to improve the positive predictive value of FHR tracings. Figure 32.6 depicts a suggested protocol for managing nonreassuring FHR tracings or fetal heart decelerations in labor, incorporating scalp pH, fetal pulse oximetry, or fetal stimulation techniques. During labor, fetal acidemia may be secondary to impaired maternal–fetal exchange in the intervillous space. In acute umbilical cord compression, rapid CO₂ accumulation leads to a respiratory acidemia. Metabolic acidemia can occur secondary to lactic acid accumulation when the anaerobic pathway of energy production is used. If sufficient hypoxemia and acidemia develop and persist,

significant fetal morbidity/mortality may result. A scalp pH ≥ 7.25 has been considered normal for a fetus during the intrapartum period.¹⁰⁵ A range of 7.20–7.24 indicates pre-acidemia, while values ≤ 7.19 indicate fetal acidemia. However, it is understood that pH values associated with pathologic fetal acidemia may be significantly lower than this. It is not common to find significant neonatal morbidity until the umbilical artery pH is < 7.10 , and this cutoff may be as low as 7.00.^{106,107} RCTs have shown that Cesarean delivery rates for fetal distress are lower in patients managed with EFM and intermittent scalp sampling.^{98,108} Thacker et al. reported recently that the addition of fetal scalp blood sampling to standard EFM reduced the odds for Cesarean section, although the odds were still increased compared with intermittent auscultation of the fetal heart.¹⁰⁴ Intermittent fetal scalp blood sampling is now rarely utilized in the United States.¹⁰⁹

Umbilical cord acid–base values are often obtained at the time of delivery, and are used to establish an objective measure of fetal status at the time of birth. Normal values for arterial and venous blood samples have been described.¹¹⁰ Although umbilical artery blood gases are preferable to venous blood, sampling of both provides information on the fetal and uteroplacental circulations respectively. It is also important to remember that, as fetal pH values normally fall during labor, abnormal cutoff values for defining acidemia at delivery are influenced by the presence or absence of labor. Values for defining the various types of acidemia at birth (labor versus no labor) have been described.¹¹⁰ Nearly 80% of infants classified as depressed (1- or 5-min Apgar score < 7) have normal umbilical cord pH values.¹¹¹

Recently, Ross and Gala¹¹² described how base excess values (versus umbilical cord pH values) have a significantly greater usefulness, because base excess does not change significantly with respiratory acidosis and demonstrates a linear correlation with the degree of metabolic acidosis. Umbilical artery base excess is the most direct measure of fetal metabolic acidosis, and threshold levels of base excess (-12 mmol/L) have been associated with an increased risk of neonatal neurological injury.¹¹² Through an interpolation of fetal base excess values throughout the course of labor, this approach can provide a framework for the assessment of FHR tracings during labor and, potentially, the timing of hypoxic/ischemic injury.¹¹²

Fetal stimulation techniques

Fetal scalp sampling has limitations and cannot be used in all patients. Equipment for pH analysis and skilled personnel to perform this technique may not be available. For these reasons, other methods of evaluating a nonreassuring FHR pattern have been proposed, such as fetal scalp stimulation and VAS. Clark et al.^{113,114} evaluated FHR responses to scalp sampling, and correlated these FHR responses with fetal scalp blood pH. Evoked FHR accelerations of 15 b.p.m. (lasting 15 s) were associated with a scalp pH of ≥ 7.20 in all cases;

there were no cases of a FHR acceleration response to the scalp puncture when the pH was < 7.20 .¹¹³ However, although acceleration presence indicated fetal well-being, a lack of response occurred in several normal, nonacidemic fetuses. A subsequent study showed that the need for scalp blood sampling could be reduced by 50% in the setting of an evoked FHR acceleration secondary to scalp stimulation.¹¹⁴ Concerning, however, was that there was a false-negative rate of 60%. Thus, while evoked accelerations (15 b.p.m. for 15 s) indicate fetal well-being and imply a normal acid–base status, a lack of accelerations does not always predict fetal compromise. Others have used less stringent criteria (acceleration of 10 b.p.m. for at least 10 s) to define fetal response to scalp stimulation to try to decrease the need for scalp blood sampling.¹¹⁵

VAS has been used intrapartum to evoke FHR accelerations and thus identify the well fetus. Many studies have compared VAS responses with fetal acid–base determinations.^{116–120} In evaluating 64 patients with abnormal intrapartum FHR patterns, all fetuses demonstrating a reactive response to VAS had a pH ≥ 7.25 .¹¹⁶ Of 34 fetuses not showing a response, half had a scalp pH of < 7.25 . Another study evaluated 188 patients with scalp stimulation and VAS.¹¹⁷ No patients demonstrated accelerations when scalp pH values were < 7.20 . Bartelsmeyer et al.¹¹⁸ suggested that VAS could predict fetal acidemia and differentiate between respiratory and metabolic acidemia. Patients with fetal scalp blood base deficits of > 10 mEq/L did not show a response of FHR accelerations after VAS; although five fetuses did show an acceleration with a scalp pH of < 7.20 , all had base deficits of < 10 mEq/L. A meta-analysis evaluating the intrapartum assessment of fetal well-being with VAS found a fivefold increase in the risk of acidemia (scalp pH < 7.20) in laboring patients who did not respond with accelerations of 15 b.p.m. for 15 s after VAS.¹²¹ Table 32.9 shows that, when data from studies using VAS^{117–120} and studies evaluating scalp stimulation^{113,114,117} are pooled and compared, the overall efficacy for predicting a scalp pH < 7.20 is similar, regardless of the method of stimulation. Although scalp and acoustic stimulation techniques are simple to perform, they are limited by falsely nonreassuring results.¹²² Interestingly, one study has shown that the fetal response to VAS decreased as

Table 32.9 Efficacy of intrapartum fetal stimulation for prediction of a scalp pH of < 7.20 .

	VAS (<i>n</i> = 405)	Scalp stimulation* (<i>n</i> = 488)
Sensitivity	83% (29/35)	98% (43/44)
Specificity	65% (241/370)	67% (298/444)
Positive predictive value	18% (29/158)	23% (43/189)
Negative predictive value	98% (241/247)	99% (298/299)

VAS, vibroacoustic stimulation.

*Scalp stimulation includes scalp puncture, digital pressure, and scalp pinch.

cervical dilation advanced.¹²³ Analgesia with low doses of nalbuphine has not been found to alter the fetal response to VAS in normal laboring patients.¹²⁴

In summary, FHR acceleration as a response to fetal stimulation indicates a nonacidemic fetus, and thus scalp blood sampling may be omitted. In our opinion, using VAS or scalp stimulation may reduce the need for scalp pH analysis when FHR tracings are equivocal/nonreassuring. These fetal stimulation techniques are noninvasive, are not technically difficult, can be performed earlier in labor, and can be done when scalp pH sampling is not feasible. If the fetus responds normally to either VAS or scalp stimulation, significant acute fetal acidemia has been ruled out, and thus a scalp pH may be unnecessary.

Fetal pulse oximetry (FPO)

Recently, a new technology with practical potential has emerged, namely FPO. This emerged in the late 1980s, and is a tool that continuously and directly measures the fetal arterial O₂ saturation during the labor process, with the intent of improving the accuracy of evaluating fetal well-being in labor. It is generally reserved for use when a nonreassuring FHR has been recorded, to assist in identifying those hypoxemic fetuses who may benefit from further intervention, and as an adjunct to (not a replacement for) FHR monitoring. The hope is to decrease the Cesarean rate for fetal distress when fetal O₂ saturation is normal. A variety of sensors have been studied; some are placed during a vaginal examination to attach to the top of the fetal head by suction,¹²⁵ and others lie against the fetal temple or cheek.¹²⁶ The sensor remains *in situ*, and FPO values are recorded for approximately 81% of the monitoring time. Fetal acidemia is rare when the fetal arterial O₂ saturation is continually > 30% (critical threshold). Thus, FPO values ≥ 30% are considered reassuring (even when the EFM is nonreassuring), whereas values < 30% warrant consideration of interventions, such as maternal position change or urgent Cesarean delivery.¹²⁷ FHR abnormalities associated with normal scalp blood analysis and normal Apgar scores at delivery have been demonstrated in association with stable arterial O₂ saturation patterns.¹²⁸ It is currently recommended for singleton pregnancies only. An ominous EFM pattern has been defined as prolonged deceleration below 70 b.p.m. for at least 7 min. In 2003, the US Food and Drug Administration guidelines expanded the EFM patterns considered to be ominous, requiring prompt delivery despite reassuring FPO readings. They re-emphasized that FPO is meant as an adjunct to (not a replacement for) EFM, and that no technology is 100% predictive of the fetal acid-base condition.

In the 1990s, a large volume of data regarding the feasibility, physiology, and clinical application of FPO were published.^{128–131} The only RCT published to date is an American multicenter study, which specifically defined mild to moderately nonreassuring EFM tracings.¹³² They compared a group monitored using EFM alone with one monitored using both EFM

and FPO. While the Cesarean rate for nonreassuring EFM was reduced by more than 50% in the EFM FPO group (without adversely affecting maternal or fetal/neonatal outcome), the overall Cesarean rate was unchanged between both control and test groups, because of an unanticipated increased incidence of Cesarean sections for dystocia (19%) in the EFM FPO group (versus 9% in control group). A higher proportion of those with nonreassuring variable decelerations were delivered by Cesarean section for dystocia in the oximetry group. The authors suggested that the nonreassuring EFM may indicate an underlying risk of dystocia.¹³² Thus, the failure to reduce the overall Cesarean rate led many to question whether there was any clear benefit to FPO, despite the improved prediction of fetal condition/outcome using FPO. A follow-up prospective cohort study in 2004¹³³ was done to further elucidate the increased Cesarean rate for dystocia seen in the American RCT. Women whose fetuses demonstrated persistent, progressive, and moderately–severely nonreassuring EFM were more likely to have a Cesarean for dystocia, and had a significantly higher rate of persistent occipitoposterior position of the fetus, than those with intermittent, mildly nonreassuring EFM, despite adequate fetal oxygenation status, as measured by FPO. They concluded that nonreassuring EFM patterns predict Cesarean delivery for dystocia among nulliparous patients with normally oxygenated fetuses. In 2001, the American College of Obstetricians and Gynecologists (ACOG) released an opinion on FPO, with concerns about signal registration time, possible false-negative readings, and lack of proven cost–benefit.¹³⁴ They could not endorse the adoption of the FPO into clinical practice, and there has since been a reversal in enthusiasm for the FPO technology.¹³⁵ The NICHD MFM Units Network is currently conducting a RCT involving 10 000 nulliparous women in labor.¹³⁵ Subjects will be randomized to FPO with information available to the clinician (open device arm) or FPO with information masked to the clinician (blinded device arm). The primary outcome will be the impact of FPO as an adjunct to EFM on the Cesarean delivery rate. It is thought that future research should: (1) determine whether other mechanisms of intrapartum fetal brain injury besides hypoxemia (e.g., infection, ischemia) could escape surveillance by FPO; (2) establish the long-term outcomes of children monitored with FPO (compared with standard methods); and (3) establish whether there is a way to use FPO effectively in the setting of labor dystocia and a nonreassuring FHR pattern, to allow safe vaginal delivery.¹³⁵

Fetal electrocardiogram (ECG) ST segment automated analysis (STAN)

Because animal and human studies have shown that fetal hypoxemia during labor can alter the shape of the fetal ECG waveform (notably the elevation or depression of the ST segment), technical systems have been developed to monitor the fetal ECG during labor, as an adjunct to continuous EFM with the aim of improving fetal outcome and minimizing unnecessary obstetric interference.¹³⁶ The fetal ECG ST

segment automated analysis (STAN) analyzes the repolarization segment of the ECG (ST) waveform, which is altered by intramyocardial potassium release, resulting from metabolic acidemia.¹³⁷ A recent Cochrane review¹³⁶ of two RCTs assessing the use of fetal ECG as an adjunct to continuous EFM during labor found that using ST waveform analysis was associated with fewer babies with severe metabolic acidosis at birth (cord pH < 7.05 and base deficit > 12 mmol/L). This was achieved along with fewer fetal scalp samples during labor and fewer operative deliveries. Their conclusion was to restrict fetal ST waveform analysis to those fetuses demonstrating disquieting features on cardiotocography. However, in a study looking at the ability of EFM plus fetal ECG STAN monitoring to predict metabolic acidemia (umbilical cord artery pH < 7.15 and base deficit \geq 12 mmol/L) at birth, they found a

poor positive predictive value (8%) and a sensitivity of 43%.¹³⁸ Another Cochrane review¹³⁹ of the addition of fetal ECG monitoring reported a nonsignificant trend toward reducing the overall Cesarean rate, when compared with EFM only. Ross et al.¹⁴⁰ found that adding fetal ECG STAN to standard FHR monitoring improved FHR tracing interpretation and improved observer consistency in both the decision for and the timing of obstetric interventions, and that it may reduce the number of unneeded obstetric interventions when fetal compromise is absent.

In conclusion, there are currently a wide variety of techniques to survey the fetus and amniotic fluid during the antepartum and intrapartum periods. By utilizing the information from surveillance, fetal outcomes can hopefully be optimized and perinatal mortality prevented.

Key points

- Both antepartum and intrapartum surveillance of the fetus have the intent of detecting fetal compromise (acidemia and/or infection), so that appropriate and timely interventions can be made. As fetal compromise has a diverse etiology, forms of testing must be able to survey both acute fetal status and more chronic disease states.
- Fetal movement monitoring ("fetal kick counts") by the mother is an advantageous form of surveillance because it lacks contraindications, is simple, inexpensive, noninvasive, and understandable to patients. The relationship between decreased fetal activity and poor perinatal outcome has been well established.
- A negative contraction stress test indicates fetal ability to tolerate uterine contractions. In general, however, a positive test implies potential uteroplacental insufficiency and has been associated with adverse perinatal outcome and an increased incidence of intrauterine demise.
- Fetal heart rate (FHR) reactivity is a good indicator of normal fetal autonomic function and well-being; it depends on normal neurologic development and normal integration of the central nervous system control of FHR.
- Preterm fetuses are less likely to have FHR accelerations in association with fetal movements.
- The predictive value of a negative nonstress test (NST) (normal outcome associated with a reactive NST) is very high. The reactive NST predicts good perinatal outcome in about 95% of cases. The false-positive rate of a nonreactive NST is also very high.
- The normal fetal response to vibroacoustic stimulation (VAS) includes not only FHR accelerations, but also increases in long-term FHR variability and gross body movements.
- VAS has been conclusively demonstrated to be effective in achieving fetal arousal, is reasonably safe, and improves the efficiency of antepartum FHR testing. Utilizing VAS on the nonacidemic fetus may elicit accelerations that appear to be valid in predicting fetal well-being. It also offers the advantage of safely reducing testing time, without compromising detection of the acidemic fetus.
- The biophysical profile (BPP) is unique in that it assesses both acute (FHR reactivity, fetal breathing movements, fetal movements, fetal tone) and chronic (amniotic fluid volume) markers of fetal condition.
- The "gradual hypoxia concept" implies that the biophysical activities developed last *in utero* are also the first to become abnormal in the presence of fetal acidemia or infection. In accordance with this concept, early stages of fetal compromise are manifested by abnormalities in FHR reactivity and breathing, while movement and tone are generally not abolished until much later stages of compromise.
- In the second half of pregnancy, the main sources of amniotic fluid include fetal urine excretion (especially) and fluid secreted by the fetal lung. However, unlike the role of the kidneys, the fetal lung does not play a role in regulating fetal body fluid homeostasis.
- Polyhydramnios (pathologic accumulation of amniotic fluid), which is defined as an amniotic fluid index > 25 cm, occurs in 0.2–1.6% of the general population. When the cause of polyhydramnios can be found, the diagnosis usually falls into the following categories: fetal malformations and genetic disorders, diabetes, Rh sensitization, and congenital infections. Fetal swallowing impairment may also result in excess amniotic fluid volume.
- Oligohydramnios (reduced amniotic fluid volume) occurs in 5.5–37.8% of pregnancies and is significant

because of its known association with adverse pregnancy outcome, such as umbilical cord occlusion, fetal distress in labor, meconium aspiration, operative deliveries, and stillbirth.

- 14 The pathophysiologic processes that can lead to fetal death/damage include decreased uteroplacental blood flow, decreased gas exchange at the trophoblastic membrane level, metabolic processes, fetal sepsis, fetal anemia, fetal heart failure, and umbilical cord accidents. Multiple parameter assessment or combinations of different tests may often be the optimal fetal strategy, depending on the testing indication. In order to improve accuracy, condition-specific fetal testing should be utilized.
- 15 The interpretation of FHR patterns should incorporate knowledge of gestational age, maternal condition, medications, and other factors that could influence FHR components.
- 16 In 1997, the National Institute of Child Health and Human Development Research Planning Workshop developed standardized definitions for electronic FHR patterns and recommendations for interpreting them.
- 17 The diagnostic accuracy of electronic FHR monitoring in predicting fetal compromise (positive predictive value) is not as good as its accuracy in confirming fetal well-being.
- 18 Other methods of evaluating an unreassuring FHR pattern have been proposed, such as fetal scalp stimulation and VAS. FHR acceleration as a response to fetal stimulation indicates a nonacidemic fetus, and thus scalp blood sampling may be omitted. Using VAS or scalp stimulation may reduce the need for scalp pH when FHR tracings are equivocal/nonreassuring.
- 19 Fetal pulse oximetry will reduce the Cesarean rate for nonreassuring electronic FHR monitoring patterns but, as currently used, will not decrease the overall Cesarean rate.
- 20 Technical systems have been developed to monitor the fetal electrocardiogram (ECG) during labor, as an adjunct to continuous electronic FHR monitoring, with the aim of improving fetal outcome and minimizing unnecessary obstetric interference. Some have found that, by adding fetal ECG ST segment automated analysis (STAN) to standard FHR monitoring, this has improved FHR tracing interpretation and improved observer consistency in both the decision for and the timing of obstetric interventions, and may reduce the number of unneeded obstetric interventions when fetal compromise is absent.

Fetal Therapy

The fetus at surgery

Robert H. Ball and Michael R. Harrison

The indications for fetal surgical interventions have expanded since the field was founded over two decades ago. Similarly, the total number of procedures performed, the centers at which they are performed, and the number of physicians performing them have increased. Nevertheless, overall, these procedures remain very limited when compared with the number of pregnancies and even the number of fetuses with malformations.

Over the last decade, technological advances have allowed a transition toward less invasive procedures. Initial fetal surgical procedures pioneered by one of the authors (MRH), at the University College of San Francisco, depended on maternal laparotomy and hysterotomy. This approach evolved into laparotomy and uterine endoscopy and, most recently, into percutaneous procedures using devices with diameters of 3 mm or less. Our experience suggests that the less invasive approaches are associated with a less complicated postoperative recovery for the mothers, but do not entirely eliminate morbidity.¹

Open fetal surgery (hysterotomy)

The human experience with open fetal surgery is now quite extensive, both from our own center and others,¹⁻³ and is primarily associated with the large numbers of fetal spina bifida repairs (Fig. 33.1). We currently reserve maternal laparotomy/hysterotomy procedures for repair of spina bifida, resection of sacrococcygeal teratoma and other tumors, and lobectomy for cystic adenomatoid malformation (CCAM).

We have recently reviewed our experience at UCSF with maternal hysterotomy¹ (Table 33.1). Eighty-seven hysterotomies were performed between 1989 and 2003. There were significant immediate postoperative complications. In the early experience, pulmonary edema related to multiple tocolytic use, particularly nitroglycerin, and aggressive fluid management was a significant problem.⁴ Thirteen percent of women required transfusion for intraoperative blood loss. Pregnancy outcomes were also significantly affected with a premature rupture of membrane (PROM) rate of 52%, 33% having

preterm labor refractory to maximal tocolytic management leading to delivery. The mean time from hysterotomy to delivery was 4.9 weeks (range 0–16 weeks). The mean gestational age at the time of delivery was 30.1 weeks (range 21.6–36.7 weeks). Others^{5,6} have had similar experiences with respect to an increased risk of preterm delivery following hysterotomy. Most of the morbidity associated with hysterotomy has decreased with experience. Significant pulmonary edema or blood loss is rare, and the mean gestational age at the time of delivery for repair of myelomeningocele (MMC) is now around 34 weeks.

The practical aspects of hysterotomy and postoperative management have evolved since the initial years of experience. Lengthy discussions regarding the risks, benefits, and alternatives of the procedure are important, including the experimental nature of the surgery. The risks to the mother are similar to any major abdominal surgery, although in this case there is no direct physical benefit to her. In addition, there are the risks associated with aggressive tocolytic therapy and bedrest in a hypercoagulable state. The risks to the fetus are primarily vascular instability and hypoperfusion intraoperatively, leading to injury or death, and prematurity due to postoperative complications. The risks to the pregnancy are primarily preterm labor and PROM and preterm delivery. Infectious complications are rare, except when premature rupture leads to prolonged latency. An important additional discussion point is that all subsequent deliveries, including the index pregnancy, must be by Cesarean section. Data regarding future fertility are reassuring, with no increased incidence of infertility in the UCSF experience in those patients attempting pregnancy.⁷ Experience from the Children's Hospital of Pennsylvania suggests a concerning risk of uterine rupture in subsequent pregnancies that may be as high as 18%, which would be considerably higher than the risk after previous low transverse Cesarean section (1% or less) or classical Cesarean section (5–10%). Another potential risk in subsequent pregnancies is placenta accreta. The reason for this is that the site of a hysterotomy performed in the second trimester is never in the same area as a Cesarean section entry. There is an

Figure 33.1 Summary of open fetal surgery techniques. (A) The uterus is exposed through a low, transverse abdominal incision. Ultrasonography is used to localize the placenta, inject the fetus with narcotic and muscle relaxant, and aspirate amniotic fluid. (B) The uterus is opened with staples that provide hemostasis and seal the membranes. Warm saline solution is continuously infused around the fetus. Maternal anesthesia, tocolysis, and monitoring are shown. BP, blood pressure; CVP, central venous pressure; ECG, electrocardiogram. (C) Absorbable staples and back-biting clamps facilitate hysterotomy exposure of the pertinent fetal part. A miniaturized pulse oximeter records pulse rate and oxygen saturation intraoperatively. A radiotelemeter monitors fetal electrocardiogram and amniotic pressure during and after the operation. (D) After fetal repair, the uterine incision is closed with absorbable sutures and fibrin glue. Amniotic fluid is restored with warm lactated Ringer's solution.

Table 33.1 Maternal morbidity and mortality for 178 interventions at UCSF with postoperative continuing pregnancy and divided into operative subgroups.

Postoperative result	Open hysterotomy	Endoscopy FETENDO/ Lap-FETENDO	Percutaneous FIGS/ Lap-FIGS	All interventions
Patients with postoperative continuing pregnancy	79	68	31	178
Gestational age at surgery (weeks)	25.1	24.5	21.1	24.2
Range (weeks)	17.6–30.4	17.9–32.1	17.0–26.6	17.0–32.1
Gestational age at delivery (weeks)	30.1	30.4	32.7	30.7
Range (weeks)	21.6–36.7	19.6–39.3	21.7–40.4	19.6–40.4
Interval surgery to delivery (weeks)	4.9	6.0	11.6	6.5
Range (weeks)	0–16	0–19	0.3–21.4	0–21.4
Pulmonary edema	22/79 (27.8%)	17/68 (25.0%)	0/31 (0.0%)	39/178 (21.9%)
Bleeding requiring blood transfusion	11/87 (12.6%)	2/69 (2.9%)	0/31 (0.0%)	13/187 (7.0%)
Preterm labor leading to delivery	26/79 (32.9%)	18/68 (26.5%)	4/31 (12.9%)	48/178 (27.0%)
Premature rupture of membranes (PROM)	41/79 (51.9%)	30/68 (44.1%)	8/31 (25.8%)	79/178 (44.4%)
Chorioamnionitis	7/79 (8.9%)	1/68 (1.5%)	0/31 (0.0%)	8/178 (4.5%)

FIGS, fetal intervention guided by sonography.

Table 33.2 Fetal conditions that may benefit from treatment before birth.

Fetal condition	Effect on development (rationale for treatment)	Result without treatment	Recommended treatment
<i>Life-threatening defects</i>			
Urinary obstruction (urethral valves)	Hydronephrosis Lung hypoplasia	→Renal failure →Pulmonary failure	Percutaneous vesicoamniotic shunt Fetoscopic ablation of valves Open vesicostomy
Cystic adenomatoid malformation	Lung hypoplasia–hydrops	→Hydrops, death	Open pulmonary lobectomy Ablation (laser/RFA) Steroids Open complete repair
Congenital diaphragmatic hernia	Lung hypoplasia	→Pulmonary failure	Temporary tracheal occlusion Tracheal clip (open and fetoscopic) Fetoscopic balloon (percutaneous/reversible)
Sacroccygeal teratoma	High-output failure	→Hydrops, death	Open resection of tumor Vascular occlusion (alcohol/RFA) RFA
Twin–twin transfusion syndrome	Donor–recipient steal through placenta	→Fetal hydrops, death, neurologic damage to survivor	Fetoscopic laser ablation of placental vessels (NIH trial) Amnioreduction (NIH trial) Selective reduction (NIH trial)
Acardiac/anomalous twin (TRAP)	Vascular steal Embolization	→Death/damage to surviving twin	Selective reduction Cord occlusion/division RFA
Aqueductal stenosis	Hydrocephalus	→Brain damage	Ventriculoamniotic shunt
Valvular obstruction	Hypoplastic heart	→Heart failure	Balloon valvuloplasty
Congenital high airway obstruction (CHAOS)	Overdistention by lung fluid	→Hydrops, death	Fetoscopic tracheostomy <i>Ex utero</i> intrapartum treatment (EXIT)
Cervical teratoma	Airway obstruction High-output failure	→Hydrops, death	Open resection EXIT Vascular occlusion (alcohol/RFA)
<i>Nonlife-threatening defects</i>			
Myelomeningocele	Spinal cord damage	→Paralysis, neurogenic bladder/bowel, hydrocephalus	Open repair (NIH trial) Fetoscopic coverage
Gastroschisis	Bowel damage	→Malnutrition/ short bowel	Serial amnio-exchange
Cleft lip and palate	Facial defect	→Persistent deformity	Fetoscopic repair* Open repair
<i>Metabolic and cellular defects</i>			
Stem cell–enzyme defects	Hemoglobinopathy Immunodeficiency Storage diseases	→Anemia, hydrops →Infection/death →Retardation/death	Fetal stem cell transplant Fetal gene therapy*
Predictable organ	Agenesis/hypoplasia heart/lung/kidney	→Neonatal heart/lung/ kidney failure	Induce tolerance for postnatal organ transplant* Tissue engineering*

NIH, National Institutes of Health; RFA, radiofrequency ablation.

*Not yet attempted in human fetuses.

increased risk of placenta accreta in any case in which implantation is in an area of uterine scarring. Multiple incisions will increase the likelihood of implantation in such an area. To our knowledge, there has not been a case of accreta in a fetal surgical patient of ours in a subsequent pregnancy.

Indications for open fetal surgery (Table 33.2)

Myelomeningocele (MMC)

Currently, the most common indication for hysterotomy-

based fetal intervention in our center is for MMCs. This is a devastating birth defect with sequelae that affect both the central and peripheral nervous systems. A change in cerebrospinal fluid (CSF) dynamics results in the Chiari II malformation and hydrocephalus. The abnormally exposed spinal cord results in lifelong lower extremity neurologic deficiency, fecal and urinary incontinence, sexual dysfunction, and skeletal deformities. This defect carries enormous personal, familial, and societal costs, as the near normal lifespan of the affected child is characterized by hospitalization, multiple operations, disability, and institutionalization. Although it has been assumed that the spinal cord itself is intrinsically malformed in children with this defect, recent work suggests that the neurologic impairment after birth may be due to exposure and trauma to the spinal cord *in utero*, and that covering the exposed cord may prevent the development of the Chiari malformation.⁸

Since 1997, more than 200 fetuses have had *in utero* closure of MMC by open fetal surgery. Preliminary clinical evidence suggests that this procedure reduces the incidence of shunt-dependent hydrocephalus and restores the cerebellum and brainstem to a more normal configuration. However, clinical results of fetal surgery for MMC are based on comparisons with historical control subjects, examine only efficacy and not safety, and lack long-term follow-up.

Cystic adenomatoid malformation (CCAM)

CCAM leading to hydrops is another indication for hysterotomy. Although CCAM often presents as a benign pulmonary mass in infants and children, some fetuses with large lesions die *in utero* or at birth from hydrops and pulmonary hypoplasia.⁹ The pathophysiology of hydrops and the feasibility of resecting the fetal lung have been studied in animals.^{9,10} Experience in managing more than 200 cases suggests that most lesions can be successfully treated after birth, and that some lesions resolve before birth.¹¹ Although only a few fetuses with very large lesions develop hydrops before 26 weeks of gestation, these lesions may progress rapidly, and the fetuses may die *in utero*. Careful sonographic surveillance of large lesions is necessary to detect the first signs of hydrops, because fetuses who develop hydrops can be treated successfully by emergency resection of the abnormal lobe *in utero*. Fetal pulmonary lobectomy has proved to be surprisingly simple and quite successful at two large fetal surgery centers. For lesions with single, large cysts, thoracoamniotic shunting has also been successful.¹² Percutaneous ablation techniques are being investigated. We have seen regression of very large lesions with hydrops after maternal steroid treatment.

Sacroccygeal teratoma (SCT)

Hysterotomy is the most common fetal surgical approach to treat fetuses in a critical condition with large SCTs. Most neonates with SCT survive, and malignant invasion is unusual. However, the prognosis of patients with SCT diagnosed prenatally (by sonogram or elevated alpha-fetoprotein levels) is less favorable. There is a subset of fetuses (fewer than 20%)

with large tumors who develop hydrops from high-output failure secondary to extremely high blood flow through the tumor. Because hydrops progresses very rapidly to fetal death, frequent sonographic follow-up is mandatory. Attempts to interrupt the vascular steal by sonographically guided or fetoscopic techniques have not yet been successful. Excision of the tumor reverses the pathophysiology if it is performed before the mirror syndrome (maternal preeclampsia) develops in the mother. Attempts to interrupt the vascular steal by ablating blood flow to the tumor by alcohol injection or embolization have not generally been successful. Hysterotomies in these cases may involve quite large incisions due to the large size of the masses.

Fetoscopic surgery (FETENDO)

With advances in technology and familiarity with endoscopic techniques, application of this technique to fetal surgery was natural. Common sense would suggest that the smaller the incision in the uterus, the lower the risk of subsequent pregnancy complications. At UCSF, endoscopic approaches were first applied to pregnancies complicated by diaphragmatic hernia, urinary tract obstruction, and twin-to-twin transfusion (Lap-FETENDO).

The initial pioneering approach involved maternal minilaparotomies, with direct exposure of the uterus. Ultrasound is used to determine the point of entry and the laparotomy site, depending on placental location and fetal lie. Once the uterus has been exposed, stay sutures are placed, and a 3- to 5-mm step trocar is advanced into the amniotic cavity under direct ultrasound visualization. Initially, several trocars were required for *in utero* dissections, placement of staples, etc. Later, many procedures could be performed through a single trocar using an endoscope with an operating channel. Initial caution regarding this approach led to similar perioperative management as in hysterotomy cases. This included general anesthesia, use of multiple tocolytics, and prolonged hospitalization. One important difference, even initially, was that patients could labor following FETENDO procedures. Since that time, endoscopic procedures have become less invasive with very small instruments passed through 3-mm ports.

Percutaneous FETENDO

Currently, we rarely use the more invasive Lap-FETENDO and have since progressed toward a completely percutaneous approach using a smaller 2 mm endoscope with an operating channel (Micro-FETENDO). We have used this technique for balloon tracheal occlusions, fetal cystoscopies, and for laser ablation in monochorionic twin gestations complicated by severe twin-to-twin transfusion. We anticipate that, based on our early experience and that of others¹² with percutaneous microendoscopy, the risk profile will be similar to that of percutaneous sonoguided procedures (see Fetal intervention guided by sonography). The perioperative

management is very different. Patients are treated with prophylactic indomethacin and antibiotics. As uterine relaxation from inhalational agents is not required, we generally use spinal anesthesia. Ultrasound is again critical for safe uterine access to determine the best entry point. This is based on fetal position, placental location, membrane position in multiple gestations, and uterine vascularity. Postoperative tocolytic therapy is usually based on contraction activity. A 24–48 h, a course of indomethacin or nifedipine is often all that is required. In cases in which there are significant postoperative changes in uterine size, such as with interventions for twin–twin transfusion syndrome (TTTS), prophylactic intravenous magnesium sulfate may be helpful.

Indications for fetoscopic surgery (FETENDO)

(Table 33.2)

Congenital diaphragmatic hernia (CDH)

The fundamental problem in babies born with a CDH is pulmonary hypoplasia. Research in experimental animal models and later in human patients over two decades has aimed to improve growth of the hypoplastic lungs before they are needed for gas exchange at birth. Anatomic repair of the hernia by open hysterotomy proved feasible, but did not decrease mortality and was abandoned. Fetal tracheal occlusion was developed as an alternative strategy to promote fetal lung growth by preventing normal egress of lung fluid. Occlusion of the fetal trachea was shown to stimulate fetal lung growth in a variety of animal models. Techniques to achieve reversible fetal tracheal occlusion were explored in animal models and then applied clinically, evolving from external metal clips placed on the trachea by open hysterotomy or fetoscopic neck dissection, to internal tracheal occlusion with a detachable silicone balloon placed by fetal bronchoscopy through a single 5-mm uterine port, as described above.

Our initial experience suggested that fetal endoscopic tracheal occlusion improved survival in human fetuses with severe CDH^{13,14}. To evaluate this novel therapy, we conducted a randomized, controlled trial comparing tracheal occlusion with standard care. Survival with fetal endoscopic tracheal occlusion (73%) met expectations (predicted 75%) and appeared to be better than that of historic control subjects (37%), but proved no better than that of concurrent randomized control subjects. The higher than expected survival in the standard care group may be because the study design mandated that patients in both treatment groups be delivered, resuscitated, and intensively managed in a unit experienced in caring for critically ill newborns with pulmonary hypoplasia. Attempts to improve outcome for severe CDH by treatments either before or after birth have proved to be double-edged swords. Intensive care after birth has improved survival, but has increased long-term sequelae in survivors, and is expensive.

Our ability to accurately diagnose and assess the severity of CDH before birth has improved dramatically. Fetuses with

CDH who have associated anomalies do poorly, whereas fetuses with isolated CDH, no liver herniation, and a lung:head ratio (LHR) above 1.4 have an excellent prognosis (100% in our experience). In this study, fetuses with a LHR between 0.9 and 1.4 had a chance of survival of > 80% when delivered at a tertiary care center. The small number of fetuses with a LHR below 0.9 had a poor prognosis in both treatment groups, and should be the focus of further studies.¹⁵

Twin–twin transfusion syndrome (TTTS)

TTTS was one of the first entities to be treated endoscopically at UCSF. It is a complication of monochorionic multiple gestations resulting from an imbalance in blood flow through vascular communications. It is the most common serious complication of monochorionic twin gestations, affecting between 4% and 35% of monochorionic twin pregnancies, or approximately 0.1–0.9/1000 births each year in the USA. Yet, despite the relatively low incidence, TTTS disproportionately accounts for 17% of all perinatal mortality associated with twin gestations.¹⁶ Standard therapy has been limited to serial amnioreduction, which appears to improve the overall outcome, but has little impact on the more severe end of the spectrum in TTTS. In addition, survivors of TTTS treated by serial amnioreduction have an 18–26% incidence of significant neurologic and cardiac morbidity. Selective fetoscopic laser photocoagulation of chorioangiopagus has emerged as an alternative treatment strategy with at least comparable, if not superior, survival to serial amnioreduction, as demonstrated in a randomized trial in Europe.¹⁷

Urinary tract obstruction

As a group at UCSF, we are particularly enthusiastic about the potential of fetal intervention in bladder outlet obstruction by percutaneous fetal cystoscopy. Fetal urethral obstruction produces pulmonary hypoplasia and renal dysplasia, and these often fatal consequences can be ameliorated by urinary tract decompression before birth. The natural history of untreated fetal urinary tract obstruction is well documented, and selection criteria based on fetal urine electrolyte and β_2 -microglobulin levels and the sonographic appearance of fetal kidneys have proved reliable.^{17–21} Of all fetuses with urinary tract dilation, as many as 90% do not require intervention. However, fetuses with bilateral hydronephrosis and bladder distention due to urethral obstruction who subsequently develop oligohydramnios require treatment. Depending on the gestational age, the fetus can be delivered early for postnatal decompression. Alternatively, the bladder can be decompressed *in utero* by a catheter Harrison vesicoamniotic shunt placed percutaneously under sonographic guidance,²² by fetoscopic vesicostomy^{23,24} or, more recently, by fetocystoscopic ablation of urethral valves.²⁵ Treatment with shunting has been relatively disappointing, as shunts often migrate or do not remain patent. Even when adequately decompressed, the obstructed bladder may not cycle correctly, resulting in a severe bladder dysfunction requiring surgery after birth. We have now devel-

oped a percutaneous fetal cystoscopic technique to disrupt posterior urethral valves through a single 3-mm port.

Fetal intervention guided by sonography (FIGS)

The first fetal procedure, developed in the early 1980s, was percutaneous sonographically guided placement of the Harrison fetal bladder catheter shunt. Many other catheter shunt procedures have been developed and described.²⁶ More recently, we have developed percutaneous sonographically guided radiofrequency ablation (RFA) procedures for management of anomalous multiple gestations. All these procedures we now group as “fetal intervention guided by sonography” or “FIGS”. Very complicated procedures may still require laparotomy (Lap-FIGS).

Percutaneous or Micro-FIGS is used to sample or drain fetal

blood, urine, and fluid collection, to sample fetal tissue, to place catheter shunts in the fetal bladder, chest, abdomen, or ventricles, and to do RFA. The most common indication at UCSF is RFA for acardiac twins/TRAP sequence or mono-chorionic twins for selective reduction. Other operators have used bipolar coagulation or umbilical cord ligation for similar indications. Compared with the 17-gauge RFA needles that we use, these techniques are more invasive, using at least 3-mm trocars. Additionally, the length of the cord or its position may preclude use of these instruments. The perioperative management of these patients is similar to that of the current Micro-FETENDO patients. The procedures are performed under spinal anesthesia, with prophylactic antibiotics and indomethacin. Postoperative tocolysis is rarely necessary, and patients are frequently discharged within hours of the procedure. Ultrasound is critical for both the planning and the execution of the procedure (Fig. 33.2).

There are a few complicated FIGS procedures that may

Figure 33.2 Drawing of the operating room setup. Note that there are two monitors at the head of the table: one for the fetoscopic picture and the other for the real-time ultrasound image.

require maternal laparotomy to allow fetal positioning and sonography directly on the uterus (Lap-FIGS). A few simple structural cardiac defects that interfere with development may benefit from prenatal correction. For example, if obstruction of blood flow across the pulmonary or aortic valve interferes with development of the ventricles or pulmonary or systemic vasculature, relief of the anatomic obstruction may allow normal development with an improved outcome. Similarly, congenital aortic stenosis may lead to hypoplastic left heart syndrome. Stenotic aortic valves have been dilated by a balloon catheter placed using both FIGS and Lap-FIGS with

some promising results.²⁶ The procedure is technically difficult. Several centers are developing experimental techniques to correct fetal heart defects.²⁷

In summary, fetal surgery has evolved considerably since its birth at UCSF two decades ago. The indications remain quite limited, but have the potential to expand numerically as patients and providers become increasingly informed. Recent advances in the development of less invasive fetal endoscopic (FETENDO) and sonography-guided techniques (FIGS) have extended the indications for fetal intervention.

Key points

- 1 The field of open fetal surgery was created at UCSF in the early 1980s.
- 2 Only a tiny fraction of fetal malformations are considered candidates for fetal surgery.
- 3 Generally, candidate malformations are ones that would be progressive and lethal *in utero* and which, if successfully treated, would lead to a near-normal outcome.
- 4 Fetal surgery is obviously maternal–fetal surgery, as the access to the fetus is through the mother.
- 5 There are three approaches to access for the procedures: open hysterotomy, FETENDO and FIGS.
- 6 Open hysterotomy involves maternal laparotomy under general anesthesia, and at least a 5- to 10-cm uterine incision.
- 7 Postoperative management includes maximal multiple tocolytic management and decreased activity for the remainder of the pregnancy.
- 8 Following open hysterotomy, delivery in the index as well as all subsequent pregnancies must be by Cesarean section.
- 9 FETENDO involves the use of small endoscopes, either percutaneously or at minilaparotomy.
- 10 Postoperative management is less challenging because suppression of contractions is less critical.
- 11 FIGS-IT involves even smaller diameter instruments, and patients often require prophylactic preoperative tocolytics only.
- 12 All fetal surgical procedures significantly increase the risk of premature rupture of membranes and premature delivery.
- 13 Currently, the most common procedure performed at open hysterotomy is fetal meningomyelocele repair.
- 14 There is some evidence that fetal repair reduces the rate of shunt placement. This is currently being studied in an NIH-funded randomized trial.
- 15 Hysterotomy is used to access the fetus for resection of chest masses and congenital tumors that have led to hydrops.
- 16 FETENDO is used for placement of intratracheal balloons to create lung growth in cases of congenital diaphragmatic hernia, treatment of the placental surface vessels leading to twin–twin transfusion syndrome, for releasing amniotic bands, and to perform fetal cystoscopy and antegrade disruption of posterior urethral valves.
- 17 FIGS-IT is used for ablation of vascular communications in acardiac twins (TRAP sequence), shunt placements, and fetal blood sampling and intrauterine transfusions.
- 18 All fetal surgical procedures depend on ultrasound and fetal magnetic resonance imaging for identification of the fetal malformation and determining the need for surgical intervention.
- 19 Fetal surgery of any sort requires a multidisciplinary team of experts, as it is as important to know when not to do a procedure as it is to know when to do it.
- 20 Maternal safety always has to be of paramount importance.

Fetal medical treatment

*Mark I. Evans, Yuval Yaron, Charles S. Kleinman,
and Alan W. Flake*

Over the past three decades, numerous methods for the diagnosis of structural and physiologic fetal abnormalities have been developed.^{1,2} When severe or lethal, pregnancy termination is viewed by many as reasonable. In countries that permit its availability and in cultures in which the fetus does not have more rights than the mother, a variable portion of patients chose this option.^{3,4} With more moderate fetal anomalies, obstetric care can sometimes be modified to optimize outcomes and prevent secondary complications. In some instances, prenatal therapy of the underlying problem has emerged. In general, structural malformations are more logically approached with surgery, while metabolic disorders may benefit from pharmacologic or genetic therapies.²

The role of fetal therapy is still misunderstood, even four decades since the first transfusions by Lilley. If something can be treated safely postnatally, then there is generally no justification for prenatal intervention. However, profound and irreparable damage occurs for many conditions before birth, making fetal intervention the best or sometimes the only way to ameliorate the damage (Table 34.1). Fetal therapy has evolved using three major approaches: surgery, pharmacologic therapy, and stem cell/gene therapy. Other chapters will discuss the surgical approaches.

Pharmacologic therapies

Neural tube defects

Neural tube defects (NTDs) result from abnormal closure of the neural tube, which normally occurs between the third and fourth week of gestation. The etiology is complex and includes genetic and environmental factors. Historical data in humans suggest increased NTD frequencies in populations with poor dietary histories or with intestinal bypasses. Analysis of recurrence patterns within families and of twin–twin concordance data provides evidence of a genetic influence in nonsyndromal cases. However, factors such as socioeconomic status, geographic area, occupational exposure, and maternal use of antiepileptic drugs are also associated with variations in the

incidence of NTDs.⁵ Smithells et al.⁶ suggested that vitamin supplementation containing 0.36 mg of folate could reduce the frequency of NTD recurrence by sevenfold.^{5–7} In 1991, a randomized, double-blinded trial designed by the MRC Vitamin Study Research Group demonstrated that preconceptional folate reduces the risk of recurrence in high-risk patients.⁸ Subsequently, it was shown that preparations containing folate and other vitamins also reduce the occurrence of first-time NTDs.⁸ In response to these findings, guidelines were issued calling for the consumption of 4.0 mg/day folic acid by women with a previous child affected with a NTD, for at least 1 month prior to conception through the first 3 months of pregnancy. In addition, 0.4 mg/day folic acid is recommended to all women planning a pregnancy, to be taken preconceptionally. The data on NTD recurrence prevention are now very well established, and have become routine for high-risk cases. Since January 1998, the United States Food and Drug Administration mandated the supplementation of breads and grains with folic acid. NTD birth prevalence during the years 1990–1999, evaluated by assessing birth certificate reports before and after mandatory fortification, decreased by 19%.⁹ Recently, Evans et al.¹⁰ have shown a nearly 30% drop in high maternal serum alpha-fetoprotein (MSAFP) values in the United States when comparing 2000 values with 1997 values, before the introduction of folic acid supplementation.

Folate plays a central part in embryonic and fetal development because of its role in nucleic acid synthesis, which is mandatory for the widespread cell division that takes place during embryogenesis. Folate deficiency can occur because of low dietary folate intake or because of increased metabolic requirements, as seen in particular genetic alternations such as polymorphism of the thermolabile enzyme methyltetrahydrofolate reductase (MTHFR). However, evidence regarding its role in NTDs is unsupported, except in certain populations, suggesting that these variants are not large contributors to the etiology of NTDs.^{11,12} Additional candidate genes other than MTHFR may be responsible for an increased risk of NTDs.¹³ Methionine synthase (MTR) polymorphism is associated with an increased risk of NTDs that is not influenced by maternal

preconception folic acid intake at doses of 0.4 mg/day.¹⁴ Other candidate genes include the mitochondrial membrane transporter gene UCP2.⁵² Despite previous studies suggesting that zinc deficiency plays a role in the etiology of NTDs,^{16,17} further studies found that this observation was inconclusive.^{18,19} Because methionine deficiency may be involved in NTDs, it may be beneficial in NTD risk reduction.²⁰ In conclusion, preconception folic acid intake, either as a sole vitamin or as part of multivitamin supplementation, reduces the risk of recurrence and first-time NTDs.

The traditional dogma that the pathogenesis of meningocele was secondary to an abnormally developed spinal cord, which did not, in turn, engender the proper development of the bony spinal column, may not be the whole story. It is possible that the primary defect is in the bony spinal column, which exposes a presumptively undamaged spinal cord. The cord is then damaged by the toxic affects of amniotic fluid, trauma from the uterine environment, and repeated contact with the uterine wall. Thus came the rationale for attempts to cover and protect the spinal cord *in utero*, to minimize the sequelae.²¹

β2-microglobulin	< 6 mg/L
Total protein	< 40 mg/dL

Endocrine disorders

Adrenal disorders: congenital adrenal hyperplasia

Congenital adrenal hyperplasia (CAH) is actually a group of autosomal recessive metabolic disorders, characterized by enzymatic defects in the steroidogenetic pathway.²² A compensatory increase in adrenocorticotrophic hormone (ACTH) secretion leads to overproduction of the steroid precursors in the adrenal cortex, resulting in adrenal hyperplasia. Excess precursors are often converted to androgens, which may result in virilization of female fetuses. The phenotype is determined by the severity of the cortisol deficiency and the nature of the steroid precursors, which accumulate proximal to the enzymatic block. The most common abnormality, responsible for > 90% of patients with CAH, is caused by a deficiency in the 21-hydroxylase (21-OH) enzyme. Other, less common causes of CAH include deficiencies in 11 β -hydroxylase and 17 α -hydroxylase. Reduced 21-OH activity results in the accumulation of 17-hydroxyprogesterone (17-OHP) because of its decreased conversion to 11-deoxycorticosterone. Excess 17-OHP is then converted via androstenedione to androgens, the levels of which can increase by as much as several hundred-fold (Fig. 34.1). Excess androgens produce virilization of the undifferentiated female external genitalia, which may vary from mild clitoral hypertrophy to the complete formation of a phallus and scrotum. In contrast, genital development in male fetuses is normal. The excess androgens cause postnatal virilization in both genders and may manifest in precocious puberty.²² A severe enzyme deficiency or even a complete block of enzymatic activity produces the “classical” form of CAH. Two-thirds to three-quarters of cases have salt loss that may be life-threatening.

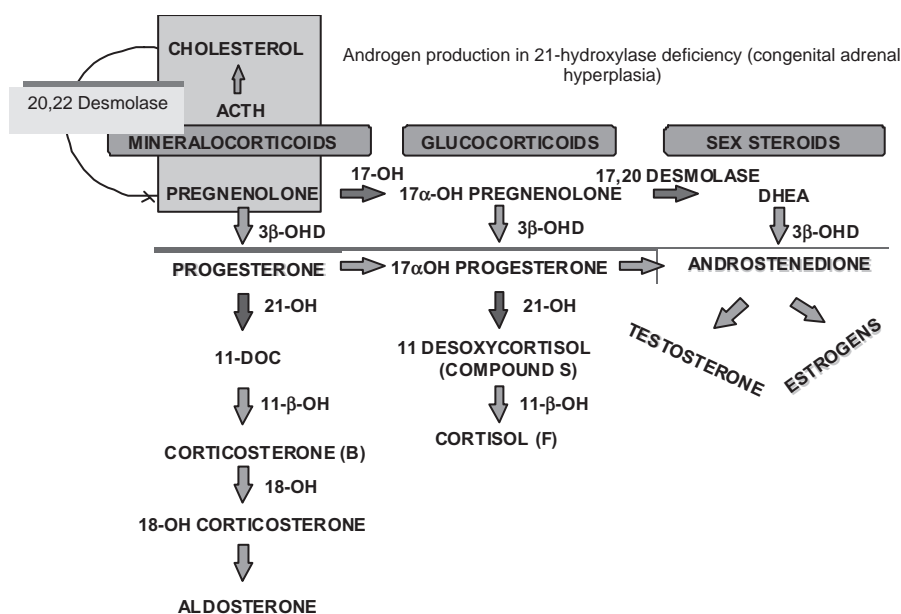

Figure 34.1 Steroidogenic pathway. Pathway of conversion from cholesterol to cortisol is vulnerable to enzymatic errors. Blockage at 21-hydroxylase (21-OH) leads to overproduction of 17-hydroxyprogesterone, which ultimately leads to excess androgens that produce masculinization of the external genitalia.

The classical form is easy to recognize in female newborns but may be overlooked in males, who may appear with severe dehydration and even demise. In the late 1970s and early 1980s, diagnosis of CAH could be made on amniocentesis by the finding of elevated levels of 17-OHP in the supernatant. In the 1980s, with the development of chorionic villus sampling (CVS), linkage-based molecular diagnosis became available in the first trimester, as the gene for 21-OH was found to be linked to the human leukocyte antigen (HLA) complex on chromosome 6.²³ The gene for 21-OH (*CYP21B*) was later mapped, allowing direct mutation analysis in informative families.²⁴

We have known for two decades that the fetal adrenal gland can be pharmacologically suppressed by maternal replacement doses of dexamethasone.²⁵ Suppression can prevent masculinization of affected female fetuses in couples who are carriers of classical CAH. Evans et al.²⁵ were the first to administer dexamethasone to a carrier mother beginning at 10 weeks of gestation in an attempt to prevent masculinization. Differentiation of the external genitalia begins at about 7 weeks of gestation. Thus, for a carrier couple, pharmacologic therapy has to be initiated prior to diagnosis. Direct DNA diagnosis or linkage studies are then performed by CVS in the first trimester, and therapy is continued only if the fetus is found to be an affected female. Detailed inclusion criteria for treatment have been issued by the European Society for Pediatric Endocrinology and Wilkins Pediatric Endocrine Society.²⁶ Hundreds of fetuses have been successfully treated resulting in prevention or amelioration of masculinization.^{26–28}

Hyperthyroidism

Neonatal hyperthyroidism is rare with an incidence of 1:4000 to 1:40 000 live births.²⁹ Fetal thyrotoxic goiter is usually secondary to maternal autoimmune disease, most commonly Graves' disease or Hashimoto's thyroiditis. As many as 12% of infants of mothers with a known history of Graves' disease are affected with neonatal thyrotoxicosis, which can occur even if the mother is euthyroid.³⁰ The underlying mechanism is the transplacental passage of maternal IgG antibodies. The antibodies, known as TSAb (or TSI), are predominantly directed against the thyroid-stimulating hormone (TSH) receptor. Often, fetal goiter is diagnosed on ultrasound in patients with elevated thyroid-stimulating antibodies. In some cases, fetal goiters are incidentally detected on routine ultrasonography. Others may be discovered in patients referred for a scan because of polyhydramnios. Untreated fetal hyperthyroidism may be associated with a mortality rate of 12–25% due to high-output cardiac failure.³⁰

Once the diagnosis of fetal hyperthyroidism is confirmed, fetal treatment should be initiated. Authors have attempted to treat fetal hyperthyroidism with maternally administered antithyroid drugs. Porreco and Bloch³¹ have reported maternal treatment of fetal thyrotoxicosis with PTU, which had a

good outcome. The initial dose used was 100mg p.o. three times a day, which was later decreased to 50mg p.o. three times a day. A favorable outcome was shown using maternal methimazole to treat fetal hyperthyroidism in a patient who could not tolerate PTU.³² Hatjis³² also treated fetal goiterous hyperthyroidism with a maternal dose of 300mg of PTU. This patient however, required supplemental synthroid to remain euthyroid. There was good fetal outcome in this case as well.

Hypothyroidism

Congenital hypothyroidism is relatively rare, affecting about 1:3000 to 1:4000 infants.³³ About 85% of cases are the result of thyroid dysgenesis, a heterogeneous group of developmental defects characterized by inadequate amounts of thyroid tissue. Congenital hypothyroidism is only rarely associated with errors of thyroid hormone synthesis, TSH insensitivity, or absence of the pituitary gland. Fetal hypothyroidism may not necessarily manifest in a goiter before birth, as maternal thyroid hormones may cross the placenta. Congenital hypothyroidism presenting with a goiter is found in only about 10–15% of cases.³⁴

Fetal goiterous hypothyroidism usually follows maternal exposure to thyrostatic agents such as propylthiouracil (PTU), radioactive ¹³¹I or iodide exposure used to treat maternal hyperthyroidism.³⁵ Maternal ingestion of amiodarone or lithium may also cause hypothyroidism in the fetus. Finally, fetal hypothyroidism may follow transplacental passage of maternal blocking antibodies (known as TBIAb or TBII). Rarely, it may be due to rare defects in fetal thyroid hormone biosynthesis.²⁹

An enlarged fetal goiter may cause esophageal obstruction and polyhydramnios, leading to preterm delivery or premature rupture of membranes. Rarely, a goiter may even lead to high-output heart failure.³⁵ A large fetal goiter can also cause extension of the fetal neck, leading to dystocia. The effects of the fetal hypothyroidism itself may be devastating. Without treatment, postnatal growth delay and severe mental retardation may ensue. Even with immediate diagnosis and treatment at birth, long-term follow-up of children with congenital hypothyroidism has demonstrated that they have lower scores on perceptual-motor, visuospatial, and language tests.³⁶

Inborn errors of metabolism

Methylmalonic acidemia

The methylmalonic acidemias (MMA) are a group of autosomal recessive enzyme deficiency diseases. Some cases are caused by mutations in the gene encoding methylmalonyl-coenzyme A mutase. Others are secondary to a defect that reduces the biosynthesis of adenosylcobalamin from vitamin B12. The disease has a wide clinical spectrum ranging from benign to fatal, characterized by severe metabolic acidosis, developmental delay, and biochemical abnormalities that include methylmalonic aciduria,

long-chain ketonuria, and intermittent hyperglycinemia. Neurologic abnormalities may result from diminution of myelin content and of ganglioside N-acetylneuraminic acid in the cerebrum.³⁷ Patients with defects in adenosylcobalamin biosynthesis may respond to administration of large doses of vitamin B12, which may enhance the amount of active holoenzyme (mutase apoenzyme plus adenosylcobalamin).

Ampola et al.³⁸ first attempted prenatal diagnosis and treatment of a vitamin B12-responsive variant of MMA. Their patient had previously had a child who died of severe MMA. It is not clear whether *in utero* treatment actually resulted in an improved outcome, but it is likely that correction of the biochemical abnormality in the fetus had some beneficial effect on fetal development. Indeed, in a cohort of eight children with MMA, Andersson et al.³⁹ described congenital malformations, probably caused by prenatally abnormal cyanocobalamin metabolism. Growth was significantly improved in most cases after initiation of therapy postnatally and, in one case, microcephaly resolved. However, developmental delay of variable severity was always present regardless of treatment onset. These data suggest that prenatal therapy of MMA may be effective and may perhaps ameliorate some of the prenatal effects. Evans et al.⁴⁰ have documented the changing dose requirements necessary over the course of pregnancy to maintain adequate levels of vitamin B12. They sequentially followed maternal plasma and urine levels in a prenatally treated pregnancy.

Multiple carboxylase deficiency

Biotin-responsive multiple carboxylase deficiency is an inborn error of metabolism caused by diminished activity of the mitochondrial biotin-dependent enzymes (pyruvate carboxylase, propionyl-coenzyme A carboxylase, and α -methylcrotonyl-coenzyme A carboxylase). The condition may arise from mutations in the holocarboxylase synthetase gene or the biotinidase gene.^{41–45} Affected patients present with dermatitis, severe metabolic acidosis, and a characteristic pattern of organic acid excretion. Metabolism can be restored toward normal levels by biotin supplementation. Prenatal diagnosis is based on the demonstration of elevated levels of typical organic acids (3-hydroxyisovalerate, methylcitrate) in the amniotic fluid or in the chorionic villi. However, the existence of a mild form of holocarboxylase synthetase gene deficiency can complicate prenatal diagnosis as organic acid levels in amniotic fluid might be normal.⁴⁶ Therefore, prenatal diagnosis must be performed by enzyme assay of cultured fetal cells in biotin-restricted medium.

Roth et al.⁴⁷ treated a fetus whose two previous siblings died of multiple carboxylase deficiency. The mother was first seen at 34 weeks' gestation, and prenatal diagnosis was not performed. Oral administration of biotin was begun at a dose of 10 mg/day. There were no apparent untoward effects. Maternal urinary biotin excretion increased by 100-fold and nonidentical twins were delivered at term. Cord blood

and urinary organic acid profiles were normal, and cord blood biotin concentrations were four to seven times greater than normal. The neonatal course for both twins was unremarkable. Other cases of such treatment have been reported.^{46,48,49}

Smith–Lemli–Opitz syndrome

Smith–Lemli–Opitz syndrome (SLOS) is an autosomal recessive disorder characterized by multiple anomalies, dysmorphic features, growth and mental retardation. Males with SLOS have ambiguous genitalia.⁵⁰ The severe form is associated with a high rate of neonatal mortality.⁵¹ The incidence of SLOS is estimated to be 1:20 000 to 1:40 000 live births with an estimated carrier frequency of 1:70.^{52,53} SLOS is caused by an inborn error of cholesterol biosynthesis due to a deficiency in the enzyme dehydrocholesterol- Δ^7 reductase, leading to reduced cholesterol levels and elevated 7- and 8-dehydrocholesterol levels (7-DHC and 8-DHC respectively) in all body fluids and tissues including amniotic fluid and chorionic villi.^{52,54,55} The diagnosis is based on elevated levels of 7-DHC (100 to 1000 times the normal value). Clinical manifestations correlate with cholesterol levels. Prenatal diagnosis of SLOS has been available since 1994 by either amniocentesis or CVS.^{56–58}

Since the identification of the cholesterol metabolic defect in SLOS, a treatment protocol to provide exogenous cholesterol has been attempted. This form of therapy has now been provided to many patients with SLOS for several years in many centers in the United States and internationally,^{56–58} with the goal of raising cholesterol levels and decreasing the levels of the precursors, 7-DHC and 8-DHC. Treatment has been attempted antenatally in several affected fetuses. In cases in which treatment was started late in pregnancy, the results were inconclusive. Although few descriptions of fetal therapy for SLOS exist, the latest report of antenatal treatment comes from that same group of investigators.⁶²

Galactosemia

Galactosemia is an autosomal recessive disorder caused by decreased activity of galactose-1-phosphate uridylyltransferase (GALT). Clinical manifestations include cataracts, growth deficiency, and ovarian failure. Clinical symptoms appear in the neonatal period and can be largely ameliorated by elimination of galactose from the diet. Cellular damage in galactosemia is thought to be mediated by the accumulation of galactose-1-phosphate intracellularly and of galactitol in the lens. Several disease-causing mutations in the *GALT* gene have been reported in classical galactosemia.⁶³ Galactosemia can also be diagnosed prenatally by biochemical studies of cultured amniocytes and chorionic villi.

Even the early postnatal treatment of galactosemic individuals with a low galactose diet may not be sufficient to ensure normal development. Some have speculated that prenatal damage to galactosemic fetuses could contribute to subsequent abnormal neurologic development and to lens cataract for-

mation. Furthermore, it has been recognized that female galactosemics, even when treated from birth with galactose deprivation, have a high frequency of primary or secondary amenorrhea because of ovarian failure. Oocytes are probably irreversibly damaged long before birth.^{64,65} There may also be some subtle abnormalities of male gonadal function as well. Thus, galactose restriction during pregnancy may be beneficial in affected fetuses. In humans, ovarian meiosis begins at 12 weeks, and ovarian damage may occur prior to prenatal diagnosis. Thus, anticipatory treatment in pregnancies at risk of having a galactosemic fetus might be best initiated very early in gestation or even preconceptually. We are unaware of studies that adequately assess the impact of prenatal administration of a low-galactose diet to galactosemic infants. Nevertheless, prenatal galactose restriction is probably desirable in galactosemia and should be harmless.

***In utero* cardiac therapy**

The ability to diagnose structural or functional heart disease prenatally has, predictably, led to a growth of interest in the potential for prenatal therapy. It is, of course, necessary to identify fetal conditions that, if left untreated, will result in fetal death, or compromised conditions that will render the neonate in a condition that will result in a lower likelihood of cure or functional survival than would be the case if the fetus were to undergo the proposed therapy. It is essential, of course, to consider the potential risks to both the mother and the fetus, whose states of well-being are inextricably interwoven.

Fetal antiarrhythmic therapy has evolved in a more invasive direction over the past decades, including injection of medication directly into the amniotic fluid, intramuscular administration of medication directly to the fetus, and direct, repetitive administration of intravenous medication through the fetal umbilical vein.⁶⁶⁻⁷⁰

Direct instrumentation of the fetal heart was initially attempted in an effort to institute "transcatheter" pacing of a moribund fetus with congenital complete heart block and hydrops fetalis.⁷¹ Subsequently, there have been several reports of attempted catheter treatment of congenital cardiac malformations, with varied success. Several centers have investigated techniques for the institution of surface cooling and rewarming, and for the provision of cardiopulmonary bypass in fetal animal models.^{72,73}

Fetal antiarrhythmic therapy

The fetus with tachycardia

The administration of antiarrhythmic therapy to the mothers of fetuses with sustained supraventricular tachycardia represented the first examples of successful prenatal cardiac therapy that were reported in the medical literature.

The most commonly encountered sustained fetal tachy-

cardia, supraventricular tachycardia, is most frequently (90-95%) a result of electrical "re-entry" at the atrioventricular junction, usually by way of an accessory connection between the atrial and ventricular myocardium, and less frequently via the atrioventricular node itself.^{66,67,74,75} Supraventricular tachycardia resulting from electrical macro re-entry circuits typically presents with a monotonous fetal heart rate of 240-260 beats per minute (b.p.m.), and is usually exquisitely sensitive to treatment with antiarrhythmic agents that alter conduction velocity and/or refractoriness of the atrioventricular node or accessory pathways. Such agents include digoxin, propranolol, flecainide, and sotalol, among others. Multiple publications have described treatment protocols for this arrhythmia. Our group has approached these patients in a conservative fashion, reserving treatment for fetuses that appear to have no reasonable alternative. The characteristics that identify such patients are the development of hydrops fetalis in the face of sustained arrhythmia, at a gestational age that is early enough to preclude safe delivery and postnatal treatment. In such cases, we begin therapy with medications that have a relatively broad therapeutic margin, with a low risk of proarrhythmia (unwanted precipitation or exacerbation of arrhythmia) in the fetus or pregnant woman.^{76,77}

The fetus with bradycardia

The most important sustained bradyarrhythmia is congenital complete heart block. Such fetuses may develop hydrops fetalis, which may occur in the subgroup of fetuses with associated congenital heart disease. The association of clinical heart failure with congenital heart block, with or without congenital heart disease, represents an absolute indication for electrical pacemaker therapy in the neonate.⁷⁸

Hydrops fetalis in the presence of complete heart block *in utero* is a dire finding. The association of hydrops fetalis, complete heart block, and complex congenital heart disease is almost invariably fatal, with or without fetal therapy.⁷⁹

The initial report of the application of electrical pacemaker therapy for fetal congenital heart block involved a fetus presenting with congenital heart block in the absence of congenital heart disease.⁸⁰ This fetus, with heart block presumably arising on the basis of immune complex-mediated damage to fetal conduction tissue and myocardium, presented with severe bradycardia and hydrops fetalis. In desperation, the treating physicians placed a pacing catheter within the fetal heart via percutaneous puncture of the maternal abdomen, uterus, and fetal thorax and ventricular wall. Fetal ventricular capture was demonstrated, without clinical improvement in the fetus. Subsequent attempts to utilize similar techniques had similarly discouraging outcomes.

Copel et al.⁸¹ reported a preliminary experience with the administration of absorbable corticosteroid to pregnant women whose fetuses have developed high-grade, second-degree or recent-onset, third-degree heart block in the

presence of high maternal titers of anti-SS-A and/or anti-SS-B antibodies. In this small subgroup of patients, there was demonstrable improvement in atrioventricular conduction that was attributed to amelioration of the immune-mediated inflammatory response of the fetal atrioventricular conduction tissue. This report has spawned a multicenter study designed to evaluate the impact of maternally administered corticosteroid on echocardiographically estimated fetal atrioventricular conduction intervals in a population of fetuses whose mothers have high anti-SS-A or anti-SS-B antibodies.⁸²

Medical treatment of congestive heart failure in the fetus

The medical literature is replete with anecdotal reports of the administration of digoxin to pregnant women whose fetuses have evidence of impaired cardiac pump function. These have included cases in which structural heart disease (e.g., aortic stenosis) is associated with ventricular dysfunction and hydrops fetalis, and in whom the initiation of digoxin therapy is temporally associated with improved ventricular shortening and resolution of hydrops fetalis, with subsequent postnatal salvage of the child.^{83,84} We have had similar personal experiences with two fetuses with similar presentation of hydrops fetalis and aortic stenosis. In addition, we have witnessed a close temporal association between the initiation of maternally administered digoxin and improved ventricular shortening and resolution of hydrops fetalis in several fetal patients who were presumed to have viral myocarditis, with viruses such as adenovirus, parvovirus, and coxsackievirus. In these cases, fetomaternal infection with the virus has been confirmed by analysis of maternal and fetal blood and amniotic fluid using the polymerase chain reaction (PCR). In two fetuses who showed an initial improvement, with eventual neonatal demise, the adenoviral genome was detected by PCR analysis of the infant's myocardial tissue. We have also recently demonstrated improved myocardial shortening and improved right ventricular dP/dT (calculated from the tricuspid regurgitant flow waveform) in two fetuses with progressively dilating right ventricles,⁸⁵ progressive tricuspid regurgitation and abnormal inferior vena caval flow waveforms, in the face of large hemangiomas with significant arteriovenous shunting. The findings of cardiomegaly, tricuspid regurgitation, and abnormal venous Doppler in the vena cavae were quite similar to those described by Tulzer and colleagues⁸⁶ in justification of the invasive pulmonary balloon valvuloplasties of two fetuses with pulmonary stenosis/atresia. We have also recently employed digoxin to empirically treat a fetus with severe dilated cardiomyopathy and marked cardiomegaly, bilateral atrioventricular valve regurgitation, and abnormal venous pulsatility, and demonstrated a remarkable improvement in biventricular shortening, partial amelioration of atrioventricular valve regurgitation, and improved biventricular dP/dT. This fetus survived pregnancy and delivery, and ultimately underwent successful cardiac transplantation, only to be

diagnosed with an electron transport defect that was not identifiable in the studies performed on skeletal muscle biopsy prior to transplant. The same enthusiasm that we have criticized in others has led us to prescribe empirical treatment, without having done our "homework" with regard to ascertaining the mechanism of action of digoxin in the fetus. On the other hand, this medication has been in use for over 200 years, and is still being administered largely on an "empiric" basis. While the popularity of this agent for the treatment of congestive heart failure waxes and wanes every few years, recent studies have suggested some rationale for its inclusion in the therapeutic arsenal. It is, however, unclear whether the salutary effects are related to Na⁺/K⁺ ATPase inhibition and enhanced calcium availability to the myofilaments, or whether alterations in catecholamine concentration/effect alter the neuroendocrine manifestations of congestive heart failure. The underlying rationale for its use remains "it works." While it is possible that some of the fetuses that we and others have observed to improve in the days following digoxin administration spontaneously recovered from the underlying pathology that caused circulatory failure, and digoxin administration was simply serendipitous, in the last case we cited above (with an electron transfer deficiency), at least, the underlying nature of the cardiomyopathy would not logically have undergone spontaneous improvement after having demonstrated severe biventricular dilated myopathy. In any event, the centuries of use of this medication, in gravid and nongravid women, convinced us that, if one monitors the mother and fetus carefully for evidence of contraindications to the administration of digoxin (ventricular pre-excitation, severe maternal hypokalemia), or for indications calling for modulation of digoxin dose [e.g., maternal renal failure or concomitant treatment with medications that alter digoxin clearance (e.g., quinidine, amiodarone)], at the very least, you are unlikely to harm either the mother or the fetus.

Interventional cardiac catheterization of the human fetus

Aortic balloon valvuloplasty

Motivated by a dismal postnatal outcome for fetuses diagnosed to have critical aortic stenosis prenatally, a group from Guy's Hospital in London embarked upon an innovative program for percutaneous cardiac catheterization and aortic balloon valvuloplasty of fetuses with this condition. The initial experience was unsuccessful, although the feasibility of percutaneous entry of the maternal abdomen, uterus, and fetal chest and left ventricle, with subsequent wire entry of the ascending aorta, passage of an angioplasty balloon catheter, and subsequent retrieval of the system,⁸⁷ was established. Ultimately, this group performed a total of four such procedures, and reported the first survivor.⁸⁸ These initial reports suggested that balloon valvuloplasty was feasible, but that the prognosis

for the fetus was dependent upon the ability to relieve aortic stenosis and to prevent or reverse damage to the left ventricular myocardium. Despite the survival of a single patient, this group declared a moratorium on such procedures until a clearer appreciation of hemodynamics and improvement in catheter technology was in place.⁸⁹

Follow-up studies from that same center, only a few years later, documented improved survival in neonates who had not undergone fetal intervention, undermining the rationale for the introduction of fetal intervention as an alternative approach to an otherwise “hopeless” condition.⁹⁰

Almost a decade later, Kohl et al.⁹¹ summarized the world experience with such techniques. This report included 12 fetuses, including the four cases from Guy’s Hospital. At the time of this review, the child from the Guy’s experience represented the sole survivor. The conclusion was that the high failure rate was related to the selection of severe cases for treatment, technical problems during the procedure, and high postnatal operative mortality among patients who survived pregnancy. The conclusion of this paper was: “Improved patient selection and technical modifications in interventional methods may hold promise to improve outcome in future cases.” This, I believe, is problematic. If one reviews this report at arm’s length, we are presented with a “world experience” that included eight attempts, at multiple centers, without a single success. In any other situation, the inability to duplicate the single success of the initial investigators would have cast a cloud of doubt over the technique, at least until a fundamental review of the technique and its indications had taken place! In this situation, the honest eagerness of the investigators to provide help for an unfortunate patient population, and their personal conviction that this technique “should” work, may have influenced their level of enthusiasm for a “therapy in search of an indication.”

Pulmonary balloon valvuloplasty

A recent report in *The Lancet*, from Tulzer and colleagues,⁸⁶ from Linz, documents the performance of pulmonary balloon valvuloplasty in two fetuses with severe right ventricular outlet obstruction (“complete” or “almost complete” pulmonary atresia), right ventricular compromise, and “imminent” hydrops fetalis. Both fetuses survived and have biventricular circulatory systems. It remains to be seen whether such therapy is justified, and whether these fetuses survived “because of,” rather than “in spite of” what was done for (to) them.

Prenatal hematopoietic stem cell (HSC) transplantation

The engraftment and clonal proliferation of a relatively small number of normal HSCs can sustain normal hematopoiesis for a lifetime. This observation provides the compelling rationale for bone marrow transplantation (BMT) and is now supported

by thousands of long-term survivors of BMT who would otherwise have succumbed to lethal hematologic disease.^{92–94} Realization of the full potential of BMT, however, continues to be limited by a critical shortage of immunologically compatible donor cells, the inability to control the recipient or donor immune response, and the requirement for recipient myeloablation to achieve engraftment. The price of HLA mismatch remains high: the greater the mismatch, the higher the incidence of graft failure, graft-versus-host disease (GVHD), and delayed immunologic reconstitution. Current methods of myeloablation have high morbidity and mortality rates. In combination, these problems remain prohibitive for most patients who might benefit from BMT. A theoretically attractive alternative, which can potentially address many of the limitations of BMT, is *in utero* transplantation of HSCs.⁹⁵ This approach is potentially applicable to any congenital hematopoietic disease that can be diagnosed prenatally and can be cured or improved by engraftment of normal HSCs.

Rationale for *in utero* transplantation

The rationale for *in utero* transplantation is to take advantage of the window of opportunity created by normal hematopoietic and immunologic ontogeny. There is a period, prior to population of the bone marrow and thymic processing of self-antigen, when the fetus should theoretically be receptive to engraftment of foreign HSCs without rejection and without the need for myeloablation. In the human fetus, the ideal window would appear to be prior to 14 weeks’ gestation, before the release of differentiated T lymphocytes into the circulation and while the bone marrow is just beginning to develop sites for hematopoiesis.⁹⁵ It may certainly extend beyond that in immunodeficiency states, particularly when T-cell development is abnormal. During this time, presentation of foreign antigen by thymic dendritic cells should theoretically result in clonal deletion of reactive T cells during the negative selection phase of thymic processing. Recent advances in prenatal diagnosis have made possible the diagnosis of a large number of congenital hematologic diseases during the first trimester. Technical advances in fetal intervention make transplantation feasible by 12–14 weeks’ gestation. The ontologic window of opportunity falls well within these diagnostic and technical constraints, making the application of this approach a realistic possibility.

Because of the unique fetal environment, prenatal HSC transplantation could theoretically avoid many of the current limitations of postnatal BMT. There would be no requirement for HLA matching, resulting in expansion of the donor pool. Transplanted cells would not be rejected, and space would be available in the bone marrow, eliminating the need for toxic immunosuppressive and myeloablative drugs. The mother’s uterus may ultimately prove to be the ultimate sterile isolation chamber, eliminating the high risk and costly 2–4 months of isolation required after postnatal BMT

prior to immunologic reconstitution. Finally, prenatal transplantation would pre-empt the clinical manifestations of the disease, avoiding the recurrent infections, multiple transfusions, growth delay, and other complications that cause immeasurable suffering for the patient and often compromise postnatal treatment.

Source of donor cells

Identifying the best source of donor cells may ultimately prove to be the most critical factor for the success of engraftment. The most obvious advantage of the use of fetal HSCs is the minimal number of mature T cells in fetal liver-derived populations prior to 14 weeks' gestation. This alleviates any concern about GVHD and avoids the necessity of T-cell depletion processes, which can negatively impact on potential engraftment.^{95,96} The disadvantages of the use of fetal or embryonic tissue relates to availability and quality control, as well as the perceived ethical issues of some groups regarding the use of fetal tissue. Perhaps a more important limitation to the use of fetal tissues is the limited quantity available, and the inability to obtain more cells for donor-specific, tolerance-based, postnatal strategies. At the present time, these issues remain prohibitive in the United States, limiting the investigation and use of potentially efficacious donor sources.

Diseases amenable to prenatal treatment

Generally speaking, any disease that can be diagnosed early in gestation, that is improved by BMT, and for which postnatal treatment is not entirely satisfactory is a target disease. Some diseases, however, are far more likely to benefit from prenatal transplantation than others. The list can be divided into three general categories: hemoglobinopathies, immunodeficiency disorders, and inborn errors of metabolism. Each of the diseases has unique considerations for treatment and, in fact, each disease may respond differently (Table 34.2). Issues such as availability of engraftment sites within the bone marrow at time of transplantation, and the capacity of a needed enzyme to cross the blood–brain barrier at a particular gestational age must be considered. Of particular relevance to the prenatal approach, in which experimental levels of engraftment have been relatively low, is the observation that, in many of the target diseases, engrafted normal cells would be predicted to have a significant survival advantage over diseased cells. This would have the clinical effect of amplification of the specific lineage with the survival advantage. In addition, even with minimal levels of engraftment, specific tolerance for donor antigen should be induced, allowing additional cells from the same donor to be given to the tolerant recipient after birth.^{97,98}

Hemoglobinopathies

The sickle cell anemia and thalassemia syndromes make up the largest patient groups potentially treatable by prenatal stem cell transplantation.^{99–102} Both groups can be diagnosed within the

Table 34.2 Potential candidates for *in utero* stem cell fetal therapy.

Hematopoietic disorders

- Disorders affecting lymphocytes
 - SCID (sex linked)
 - SCID (adenosine deaminase deficiency)
 - Ommen syndrome
 - Agammaglobinemia
 - Bare lymphocyte syndrome
- Disorders affecting granulocytes
 - Chronic granulomatous disease
 - Infantile agranulocytosis
 - Neutrophil membrane GP-180
 - Lazy leukocyte syndrome
- Disorders affecting erythrocytes
 - Sickle-cell disease
 - α-Thalassemia
 - β-Thalassemia
 - Hereditary spherocytosis
 - Fanconi anemia
- Mannosidosis
 - α-Mannosidosis
 - β-Thalassemia
- Mucopolidoses
 - Gaucher's disease
 - Metachromatic leukodystrophy
 - Krabbe disease
 - Niemann–Pick disease
 - β-Glucuronidase deficiency
 - Fabry disease
 - Adrenal leukodystrophy
- Mucopolysaccharidoses
 - MPS I (Hurler's disease)
 - MPS II (Hunter's disease)
 - MPS IIIB (Sanfilippo B syndrome)
 - MPS IV (Morquio syndrome)
 - MPS VI (Maroteaux–Lamy syndrome)

SCID, severe combined immunodeficiency.

first trimester. Both have been cured by postnatal BMT, but BMT is not recommended routinely because of its prohibitive morbidity and mortality rates, and the relative success of modern medical management. In both diseases, the success of BMT is indirectly related to the morbidity of the disease, that is, the younger the patient, the fewer transfusions received, and the less organ compromise from iron overload, the better the results. In both disorders, there is a survival advantage for normal erythrocytes, which results in amplification of the level of bone marrow engraftment in the peripheral red cell compartment. Thus, patients with relatively low levels of mixed chimerism after postnatal BMT have demonstrated high levels of normal hemoglobin peripherally with partial or complete amelioration of their disease.^{92,93} Experimentally, this has been shown to be the case after *in utero* transplantation as well, with relatively high levels of circulating donor-derived erythrocytes despite low levels of mixed chimerism in the bone

marrow.¹⁰³ This observation, in combination with the observation that engraftment can be enhanced after birth using nonmyeloablative approaches in the tolerant recipient,^{97,98} makes it likely that hemoglobinopathies will be successfully treated by *in utero* transplantation in the future.

Immunodeficiency diseases

These represent an extremely heterogeneous group of diseases, which differ in their likelihood of cure by their capacity to develop hematopoietic chimerism.^{104,105} Once again, the most likely to benefit from even low levels of donor cell engraftment are those diseases in which a survival advantage exists for normal cells. The best example of this situation is severe combined immunodeficiency (SCID) syndrome. Several different molecular causes of SCID have been identified, with approximately two-thirds of cases being of X-linked recessive inheritance (X-SCID). The genetic basis of X-SCID has been defined¹⁰⁶ as a mutation of the gene encoding the common γ chain (γ c), which is a common component of several members of the cytokine receptor superfamily. Children affected with X-SCID have a block in thymic T-cell development and diminished T-cell response. B cells, although present in normal or even increased numbers, are dysfunctional, either secondary to the lack of helper T-cell function or an intrinsic defect in B-cell maturation. Clinical experience with HLA-matched sibling bone marrow, fetal liver, or thymus transplantation has generally been successful without myeloablative therapy, suggesting that the lymphoid progeny of relatively few engrafted normal HSCs have a selective growth advantage *in vivo* over genetically defective cells.¹⁰⁷ The competitive advantage of normal cell populations in X-SCID is best supported by the discovery of skewed X-inactivation in female carriers.¹⁰⁸ Only T cells containing the normal X chromosome were found to be present in the circulation of carriers. Other characterized mutations in cytokine receptor signaling pathways (i.e., Jak 3 or ZAP-70), or adenosine deaminase deficiency, resulting in SCID, should also be favorable candidate diseases for *in utero* HSC transplantation. Based on the available clinical and experimental evidence, it is likely that any member of this group of disorders can be treated effectively by *in utero* HSC transplantation, using established protocols, with results comparable to the reported results for X-SCID. Ideally, clinical trials of *in utero* treatment for SCID would be established, and the results compared with early postnatal transplantation protocols, to determine whether there is a biologic advantage favoring *in utero* therapy. Unfortunately, such trials may not be possible because of the rarity of these diseases and the perception that postnatal therapy is adequate.¹⁰⁸ Unfortunately, other diseases such as chronic granulomatous disease would not be expected to provide a competitive advantage for donor cells. Nevertheless, in all these conditions, even a partial engraftment and expression of normal cell phenotype might at least partially ameliorate the clinical manifestations of the disease, and

should result in donor-specific tolerance for later transplantation. If higher levels of engraftment are needed, further HSC transplants from the same donor could be performed after birth without fear of rejection.

Flake et al.¹⁰⁹ reported the successful treatment of a fetus with X-linked SCID in a family in which a previously afflicted child died at 7 months of age. Diagnosis by CVS at 12 weeks in the second pregnancy showed another affected male. For this couple, abortion was not an option. After lengthy informed consent, paternal bone marrow was harvested, T cells depleted, and enriched stem-cell populations injected intraperitoneally into the fetus beginning at about 16 weeks of gestation. Subsequent injections were performed at 17 and 18 weeks. The child presently shows a split chimerism with all of his T cells being derived from his father's and the majority of B cells being his own. He has achieved normal developmental milestones, and has had no serious infections through 10 years of age.¹¹⁰ Additional cases have now been reported by Porta et al.¹¹¹ and Westgren et al.¹¹² with similarly favorable results.

Inborn errors of metabolism

An even more heterogeneous group of diseases, inborn errors of metabolism, can be caused by a deficiency in a specific lysosomal hydrolase, which results in the accumulation of substrates such as mucopolysaccharide, glycogen, or sphingolipid.¹¹³ Depending on the specific enzyme abnormality and the compounds that accumulate, certain patterns of tissue damage and organ failure occur. These include central nervous system (CNS) deterioration, growth failure, dysostosis multiplex and joint abnormalities, hepatosplenomegaly, myocardial or cardiac disease, upper airway obstruction, pulmonary infiltration, corneal clouding, and hearing loss. The potential efficacy of prenatal HSC transplantation for the treatment of these diseases must be considered on an individual disease basis. The purpose of BMT in these diseases is to provide HSC-derived mononuclear cells that can repopulate various organs in the body, including the liver (Kupffer cells), skin (Langerhans cells), lung (alveolar macrophages), spleen (macrophages), lymph nodes, tonsils, and the brain (microglia).¹¹⁴ Patients whose conditions have been corrected by postnatal BMT, such as Gaucher's disease or Maroteaux-Lamy syndrome (minimal CNS involvement), are certainly reasonable candidates for prenatal treatment. In many cases, postnatal BMT has corrected the peripheral manifestations of the disease and has arrested the neurologic deterioration. However, postnatal BMT has not reversed neurologic injury that is present in such disorders as metachromatic leukodystrophy and Hurler's disease.^{115,116} In these cases, the neurologic injury may begin well before birth. Postnatal maturation of the blood-brain barrier restricts access to the CNS of transplanted cells or the deficient enzyme. Thus, a compelling rationale exists for prenatal therapy of these diseases. The primary unanswered question is whether donor HSC-derived

microglial elements would populate the CNS, providing the necessary metabolic correction inside the blood–brain barrier. Based on experimental results with *in utero* HSC transplantation alone for these disorders, it is likely that a combination of *in utero* HSC transplantation and CNS-directed cellular or gene therapy will be needed to correct CNS manifestations of these diseases.¹¹⁷

To summarize, the only definitively successful transplants to date have been for SCID syndrome. All others have either failed to take or were afflicted with GVHD. Despite only limited evidence of clinical efficacy, interest in the field continues to gain momentum. Parallel advances in prenatal screening, molecular diagnosis, and the Human Genome Project make it highly likely that opportunities for the application of this approach will increase. However, at this point in the evolution of *in utero* HSC transplantation, there are more questions than answers. Widespread clinical application is premature, based on the extremely limited clinical success that has been achieved. The biology of each disease is unique, and expectations of success or failure can only be based on sound clinical investigation guided by experimental work in

relevant animal models. The barriers to prenatal engraftment need to be investigated and understood prior to further clinical efforts in diseases in which host cell competition is prohibitive. Clinical centers should be associated with an active research effort to solve the remaining problems with this potentially promising clinical approach. In the near future, advances in our understanding of stem cell biology in the context of the prenatal microenvironment may allow *in utero* stem cell transplantation to achieve its full potential.

Conclusion

There are an increasing number of congenital and genetic abnormalities for which *in utero* treatment is possible and, in some cases, now relatively routine. Advances in therapies have progressed at different paces for different disorders, but there is great hope and enthusiasm that progress will continue to expand the number of disorders for which therapy can be effective.¹¹⁸

Key points

- 1 Prenatal diagnosis of fetal abnormalities has been developing over the last 30 years.
- 2 When congenital abnormalities are detected, couples should have the option of continuing, terminating (when legal) or, in selected cases, attempting prenatal therapeutic procedures.
- 3 Structural abnormalities are best approached surgically, and metabolic ones pharmacologically or genetically.
- 4 Neural tube defects (NTDs) are a multifactorial genetic disorder with a wide variation in incidence among racial and ethnic groups.
- 5 The neural tube normally closes within 30 days of conception.
- 6 The recurrence incidence of NTDs can be reduced from about 3–5%, depending upon the ethnic group, to about 1% with the use of 4.0 mg of preconceptual folic acid.
- 7 Since 1998, the United States FDA has mandated the supplementation of breads and grains with folic acid.
- 8 The primary incidence of NTDs has been reduced by about 30% in the United States from about 1:700 in the Caucasian population, 1:1000 in the African population, and 1:1200 in the Asian population.
- 9 Congenital adrenal hyperplasia, an autosomal recessive condition, is the most common cause of female hermaphroditism.
- 10 21-Hydroxylase deficiency produces a salt-losing, glucocorticoid and mineralocorticoid deficiency, which can be life-threatening in the nursery if unrecognized.
- 11 Prenatal therapy by pharmacologic suppression of the fetal adrenal gland has been performed for over 20 years through the use of maternally administered dexamethasone, which “turns off” the fetal adrenal gland and is the model for the first prevention of a birth defect.
- 12 Such babies still have the biochemical abnormality, which requires medication, but are spared from the anatomic masculinization of the external genitalia.
- 13 Fetal hyperthyroidism can produce high-output cardiac failure and can be treated.
- 14 Fetal hypothyroidism can produce classic “cretinism” and can be treated with intra-amniotic fluid thyroxine.
- 15 Methylmalonic aciduria and multiple carboxylase deficiency are biochemical defects that have neonatal consequences; they can be treated *in utero*, but it is unclear how much prenatal amelioration helps.
- 16 Smith–Lemli–Opitz syndrome can be treated with cholesterol, but the data to show any efficacy are still lacking. Galactosemia can produce rapid depletion of ovarian follicles in female fetuses. No one has yet tried to reverse the process.
- 17 Fetal cardiac arrhythmias can be diagnosed by their specific type. The implications vary tremendously by type.

- 18 *In utero* treatment of such arrhythmias has to be tailored to the specific diagnosis, but correction is commonly feasible and lowers perinatal morbidity and mortality in appropriate cases.
- 19 Valvoplasties have been performed in a very limited number of cases with conflicting interpretations of their success.
- 20 Genetic therapies using stem cells have been attempted for immunodeficiency disorders and inborn errors of metabolism. To date, only the treatment of immunodeficiency disorders has had any success. New methods are needed to improve the receptivity of the fetus to stem cell transplants.

Maternal biological adaptations to pregnancy

Maternal biological, biomechanical, and biochemical changes in pregnancy

Edward K.S. Chien and Helen Feltovich

Pregnancy induces changes in all maternal physiologic systems to accommodate the developing fetus. A thorough understanding of normal adaptations is important in identifying pathologic changes that may adversely affect both fetus and mother. In this chapter, we focus on general maternal physiologic changes, as well as specific changes within the uterus, in order to understand how these changes protect the fetomaternal environment and ultimately allow normal delivery.

Cardiovascular system

Profound cardiovascular changes are required throughout gestation to meet fetal oxygen and nutritional requirements as well as to meet the increased demands of maternal organ systems (Fig. 35.1). Many of these can be detected in the first trimester, such as changes in heart rate, cardiac output, vascular tone, and blood pressure.

The maternal heart is displaced by the growing uterus and increases in mass, which may lead to misinterpretation of both the electrocardiogram (ECG) and the chest radiograph (as depicted in Fig. 35.2).¹ Left axis deviation due to diaphragmatic elevation is approximately 15°, although deviation up to 28° has been described. ECG changes include low-voltage QRS complexes, flattened or inverted T waves in anterior chest leads and lead III, as well as ST segment depression in chest and limb leads.¹ Conduction abnormalities resulting from pregnancy are uncommon, although extrasystoles of atrial and ventricular origin are more frequent in pregnancy.

Auscultation of the heart reflects the change in its position (Fig. 35.3).^{2,3} Splitting of the first heart sound, due to closure of the mitral valve prior to the tricuspid valve, is commonly heard. The second heart sound (closure of the aortic and pulmonary valves) typically does not change. Between the first and second heart sounds, it is common to detect systolic ejection murmurs because of increased cardiac output. The third heart sound (diastolic filling) can often be heard during mid- to late pregnancy when end-diastolic volume peaks.

Blood pressure is followed closely during pregnancy and

undergoes a series of changes (Fig. 35.1).⁴ The mean arterial pressure decreases gradually over the first half of gestation, with a nadir at approximately 20 weeks.⁵ A greater decrease in diastolic (average 10–20 mmHg) versus systolic (average 5–10 mmHg) pressure is observed in the first half of gestation, whereas in the second half of gestation, greater elevations are seen in systolic versus diastolic pressures. Vascular tone is altered during pregnancy, leading to the decline in systemic blood pressure.⁶ Venous compliance increases as a result of a number of circulating factors, leading to an increase in venous capacitance and stasis.⁷ Blood pressure during pregnancy is dependent on maternal position; both systolic and diastolic blood pressures are elevated an average of 10 mmHg in the sitting compared with the lateral recumbent position.⁸

Pregnancy leads to redistribution and a 30–50% increase in cardiac output (heart rate \times stroke volume) to accommodate increased demand by all maternal organ systems, particularly the pregnant uterus, which at term requires a fifth of the total cardiac output (500–800 mL/min) (Fig. 35.1).^{9–11} The increase in cardiac output is secondary to changes in both heart rate and stroke volume, and can be detected as early as the 5th week of gestation.⁹ Most investigators have demonstrated that cardiac output peaks around the 32nd week of gestation, although some have suggested that it continues to rise to term; however, this may represent technical differences in measurements.¹² During the late second and third trimesters, vena-caval compression secondary to maternal supine positioning can decrease venous return, reducing cardiac output by 25–30%.^{13,14} For this reason, the supine position is not recommended.

Respiratory system

The pulmonary system must also adapt to the increased oxygen and ventilatory demands placed upon it by pregnancy. Oxygen consumption undergoes a 15–20% increase by the end of gestation (Fig. 35.4).^{15,16} This increased requirement for oxygen is compensated for by an increase in ventilation.¹⁷ The

Figure 35.1 The body makes a number of physiologic adjustments throughout pregnancy, which can be detected as early as 5 weeks from the last menstrual period. Systems with easily measurable changes include the cardiovascular, hematologic, and renal systems. To accommodate the increased cardiovascular demands, blood volume progressively increases with advancing gestation. The blood volume is determined by both red cell mass and plasma volume. Plasma volume increases occur during the first trimester and continue to late in the third trimester. The red cell mass increases at a slower rate, leading to a dilutional anemia, which usually reaches its nadir around 28 weeks of gestation. Blood pressure also falls owing to decreased peripheral vascular resistance, reaching a nadir around 20 weeks. A decrease in both systolic and diastolic pressure

is observed. From mid-gestation to term, blood pressure rises to near nonpregnant levels. Cardiac output, which is determined by both pulse and stroke volume, increases progressively throughout gestation. Cardiac output is believed to peak around 32 weeks, although some studies suggest a gradual increase to term. Early increases in cardiac output are mainly due to increases in heart rate, but increases in stroke volume contribute a greater proportion later in pregnancy. Glomerular filtration increases with the increase in cardiac output. The marked increase in glomerular filtration rate (GFR) is primarily due to an increase in effective renal plasma flow. The increase in effective renal plasma flow results from an increase in perfusion and decreased renal vascular resistance. MAP, mean arterial pressure; NP, nonpregnant; RBC, red blood cell.

Figure 35.2 Anatomic changes in the pulmonary and cardiovascular systems are well demonstrated on chest radiography. The heart is rotated forward and deviated upward during pregnancy owing to diaphragmatic elevation, resulting in apical displacement into the fifth intercostal space. This rotation may falsely suggest right atrial enlargement on lateral views of the chest. It also causes increased prominence of the left cardiac border, giving the impression of

cardiac hypertrophy. Together, these changes cause the cardiac volume to increase by approximately 12%. The chest dimensions are also altered. The diaphragm is elevated by 4 cm, which leads to flattening of the subcostal angle from 68° to 103° . This potential decrease in lung volume is compensated by a 2-cm increase in chest diameter, which allows maintenance of vital capacity.

Figure 35.3 Identification of additional heart sounds on auscultation of the maternal heart is common. These include splitting of the first heart sound and systolic ejection murmurs. Splitting of the first heart sound is due to closure of the tricuspid valve after the mitral valve. Delayed closure results from an increase in blood volume and extended filling of the left ventricle. Flow murmurs detected between the first and second heart sounds are also common owing to increased blood flow. The electrical changes associated with the cardiac cycle and heart sounds are also depicted. Atrial and ventricular systole are depicted below the heart sounds as well as diastolic filling periods.

Figure 35.4 Oxygen consumption increases progressively by 15–20% over the course of pregnancy. The increase in oxygen consumption is due mainly to increased cardiac, pulmonary, renal, and reproductive system demands. The reproductive system accounts for over half of the required increase. The cardiovascular and renal systems require a similar increase in oxygen consumption, although the increase in the renal system is seen early in pregnancy and remains constant throughout gestation. The increase in oxygen consumption parallels the increase in cardiac output.

respiratory system, although adaptable, is also remarkably susceptible to failure in the event of injury to other physiologic systems.

The increased ventilatory requirements are met by anatomic, ventilatory, and biochemical mechanisms (minute ventilation = tidal volume \times respiratory rate). Increased ventilation is due to increased tidal volume (Fig. 35.5);^{18,19} respiratory rate does not change during pregnancy. Maternal hyperventilation leads to changes in normal blood gas parameters (Table 35.1).²⁰ Beginning early in the first trimester, tidal volume increases by 40% (500 mL to 700 mL) due to direct stimulation of the central respiratory control center by progesterone.^{18,19} This increase in tidal volume comes at the expense of functional residual capacity (the volume remaining in the lungs at forced end expiration) (Fig. 35.5).^{18,21,22} The vital capacity does not change, nor do a number of spirometric parameters.²³ Anatomic changes are demonstrated in Figure 35.2.

Hematologic system

Pregnancy affects all components of the hematologic system, and includes changes in plasma volume and red blood cell volume, the immunologic system, and coagulation components.

Both plasma volume and red blood cell volume increase over the course of gestation, together contributing to a 20–40% increase in blood volume during pregnancy (Fig. 35.1).^{24,25} Plasma volume expands as early as 6 weeks and continues

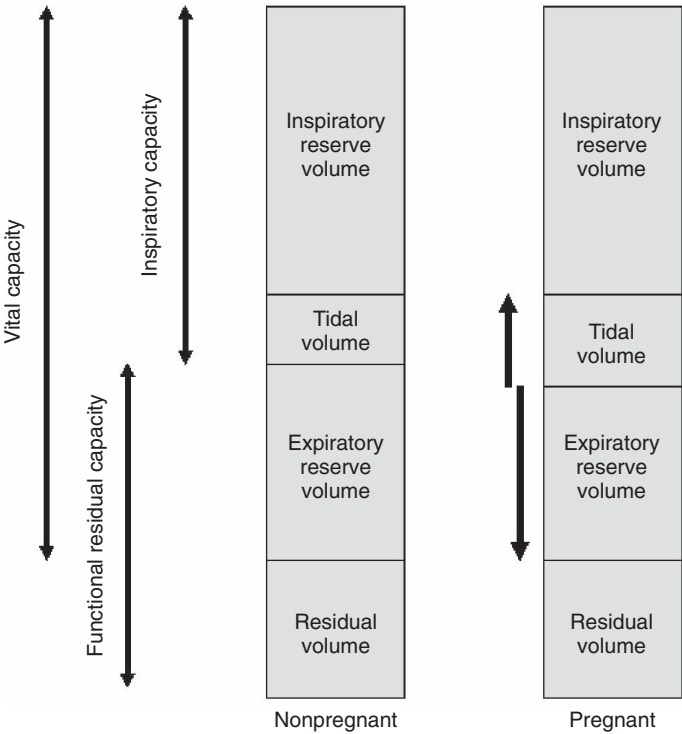

Figure 35.5 The increase in oxygen requirement is accommodated by an increase in tidal volume without an increase in respiratory rate. This increase in tidal volume is at the expense of the end-expiratory reserve volume. The inspiratory reserve volume and the vital capacity remain constant. The forced expiratory volume in 1 s (FEV₁) and forced vital capacity (FVC) remain unchanged during pregnancy.

Table 35.1 Arterial blood gas values in pregnancy.

	pH	PO ₂ (mmHg)	PCO ₂ (mmHg)	HCO ₂ (mEq/L)	SaO ₂ (%)
Nonpregnant	7.40	98	40	22–26	98
Pregnant	7.44	101	28	18–22	98

Increased ventilation leads to alterations in normal blood gas values in pregnancy. The PO_2 is elevated from the normal nonpregnant value of 98 to 101 mmHg in pregnancy, and PCO_2 falls from 40 to 28 mmHg. The renal system compensates for the decline in PCO_2 by increasing bicarbonate (HCO_2) secretion to 18–22 mEq/L. These changes result in slightly higher average pH values (7.44 vs. 7.40). This pH alteration also permits increased oxygen delivery by shifting the oxygen dissociation curve, which allows for enhanced oxygen release into tissue where oxygen is being consumed.

through 32 weeks of gestation, leading to an increase of 40–50% in singleton pregnancies, and more with multiple gestations.²⁶ Red blood cell volume only increases by 20–30% over gestation, which leads to a fall in hemoglobin concentration often referred to as the physiologic anemia of pregnancy.²⁴

Platelet quantity generally remains unchanged throughout

Table 35.2 Coagulation components and test values in pregnancy.

Component or test	Change	Nonpregnant	Pregnant (relative change compared with nonpregnant values)
PT	None	11–12 s	No change
PTT	None	24–36 s	No change
Bleeding time	None	1–5 min	No change
Platelet count	None	150–400 × 10 ³ /mm ³	No change
Fibrinogen	Increase	200 mg/dL	50–100%
Factor IIc	Increase	20 mg/dL	10–20%
Factor Vc	None	100 U/dL	No change
Factor VIIc	Increase	100 IU/dL	30–50%
Factor VIIIc	Increase	100 IU/dL	100%
Factor IXc	None	100 IU/dL	No change
Factor Xc	Increase	100 IU/dL	20–60%
Factor XIc	Decrease	100 U/dL	20–30%
Factor XIIc	Increase	100 IU/dL	40%
vW An	Increase	100 IU/dL	100–300%
Protein C	None	100%	No change
Protein S	Decrease	100%	50%
Antithrombin III	None	100%	No change

vW An, von Willebrand antigen.

gestation, although up to 10% of women will have a decrease in total platelets due to increased turnover.^{27,28} Although pregnancy does not appear to change the platelet's lifespan, studies suggest that pregnancy is associated with increased platelet activation, which may contribute to increased turnover and gestational thrombocytopenia.²⁸

Altered levels of coagulation components, together with increased venous stasis, create a hypercoagulable state during pregnancy. The alterations in coagulation components are complex with both increases and decreases in specific components (Table 35.2).^{29,30} These alterations make identification of coagulation disorders difficult, although tests of coagulation such as prothrombin time (PT), partial thromboplastin time (PTT), and bleeding time are unchanged by pregnancy. By 6 weeks' postpartum, most coagulation factors have returned to prepregnant values, although the timing varies by component.

Maternal immunologic adaptation to pregnancy is poorly understood. Pregnancy requires the recognition and acceptance of the fetus, which is considered a semi-allograft because it expresses antigens of both maternal and paternal origin. Studies suggest that local immunity within the uterus is altered to permit the development of the fetoplacental unit. A subset of T cells (helper T cells) is believed to be important in the recognition of the fetal allograft and local immune suppression.^{31–34}

Other immune system changes include an increase in the white blood cell count (WBC) (Table 35.3), even in the absence of an acute infection.³¹ This increase is due primarily to an increase in granulocytes belonging to the innate immune response that is mediated by neutrophils, macrophages, monocytes, and natural killer cells. These cell types reside locally in

Table 35.3 Change in WBC populations.

Component	Change in pregnancy
WBC	Increase
Granulocytes	Increase
Lymphocytes	No change
Monocytes	No change
Total T cells	Decrease
B cells	No change
T-helper cells	Decrease
T-suppressor cells	No change

tissues and are recruited in response to local challenges. Changes in the adaptive immune response can be subdivided into cellular and humoral responses mediated by T and B lymphocytes.³² Total lymphocyte counts remain unchanged during pregnancy, but alterations in lymphocyte populations do occur.

Urinary tract system

Pregnancy produces both anatomic and functional changes in the urinary tract. Renal abnormalities are associated with an increased risk of preterm delivery.³⁵ The renal system increases in size during pregnancy. The dimensions of the kidneys increase with the increase in glomerular filtration rate (GFR). These changes resolve during the postpartum period. Dilation of the collecting system can often be seen and is more common on the right than on the left side. Ureteral dilation is commonly seen above the pelvic brim, but can be observed all the

way down to the level of trigone, thought to be secondary to hormonal effects on smooth muscle tone. The pregnant uterus may contribute to intermittent obstruction of the ureters, especially at the level of the pelvic brim. Standard tests to assess renal function are often inaccurate in the pregnant state because of anatomic changes in the renal system.³⁶ Thus, accepted normal values of renal function outside of pregnancy may suggest intrinsic renal disease in pregnancy.

The kidney becomes hypertrophied during pregnancy, then returns to normal in the postpartum period. Hormonal changes likely contribute to the alterations in renal anatomy and function,³⁷ as well as to increases in renal parenchyma and the collecting system.^{38,39} Dilation of renal calices and ureters is observed as early as the first trimester, often more on the right side compared with the left. Mechanical obstruction of the ureters by the expanding uterus is believed to be responsible for some of the anatomic changes.⁴⁰ Radiologic studies indicate that ureteral dilation occurs mainly above the pelvic brim, suggesting compression against the bony pelvis. This intermittent obstruction and increased stasis produces inaccurate results of renal function using spot collections and increases the risk of lower urinary tract infections.

Increases in the GFR (Fig. 35.1) and effective renal plasma flow (ERPF) occur early in the first trimester;^{41,42} GFR increases by 30–50% while ERPF increases by 50–80%. These increases peak by the end of the first trimester and persist throughout gestation. Measurements of plasma solutes are altered by the increased GFR.⁴³ Normal serum creatinine declines by 0.1–0.2 mg/dL and blood urea nitrogen decreases by more than 10 mg/dL. Glycosuria during pregnancy is common, and may be normal due to increased solute filter load and decreased tubular resorption.^{44,45} Decreased uric acid levels result more from increased filtration load than decreased tubular resorption.⁴⁶ The physiologic hyperventilation of pregnancy reduces PCO_2 and therefore serum bicarbonate levels, which decreases the body's buffering capacity, increasing its susceptibility to acidosis.

Plasma osmolality decreases during pregnancy,⁴⁷ beginning after conception and reaching a nadir by the end of the first trimester. This is due largely to a decrease in serum sodium and, to a lesser extent, to a fall in blood urea nitrogen. The change in osmotic threshold is attributed to alterations in vasopressin metabolism.⁴⁸ Vasopressin secretion is not suppressed at normal osmotic thresholds, which leads to fluid retention. The increased secretion is balanced partly by placental vasopressinase, an enzyme that degrades vasopressin.

The body's volume sensor response is unaltered during pregnancy, while the alterations in osmolality and AVP metabolism produce a relative state of hypervolemia. Thus, pregnancy is associated with relative activation of the renin–angiotensin–aldosterone system.⁴⁸ This activation is thought to contribute to the retention of sodium as well as an increase in total body water. Pregnancy is associated with a 6- to 8-L increase in total body water, two-thirds of which is stored extracellularly.

Table 35.4 Change in liver function tests during pregnancy.

	Change
Total bilirubin	None
Alkaline phosphatase	Increase
Alanine aminotransferase	None
Aspartate aminotransferase	None
γ -Glutamyl transferase	Increase
Albumin	Decrease
Cholesterol	Increase
Triglycerides	Increase
Binding globulins	Increase
Lactate dehydrogenase	Increase
Fibrinogen	Increase

Gastrointestinal system

Gastrointestinal complaints are common in pregnancy. Symptomatic complaints such as nausea and vomiting, while common, may represent conditions with significant morbidity and mortality. However, many of the symptoms are pregnancy limited, resolving spontaneously after delivery.

Anatomic changes occur throughout the alimentary system and affect physiological function. Gastroesophageal reflux is a common complaint that is related to decreased pyloric sphincter tone resulting from smooth muscle relaxation and increased intra-abdominal pressure from the expanding uterus.^{49,50} Gastric emptying times are elevated by 50% with pregnancy,^{51,52} and delayed emptying contributes to symptomatic complaints.

Biochemical and physiologic parameters in the biliary system are affected by pregnancy, although no anatomic changes occur.⁵³ Gallbladder size is unchanged, while motility is diminished because of decreased smooth muscle activity, similar to that occurring in the intestine. The liver does not change in size, although parameters of liver function may be altered (Table 35.4). Increased alkaline phosphatase occurs secondary to increased placental production.⁵⁴ In contrast, aspartate aminotransferase (AST) and alanine aminotransferase (ALT) may be elevated in normal pregnancy.⁵⁵ Albumin production is unchanged, but plasma levels are often decreased on account of plasma volume expansion.⁵⁶ Pregnancy has major effects on the lipid profile, with significant elevations of both triglycerides and cholesterol.⁵⁷ Increases in binding globulins alter normal total circulating hormone levels.

The exocrine pancreas is less well studied than the endocrine pancreas. Its secretory response does not appear to be altered, although animal studies suggest that pregnancy increases the basal secretion of digestive enzymes.⁵⁸ Amylase and lipase levels are unaffected by pregnancy.

Endocrine system

Multiple anatomic and functional changes occur throughout pregnancy within the endocrine system. A thorough understanding of these changes is key to interpreting laboratory results during pregnancy.

Euglycemia in pregnancy is important. The fetus requires adequate maternal glucose, but hyperglycemia is associated with birth defects and fetal macrosomia.⁵⁹ Pregnancy changes carbohydrate metabolism, causing fasting hypoglycemia, postprandial hyperglycemia, and hyperinsulinemia.⁶⁰ The normal response to a carbohydrate challenge in pregnancy is a twofold or greater increase in stimulated insulin release compared with the nonpregnant state.⁶⁰

Basal glucose levels in pregnancy, particularly during the first trimester, are lowered by approximately 10%.⁶¹ Placental secretion of counter-regulatory hormones causes decreased peripheral insulin sensitivity. Unlike glucose, insulin and other protein hormones do not cross the placenta, although insulin probably does affect nutrient transport and availability to the fetus.

An increase in anterior pituitary size during pregnancy, primarily because of an increase in the number of prolactin-secreting cells, has been described.⁶² In contrast to the increased number of lactotrophs, growth hormone-secreting cells decrease in number along with the number of gonadotropin-secreting cells. No changes in thyrotropic or adrenocorticotropin-secreting cells have been identified. Increased pituitary size seems to correlate with increased levels of circulating hormones. During pregnancy, prolactin levels are up to 10 times higher than in the nonpregnant state.⁶³ Elevations of both corticotropin-releasing hormone (CRH) and adrenocorticotrophic hormone (ACTH) occur during delivery.⁶⁴ Gonadotropin-releasing hormone (GnRH), follicle-stimulating hormone (FSH), and luteinizing hormone (LH) levels are suppressed in pregnancy.

Thyroid hormone metabolism is altered during pregnancy.^{65,66} The thyroid gland does not normally change in size. Iodine absorption during pregnancy is improved, although excretion is also increased owing to enhanced GFR. Thyroxine (T_4) is bound by thyroid-binding globulin (85%) and thyroxine-binding prealbumin (15%). Less than 1% of T_4 circulates in the unbound, active form. The increased production of estrogens during pregnancy stimulates an increase in T_4 -binding proteins (over twofold), leading to elevated levels of total T_4 . Free T_4 levels remain in the normal range, but have been shown to fluctuate.

T_4 production and release is regulated by thyrotropin (TSH), which in turn is under the direct control of thyrotropin-releasing hormone (TRH). TRH is produced in the hypothalamus, released from the pituitary gland, and inhibited via direct feedback by T_4 . Elevated levels of human chorionic gonadotropin (hCG) during the first and early second trimesters stimulate the release and production of T_4 , which

feeds back on the pituitary to decrease the secretion of TSH. This may cause a transient low TSH level. Triiodothyronine (T_3), produced by both the thyroid and peripheral conversion of T_4 , is also metabolically active. Two of the three enzymes responsible for converting T_4 to metabolically active T_3 or to inactive reverse T_3 are expressed in the placenta, causing elevated local and peripheral levels of these hormones.

The maternal adrenal cortex plays a significant metabolic role through the production of mineralocorticoids, glucocorticoids, and sex steroids.⁶⁴ Aldosterone (mineralocorticoid) is regulated mainly by the renin-angiotensin system. Cortisol (glucocorticoid) levels are elevated during pregnancy. Cortisol secretion is normally regulated by hypothalamic CRH and pituitary ACTH. The latter normally feeds back to inhibit CRH production, thereby decreasing cortisol release. In pregnancy, the placenta and fetal membranes both produce CRH, particularly in the third trimester, which circumvents the normal regulatory loop, leading to elevations in circulating cortisol.

Pregnancy requires enhanced absorption of calcium to meet fetal demands. This demand is met by increased synthesis of vitamin D and by physiological hyperparathyroidism.^{67,68} Vitamin D is synthesized by the skin and activated by hydroxylation in the kidneys and placenta. Activated vitamin D increases calcium membrane channel activity, which increases transplacental transport to the fetus. Physiological hyperparathyroidism is due to both parathyroid hormone (PTH) and parathyroid hormone-related peptide (PTHrp).⁶⁹ PTH levels decline over gestation, but this is compensated for by placental production of PTHrp, which has amino acid homology to PTH and is thus able to stimulate PTH receptors. PTHrp mediates placental calcium transport more than increased synthesis of activated vitamin D.

Reproductive system

Of all maternal physiologic systems, the reproductive system undergoes the most dramatic changes during pregnancy. The uterus can be divided into three functional components, all of which must adapt to the developing fetus: the cervix, the endometrium (decidua), and the myometrium.

Cervix

The cervix performs two opposite functions during pregnancy: it maintains the fetus *in utero* and then dilates with the onset of labor. Cervical biomechanics and biochemistry are less well understood than that of the myometrium, although greater attention has been paid to the cervix in the past decade, since the recognition that early cervical shortening often precedes the increased uterine activity associated with preterm delivery.⁷⁰

The cervix is composed of a cellular component and an extracellular matrix.⁷¹ The latter is composed of many different macromolecules, including collagen (primarily types I and

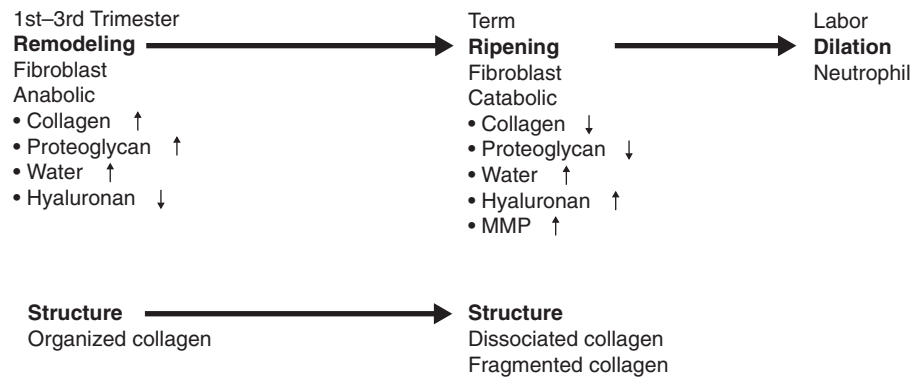

Figure 35.6 The cervix remodels during pregnancy in order to perform its two main functions. The first phase is an anabolic process, which involves an increased production of both collagen and proteoglycans. The increase in cervical size is associated with an increase in water content. The production of hyaluronan is diminished during this phase of remodeling. Imaging of cervical collagen demonstrates a packed and organized structure. As term approaches, the concentration of both collagen and proteoglycans is

diminished, which may be due to either decreased production or increased degradation, which are catabolic processes. Increased expression of degradative enzymes has been described including members of the MMP (matrix metalloproteinase) family. Cervical ripening is associated with dissociation and fragmentation of collagen fibers. The degradative enzymes are thought to be produced from fibroblasts prior to the onset of labor and from infiltrating neutrophils with the onset of labor.

III), proteoglycans (decorin and biglycan), glycosaminoglycans (dermatan sulfate, chondroitin sulfate, and heparin sulfate), and the nonsulfated, nonprotein-bound glycosaminoglycan hyaluronate.⁷² Throughout gestation, but particularly in the second half of pregnancy, cervical mass increases due to the influence of estrogen, progesterone, and relaxin.⁷³ The increase in mass results from increases in both the cellular and the extracellular components. Increases in collagen, proteoglycans, glycosaminoglycans, and water have been measured. Smooth muscle cells undergo both hyperplasia and hypertrophy.⁷⁴

Cervical changes during pregnancy can be divided into remodeling and ripening phases (Fig. 35.6).⁷² Remodeling is an anabolic process regulated by the hormonal milieu of pregnancy. During this phase, collagen, proteoglycans, and glycosaminoglycans are deposited into the extracellular matrix. An increased deposition of hyaluronate leads to an influx of water that is associated with cervical softening. The alterations in the proportion of collagen, proteoglycans, and glycosaminoglycans are believed to contribute to the progressive decline in cervical tensile strength, as is a gradual decrease in collagen fibril length.⁷⁵

The ripening phase is believed to be a catabolic process in which the extracellular matrix components are degraded.⁷² Unlike remodeling, which is affected by steroid hormones, ripening involves release of proteases that degrade collagen

and other extracellular matrix components. Elevated levels of prostaglandins, seen with both term and preterm labor, can stimulate the release of extracellular proteases. Marked collagen fragmentation, believed to be important to cervical dilation, occurs during the active phase of labor.⁷⁶ Ripening is thought to be an inflammatory process, and is accelerated by infiltration of leukocytes and release of proinflammatory cytokines.⁷⁷ Leukocytes such as neutrophils are a rich source of proteases that may contribute to the degradative process. Proinflammatory cytokines such as tumor necrosis factor (TNF)-alpha or interleukin (IL)-8, which induce an inflammatory infiltrate, can induce cervical ripening.^{77,78}

Regulation of this process is poorly understood, although a number of pharmacologic and mechanical methods artificially reproduce these changes. For instance, administration of prostaglandin E₂ induces structural changes in the cervix similar to those seen with physiologic ripening.⁷⁶

Progesterone also plays a role in cervical remodeling, but has not been well studied. Progesterone receptor antagonists such as mifepristone (RU-486) also decrease cervical resistance.⁷⁹ This is used for cervical ripening in the first and second trimesters. In humans, circulating progesterone levels do not decrease prior to or at the onset of labor; however, a shift in expression of progesterone receptors (from predominantly the B isoform to the A isoform) occurs within the uterus,⁸⁰

Figure 35.7 The uterus undergoes marked changes during pregnancy, from an organ weighing approximately 60g to one weighing approximately 1000g at term. The uterus progressively increases in size from the size of a small pear at 6 weeks, completely filling the pelvis at 12 weeks to reaching the xiphoid at term. The uterus at 16 weeks is midway between the umbilicus and the symphysis pubis, and at the umbilicus at 20 weeks. From 20 weeks until term, fundal height in centimeters, as measured from the symphysis to the top of the uterine fundus, corresponds roughly to the gestational age from the last menstrual period.

possibly simulating progesterone withdrawal, which is seen in other species.

Endometrium (decidua)

The decidua has been poorly studied during pregnancy. It is clear that it plays an important role in anchoring the placenta, is metabolically active, and is critical to the early establishment and continued maintenance of pregnancy. It is infiltrated by maternal leukocytes, which assist in pregnancy maintenance by regulating immune responses. The decidua produces a number of different hormones, including prolactin, relaxin, CRH, and prostaglandin dehydrogenase (prostaglandin-inactivating enzyme).⁸¹

Myometrium

The myometrium, like the cervix, undergoes marked changes in size during pregnancy, increasing from approximately 60g in early pregnancy to 1000g at term.⁸² This is primarily due to hypertrophy rather than hyperplasia of smooth muscle. Myometrial cells increase in size from 50–90 μ m to 500–800 μ m in length. The increase in size appears to be

dependent on the presence of both estrogen and progesterone. The uterus remains a pelvic organ until approximately 12 weeks. At this point, the uterus becomes spherical compared with its nonpregnant pear-like shape. The myometrium becomes soft to palpation, probably due to the increase in amniotic fluid within the uterine cavity. The uterus continues to increase in size, reaching the level of the umbilicus at approximately 20 weeks of gestation. A measurement of fundal height (distance from the symphysis pubis to the top of the uterine fundus) in centimeters roughly corresponds to gestational age from this point until term (Fig. 35.7).⁸³ At term, fundal heights may decline as the fetal head becomes engaged within the maternal pelvis.

To accommodate the increased uterine size as well as the developing fetus, blood flow increases throughout gestation to approximately 500 mL/min by term.^{84,85} It is unclear what mechanism is responsible for the increase in uterine blood flow, but it is thought to be secondary to an increase in production of placental hormones. The uterine vessels increase in both diameter and length to accommodate the increase in blood flow. An increase in vasodilating substances such as prostaglandins and nitric oxide within the uterine circulation is believed to contribute to the decrease in vascular tone and increase in uterine blood flow.⁸⁶ In addition, the uterine vasculature becomes less responsive to vasoactive substances such as angiotensin.

Although the myometrium readily contracts when stimulated in pregnancy, spontaneous uterine contractions are relatively infrequent, occurring up to two or three times per hour during normal gestation.⁸⁷ These uterine contractions are usually appreciated during the third trimester, if not earlier, and are referred to as “Braxton-Hicks” contractions. Low-amplitude irregular bursts of electrical activity can be detected using electromyography and correlate with uterine contractions.⁸⁸

As term approaches, spontaneous activity increases gradually, particularly during the late third trimester. In addition, the uterus becomes significantly more responsive to stimulatory agents. This increase in uterine activity is believed to be due to increased electrical coupling of myometrial cells.⁸⁹ Coupling occurs because of channels between cells produced by connexin proteins. These proteins provide low-resistance channels for the passage of ions such as calcium. Animal studies have demonstrated a correlation between increased levels of connexin proteins and increased uterine electrical activity. An increase in a number of other proteins associated with contractile activity has been described in parallel with connexin proteins.⁹⁰ This group of proteins, which is necessary for force production, is often referred to as contractile-associated proteins.

In summary, a comprehensive understanding of normal maternal physiologic adaptations to pregnancy is paramount to diagnosing pathologic changes associated with disease states during gestation.

Key points

- 1 Pregnancy-associated cardiovascular changes seen as early as the first trimester include increases in heart rate and cardiac output, and decreases in vascular tone and blood pressure.
- 2 Displacement of the maternal heart by the expanding uterus results in predictable chest radiograph and ECG changes.
- 3 Cardiac output peaks at approximately 32 weeks' gestation owing to increases in both heart rate and stroke volume.
- 4 Systolic ejection murmurs are common during pregnancy owing to increased cardiac output.
- 5 Systemic blood pressure normally declines until around 20 weeks' gestation, then gradually increases, but should remain equal to or below nonpregnant values throughout pregnancy.
- 6 Pulmonary changes in the first trimester include an increase in tidal volume and, therefore, minute ventilation.
- 7 Respiratory rate does not change during pregnancy.
- 8 Maternal hyperventilation leads to a slight metabolic alkalosis, with an increase in pH, decrease in PCO_2 , decrease in bicarbonate, and an increase in PO_2 .
- 9 Because spirometric parameters should not change during pregnancy, this can be used to evaluate for obstructive and restrictive airway disease.
- 10 Pregnancy often causes a "physiologic anemia" because plasma volume increases to a greater extent than red blood cell volume.
- 11 Pregnancy typically does not affect platelet count, although up to 10% of the population may become thrombocytopenic, believed to be secondary to increased platelet activation and consumption.
- 12 Bleeding time, PT, and PTT are not altered during pregnancy despite marked changes in different coagulation components.
- 13 An elevated WBC count may be normal during pregnancy because of an increase in circulating granulocytes.
- 14 The kidney and renal collecting system may increase in size during pregnancy, potentially causing urinary stasis, which may contribute to lower and upper tract infections.
- 15 The GFR increases during pregnancy and is associated with increased (nonpathologic) glucosuria and decreases in serum creatinine and blood urea nitrogen.
- 16 The osmotic threshold is altered during pregnancy, reflected by a decrease in plasma osmolality and an increase in fluid retention.
- 17 Decreased plasma osmolality during pregnancy is reflected by decreases in serum albumin, serum sodium, and blood urea nitrogen.
- 18 Gastric emptying is delayed during pregnancy, and contributes to benign gastrointestinal complaints as well as an increased risk of aspiration from anesthesia.
- 19 Diminished esophageal sphincter tone during pregnancy increases the incidence of gastroesophageal reflux.
- 20 Pregnancy alters some parameters of liver function, including alkaline phosphatase and lipid profile.
- 21 Decreased TSH and increased total thyroxine may be seen in pregnancy, although free thyroxine levels should not be altered.
- 22 Cervical remodeling mainly occurs during the second half of pregnancy.
- 23 Cervical ripening, which decreases tensile strength, is associated with changes in collagen, proteoglycan, and glycosaminoglycan composition.
- 24 The uterus grows mainly because of uterine myocyte hypertrophy, although hyperplasia also occurs.
- 25 Blood flow to the uterus consumes approximately 20% of the total cardiac output at term.
- 26 Increase in uterine activity at term involves expression of contractile-associated proteins and increased electrical coupling.

Nutrition in maternity has experienced a renaissance in recent years, with increasing evidence linking alterations in both fetal growth and maternal health with subsequent metabolic and vascular disease.^{1–8} For the developing fetus, altered nutrition *in utero* may result in developmental adaptations that permanently change structure, physiology, and metabolism, favoring fetal survival, but with metabolic and vascular disease consequences in adulthood. For the mother, pregnancy complications such as gestational diabetes, preeclampsia, intrauterine growth restriction, and preterm delivery, and subsequent metabolic and vascular disease may share common underlying disease mechanisms. Maternal nutrition, therefore, plays a central role in the immediate and long-term health of the mother and her child. This chapter presents an overview of current knowledge in this area. The *Guidelines for perinatal care* (5th edn, 2002)⁹ acknowledge that nutrition counseling is an integral component of perinatal care, and that it is most effectively accomplished by referral to a nutritionist or registered dietitian. Their recommendations, which are issued jointly by the American Academy of Pediatrics and the American College of Obstetricians and Gynecologists, cover preconception care, nutrition in pregnancy, postpartum guidelines, and neonatal nutrition.

Diet during pregnancy

Both the quality and the quantity of the diet during pregnancy critically influence the health of the mother and her unborn child.¹⁰ Energy and nutrient requirements increase during pregnancy to insure appropriate maternal adaptation to pregnancy and optimal fetal growth. In singleton pregnancies, the daily caloric requirement is approximately 27–30 kcal/kg maternal prepregnancy weight during the first trimester, and 30 kcal/kg maternal prepregnancy weight plus 200–300 kcal during the second and third trimesters. In underweight women, these caloric prescriptions would need to be adjusted upward. The recommended caloric distribution of macronutrients during pregnancy is the same as for all healthy adults:

20% of kcal from protein, 30–35% of kcal from fat, and the remainder (45–50% of kcal) from carbohydrates. A summary of recommended dietary allowances (RDAs) and dietary reference intakes from the Food and Nutrition Board, the Institute of Medicine (IOM), is given in Table 36.1.

Use of vitamin–mineral supplements

Ideally, pregnant women should get the level and range of required nutrients through a balanced diet. However, in order to insure the adequate intake of prenatal vitamins, it is recommended that all pregnant women take prenatal vitamins daily throughout the course of pregnancy. Recent national dietary surveys indicate that adult women fail to meet the RDAs for five nutrients: calcium, magnesium, zinc, and vitamins E and B₆.¹¹ In addition, prenatal use of vitamin–mineral supplements among low-income women has been shown to reduce the risks of preterm delivery and low birthweight, particularly if initiated during the first trimester.¹² Data from national surveys indicate that the majority of Americans, including half to two-thirds of women of childbearing age, take some form of vitamin–mineral supplements.^{13–15} Vitamin–mineral supplement use is more common among women than men, among individuals with one or more health problems, and among older individuals.¹³

Supplementation in excess of twice the RDA (see Table 36.1) should be avoided, because of the potential for birth defects. The fat-soluble vitamins, particularly vitamins A and D, are the most potentially toxic during pregnancy. The pediatric and obstetric literature includes case reports of kidney malformations in children whose mothers took between 40 000 and 50 000 IU of vitamin A during pregnancy. Even at lower doses, excessive amounts of vitamin A may cause subtle damage to the developing nervous system, resulting in serious behavioral and learning disabilities in later life. The margin of safety for vitamin D is smaller than for any other. Birth defects of the heart, particularly aortic stenosis, have been reported in both humans and experimental animals with

Table 36.1 Summary of recommended dietary allowances and dietary reference intakes for nonpregnant, pregnant, and lactating women aged 1–50 years.

Nutrient	Nonpregnant 19–30 years	Nonpregnant 31–50 years	Pregnancy	Lactation (first 6 months)	Food sources
Folate	400 mcg	400 mcg	600 mcg	500 mcg	Liver, green leafy vegetables, enriched cereals, oranges
Thiamin	1.1 mg	1.1 mg	1.4 mg	1.5 mg	Meats, poultry, pork, beans, enriched cereals and breads
Riboflavin	1.1 mg	1.1 mg	1.4 mg	1.6 mg	Dairy products, meats, liver, eggs, enriched cereals
Niacin	14 mg	14 mg	18 mg	17 mg	Meats, poultry, fish, nuts, legumes, enriched cereals
Vitamin A	800 mcg	800 mcg	800 mcg	1300 mcg	Dark green, yellow, or orange fruits and vegetables, liver
Vitamin B6	1.3 mg	1.3 mg	1.9 mg	2.0 mg	Meats, liver, poultry, fish, nuts, legumes, enriched cereals
Vitamin B12	2.4 mcg	2.4 mcg	2.6 mcg	2.8 mcg	Meats, liver, poultry, eggs, fish, dairy products
Vitamin C	60 mg	60 mg	70 mg	95 mg	Citrus fruits, tomatoes, green leafy vegetables
Vitamin D*	5 mcg	5 mcg	5 mcg	5 mcg	Fortified dairy products
Vitamin E	8 mg α -TE	8 mg α -TE	10 mg α -TE	12 mg α -TE	Vegetable oils, seeds, and cereal grains
Calcium	1000 mg	1000 mg	1000 mg	1000 mg	Dairy products, salmon
Iron	15 mg	15 mg	30 mg	15 mg	Meats, liver, eggs, enriched and whole grains
Magnesium	310 mg	320 mg	350 mg	310 mg	Whole grains, legumes, nuts, green vegetables
Phosphorus	700 mg	700 mg	700 mg	700 mg	Meats, poultry, eggs, pork, fish, dairy products
Zinc	12 mg	12 mg	15 mg	19 mg	Meats, pork, seafood, eggs, legumes
Energy	2200 kcal	2200 kcal	2500 kcal	2700 kcal	Proteins, fats, and carbohydrates
Protein	50 g	50 g	60 g	65 g	Meats, poultry, eggs, fish, and dairy products

Adapted from the National Academy of Sciences, Food and Nutrition Board. Recommended Dietary Allowances, 10th edn, 1989; and Dietary Reference Intakes, 1998.

*As cholecalciferol, 1 mcg = 40 IU of vitamin D.

doses as low as 4000 IU, which is 10 times the RDA during pregnancy.

Maternal iron status

There are no absolute requirements for routine dietary supplementation, with the possible exception of iron. In instances in which inadequacies cannot be remedied through diet, or if a woman has unique nutritional requirements, such as multiple gestation, diagnoses of hemoglobinopathies or seizure disorders, or other circumstances, daily supplementation may be the most reasonable alternative. The IOM 1990 report¹⁶ recommended daily iron supplementation with 30 mg/day during the second and third trimesters, as prophylaxis for iron deficiency. The treatment of iron-deficiency anemia requires daily doses of 60–120 mg of elemental iron, to be taken between meals or at bedtime to facilitate absorption. Iron should not be taken as part of a vitamin–mineral supplement, on account of inhibition by other minerals, as well as poor iron release.¹⁷ To minimize their side-effects, iron supplements should be taken with a nondairy snack.

Iron-deficiency anemia is significantly associated with low birthweight (LBW), preterm delivery, and inadequate maternal weight gain. In a study of adolescent and young gravidas, iron-deficiency anemia (based on the Centers for Disease Control criteria of hemoglobin values < 11.0 g/dL for the first and third trimesters and < 10.5 g/dL for the second trimester)

was significantly associated with inadequate maternal weight gain [adjusted odds ratio (AOR) 2.67, 95% confidence interval (CI) 1.13 to 6.30], preterm delivery (AOR 2.66, 95% CI 1.15 to 6.17), and LBW (AOR 3.10, 95% CI 1.16 to 4.39).¹⁸ Iron-deficiency anemia during the second trimester of pregnancy has also been significantly associated with preterm delivery (AOR 4.3, 95% CI 1.2 to 15.5), particularly among black women (AOR 1.9, 95% CI 1.5 to 2.3).¹⁹

Iron-deficiency anemia, as measured at 16–18 weeks (second trimester) and at 25–32 weeks (third trimester), is significantly associated with preterm delivery, with increased risks with ORs ranging from 2.7 to 4.3 and 1.8 to 3.5, respectively, depending on the age and racial composition of the study populations.^{18–21} Serum ferritin levels, which are elevated in the presence of infection and lowered with iron deficiency, have also been linked to prematurity. Extremes of maternal serum ferritin, measured early in the second trimester (15–17 weeks), as well as elevated levels at 24, 26, or 28 weeks have been associated with preterm birth.^{22–26} Recently, it has been shown that, when elevated third-trimester serum ferritin levels show a failure to decline, they are significantly associated with preterm and very preterm birth (AOR 8.77, 95% CI 3.9 to 19.7 and AOR 3.81, 95% CI 1.93 to 7.52 respectively), with iron-deficiency anemia and poor maternal nutritional status underlying the relationship.²⁶

Iron status during pregnancy has also been linked to fetal programming and the development of chronic disease. Low maternal hemoglobin is strongly related to the development

of a large placenta and high placental–birthweight ratio, which is seen as predictive of long-term programming of hypertension and cardiovascular disease. Severe maternal iron-deficiency anemia leads to placental adaptive hypertrophy, a fall in the cortisol metabolizing system, and increased susceptibility to hypertension in later life. Because the iron demands of pregnancy may exceed 1 g, with nearly half this amount in the red cell mass increase in blood volume, the maternal preconceptional and early pregnancy iron status is extremely important.

Mineral intake and supplementation

In addition to being the nutrients most often lacking in women's diets, calcium, magnesium, and zinc have been identified as having the most potential for reducing pregnancy complications and improving outcomes.^{11,27–29} A recent review by the World Health Organization concluded that these nutrients “be rigorously evaluated as these . . . substances may have effects on both impaired fetal growth and preterm delivery.”²⁷

Calcium

During pregnancy, there is an increased physiologic demand for calcium such that a full-term infant accretes about 30 g, primarily in the third trimester, when there is active ossification of the fetal skeleton. Prenatal diets low in calcium have been associated with increased blood pressure because of heightened smooth muscle reactivity, resulting in an increased risk of pregnancy-induced hypertension and preterm delivery. Nearly all calcium supplementation trials have been shown to lower blood pressure levels.^{30–35}

Results of calcium supplementation trials among high-risk women have been promising, with significant reductions in preterm deliveries among teenagers (7.4% versus 21.1%, $P < 0.007$) and significantly longer mean gestations among women with very low dietary calcium intakes (37.4 versus 39.2 weeks, $P < 0.01$).^{30,31,34} Other studies have shown inconsistent results in lowering the rates of pregnancy-induced hypertension, or no effect on preterm delivery and small for gestational age births.^{32,35} Calcium supplementation trials among high-risk women (teenagers in Baltimore and women with very low calcium intakes in Quito, Ecuador) were promising in decreasing the rate of preterm delivery. Among teenagers (aged 16 years) in Baltimore, with similar overall dietary calcium intakes, the calcium-supplemented group had a lower incidence of preterm delivery than the placebo group (7.4% versus 21.1%, $P < 0.007$).³⁰ Life-table analysis demonstrated an overall shift to a higher gestational age in the calcium-supplemented group. In Ecuador, length of gestation was increased from 37.4 to 39.2 weeks for the calcium-supplemented group versus the placebo group.^{31,34} On the

other hand, a large calcium supplementation trial of over 1000 adult women from Argentina showed a decrease in pregnancy-induced hypertension, but no effect on preterm delivery,³² and a recent multicenter trial of calcium supplementation in the United States with more than 4500 adult women showed no difference in pregnancy-induced hypertension, preterm deliveries, or small for gestational age births.³⁵ The ability of supplemental calcium to decrease the risk of preterm delivery may be confined to high-risk populations where there is either a severe dietary restriction of calcium or, as in the case of adolescents and multiple pregnancy, an increased demand for this nutrient.

Prenatal calcium supplementation may have more far-reaching effects, beyond pregnancy. Belizán et al.³⁶ evaluated blood pressure in 7-year-old children whose mothers had received calcium supplementation during pregnancy. They reported significantly lower systolic blood pressure and lower risk of high systolic blood pressure [relative risk (RR) 0.59, 95% CI 0.39 to 0.90], particularly among children in the highest quartile of body mass index [BMI, weight/(height)²], (RR 0.43, 95% CI 0.26 to 0.71).

Magnesium

Magnesium supplementation trials have also reported inconsistent results.^{37–39} These inconsistencies may have been due to differences in study design, study populations, and the concurrent use of other medications such as β -sympathomimetic agents.³⁹ Recent studies have demonstrated that magnesium is not only effective as therapy for and prophylaxis against eclampsia, but is safe and potentially beneficial for the neonate.^{40,41} In a case–control study examining the risk of cerebral palsy in premature infants exposed to magnesium *in utero*, Nelson and Grether⁴² reported a protective effect (OR 0.14, 95% CI 0.05 to 0.51), regardless of whether the magnesium had been given for preeclampsia or as treatment for preterm labor. In a population-based cohort study of prenatal magnesium exposure among children who had very LBW, Schendel et al.⁴³ also reported a protective effect against cerebral palsy (OR 0.11, 95% CI 0.02 to 0.81), and possibly against mental retardation (OR 0.30, 95% CI 0.07 to 1.29). Recent analyses indicate that reduced long-term morbidity with prenatal magnesium exposure is unlikely because of selective mortality of vulnerable infants.⁴⁴ Magnesium therapy, as prenatal supplementation or as therapy for preeclampsia or preterm labor, may play a neuroprotective role.

Maternal zinc status

During pregnancy, plasma zinc concentrations decline by 20–30% compared with nonpregnant values, reflecting the transfer of zinc from mother to fetus and the normal

expansion of the maternal plasma volume. Plasma zinc concentrations and available zinc intakes are significantly correlated, with zinc supplementation increasing maternal plasma levels.⁴⁵ Using plasma zinc as an indicator of zinc status, Neggers et al.⁴⁵ found a positive correlation between duration of gestation and zinc concentration at entry to prenatal care. A recent randomized trial of zinc supplementation of women with plasma zinc levels below the median showed that zinc supplementation resulted in an increase in gestation duration by approximately 0.5 weeks and an increase in birthweight.⁴⁶ Plasma zinc levels in the lowest quartiles are associated with significantly greater frequency of maternal complications, including infection.^{47,48} Maternal zinc nutriture, as a composite index of zinc measured from maternal whole blood, hair, and colostrum, has been shown to be related to the risk of premature rupture of membranes (PROM).⁴⁸ Women with PROM were found to have significantly lower levels of zinc compared with women who gave birth at term.

Scholl et al.⁴⁹ evaluated the association between dietary zinc intake and pregnancy outcome in a cohort of 818 low-income, mostly minority women in Camden, NJ, USA. A low zinc intake during pregnancy (< 6 mg/day or < 40% of the RDA for pregnancy) was associated with an increased incidence of iron-deficiency anemia at entry to care, a lower use of prenatal supplements during pregnancy, and a higher incidence of inadequate weight gain during pregnancy. Even after adjusting for other confounding variables (e.g., energy intake, maternal age, ethnicity, cigarette smoking), a low dietary intake of zinc was associated with a twofold increase in the risk of LBW (AOR 2.10, 95% CI 1.19 to 3.67), a nearly twofold increase in preterm delivery (AOR 1.86, 95% CI 1.11 to 3.09), and a threefold increased risk of early preterm birth (< 33 weeks' gestation) (AOR 3.46, 95% CI 1.04 to 11.47). In addition, there was a joint effect of iron-deficiency anemia at entry to care and a low zinc intake during pregnancy. When both were present, there was a fivefold increased risk of preterm delivery (AOR 5.44, 95% CI 1.58 to 18.79).

Although maternal zinc nutriture has been significantly related to length of gestation, infection, and risk of premature rupture of membranes,^{45,47,48} clinical trials of zinc supplementation have yielded equivocal results.^{50,51} A clinical trial that randomly supplemented only women with plasma zinc levels below the median reported an increase in length of gestation of approximately 0.5 weeks ($P = 0.06$), and an increase in birthweight, about half of which was explained by the longer duration of gestation.⁴⁶ Consistent with prior results, effects were increased for nonobese women (pregravid BMI < 26.0). Studies of prenatal zinc supplementation have reported an improvement in fetal neurobehavioral development.⁵²

Maternal pregravid weight and gestational weight gain

The factors most strongly correlated with both length of gestation and birthweight are maternal height, pregravid or early pregnancy body weight, maternal fat deposition, and gestational weight gain. Although each factor independently influences birthweight and length of gestation, their effects are neither equal nor additive. The landmark studies in this area are from the Collaborative Perinatal Project, which was conducted between 1959 and 1964.^{53–56} Based on term singleton pregnancies, these studies demonstrated that: (1) a progressive increase in weight gain was paralleled by an increase in mean birthweight and a decline in the incidence of LBW; (2) increasing pregravid weight diminishes the effect of weight gain on birthweight; (3) there is an inverse relationship between weight gain and perinatal mortality, with gains up to 30 pounds (13.6 kg); and (4) higher gestational weight gains are related to higher birthweights and better growth and development during the first postnatal year. As a result of these and subsequent studies, in 1990, the IOM issued pregravid BMI-specific weight gain guidelines for singleton pregnancies (Table 36.2).¹⁶ Many investigators have subsequently confirmed these

Table 36.2 Institute of Medicine (IOM) categories of pregravid body mass index (BMI) and suggested weight gain ranges for singleton pregnancies.

Weight status	BMI range (kg/m ²)	Total gain at 40 weeks	Weight gain at trimester 1	Rate of gain at trimesters 2 and 3
Underweight	< 19.8 kg/m ²	12.5–18.0 kg (28–40 lb)	2.3 kg (5.1 lb)	0.49 kg/week (1 lb/week)
Normal weight	19.8–26.0 kg/m ²	11.5–16.0 kg (25–35 lb)	1.6 kg 0.44 kg/week (3.5 lb)	(1 lb/week)
Overweight	26.1–29.0 kg/m ²	7.0–11.5 kg (15–25 lb)	0.9 kg 0.30 kg/week (2.0 lb)	(0.5–0.75 lb/week)
Obese	> 29.0 kg/m ²	≥ 6.8 kg (≥ 15 lb)	No recommendation	

associations, including the link between low prepregnancy weight and both prematurity and intrauterine growth retardation (IUGR), with reported increased risks ranging from 1.7 to 3.0, depending on the study population.⁵⁷ The population-attributable risk for early preterm birth (< 32 weeks) with low prepregnancy weight is as much as 31–43%, depending on race and ethnicity.⁵⁸ Low maternal weight gain has also been significantly associated with both IUGR and preterm birth, with reported risks with ORs in the range of 2.1–4.3.^{16,59–63} Significant interaction has also been documented between low pregravid weight and low weight gain on the risk of preterm birth (AOR 5.63, 95% CI 2.35 to 13.8).⁶¹

Pattern of weight gain

Although cumulative or total weight gain is an important predictor of birthweight, the pattern of weight gain and rates of gain also play significant roles in modifying birthweight and predicting preterm delivery.^{64,65} Hediger et al.⁶⁴ demonstrated that both early gains (before 24 weeks' gestation) and later weight gains (after 24 weeks) have independent effects on the outcome of singleton births. In a multiracial sample of 1790 teenagers from Camden County, NJ, USA, early inadequate weight gain (< 4.3 kg by 24 weeks) was associated with an increased risk of small for gestational age outcomes (SGA, < 10th percentile for gestation) (AOR 2.08, 95% CI 1.31 to 3.30).⁶⁴ Even if there were compensatory gains after 24 weeks, bringing the cumulative total gain up to levels deemed adequate, the risk of an SGA birth was still increased (AOR 1.88, 95% CI 1.08 to 3.27). This strongly suggests that early weight gains, which presumably reflect gains in maternal nutrient stores, are important in enhancing fetal growth, whether by serving as a nutrient reserve later in pregnancy or as a marker for adequate placental growth and development. In these studies, preterm delivery (< 37 weeks) was relatively unaffected by early inadequate weight gain, but was increased with late inadequate weight gain (< 400 g/week). Again, this occurred even when the total pregnancy weight gain never fell below the targets set in clinical standards (AOR 1.69, 95% CI 1.12 to 2.55).⁶⁴

Changes in maternal body fat

A substantial portion of gestational weight gain is maternal body fat, which, when measured as the triceps skinfold thickness or mid-upper arm circumference (MUAC), increases in the first two trimesters and decreases in the third, reflecting the early accretion of maternal body fat and the subsequent utilization in late gestation to meet increasing energy needs. The components of maternal weight gain, particularly changes in body fat, may be more important determinants of pregnancy outcome than absolute weight gain. Prior studies of well-nourished women, based on deuterium oxide and under-

water weighing^{66–69} as well as anthropometric measures,^{70–72} have reported a pattern of small gains in maternal body fat early in pregnancy, rapid accumulation between 20 and 30 weeks' gestation, and a leveling off between 30 weeks and delivery. A consistent finding in studies with diverse ethnic and racial groups is the correlation between triceps skinfold or MUAC measures during the second trimester and birthweight, with the loss of upper arm fat or the failure to accrue maternal fat during the second trimester associated with poor fetal growth and subsequent lower birthweights.^{70–74}

Examining the components of weight gain in pregnancy, Hediger et al.⁷⁵ demonstrated that, for teenagers and adults whose pregravid weights were above the 25th percentile for age, the loss of subcutaneous fat (> 6.4 cm²) from 28 weeks through 4–6 weeks postpartum (measured at the mid-upper arm) was associated with a higher birthweight (+ 144 g, $P < 0.01$). At the same time, there appeared to be a mobilization of fat stores; there was an increase in arm muscle area. However, when pregravid weight was below the 25th percentile for age, a loss of upper arm fat was associated instead with a lower birthweight (–339 g, $P < 0.01$), suggesting that the nutrient stores of these women may have been relatively depleted. Continued weight gain and increases in upper arm fat area (> 5 cm²), accompanied by a loss of upper arm muscle, was also associated with a lower birthweight (–123 g, $P < 0.02$). Thus, a change in upper arm fat is a significant predictor of variation in infant birthweight, and serial monitoring by arm anthropometry, as well as maternal weight, may help to determine risk for IUGR.

Postpartum weight retention

Gestational weight gain is the single most important factor influencing postpartum weight retention, a finding consistent throughout the medical literature. The challenge with pregnancy weight gain is to have an optimal balance. That is, sufficient gain for good fetal growth, but low enough to avoid postpartum weight retention. Li et al.⁷⁶ have shown that each kilogram of maternal weight gain in the second and third trimester was associated with significant increases in birthweight of 62 g ($P < 0.001$) and 26 g ($P < 0.05$) respectively. Each kilogram of maternal weight gain during midpregnancy (but not late pregnancy) was also associated with significant increases in birth length of 0.24 cm ($P < 0.01$) and head circumference of 0.14 cm ($P < 0.001$). Brown et al.⁷⁷ reported that each kilogram of maternal weight gain in the first and second trimesters significantly increased birthweight by 31 g ($P < 0.0007$) and 26 g ($P < 0.0007$), but maternal gain in the third trimester had a minimal and nonsignificant effect (7 g, $P = 0.40$). These researchers also reported that, per kilogram of maternal weight gain in the first trimester, newborn ponderal index (in kg/m³) increased by 0.21 units ($P < 0.0003$) and, per kilogram maternal gain in the third trimester, newborn ponderal index increased by 0.12 units ($P < 0.03$),

but not by maternal gain in the second trimester. Newborn birthweight was 211 g lower ($P < 0.006$) and ponderal index 1.2 units lower ($P < 0.02$) with maternal weight loss in the first trimester.

Likewise, Strauss and Dietz,⁷⁸ in their analyses of the National Collaborative Perinatal Project (NCPP) and the Child Health and Development Study (CHDS), reported that maternal weight gain $< 0.3\text{kg/week}$ in the second or third trimester was associated with increased risks for IUGR. Low maternal gain in the second and third trimesters was associated with relative risks of IUGR of 1.8 (95% CI 1.3 to 2.6) and 1.7 (95% CI 1.3 to 2.3), respectively, in the NCPP cohort and 2.6 (95% CI 1.6 to 4.1) and 2.5 (95% CI 1.7 to 3.8), respectively, in the CHDS cohort. To and Cheung⁷⁹ have shown that women who gain weight excessively after mid-pregnancy retained more weight postpartum, and their weight gain had less of an effect on the birthweight of their infants than women who had gained weight earlier in pregnancy but who did not gain weight excessively in late pregnancy. Kac et al.,⁸⁰ in their study of 405 Brazilian women aged 18–45 years, reported that women with the highest gestational weight gain and with baseline body fat $\geq 30\%$ had the highest likelihood of developing maternal obesity. They reported that 35% of each kilogram of weight gained during pregnancy was retained at 9 months postpartum, even after adjustment for age, prepregnancy BMI, body fat at baseline, and years since first parturition. In their study of healthy, nonsmoking, white women in Canada, Muscati et al.⁸¹ reported that a pregnancy weight gain of 12 kg was associated with 2.5 kg postpartum weight retention, and that total pregnancy weight gain was more strongly associated with postpartum weight retention than infant birthweight.

Multiple pregnancy

In 2002, in the United States, there were 132 535 infants of multiple births, the highest number ever recorded in the history of the vital statistics system.⁸² The incidence of twin births has increased by 65% since 1980 and by 38% since

1990, while the triplet and higher order multiple rate increased an average of 13% per year between 1980 and 1998, and is currently 5% lower than the 1998 peak.⁸² An estimated one-fourth of this rise is due solely to older maternal age, which is associated with a higher natural frequency of multiple births.^{83,84} It is likely that the single most important factor in the rising multiple birth rate is fertility-enhancing therapies: fertility drugs, artificial insemination, and assisted reproductive technology (ART). Recent analyses by the CDC estimated that ART has contributed 39–43% of the increase in triplet and higher order multiple births in the US since 1996, and about 40% was due to ovulation-inducing drugs.^{85,86} The twin and triplet and higher rates for ART patients are estimated to be 14-fold and 54-fold higher, respectively, than for the United States as a whole.⁸⁶ It is estimated that ART accounted for more than 40% of all triplet births in 2000, double the proportion of triplet and higher order births that were estimated to have been conceived using ART in 1990.⁸⁵ By 2000, it is estimated that only about two-thirds of twins and one-fifth of triplet and other higher order multiples were conceived spontaneously.⁸⁷ Infants of multiple births are disproportionately represented among the LBW ($< 2500\text{g}$), very LBW ($< 1500\text{g}$), preterm (< 37 weeks) and very preterm (< 32 weeks) infant populations (Table 36.3). Specialized prenatal care has been shown to reduce adverse outcomes in these high-risk pregnancies, including targeted diet therapy (Table 36.4) and BMI-specific weight gain recommendations (Table 36.5).⁸⁸

Conclusions

Technological advances during the twentieth century will continue to push back the limits of viability. In future decades, the nutrition–fertility link will be expanded at the opposite end of the spectrum, and nutrition *in utero* will emerge as a powerful tool with which to augment growth, development, and vitality. Careful evaluation and aggressive therapy will help to ensure the most positive outcomes during gestation as a foundation for childhood health.

Table 36.3 Birthweight and gestation by plurality, USA, 2002.

Plurality	Singletons	Twins	Triplets	Quadruplets	Quintuplets
Number	3 889 191	125 134	6898	434	69
Percent very preterm (< 32 weeks)	1.6%	11.9%	36.1%	59.9%	78.3%
Percent preterm (< 37 weeks)	10.4%	58.2%	92.4%	96.8%	91.3%
Mean gestational age (weeks, SD)	38.8 (2.5)	35.3 (3.7)	32.2 (3.8)	29.9 (4.0)	28.5 (4.7)
Percent very low birthweight ($< 1500\text{g}$)	1.1%	10.2%	34.5%	61.1%	83.8%
Percent low birthweight ($< 2500\text{g}$)	6.1%	55.4%	94.4%	98.8%	94.1%
Mean birthweight (g, SD)	3332 (573)	2347 (645)	1687 (561)	1309 (522)	1105 (777)

Table 36.5 Optimal rates of maternal weight gain and cumulative gain by pregravid BMI status.

Pregravid BMI	Rates of weight gain (lbs/week)			Cumulative weight gain (lbs)		
	0–20 weeks	20–28 weeks	28 weeks to delivery	to 20 weeks	to 28 weeks	to 36–38 weeks
Underweight (BMI < 19.8)	1.25–1.75	1.50–1.75	1.25	25–35	37–49	50–62
Normal weight (BMI 19.8–26.0)	1.00–1.50	1.25–1.75	1.00	20–30	30–44	40–54
Overweight (BMI 26.1–29.0)	1.00–1.25	1.00–1.50	1.00	20–25	28–37	38–47
Obese (BMI > 29.0)	0.75–1.0	0.75–1.25	0.75	15–20	21–30	29–38

Adapted from ref. 88.

Results are from models controlling for diabetes and gestational diabetes, preeclampsia, smoking during pregnancy, parity, placental membranes, and fetal growth before 20 weeks.

BMI, body mass index.

Key points

- 1 Altered nutrition *in utero* may result in fetal developmental adaptations that permanently alter structure, physiology, and metabolism, and may manifest as chronic disease in adulthood.
- 2 Pregnancy complications and subsequent metabolic and vascular disease may share common underlying disease mechanisms.
- 3 Supplementation in excess of twice the recommended dietary allowance during pregnancy should be avoided, because of the potential for birth defects.
- 4 Iron should not be taken as part of a vitamin–mineral supplement, because of inhibition by other minerals as well as poor iron release.
- 5 Low maternal hemoglobin is strongly related to the development of a large placenta and high placental–birthweight ratio, which is seen as predictive of long-term programming of hypertension and cardiovascular disease.
- 6 Severe maternal iron-deficiency anemia leads to placental adaptive hypertrophy, a fall in the cortisol metabolizing system, and increased susceptibility to hypertension in later life.
- 7 Calcium is actively transferred to the fetus during pregnancy, and diets low in calcium have been associated with increased maternal blood pressure.
- 8 The ability of supplemental calcium to decrease the risk of preterm delivery may be confined to high-risk populations in which there is either a severe dietary

restriction of calcium or, as in the case of adolescents and multiple pregnancy, an increased demand for this nutrient.

- 9 Magnesium is neuroprotective and is an effective therapeutic agent for preterm labor.
- 10 Zinc is actively transferred to the fetus during pregnancy, with low maternal intakes and levels significantly associated with complications, including infections.
- 11 Many investigators have confirmed the associations between low prepregnancy weight and both prematurity and intrauterine growth retardation.
- 12 The population-attributable risk for early preterm birth (< 32 weeks) with low prepregnancy weight is as much as 31–43%, depending on race and ethnicity.
- 13 Although cumulative or total weight gain is an important predictor of birthweight, the pattern of weight gain and rates of gain also play significant roles in modifying birthweight and predicting preterm delivery.
- 14 The components of maternal weight gain, particularly changes in body fat, may be more important determinants of pregnancy outcome than absolute weight gain.
- 15 Gestational weight gain is the single most important factor influencing postpartum weight retention.
- 16 Maternal weight gain in the third trimester has less effect on fetal growth and more effect on retained maternal weight postpartum.
- 17 Maternal weight loss in the first trimester is associated with significantly lower subsequent birthweights.
- 18 Multiple births in the United States are at their all-time high.
- 19 Infants of multiple births are disproportionately represented among the low birthweight and premature infant populations.
- 20 Targeted diet therapy, BMI-specific weight gain goals, and specialized prenatal care have all been shown to improve outcomes in multiple pregnancies.

Maternal Diseases Complicating Pregnancy

37

Trauma, shock, and critical care obstetrics

Erin A.S. Clark, Gary A. Dildy, and Steven L. Clark

Definition of shock

Shock is a condition in which circulation fails to meet the nutritional needs of the cell and remove metabolic wastes.¹ This may result from cardiac dysfunction, hypovolemia (relative or absolute), maldistribution of flow, or intravascular obstruction (Table 37.1). When the circulating blood volume is less than the capacity of its vascular bed, hypotension with diminished tissue perfusion results, leading to cellular hypoxia and, ultimately, cell death.² Depending on the duration and severity of the insult, irreversible organ damage or even death may ensue.

Incidence of shock in the obstetric population

The actual incidence of shock in obstetric patients is unclear. However, by extrapolating mortality data, we can obtain an indication of the relative incidence of shock severe enough to result in the death of the patient. A steady decline in maternal mortality has been noted since 1915, when national vital statistics in the United States were first recorded (Fig. 37.1). Recent statistics for the United States suggest that overall maternal mortality was 11.5 maternal deaths per 100 000 live births during 1991–97.³ The pregnancy-related maternal mortality ratio was threefold greater among black women than in white women⁴ (Table 37.2). The National Health Promotion and Disease Prevention objectives of the *Healthy People 2010* indicators specifies a goal of no more than 3.3 maternal deaths per 100 000 live births in the United States.⁵ This objective remains elusive. The chief cause of a pregnancy-related maternal death depends on whether the pregnancy results in a liveborn, stillbirth, ectopic pregnancy, abortion, or molar gestation (Table 37.3). For the period 1987–1990, hemorrhage was recorded in 28.8% of all deaths, leading to an overall pregnancy-related mortality ratio (PRMR) for hemorrhage of 2.6 per 100 000 live births, followed by embolism-related

deaths (1.8), and hypertensive diseases (1.6). Among live births, hypertensive diseases were the most frequent cause of death (23.8%). Among stillbirths and ectopic pregnancies, the chief cause of death was hemorrhage (27.2 and 94.9% respectively). Infections were the leading cause of abortion-related deaths (49.4%).

Tracking maternal deaths is helpful, but may not give the best indication of the incidence of shock and critical illness in the obstetric population as the majority of such cases do not result in maternal death. Unlike mortality, which is a definable endpoint, shock and critical illness in pregnancy are difficult to define and, therefore, difficult to measure and study precisely. Furthermore, maternal mortality data collection is well established in many places, but specific surveillance systems that record severe complications of pregnancy not associated with maternal mortality are rare. An examination of cases admitted to intensive care units (ICUs) has provided insight into the incidence and etiology of shock and critical illness in the obstetric population, although nearly two-thirds of maternal deaths may occur in women who never reach an ICU.⁷ In 2004, Ananth and Smulian⁸ reviewed 22 studies involving 1 550 723 deliveries and found that 0.07–0.88% of deliveries resulted in admission to an ICU. Reported maternal mortality for critically ill obstetric patients admitted to an ICU was 5.0%. Hypertensive diseases and obstetric hemorrhage were responsible for over 50% of the primary admitting diagnoses, and specific organ system dysfunction was responsible for the majority of the remaining admissions.

General supportive measures

Initial treatment

Several important initial steps should be performed when the diagnosis of shock is made in the obstetric patient. Placement of two large-bore intravenous lines, preferably 16-gauge, for rapid expansion of intravascular volume is the first step. One liter of crystalloid solution should be infused over the first 15 min while other measures are taken. An indwelling bladder

Table 37.1 Classification scheme for shock.

Type	Physiologic derangement	Examples
Cardiogenic	Diminished cardiac function	Cardiomyopathy, myocardial infarction
Hypovolemic	Decreased intravascular volume	Hemorrhage, dehydration
Distributive	Inappropriate distribution of perfusion	Septic shock, neurogenic shock
Obstructive	Intravascular obstruction	Pulmonary embolus

catheter is placed for hourly determination of urine output. An arterial line allows continuous measurement of systemic blood pressure, as well as easy access for laboratory investigations. Oxygen should be administered via a face mask at 8–10 L/min, and the inspired oxygen concentration adjusted according to arterial blood gas results. Inability to maintain an adequate tidal volume, poor arterial oxygenation, and airway obstruction may require endotracheal intubation with

positive pressure ventilation. Initial laboratory investigation should include blood type and cross-match, complete blood count, platelets, fibrinogen, electrolytes, blood urea nitrogen, creatinine, and arterial blood gas. Urine should be sent for analysis and microscopic evaluation. When the patient is stabilized, cultures from blood, urine, sputum, amniotic fluid, endometrial cavity, and stool are taken, as indicated, if sepsis is suspected.

Volume replacement

Whether to give crystalloid or colloid solutions for initial treatment is controversial.⁹ Rackow and colleagues¹⁰ showed that two to four times as much 0.9% saline was required to reach the same hemodynamic endpoints as 6% hetastarch and 5% albumin. Colloid osmotic pressure rose when albumin and hetastarch were administered and fell when saline was given. Resuscitation with normal saline resulted in a higher incidence of pulmonary edema, probably related to the fall in colloid osmotic pressure. Standard dextran, with a molecular weight averaging 75 000, may initiate intravascular coagulation. Low-molecular-weight dextran, with a molecular weight aver-

aging 40 000, carries a smaller risk of initiating disseminated intravascular coagulopathy (DIC), but also has less tendency to pull fluid into the intravascular space.¹¹ A 1984 American College of Obstetricians and Gynecologists technical bulletin titled *Hemorrhagic Shock* recommends avoidance of dextran because of its anticoagulant effect and risk of anaphylaxis.¹² Owing to its expense and tendency to extravasate into the interstitium, albumin is also probably not a colloid of first choice. Given these objections, hetastarch may be a better choice of colloid if initial crystalloid therapy does not result in the desired clinical improvement. In a meta-analysis of several randomized controlled trials, there was no evidence that colloids achieve a superior clinical outcome when compared with crystalloid therapy.¹³ Crystalloids are therefore reasonable and cost-effective first-line therapy for volume resuscitation. When severe, correction of metabolic acidosis may be aided by adding sodium bicarbonate to intravenous fluids. Lactated solutions should be avoided because aerobic metabolism is required for the conversion of lactate to bicarbonate.^{2,14}

Blood component therapy

In the case of hemorrhagic hypovolemic shock and DIC, blood component therapy is often indicated. Which components should be used is determined largely by laboratory parameters. An obvious exception is profuse hemorrhagic shock, for which immediate blood components, specifically packed red blood cells, are indicated. It must be remembered that the degree of hemorrhage is often underestimated by as much as 50%.¹⁵

Packed red blood cells are administered through an 18-gauge or larger intravenous line in order to increase blood volume and oxygen-carrying capacity to the tissues. The term

massive blood replacement is used when the total blood volume of the patient is replaced over a 24-hour period.¹⁵ In those patients who have been typed and screened for antibodies, the risks of abbreviating the major cross-match in an urgent transfusion (after the “immediate spin” phase of the cross-match) are low and are often outweighed by the risk of hemorrhagic shock.¹⁶

The use of fresh frozen plasma (FFP) requires specific indications: replacement of isolated or combined factor deficiencies, reversal of warfarin effect in patients actively bleeding or requiring emergency surgery, antithrombin III deficiency, immunodeficiencies, thrombotic thrombocytopenia purpura, and massive blood transfusion in cases in which factor deficiencies are presumed to be the sole or principal derangement.^{17,18} Besides containing the components of the coagulation, fibrinolytic, and complement systems, FFP also contains proteins that maintain oncotic pressure and modulate immunity. Because of risks, including disease transmission, anaphylactoid reactions, alloimmunization, and volume overload, alternative therapy with crystalloids is encouraged for volume replacement. Pathologic hemorrhage in the patient receiving massive transfusion is usually due to thrombocytopenia rather than depletion of coagulation factors. Empiric administration of FFP should therefore be allowed only in those patients in whom factor deficiencies are presumed to be the sole or principal derangement.¹⁷ In massively transfused patients, there is no evidence to support prophylactic transfusion of FFP after transfusion of a certain number of units of packed red blood cells unless coagulation factor defects have been documented.¹⁹ The most useful tests for predicting abnormal bleeding and guiding therapy in massively transfused trauma patients are the platelet count and fibrinogen level.²⁰ Normal hemostasis requires no more than 30% of normal values of clotting factors. Bleeding would therefore not be expected

until the prothrombin time (PT) and activated partial thromboplastin time (aPTT) have exceeded 1.5 times their reference values.²¹

Thrombocytopenia may be secondary to a dilutional effect or to consumption of platelets. Adults have a limited mobile platelet pool and a limited ability to increase production acutely.²² Moreover, platelets in refrigerated blood quickly become nonviable.²³ Platelet transfusion should be considered when the platelet count falls to less than 10 000/ μ L, or to less than 35 000/ μ L in preparation for a surgical procedure or in the face of active bleeding. Minimization of blood product transfusion can be effected by correcting thrombocytopenia and specific coagulation factor defects.¹⁵ In trauma patients, platelets are usually required after a patient receives more than 20 units of blood in a 12-hour period.²³ However, in obstetric patients who experience thrombocytopenia secondary to other causes (e.g., preeclampsia), platelet transfusion may be indicated much earlier in the course of treatment.

Cryoprecipitate should be administered instead of FFP when the calculated coagulation factor deficit based on blood fibrinogen levels suggests that FFP will result in inadequate replacement or in volume overload (Fig. 37.2). Table 37.4 demonstrates the therapeutic contents per volume of each blood product.²⁴

Pharmacologic agents

If adequate intravascular volume replacement is not successful in supporting blood pressure (i.e., mean arterial pressure ≥ 65 mmHg) and other reversible causes of shock are not found (e.g., cardiac arrhythmia, tension pneumothorax), an advanced stage of shock should be suspected. In order to ensure tissue perfusion in these refractory cases, cardiac performance should be enhanced through the use of inotropic agents (Table 37.5). Dopamine is considered a first-line inotropic agent. Dopamine is an endogenous catecholamine, structurally similar to norepinephrine and epinephrine. Dopamine increases myocardial contractility and heart rate via beta-adrenergic receptors and releases norepinephrine from myocardial storage sites. Its action on blood vessels is dose dependent, resulting in vasodilation of renal, mesenteric, coronary, and intracerebral vessels via dopamine receptors, and vasoconstriction of all vascular beds in higher doses via alpha-adrenergic receptors.²⁶ Dopamine should be started at 2–5 μ g/kg/min and titrated to the desired clinical parameters.²⁶ Although there is considerable variance, generally, doses between 2 and 5 μ g/kg/min result in vasodilation of renal and mesenteric vasculature via β_2 and dopaminergic receptors, whereas doses between 5 and 10 μ g/kg/min tend to result in

Table 37.4 Summary chart of blood components.

Component	Content	Indications for use	Amount of active substance per unit	Volume (mL)
Red blood cells	Red blood cells, some plasma, some white blood cells and platelets their degradation products	Increase red blood cell mass for symptomatic anemia	200 mL packed red blood cell mass	250–350
Leukocyte-poor red blood cells	Red blood cells, some plasma, few white blood cells	Prevent febrile reactions due to leukocyte antibodies, and increase red blood cells mass	185 mL packed red blood cell mass	200–250
Frozen–thawed washed red blood cells	Red blood cells, no plasma, minimal white blood cells and platelets	Increase red blood cell mass; prevent sensitization to HLAs; prevent febrile or anaphylactic reactions to white blood cells, platelets, and proteins (IgA); provide rare blood cells	170–190 mL packed red blood cells	300
Platelet concentrations	Platelets, few white blood cells, some plasma	Bleeding due to thrombocytopenia or thrombocytopathia	At least 5.5×10^{10} platelets	30–50
Fresh frozen plasma	Plasma, all coagulation factors, no platelets	Treatment of coagulation disorders	0.7–1.0 U factors II, V–VI, VIII–XIII, 500 mg fibrinogen	220–250
Cryoprecipitate	Fibrinogen, factor VIII, factor XIII, von Willebrand's factor	Factor VIII deficiency (hemophilia A) von Willebrand's disease; factor XIII deficiency; fibrinogen deficiency	80 U factor VIII; 200 mg fibrinogen	20–25

increased myocardial contractility and cardiac output via β_1 receptors.²⁷ Doses of more than 20 $\mu\text{g/kg/min}$ result in generalized vasoconstriction via alpha-adrenergic receptors. High-dose dopamine has been demonstrated to decrease uterine blood flow in healthy and hypotensive pregnant sheep.^{28,29} This should be kept in mind when administering dopamine during pregnancy.

If satisfactory hemodynamic performance is not achieved and the patient is not profoundly hypotensive, dobutamine may be added to the dopamine regimen at 2.5–10 $\mu\text{g/kg/min}$ (Fig. 37.3). Dobutamine increases cardiac output with minimal tachycardia by acting as a myocardial beta-receptor stimulant. Unfortunately, it may also reduce afterload and lower systemic blood pressure, and must be used with caution in severe hypotension. If dobutamine does not provide adequate improvement, isoproterenol, a beta-adrenergic agonist, may be added. Increased heart rate and contractility are achieved at the risk of ventricular ectopy, excessive tachycardia, and peripheral vasodilation. Although rarely used in acute hypotension, other inotropic agents, such as digoxin and amrinone, may also be used to improve myocardial contractility.³⁰ Digoxin is usually administered with continuous electrocardiographic monitoring by giving an initial bolus of 0.5 mg by intravenous push, followed by 0.25-mg doses every 4 hours for a total loading dose of 1.0 mg. The maintenance dosage in pregnant patients is usually at least

Table 37.6 Vasopressor agents.

Vasopressor agent	Mechanism of action	Dosage
Phenylephrine (Neo-synephrine)	Alpha-adrenergic increased systemic vascular resistance	1–5 $\mu\text{g/kg/min}$
Norepinephrine (Levophed)	Mixed adrenergic alpha and beta generalized vasoconstriction increased systemic vascular resistance	1–4 $\mu\text{g/min}$

Source: modified from ref. 25.

0.25–0.37 mg/day, depending on plasma levels.^{25,31} Amrinone, an inotropic agent with vasodilatory activity, is indicated for the short-term management of cardiac failure.³⁰ A bolus of 0.75 mg/kg over 2–3 min is given, and an infusion of 5–10 $\mu\text{g/kg/min}$ should follow. Vasodilation may be undesirable, particularly in distributive shock, and agents producing vasodilation should only be used with caution.

When blood pressure does not respond to inotropic therapy, a peripheral vasoconstrictor should be considered to maintain appropriate vascular tone (Table 37.6). Phenylephrine, an alpha-adrenergic agonist, may be initiated at 1–5 $\mu\text{g/kg/min}$. Norepinephrine, a mixed alpha- and beta-agonist with powerful vasoconstrictive properties, may be added to provide generalized vasoconstriction and increased systemic vascular resistance. This agent is used in situations in which blood pressure is dangerously low (mean arterial pressure < 60 mmHg) despite other therapy, because perfusion to vital organs, such as the kidneys and lungs, may be reduced by the vasoconstriction. Although vasoconstrictors are commonly used, there are few data to suggest they improve outcome.^{31,32}

Particular caution must be exercised with the use of these agents in gravid patients. Only correction of maternal hypovolemia will maintain placental perfusion and prevent fetal compromise. Although vasopressors may temporarily correct hypotension, they do so at the expense of uteroplacental perfusion, as the uterine spiral arterioles are especially sensitive to these agents. Vasopressors should therefore be used in the treatment of obstetric hemorrhagic shock only when essential for maternal survival.

In hypovolemic shock, vasopressors or inotropic agents are rarely indicated and should not be given until the intravascular volume has been adequately replaced.

Hemodynamic monitoring

The pulmonary artery catheter was introduced in 1970 for the determination of pressures in the right side of the heart and pulmonary capillary wedge pressure.³³ The pulmonary artery catheter provides direct measurement of central venous pressure, pulmonary artery systolic and diastolic pressure, and

Table 37.7 Hemodynamic indices in nonpregnant and normal third-trimester pregnant women measured by pulmonary artery catheter.

pulmonary capillary wedge pressure, whereas thermodilution techniques and physiologic equations allow derivation of cardiac output, systemic vascular resistance, and other hemodynamic parameters. Normal values during pregnancy have been published^{34,35} and are summarized in Table 37.7. In select cases, placement of a pulmonary artery catheter should be considered to aid in assessing cardiac function and hemodynamic status. Several prospective trials have demonstrated the benefits of pulmonary catheterization in selected critically ill patients. These benefits may include a reduction in morbidity and mortality in complicated surgical patients and in patients in shock. This technique, however, is not without its critics.³⁸ A nonrandomized observational study demonstrated increased mortality and cost associated with pulmonary artery catheterization.³⁹ In contrast, a recent randomized controlled trial (*n* = 201) of the pulmonary artery catheter in critically ill patients by Rhodes et al.⁴⁰ concluded that its use is not associated with increased mortality.

Some pathophysiologic conditions secondary to, or in association with, the pregnant state may be diagnosed and treated appropriately with the Swan–Ganz catheter. The differentiation between pulmonary edema secondary to high pulmonary capillary wedge pressure versus low pulmonary capillary wedge pressure can be determined with the pulmonary artery catheter. Kirshon and Cotton³⁰ found that the development of hydrostatic pulmonary edema may occur at lower pulmonary capillary wedge pressures during pregnancy secondary to a lower colloid osmotic pressure. Numerous studies have documented the frequent discrepancy between measurements of central venous pressure and pulmonary capillary wedge pressure during pregnancy.^{37,41–43} Central venous pressure would

Table 37.8 Indications for pulmonary artery catheterization during pregnancy.

1. Massive blood loss with large transfusion requirements, particularly in the face of oliguria or pulmonary edema
2. Septic shock, especially when accompanied by hypotension or oliguria, required volume resuscitation or vasopressor therapy
3. Cardiac failure or pulmonary edema of uncertain etiology
4. Severe pregnancy-induced hypertension complicated by pulmonary edema, oliguria unresponsive to initial fluid challenge, or severe hypertension refractory to conventional therapy (hydralazine)
5. Labor and delivery in patients with significant cardiovascular disease (New York Heart Association functional class III and IV patients)
6. Intraoperative cardiovascular decompensation (e.g., pulmonary hypertension with shunting secondary to amniotic fluid embolism)
7. During peripartum period in patients with severe preeclampsia and structural cardiac defects
8. Thyroid storm with evidence of high output failure
9. Diabetic ketoacidosis with severe hypovolemia and oliguria

be misleading in these circumstances, and so central venous monitoring is seldom indicated in obstetric critical care. Potential clinical indications for use of the pulmonary artery catheter in obstetric patients are summarized in Table 37.8. One simple but clinically helpful use for the Swan–Ganz catheter is to guide volume resuscitation through use of the volume challenge (Fig. 37.4).

On insertion of the Swan–Ganz catheter, advancement to

Figure 37.4 Swan-Ganz catheter placement. Swan-Ganz catheter depicting central venous pressure (CVP) port, pulmonary artery and balloon port, and attachment for thermistor. During advancement through the right side of the heart, characteristic pressure tracings are recorded from the right atrial, right ventricular, pulmonary artery, and pulmonary capillary wedge positions (reprinted from ref. 46, with permission).

Table 37.9 Hemodynamic and ventilatory parameters.

	Nonpregnant	Pregnant
Central venous pressure (mmHg)	1–7	Unchanged
Pulmonary capillary wedge pressure (mmHg)	6–12	Unchanged
Mean pulmonary artery pressure (mmHg)	9–16	Unchanged
Systemic vascular resistance (dyne/cm/s ⁻⁵)	800–1,200	Decreased 25%
Pulmonary vascular resistance (dyne/cm/s ⁻⁵)	20–120	Decreased 25%
Cardiac output (L/min)	4–7	Increased 30–45%
Arterial P_{O_2} (mmHg)	90–95	104–108
Arterial P_{CO_2} (mmHg)	38–40	27–32
Arterial pH	7.35–7.40	7.40–7.45
Oxygen consumption (mL/min)	173–311	249–331

the right side of the heart demonstrates characteristic pressure tracings through the right atrium, right ventricle, pulmonary artery, and pulmonary capillary wedge positions (Fig. 37.5). From these waveforms, specific hemodynamic and ventilatory parameters can be determined (Table 37.9). Cardiac output may then be used to construct a ventricular function curve (Fig. 37.6). Hemodynamic subsets of ventricular function can be evaluated by plotting stroke index against left ventricular filling pressure (Fig. 37.7). A knowledge of pulmonary

capillary wedge pressure, pulmonary artery diastolic-wedge gradient, and the arteriovenous oxygen difference makes it possible to ascertain the precise etiology of cardiopulmonary compromise (Fig. 37.8).

After placement of the Swan-Ganz catheter, a chest radiograph should be obtained to rule out pneumothorax and to confirm the catheter's position. Most complications encountered in patients undergoing pulmonary artery catheterization are a result of obtaining central venous access. These compli-

Figure 37.5 Normal ventricular function curve. (reprinted from ref. 36, with permission).

cations, which include pneumothorax and insertion site infection, occur in 1–5% of patients undergoing the procedure.^{47–49} Potential complications of pulmonary artery catheterization include air embolism, thromboembolism, pulmonary infarction, catheter-related sepsis, direct trauma to the heart or vessels, Horner's syndrome and catheter intrapneumothorax.^{50–55} These complications are uncommon and occur in 1% or fewer patients.

Development of accurate noninvasive methods of central hemodynamic assessment would help to minimize risks associated with invasive techniques. Such methods generally focus on sonographic or bioimpedance techniques to estimate cardiac output and have been described in both pregnant and nonpregnant patients.^{31,56–59} Techniques to investigate noninvasive central pressure determination are also continuing.⁶⁰ For now, invasive techniques remain the standard for ongoing management of critically ill obstetric patients.

Electronic fetal heart rate monitoring

During the development of shock in the pregnant patient, redistribution of maternal cardiac output to vital organs such as the brain and heart may occur at the expense of the utero-placental fetal unit. In the pregnant patient, fetal hypoxia may lead to changes in the heart rate pattern before the mother becomes overtly hypotensive.⁶¹ In the absence of abnormal changes in the fetal heart rate pattern, significant maternal shock is unlikely.⁶¹ Consequently, fetal heart rate is a clinically useful window to endorgan perfusion, and continuous electronic fetal heart rate monitoring with appropriate interpretation may be an important adjunct in the care of the critically ill pregnant patient.

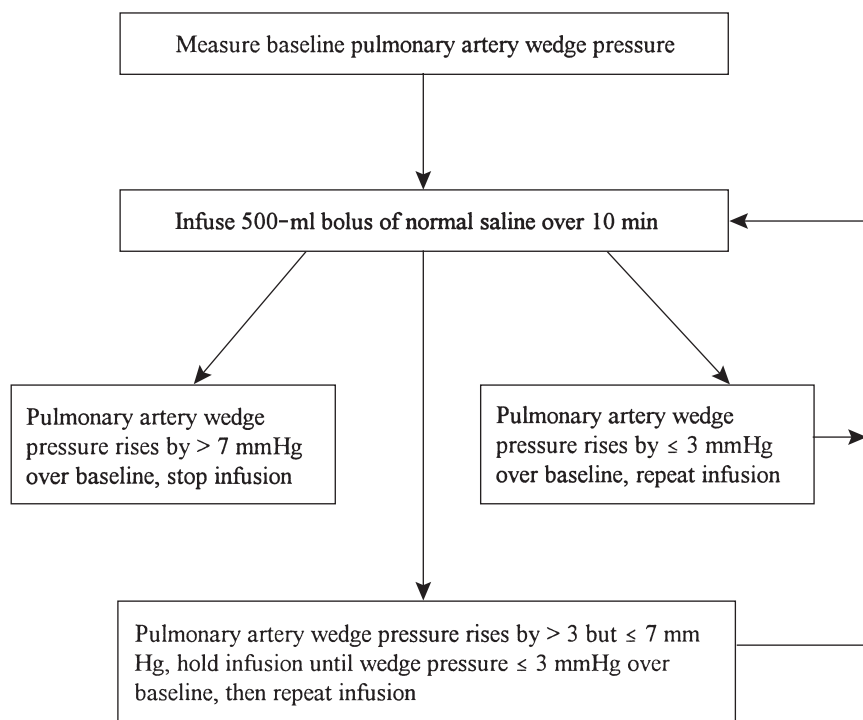

Figure 37.8 Pulmonary artery catheter-guided volume challenge.

The appropriate duration of electronic fetal monitoring after trauma has been the subject of investigation. The occurrence of adverse outcomes including abruptio placentae is not always predictable on the basis of injury severity.⁶² Williams et al.⁶³ and Pearlman et al.⁶⁴ studied pregnant trauma patients with electronic fetal monitoring. No cases of placental abruption were seen in the absence of uterine contractions or if contractions occurred at a frequency of less than one every 10 min

after 4 hours of monitoring. In patients with more frequent contractions, nearly 20% had placental abruptions. If complications do not occur after 4 hours of monitoring, an outcome similar to uninjured control subjects may be expected.⁶⁴ If uterine contractions, uterine tenderness, vaginal bleeding, rupture of membranes, nonreassuring fetal heart rate, or serious maternal injury are present, further monitoring and evaluation are indicated. Current evidence suggests

that a period of continuous fetal monitoring is prudent in most cases of trauma during pregnancy of more than 22–24 weeks' gestation. In patients without signs or symptoms of abruption, a period of 2–6 hours of monitoring will suffice.⁶⁰ Prolonged monitoring is indicated in clinically unstable patients. In cases of hemodynamic instability, the maternal condition should be stabilized before delivery is considered for persistent evidence of fetal distress. The fetus may recover as maternal hypoxia, acidosis, and hypotension are corrected. Serial evaluations of fetal status and *in utero* resuscitation are generally preferable to the emergency delivery of a depressed infant from a hemodynamically unstable mother.

Surgical therapy

Surgical therapy may be an integral part of managing obstetric patients in hemorrhagic shock. Uterine bleeding can occur in the antepartum, intrapartum, and postpartum periods, and requires prompt evaluation and management. As in the case of uterine rupture, definitive surgical therapy may need to be initiated prior to stabilization. With postpartum hemorrhage resulting from uterine atony, surgical therapy may be required if the conventional treatments of uterine compression and pharmacologic therapies have been unsuccessful. Uterine artery ligation, initially described by Waters,⁶⁶ is performed by grasping the uterine wall and broad ligament and passing a single no. 1 chromic catgut suture anteroposteriorly through the lower uterine segment. The ascending uterine vessels are encompassed, and the suture is exited through the avascular area at the base of the broad ligament.⁶⁷ The fundus compression suture as described by B-Lynch⁶⁸ has also been reported to abate uterine hemorrhage in many cases.

If hemorrhage persists after these measures, the hemodynamic stability of the patient should determine whether one proceeds with a hypogastric artery ligation or hysterectomy. Hypogastric artery ligation should likely be reserved for stable patients of low parity who strongly desire further childbearing, as hypogastric artery ligation has been associated with a high complication rate and a low success rate in obtaining control of uterine hemorrhage. The ligation should be performed distal to the posterior division of the hypogastric artery. Hysterectomy is clearly indicated for profound intractable hemorrhage if the patient is unstable or not desirous of future childbearing.⁶⁹

Transcatheter arterial embolization

Advances in interventional radiology have produced alternatives to the surgical management of obstetric hemorrhage. Arterial embolization with gel foam, coils, and glue have been reported to successfully control massive bleeding.^{70,71} Vascular access is usually via the femoral or axillary artery, and diagnostic localization is performed with an intra-aortic injection of radiopaque dye below the renal arteries.⁷² Once the site of hemorrhage is identified, selective catheterization is per-

formed, and the vessel embolized. If catheterization of the bleeding artery is unsuccessful, embolization is attempted at or near the distal end of the anterior division of the internal iliac artery.⁷² In patients with prior hypogastric artery ligation, collateral arteries may be identified, selectively catheterized, and embolized. However, embolization appears to be easier if performed before arterial ligation. Complications due to the procedure may include tissue ischemia (e.g., buttock claudication), guidewire perforation of an arterial blood vessel, and "postembolization syndrome."⁷³ Gelfoam appears to be the embolizing agent of choice in most obstetric series.^{72–75} Prophylactic arterial catheterization for selective embolization has been proposed in cases at high risk for obstetric hemorrhage requiring surgical intervention.^{73,76} Techniques for achieving medical and surgical hemostasis in patients with postpartum bleeding have been discussed more comprehensively by Dildy.⁷⁷

Military antishock trousers

Military antishock trousers may be useful in controlling intra-abdominal and pelvic hemorrhage and in stabilizing pelvic and lower extremity fractures. In the pregnant shock victim, the abdominal compartment is not inflated, as uterine compression against the inferior vena cava may decrease venous return, thus reducing cardiac output and worsening the hemodynamic condition.⁷⁸ Although widely accepted recommendations for use during pregnancy have not been delineated, obstetric and gynecologic applications of the gravity suit have been proposed.⁷⁹

Pelvic pressure pack

After hysterectomy for severe obstetric hemorrhage, diffuse bleeding may persist from pelvic surgical sites due to associated coagulopathy. The use of a transvaginal pressure pack was first reported by Logothetopoulos in 1926⁷⁹ to tamponade diffuse venous bleeding. Others have since described a similar approach.^{80,82} Hallak and colleagues⁸² used a mushroom-shaped pack, created from a sterile plastic bag filled with gauze, placed transabdominally in the pelvis, with the stalk exiting the vagina. Traction on the stalk produces pressure on the pelvic floor, which tamponades low-pressure venous bleeding and controls hemorrhage. The pack is removed either transabdominally or transvaginally once the patient is hemodynamically and hematologically stable.

Cardiopulmonary resuscitation

If cardiac or pulmonary arrest occurs in the pregnant woman, cardiopulmonary resuscitation is initiated in the same fashion as for nonpregnant victims.⁸³ Technical variations specific for pregnancy include lateral uterine displacement to improve venous return and cardiac output, and perimortem Cesarean

section if resuscitation is not successful within 4 min of the initial event.⁸⁴

Perimortem Cesarean section

Postmortem Cesarean delivery has been described for centuries as an attempt to save the life of the unborn child.^{84,85} Katz and colleagues⁸⁴ stress that the chance of fetal survival after perimortem Cesarean section is improved if maternal death is sudden. The timing of the operation is also important, and they have suggested that Cesarean delivery should be initiated within 4 min, and the baby delivered within 5 min of maternal cardiac arrest. The longest documented time interval from maternal death to delivery with fetal survival is 25 min,⁸⁶ although this remains disputed. In a series of patients who underwent cardiac arrest in association with amniotic fluid embolism, if delivery occurred within 15 min, most fetuses survived neurologically intact. However, even poor neonatal outcomes have been encountered with delivery within 5 min of maternal cardiac arrest.⁸⁷ Given the critical nature of time, perimortem Cesarean section should not be delayed to obtain an obstetric ultrasound; the physician should assess fundal height to confirm a potentially viable gestational age before making the abdominal incision.⁸⁸ In cases of moribund patients suffering from chronic disease, preparation for perimortem Cesarean section should be planned well in advance.

Case reports have indicated an increased success rate of delivering live infants, which may be related to both changing causes of maternal death and improved neonatal resuscitation. Most important, fetal outcome is related to fetal gestational age and the amount of time that has elapsed between maternal death and delivery.⁸⁹ However, underreporting of unsuccessful cases may prohibit an establishment of the actual success rate.

Katz and colleagues⁸⁴ have concluded that there is minimal legal risk for the physician in performing a perimortem section. The benefits include a chance for infant survival and improved maternal cardiopulmonary resuscitation. Removal of the placenta at the time of delivery is encouraged, as postoperative placental expulsion has been known to occur.^{85–89}

Controversial and experimental modalities

Corticosteroids

Historically, the most controversial modality in the treatment of septic shock has been the use of high-dose steroids. Theoretic benefits include stabilization of lysosomal membranes, inhibition of complement-induced inflammatory changes, and attenuation of the effects of cytokines and other inflammatory mediators.⁹⁰ Numerous animal model studies and a few human studies have produced widely conflicting results. Human clinical studies have been criticized for flaws in study

design and nonstandardization of regimens.⁹¹ In 1984, Sprung et al.⁹² demonstrated in a prospective, randomized study of 56 patients that corticosteroids may improve outcome if administered early in septic shock. Although short-term improvement was noted, mortality rates were not altered, and more than 25% of patients treated with steroids developed superinfections. Hoffman et al.⁹³ reported in 1984 that the mortality of patients with severe typhoid fever could be decreased by treatment with corticosteroids. In contrast, in 1987, the Methylprednisolone Severe Sepsis Study Group published data from a prospective, randomized, double-blind, placebo-controlled trial of 382 patients, concluding that the use of high-dose corticosteroids provided no benefit in the treatment of septic shock. Furthermore, they reported an increased mortality secondary to infections.⁹¹ Additionally, potential side-effects from the administration of corticosteroids include gastrointestinal bleeding, hyperglycemia, and superinfection.^{90,94} Currently, there is insufficient evidence to recommend the use of corticosteroids for septic shock, and their use should be reserved for patients with documented adrenal insufficiency.

Naloxone

Naloxone, an opiate antagonist, has been studied in animals⁹⁵ and humans^{96–98} for the reversal of opiate-induced hypotension in endotoxic shock. The rationale for use of naloxone is that the endogenous opiate beta-endorphin is stored with adrenocorticotrophic hormone, and both seem to be released simultaneously under physical stress.^{98,99} Studies using the rat endotoxic shock model have suggested that naloxone both prophylactically blocks and rapidly reverses endotoxin-induced hypotension, which appears to be partially mediated by endogenous opiates.¹⁰⁰ Naloxone has been shown to inhibit the production of tumor necrosis factor- α induced by lipopolysaccharide.¹⁰¹ Canine studies demonstrated improved cardiovascular parameters and survival in animals treated with naloxone in endotoxic shock.^{102–104} Data published so far on humans have been controversial. Roberts and colleagues⁹⁷ suggest that earlier studies found no positive effects secondary to short observation periods.^{96,105} Their data suggested that the continuous intravenous infusion of naloxone resulted in decreased inotrope and vasopressor requirements in patients with septic shock. Positive hemodynamic effects (decreased heart rate with increased stroke volume) were observed more than 4 hours after an initial naloxone bolus, and no side-effects were identified. A meta-analysis showed naloxone therapy to be associated with statistically significant hemodynamic improvement, but the case fatality rate was not decreased.¹⁰⁶ Further controlled clinical studies are required before the general use of naloxone for endotoxic shock can be recommended. It should be noted that the treatment of patients who are receiving opiates for chronic pain relief with naloxone can precipitate opiate withdrawal and even cardiovascular collapse.¹⁰⁰

Nonsteroidal anti-inflammatory drugs

Prostaglandins are suspected to play a central role in septic shock, particularly in controlling regional blood flow distribution. Nonsteroidal anti-inflammatory drugs (NSAIDs) are thought to protect against the many deleterious effects of the prostaglandins on the cardiovascular, pulmonary, and coagulation systems during endotoxic shock. Increased production and decreased degradation of prostaglandins in severe sepsis has been demonstrated.¹⁰⁷ These alterations may be associated with endotoxin-induced pulmonary vascular changes.¹⁰⁸ Prostaglandin synthetase inhibitors have been used to blunt this pathophysiologic response in sheep.¹⁰⁹ Similar beneficial effects have been observed in other organ systems when experimental animals were pretreated with prostaglandin synthetase inhibitors prior to endotoxin exposure.^{110–112} Current data regarding the effects of NSAIDs on humans are lacking, and future clinical investigation in humans appears to be warranted before routine clinical use.

Immunotherapy

Preliminary immunotherapy studies have shown that antibodies specifically directed against endotoxin or inflammatory mediators reduce mortality in animal models and human septic shock patients.¹¹³ Clinical trials, however, have produced inconsistent results. Anti-lipopolysaccharide (anti-LPS) immunoglobulin has been found to bind to LPS from a wide range of Gram-negative bacteria.¹¹⁴ Anti-LPS IgG has been administered to obstetric patients in septic shock with reductions in morbidity and mortality.¹¹⁵ Control patients demonstrated a mortality of 47.4% (9 of 19), compared with a mortality of 7.1% (1 of 14) in the treated group. Ziegler and colleagues¹¹⁶ treated bacteremic patients with human anti-serum to a mutant *Escherichia coli* during the onset of the illness and observed a significant reduction in deaths from Gram-negative bacteremia and septic shock. Despite some promising studies, clinical success with antiendotoxin and anticytokine therapies has been less than hoped for,^{117–121} and these agents are still of questionable benefit in the therapy of septic shock. Circulating natural inhibitors of proinflammatory cytokines have been described and, in animal models, these inhibitors have been shown to decrease mortality in endotoxic shock. The effect of these natural inhibitors on the clinical course of sepsis is being investigated. The presence of these inhibitors may explain the inconsistent results observed with the exogenous administration of inflammatory mediators in clinical trials.¹²²

Anticoagulants

Activation of the coagulation system and depletion of endogenous anticoagulants have been found in patients with severe sepsis and septic shock. Diffuse microthrombus formation may induce organ dysfunction and lead to excess mortality in

this situation. It has been hypothesized that antithrombin III may provide protection from multiorgan failure and improve survival in critically ill patients. However, studies using antithrombin III replacement in septic shock have shown no survival benefit. A double-blind, placebo-controlled, multicenter phase 3 trial of antithrombin III replacement showed no survival benefit and was associated with a significant increase in the risk for hemorrhagic complications in patients receiving antithrombin III in combination with heparin.¹²³ Recombinant activated protein C has also been studied. Bernard et al.¹²⁴ showed a significant reduction in mortality with the administration of recombinant activated protein C in septic shock. Unfortunately, an increased risk of bleeding was also noted, including two fatal intracranial hemorrhages. The authors calculated a rate of one serious bleeding event for every 66 patients treated and a 28-day survival benefit for one patient out of every 16 treated.

Specific etiologies and their management: hypovolemic shock

Hypovolemia may result from hemorrhage or solely from loss of intravascular fluids. The causes of hemorrhage in obstetrics are numerous, with the most common cause of postpartum hemorrhage being uterine atony followed by obstetric trauma.¹⁵ Hemorrhage is still the leading cause of pregnancy-related mortality in the United States.⁴ Pritchard¹²⁵ showed that the average amount of blood volume expansion during pregnancy is approximately 1500 mL. The average amount of blood lost during a vaginal delivery and elective repeat Cesarean section is 500 mL and 1000 mL respectively. No physiologic compromise should be encountered so long as the volume of blood lost at delivery does not exceed the amount added during pregnancy. When this balance is exceeded, hypovolemia results in decreased venous return and reduced cardiac output. The diagnosis of shock is most often made by the presence of hypotension, oliguria, acidosis, and collapse in the late stage, when therapy is frequently ineffective. Early in the course of massive hemorrhage, there are decreases in mean arterial pressure (MAP), cardiac output (CO), central venous pressure (CVP), and pulmonary capillary wedge pressure (PCWP), stroke volume and work, mixed venous oxygen saturation, and oxygen consumption. Increases are seen in systemic vascular resistance (SVR) and arteriovenous oxygen content differences, which serve to improve tissue oxygenation in the face of reduced blood flow. Catecholamine release causes a generalized increase in venular tone, resulting in an autotransfusion effect. These changes are accompanied by compensatory increases in heart rate, SVR, pulmonary vascular resistance, and myocardial contractility. Redistribution of CO and blood volume occurs via selective arteriolar constriction mediated by the central nervous system and adrenomedullary stress response. This results in diminished perfusion to the skin, kidneys, gut, and uterus and

Table 37.10 Uterotonic agents for uterine atony.

Agent	Administration route	Dose	Comments
Oxytocin (Pitocin)	Intravenous	10–40 U in 1000 mL of LR or NS	Not to exceed 100 mU/min
Methylergonovine (Methergine)	Intramuscular	0.2 mg q6h	Avoid in hypertensive patients
15-methyl PGF _{2α} (Hemabate)	Intramuscular or intramyometrial	0.25 mg q15–60 min	Side effects include arterial O ₂ desaturation, bronchospasm, hypertension
Dinoprostone (Prostin E ₂)	Per rectum	20-mg suppository	Use with caution in hypotensive patient because of vasodilation; if available, PGF _{2α} is preferable

LR, lactated Ringer's solution; NS, normal saline; PGF_{2α}, prostaglandin F₂ alpha.

Source: modified from ref. 128.

maintenance of blood flow to the heart, brain, and adrenal glands. In the pregnant patient, this redistribution may result in fetal hypoxia and distress. This will likely occur before the mother becomes overtly hypotensive. Regardless of the maternal MAP, significant maternal shock is unlikely in the absence of fetal distress.⁶¹ Three vital organs in addition to the placenta are especially susceptible to damage in the setting of hypotension due to hemorrhagic shock. These organs are the anterior pituitary gland, the kidneys, and the lungs. Sheehan and Murdoch¹²⁶ first described the syndrome of hypopituitarism secondary to postpartum hemorrhage and subsequent hypotension. This condition is now a rare obstetric complication. Hypovolemia leading to reduced renal perfusion can result in acute tubular necrosis. Severe hemorrhage may also precipitate ARDS.

Treatment of hemorrhagic shock involves correcting the initiating process as well as instituting general supportive measures, as previously discussed. When hemorrhage is suspected, the clinician should: (1) estimate actual blood loss and prehemorrhage blood volume as accurately as possible; (2) consider factors affecting the patient's ability to tolerate blood loss; (3) seek clinical evidence of hypovolemia and shock; (4) identify and correct the source of blood loss; (5) restore blood volume and oxygen carrying capacity; and (6) attempt to prevent further blood loss.¹²⁷ If medical therapy is unsuccessful, surgical procedures such as uterine artery ligation, internal iliac artery ligation, and emergency hysterectomy may be required. Other modalities, such as percutaneous transcatheter hypogastric artery embolization, may have their place in certain situations, but are not without their own risks. Response to therapy is reflected by hemodynamic parameters and laboratory values. Blood products should be administered after identifying the underlying disorder by laboratory indices.

Uterine atony

Uterine atony is the most common cause of primary postpartum hemorrhage, accounting for 80% of all cases. Diagnosis is made after delivery of the placenta when excessive

bleeding is noted per vagina, and the uterine fundus is boggy. Examination of the birth canal reveals no lacerations that may account for bleeding. The uterine cavity should be explored to rule out retained placenta, retained blood clots, and disruption of the uterine wall. Initial management includes bimanual fundal massage and administration of uterotonic agents (Table 37.10).

Oxytocin (Pitocin, Syntocinon) is administered intravenously or via intramyometrial injection. Given intravenously, it has an almost immediate onset of action. The usual dose is 20–40 units/L of crystalloid. It has approximately 5% of the antidiuretic effect of vasopressin and, if given in large volumes of electrolyte-free solution, can cause water overload.

Methylergonovine maleate (Methergine) acts via stimulation of α -adrenergic myometrial receptors. The dose is 0.2 mg intravenously or via intramyometrial injection and may be repeated after 2–4 hours if necessary. Vasoconstriction is a side-effect, and contraindications include patients with heart disease, hypertension (including preeclampsia/eclampsia), and peripheral vascular disease.

Prostaglandin derivatives have been shown to be effective in treating postpartum uterine atony where other modalities have failed. Prostaglandin F_{2α} results in contraction of smooth muscle cells.^{127,129} Carboprost/hemabate (15-methyl prostaglandin F_{2α}) is an established second-line treatment for postpartum hemorrhage unresponsive to oxytocic agents. It is available in single-dose vials of 0.25 mg to be given intramuscularly. Small case series have reported an efficacy of 85% or more in refractory postpartum hemorrhage.^{130,131} The largest case series to date involved a multicenter surveillance study of 237 patients with postpartum hemorrhage refractory to oxytocin, which found that 15-methyl prostaglandin F_{2α} was effective in 88% of patients.¹³² Takagi and associates¹³³ showed that intramyometrial injection of prostaglandin F_{2α} was superior to intravenous or intramuscular administration. The intramyometrial route of administration may be preferred to peripheral intramuscular injection, especially in patients who are in shock with compromised circulation. Side-effects include bronchospasm, nausea, vomiting, and diarrhea. There

are case reports of hypotension and intrapulmonary shunting with arterial oxygen desaturation. This medication is therefore contraindicated in patients with cyanotic cardiac or pulmonary disease.

Misoprostol is a synthetic analog of prostaglandin E1 and can be given orally, vaginally, or rectally. An international multicenter randomized trial reported that oral misoprostol is less successful than parenteral oxytocin administration as prophylaxis for postpartum hemorrhage.¹³⁴ However, two small case series have reported good responses in postpartum hemorrhage refractory to oxytocin and syntometrine (oxytocin and ergometrine) with rectal doses of 600–1000 µg.^{135,136} A single-blinded randomized trial of misoprostol 800 mg rectally versus syntometrine intramuscularly plus oxytocin by intravenous infusion found that misoprostol resulted in cessation of bleeding within 20 min in 30/32 cases (93%) compared with 21/32 (66%).¹³⁷ There was no difference in need for blood transfusion. The advantages of misoprostol include low cost and ease of administration. If hemorrhage persists despite medical therapy, surgical intervention is mandated.

Placenta accreta, increta, and percreta

Placenta accreta occurs when Nitabuch's membrane is deficient and trophoblastic tissue attaches directly to the deciduas basalis or myometrium. If the trophoblast invades the myometrium or penetrates adjacent structures, placenta increta or placenta percreta exist. In a study of 40 cases of such placental abnormalities, the relative proportions of accreta, increta, and percreta were 78%, 17%, and 5% respectively.¹³⁸ When the placenta detaches, areas of adherence prevent the normal mechanism of myometrial contraction and compression of vascular channels from occurring, resulting in hemorrhage. Clinical studies reveal an increasing trend in incidence, perhaps secondary to better case reporting and increasing rates of Cesarean section. Read and colleagues¹³⁹ state that the hallmark of placenta accreta is multiparity. The most common associated factors were placenta previa and previous Cesarean sections. A linear increase in risk of placenta accreta in patients with placenta previa and previous uterine scars has been demonstrated.¹⁴⁰ It has been noted that patients presenting with placenta previa and an unscarred uterus have a 5% risk of having placenta accreta. The risk of placenta accreta increased to 24% in patients with a placenta previa and one previous Cesarean section. Those patients with placenta previa and four previous Cesarean sections experienced a 67% incidence of placenta accreta.¹⁴⁰

Treatment generally involves hysterectomy; however, conservative management may be appropriate in certain cases. McHattie's 1972¹⁴¹ review of the literature showed a maternal mortality of 41.9% with conservative management and a maternal mortality of 6.5% with hysterectomy. In a review of patients treated between 1977 and 1983, no maternal deaths were observed in the 28% of those patients treated with conservative methods.¹⁴⁰ Individualized treatment and conserva-

tive procedures, such as curettage, local repair, and uterine artery ligation, may be appropriate in selected patients. When future fertility is desired and the placental site is not bleeding, conservative management has been advocated leaving the placenta *in situ*.¹⁴² Methotrexate chemotherapy has also been used to enhance destruction of placental tissue;¹⁴³ however, cumulative experience is limited, and this approach may not always be successful.¹⁴⁴

Placental invasion into extrauterine structures, such as the bladder (requiring bladder resection and massive transfusion) has been reported.^{145–148} According to Thorp's¹⁴² review of the English language literature, the maternal mortality of placenta percreta with bladder involvement is 9.5% (2 in 21). Antenatal detection by color Doppler ultrasound or magnetic resonance imaging has afforded predelivery preparation in some cases.^{142,148,149}

Uterine rupture

Uterine rupture may occur in an unscarred uterus or at the site of a previous Cesarean section or gynecologic surgery. The overall rate varies from 2 to 8 per 10000 deliveries.¹⁵⁰ The most common clinical sign in labor is the sudden onset of fetal decelerations, reported in 81% of cases.¹⁵⁰ Abdominal pain, cessation of contractions, and recession of the presenting part are less common. Bleeding may be intraperitoneal and into the broad ligament rather than revealed vaginally, and profound shock may occur before rupture is suspected. Uterine rupture should be considered in every obstetric patient with undiagnosed hemorrhagic shock. Rupture of an unscarred uterus is frequently related to obstetric intervention. This includes the excessive use of uterotonic drugs for induction or augmentation of labor, mid-forceps delivery, or breech extraction with internal podalic version.¹⁵¹ Prolonged labor in the presence of malpresentation or cephalopelvic disproportion also predisposes to uterine rupture. External trauma and grand multiparity are also risk factors. The overall risk of uterine rupture for women attempting a trial of labor following low transverse Cesarean section is 0.5–1%, but higher if the trial of labor is unsuccessful.¹⁵² A previous classical Cesarean section has a risk of rupture of 3–6%; this becomes 12% if a trial of labor takes place. Use of uterotonic drugs has been associated with an increased risk of rupture in the presence of a Cesarean section scar. Prostaglandin agents used for labor induction or cervical ripening have been associated with an even higher risk.¹⁵³ Management options include surgical repair and hysterectomy. Many authors consider hysterectomy to be the procedure of choice.^{151,154} Repair may be considered when technically feasible, especially in cases of desired fertility. In these cases, planned Cesarean section should be performed as soon as fetal lung maturity can be confirmed. Repair may also be considered in cases where successful control of hemorrhage can be attained in hemodynamically unstable patients in order to avoid risking further blood loss.

Nonobstetric trauma

The incidence of accidental injury during pregnancy is estimated to be 6–7%.⁸⁹ An increased incidence of minor trauma has been observed as pregnancy progresses.¹⁵⁵ In most cases, injury is minimal and is not associated with a significant increase in perinatal mortality.^{151,156} Major trauma, however, may place the mother and infant at severe risk.

The initial management of a pregnant woman who has sustained severe or major trauma is essentially the same as that of a nonpregnant person.¹⁵⁷ Crosby¹⁵⁸ has described in detail the initial evaluation of the gravid trauma patient. Maternal stabilization often leads to fetal stabilization, and delivery of the fetus before stabilization of the mother may worsen the mother's condition and result in the delivery of a premature fetus. Electronic fetal monitoring during maternal evaluation provides information regarding fetal and maternal well-being because deteriorating maternal cardiovascular status may be reflected early via fetal distress.¹⁵⁹ Signs of fetal well-being reflect maternal cardiovascular stability.

Blunt trauma

Causes of blunt abdominal trauma include motor vehicle accidents, pedestrian accidents, falls, and assaults. A recent large retrospective study revealed motor vehicle accidents to be the leading cause of fetal death related to maternal trauma.¹⁵⁹ In these accidents, the most common cause of fetal death is maternal death.¹⁶⁰ Among maternal survivors, premature separation of the placenta was the most frequent cause of fetal death. Fetal injuries, usually skull fractures and intracranial hemorrhage, tend to occur later in gestation because of a reduced amniotic fluid–fetus ratio, fixation of the fetal head in the bony pelvis, and placement of the fetal body outside the bony pelvis.¹⁶¹ Expulsion from the vehicle and maternal head trauma are associated with poor maternal and fetal outcomes. Automobile passenger restraining systems have been shown to improve maternal and fetal outcomes. Crosby and Costiloe¹⁶² noted a 33% mortality in unrestrained gravid automobile accident victims compared with a 5% mortality when two-point restraints (traditional lap belt) were used. In a more recent study of gravid accident victims using three-point restraint belts, it was noted that proper use of seat belts was the best predictor of maternal and fetal outcomes.¹⁶³

The severity and mechanism of injury may not correlate directly with the incidence or severity of fetomaternal hemorrhage. Relatively minor blunt abdominal trauma may result in abruption. Up to 40% of severe blunt abdominal trauma is associated with placental abruption, but a 2.6% rate of abruption is seen with relatively minor abdominal trauma.^{62,164–166} Uterine rupture is a relatively infrequent result of blunt traumatic injury during pregnancy. The incidence increases with advancing gestation and severity of force. Most traumatic uterine ruptures involve the uterine fundus or posterior aspect of the uterus.¹⁶¹ Patients with a history of prior Cesarean delivery may be at increased risk.

Evaluation of the pregnant trauma patient is similar to evaluation of the nonpregnant patient with a few exceptions. The presence of the gravid uterus may alter the patterns of injury observed. Bowel injury is less frequent,¹⁶⁷ but hepatic and splenic injury appears to be more frequent.¹⁶⁸ Abdominal ultrasound is an important diagnostic tool in the identification of intraperitoneal fluid collections secondary to hemorrhage and has been demonstrated to have similar sensitivity and specificity as in nonpregnant trauma patients. Computed tomography (CT) scans may add additional diagnostic information. Exploratory laparotomy is indicated in pregnant patients who are hemodynamically unstable, have evidence of viscus perforation, infection, or fetal distress at a viable gestation. Diagnostic peritoneal lavage may be useful in less severe cases and is as useful in pregnancy as in nonpregnant abdominal trauma patients.¹⁵⁶ An open technique should be performed (analogous to open laparoscopy) in pregnant patients to help the catheter to avoid the gravid uterus. It should be noted that, because of changes in maternal physiology and pregnancy-related anatomic alterations, pregnant patients with significant abdominal injuries may not have significant abdominal signs or symptoms at presentation. Maternal hypotension (systolic pressure < 90 mmHg) and tachycardia may represent late findings. Diagnosis may be significantly delayed and result in a higher risk of pregnancy loss.¹⁶⁹ The presence of rib or pelvic fractures should increase the suspicion for other abdominal and pelvic injuries. Pelvic fractures are usually associated with motor vehicle accidents, and serious complications are related to urologic and vascular damage. Retroperitoneal hemorrhage may be massive. Less than 10% of patients with pelvic fractures require subsequent Cesarean section secondary to pelvic deformity or instability.¹⁷⁰

Providers should have a high index of suspicion for physical abuse during pregnancy. Blunt abdominal trauma and other injuries, especially to the face, neck, breasts, and proximal extremities, may occur as a result of physical abuse.

Penetrating trauma

As the uterus expands during pregnancy, the bowel is compartmentalized into the upper abdomen and, therefore, the gravid uterus becomes the most frequently injured organ in cases of penetrating abdominal trauma.¹⁵⁸ Because of the physical forces involved, gunshot wounds carry a substantially higher mortality than stab wounds. Gunshot wounds are the most common type of penetrating injury during pregnancy.¹⁷¹ A review by Buchsbaum¹⁷¹ indicated a lower than expected maternal mortality in association with gunshot wounds to the uterus, as reflected by no reported deaths between 1912 and 1979. Fetal mortality, however, was high. An 89% incidence of fetal injury and a 66% perinatal mortality were noted in this series. Reported data from stab wounds are similar in that fetal mortality was high (42%) and maternal mortality was not seen.¹⁷² Prematurity contributes significantly to perinatal mortality.

Traditional management of gunshot wounds to the

abdomen has included exploratory laparotomy to determine the extent of visceral injury.^{171,173} Patients in whom the projectile or object enters anteriorly and below the level of the uterine fundus often do not have maternal visceral involvement.¹⁷⁴ Most authors recommend abdominal exploration for all extrauterine intra-abdominal gunshot wounds and most intrauterine wounds. Some authors suggest an individualized approach to intrauterine injuries, and that selective laparotomy may be considered in gravidas with stable vital signs, when the missile entry site is anterior and subfundal, and when imaging studies indicate that the missile has not crossed the posterior uterine wall.^{175–177} Posterior abdominal wounds, upper abdominal wounds, uterine location of the projectile, and fetal or maternal compromise are not optimal for expectant management.¹⁷⁶ Surgical exploration of all pregnant intra-abdominal gunshot wounds is generally advocated.¹⁷⁸

Stab wounds require surgical repair in approximately one-half of reported cases.¹⁷⁹ Small bowel involvement is more frequent with upper abdominal stab wounds in pregnancy.^{174,180} Because of the propensity of small intestinal injury and the potentially lethal effect of diaphragmatic rupture with herniation of intra-abdominal organs, exploration of upper abdominal stab wounds during pregnancy is recommended. As with gunshot wounds, if the wound is confined to the lower abdomen, the uterus usually sustains most injuries, whereas other viscera are spared.

Cesarean section is indicated for fetal distress at a viable gestational age. Exploratory laparotomy is not a reason to perform a Cesarean section if another indication does not exist. If direct uterine perforation is noted in the presence of a viable pregnancy, abdominal delivery is probably warranted. Maternal indications for delivery include severely compromised maternal cardiovascular status and obstruction of the operating field by the gravid uterus that limits surgical exposure of damaged vital structures. Fetal indications for delivery include fetal hemorrhage and distress and intra-amniotic infection. Such factors as suspected fetal injury and fetal distress must be balanced against those of fetal maturity. Even if labor has begun, some authors believe that vaginal delivery after exploratory laparotomy is preferable to hysterotomy.¹⁵⁹ However, if significant uterine injury involves the active uterine segment, Cesarean section is the preferred route of delivery to avoid uterine rupture in labor.

Burns

Approximately 2.2 million people each year in the United States suffer burns significant enough to present for medical treatment.¹⁸¹ Most burns are minor, defined as superficial or partial-thickness injuries covering less than 10% of the total body surface. Major burns are partial-thickness or full-thickness injuries covering more than 10% of the total body surface. Major burns may be further classified as moderate (10–19% total body burn), severe (20–39% total body burn), or critical (40% or greater total body burn).¹⁸² The first step in the management of the pregnant burn patient is to deter-

mine the depth of the burn and the percentage of body surface involved. The more severe the maternal burn, the higher the maternal and perinatal mortality.^{182,183} With a burned total body surface area greater than or equal to 60%, the rate of maternal and fetal mortality was 100%, whereas a burned total body surface area of 40–59% was associated with 50% maternal and fetal mortality.¹⁸⁴ Pregnancy alone does not appear to alter maternal survival; however, with serious maternal burns, the fetal death rate is high.

Early complications of burns include severe hypovolemia secondary to fluid and electrolyte shifts resulting from vascular damage.¹⁸⁵ Hypovolemia, hypotension, and shock are prevented by aggressive fluid and electrolyte replacement.¹⁸³ Electrolytes must be monitored carefully as sodium and potassium values may fluctuate widely.¹⁸² Hypoxemia may occur in conjunction with hypovolemia or secondary to upper and lower respiratory damage as a result of inhalation of noxious fumes. Oxygenation warrants close monitoring, and supplemental oxygen should be administered as required, occasionally via endotracheal intubation.

Later complications of burns include wound infection and sepsis. Hospital-acquired resistant organisms may complicate therapeutic management. Septicemia and pneumonia are reported to contribute to nearly one-half of all deaths in burn patients.¹⁸¹ Abdominal scarring can also be problematic. Rai and Jackson¹⁸⁶ reported no increase in difficulties during labor or Cesarean section from severe abdominal scarring secondary to burns. Adverse effects of previous abdominal burn scars on subsequent pregnancies have been reported to include scar pain, occasional scar tissue breakdown, and uterine displacement.^{186,187}

Because experience with pregnant burn patients is limited, few specific treatment guidelines beyond electrolyte and fluid replacement, adequate ventilatory support, and antibiotic therapy have been proposed. The route and timing of delivery should likely be based on obstetric indications, although assessment of fetal well-being in the burn patient may be difficult. The ability to determine fetal status with ultrasound or fetal monitoring will depend on the size and location of the burn. Because of such monitoring difficulties and the direct relationship between the size of the burn and perinatal outcome, some practitioners^{184,188} have recommended immediate Cesarean delivery in any pregnant burn patient with a fetus of potentially viable age and a burn that involves 50% or more of the maternal body surface area. Early delivery of third-trimester pregnancies is an alternative option.¹⁷⁸

Specific etiologies and their management: distributive shock

Causes of distributive shock include neurogenic, anaphylactic, and septic shock. Neurogenic shock in obstetrics may accompany conduction anesthesia, central nervous system trauma and puerperal uterine inversion. Uterorelaxant agents used for

uterine inversion are listed in Table 37.11. Anaphylactic and septic shock will be discussed in detail.

Anaphylactic shock

Anaphylactic reactions are rare events, but may be fatal in as many as 10% of cases (Table 37.12).¹⁸⁹ Antibiotics, NSAIDs,

Table 37.11 Uterorelaxant agents for uterine inversion.

MgSO ₄	2 g i.v. over 5–10 min

oxytocin, anesthetic agents, blood products, colloid solutions, and latex exposures are some of the more common causes of anaphylaxis in pregnancy. Few reports exist in the current obstetric literature regarding this subject. Anaphylaxis is a series of events that occur in a sensitized individual on subsequent exposure to a specific antigen. It refers to an IgE-mediated, type I hypersensitivity response, produced by antigen-stimulated mast cell mediator release. The result may range from a localized response to a life-threatening systemic reaction with subsequent hypotension, cardiovascular collapse, and multiorgan system failure (Table 37.13). An anaphylactoid reaction may be clinically indistinguishable, and involves similar mediators, but does not require IgE antibody or previous exposure to the inciting substance. Exposure to the triggering agent results in release of primary mediators, such as histamine, prostaglandins, leukotrienes, eosinophil chemotactic factor of anaphylaxis, neutrophil chemotactic factor, and platelet-activating factor. These initiate release of

Table 37.12 Clinical spectrum of anaphylactic reactions.

Mild	Moderate	Severe
Local erythema and itching	Dizziness	Hypotension, cyanosis
Pruritus and urticaria	Generalized skin reactions	Angioedema
Coryza	Hoarseness	Stridor and wheezes
Nausea/vomiting	Swelling of lips and tongue	Cardiac arrhythmias
Diarrhea	Tachypnea	Syncope and seizures
Conjunctiva suffusion	Tachycardia	Altered mental status
Anxiety	Increasing respiratory distress and anxiety	Shock, cardiopulmonary arrest

Table 37.13 Specific organ failure in multisystem organ failure.

Organ	Pathophysiology	Result
Lung	Increased permeability and ventilation-perfusion mismatch; decreased metabolism of vasoactive substances; antimicrobial dysfunction and impaired lung defenses	Decreased compliance and hypoxemia; hemodynamic instability; nosocomial pneumonia
Liver synthesis	Early increase; late decrease; decreased IgA production; decreased bile salts	Acute-phase protein synthesis and hypermetabolism; jaundice and coagulopathy; increased gastrointestinal tract bacteria; increased gastrointestinal tract endotoxin
Immunologic	Kupffer's cell activation; decreased fibronectin and decreased phagocytosis	Hepatocyte depression and peripheral catabolism; bacteremia, endotoxemia, and microvascular emboli
Kidney	Hypovolemia, redistribution of renal blood flow, and nephrotoxic drugs	Azotemia with or without oliguria
Gastrointestinal tract	Decreased IgA and use of antibiotics and antacids; mucosal atrophy and increased permeability	Increased luminal bacteria and endotoxin; leaks bacteria and endotoxin, stress bleeding
Heart	Circulating myocardial depressant factor	Decreased ejection fraction
Central nervous system	Circulating false neurotransmitters; endogenous opioid-mimetics	Altered mental status; hemodynamic stability

the secondary mediators via the complement, intrinsic coagulation, fibrinolytic, and kallikrein-kinin enzyme systems. Multiple products, such as leukotrienes, prostaglandins, vasoactive amines, and oxygen radicals, are then released from white blood cells, platelets, and eosinophils.¹⁸⁹

Early recognition and treatment of anaphylactic reactions is essential. Risk factors, including a prior history of anaphylaxis, should be noted carefully at admission. The clinical presentation of anaphylactic and anaphylactoid reactions has been reviewed.¹⁹¹ Hypotension and tachycardia are universal, and rhythm and conduction disturbances are frequently seen. The first priority is removal of the offending antigen, if possible. Further management in severe cases includes ventilation, oxygenation, and external cardiac massage, which, in general, is followed by the subcutaneous administration of epinephrine in 0.2-mg increments every 20 min up to a total dose of 1.0 mg.¹⁹² In obstetric patients, ephedrine, 25–50 mg by intravenous push, has been recommended for treatment of hypotension because other vasoactive agents carry detrimental uteroplacental effects. However, failure to achieve rapid clinical response with ephedrine should be followed by the use of other, more potent agents, such as epinephrine or dopamine. A trial of terbutaline may also be an acceptable alternative treatment in cases of mild anaphylaxis or asthma but, in cases of life-threatening reactions, epinephrine should be used. Other drugs, such as corticosteroids, aminophylline, and antihistamines, have been recommended to enhance clinical response.^{189,193} Hydrocortisone (100 mg), or its equivalent, should be administered every 6 hours. If wheezing is unresponsive to epinephrine, aminophylline (5–6 mg/kg) may be given over 20 min, followed by a maintenance dose of 0.9 mg/kg/hour. Aggressive fluid replacement is required. In severe cases of anaphylactic shock, colloid volume expanders may be required, because crystalloids have been observed to be ineffective in volume replacement.^{192,193}

Septic shock

Septic shock is characterized by hypotension and inadequate tissue perfusion resulting from overwhelming sepsis.¹⁹⁴ Septic shock is rare in obstetrics, yet it remains one of the most frequent causes of maternal mortality in the United States.¹⁹⁵ Even with optimal care, the mortality rate from septic shock remains 40–50% in most series.¹⁹⁶ Many infections may result in septic shock in obstetric patients, but endometritis, chorioamnionitis, and pyelonephritis are the most common causes. Before legalization of abortion, septic shock resulting from criminal abortion was common.^{197,198} Other infections that may develop in obstetric patients include pneumonia, appendicitis, septic abortion, toxic shock syndrome, septic pelvic thrombophlebitis, and endocarditis. Significant risk factors for septic shock include prolonged rupture of membranes, retained products of conception, and instrumentation of the genitourinary tract.²⁵

Although genitourinary and other infections are common

among obstetric patients, septic shock is an infrequent event. The incidence of septic shock in bacteremic obstetric and gynecologic patients is estimated to be 0–12%.^{199–201} Physiologic changes in pregnancy may result in higher pulmonary morbidity in septic pregnant patients. Pregnancy decreases the gradient between colloid oncotic pressure and PCWP.³⁵ This results in an increased propensity for pulmonary edema in the setting of infection.

Mortality from septic shock in the general population is reported to be as high as 40–90%, as opposed to less than 3% in obstetric and gynecologic patients.^{2,199,201,202} This may be explained by the relative good health and youth of obstetric patients, prompt vigorous treatment, and infrequency of underlying disease processes.²⁰¹ Obstetric infections are usually caused by organisms normally found in the genital tract and thus are often polymicrobial.^{203–205} Common organisms include *E. coli*, *Klebsiella-Enterobacter*, *Pseudomonas*, and *Serratia*.²⁰⁶ Most cases of bacterial infection complicated by shock are caused by Gram-negative enteric organisms.²⁰⁷ Lee and colleagues²⁵ found that 80% of cases of septic shock during pregnancy developed during the postpartum period.

Septic shock has classically been described in three phases that correlate with progressive physiologic derangement: early (warm) shock, late (cold) shock, and secondary (irreversible) shock.^{14,206} Flushed warm skin, fever, chills, diaphoresis, and tachycardia are manifest in the early phase. Pulse pressure and urine output remain stable. The late phase is characterized by cool and clammy skin, a decrease in body temperature, and diminished mental status. Hypotension, tachycardia, and oliguria develop. Myocardial depression becomes a prominent feature of severe septic shock, with marked reductions in cardiac output and SVR.²⁰⁸ This phase is reversible with treatment. If medical intervention is not begun and cellular hypoxia and anaerobic metabolism continue, the irreversible phase of septic shock develops. Metabolic acidosis, anuria, respiratory distress, cardiac distress, DIC, and coma are ominous signs.

Cultures should be obtained in all patients from the urine, blood, and, if possible, the amniotic fluid or the endometrium. Other specific sources (e.g., stool, wound, and sputum) are cultured as indicated, and lumbar puncture should be considered in patients with altered mental status.⁹⁴ Chest radiography should be obtained to rule out infiltrates, evidence of pulmonary edema, and acute respiratory distress syndrome. Abdominal radiography should be considered to rule out free air under the diaphragm or a foreign body in some clinical circumstances.¹⁴

Treatment of septic shock requires general supportive measures, including restoration of intravascular volume and inotropic support (see section on general supportive measures). Lee and colleagues¹⁹⁴ recommend that acute stabilization of obstetric patients with septic shock be performed in the following sequence: (1) volume repletion and hemostasis; (2) inotropic therapy with dopamine on the basis of left

ventricular function curves; and (3) addition of peripheral vasoconstrictors (phenylephrine first, then norepinephrine) to maintain vascular afterload. Considerable fluid resuscitation is often necessary secondary to profound vasodilation, increased capillary permeability, and extravasation of fluid into the extravascular space. Blood pressure, heart rate, urine output, and hematocrit may be used to initially guide resuscitation, but a PA catheter may ultimately be the best means of guiding optimal fluid and inotrope management in critically ill patients with septic shock and/or multiorgan system dysfunction.^{33,209,210} Adequate oxygenation is essential. Antibiotic therapy for sepsis should be tailored directly to the suspected source and guided by information obtained by Gram's stain. Empiric therapy in the obstetric patient should include broad coverage for aerobic and anaerobic Gram-negative and Gram-positive bacteria.

Failure of the patient to respond promptly to simple volume resuscitation warrants transfer to an intensive care setting.²¹¹ If response to treatment is not satisfactory, close examination for abscessed or necrotic tissue must be carried out and surgical intervention considered.²⁰⁹ Timely drainage of abscesses and debridement of necrotic tissue, sometimes via hysterectomy, are required for clinical improvement.

Specific etiologies and their management: cardiogenic shock

Most etiologies of cardiogenic shock are described elsewhere in the text. In this chapter, cardiac compression and electric shock will be discussed.

Cardiac compression

Tension pneumothorax, pericardial tamponade, and rupture of the diaphragm with herniation of the abdominal contents into the thoracic cavity may cause significant cardiac compression resulting in decreased venous return and decreased cardiac output.

Placement of a chest tube alleviates compression secondary

to a tension pneumothorax. Pericardiocentesis relieves the high intrapericardial pressure produced by cardiac tamponade. Diaphragmatic rupture with herniation of abdominal viscera is a surgical emergency.²¹² Maternal death secondary to constrictive pericarditis occurring after thoracic radiotherapy has been reported.²¹⁴

Electric shock

Reports of electrical injury during pregnancy are relatively few in the medical literature. The electric shock threshold for a mild sensation is 1 mA, for local muscular tetany 10 mA, and for ventricular fibrillation about 100 mA.²¹⁴ The fetus appears to be more susceptible to the adverse effects of electric shock, as the hyperemic gravid uterus, amniotic fluid, and fetal skin are all excellent conductors of electricity.²¹⁵ In a series of 15 cases of electric shock in pregnancy, there were no maternal deaths, 11 fetal deaths, and only one normal fetal outcome.²¹⁵ The path of the current appears to be an important factor, as accidental shocks have a hand-to-foot (including the uterus) passage of current. Intentional therapeutic shock (electroconvulsive therapy and DC cardioversion) does not include the uterus in the current path, and published reports would suggest its safety during pregnancy. Fatovich²¹⁵ recommends immediate obstetric evaluation with fetal monitoring and ultrasound in any pregnant victim of electric shock. Maternal cardiac monitoring after electric shock with single-phase alternating current at household voltage may not be necessary if the patient is asymptomatic and has had a normal electrocardiographic result on presentation.²¹²

Specific etiologies and their management: obstructive shock

Obstruction of the pulmonary vessels may result in pulmonary hypertension, right-sided heart failure, cardiogenic shock, and death. Pulmonary embolism is one of the leading causes of maternal death in the United States and is discussed elsewhere in this text.

Key points

- 1 Maternal mortality in the United States is steadily declining, and recent statistics for the United States suggest an overall maternal mortality of 11.5 maternal deaths per 100 000 live births.
- 2 Hemorrhage is the leading cause of pregnancy-related mortality, followed by embolism-related deaths and hypertensive diseases.
- 3 Shock in the obstetric patient includes hypovolemic, distributive, cardiogenic, and obstructive etiologies.
- 4 Initial supportive measures in the treatment of shock include volume resuscitation, blood component replacement, ensuring adequate oxygenation, and supporting blood pressure with pharmacologic agents if indicated.
- 5 Crystalloids are first-line therapy for volume resuscitation.
- 6 Blood component replacement should be guided by clinical evaluation and by laboratory parameters. FFP

- and platelets should be transfused only if factor or platelet deficiencies are presumed to be the principal derangement.
- 7 If intravascular volume replacement is not successful in supporting blood pressure and other reversible causes of shock are not found, inotropic agents may be necessary. When blood pressure does not respond to inotropic therapy, use of a peripheral vasoconstrictor should be considered.
 - 8 In hypovolemic shock, vasopressors or inotropic agents are rarely indicated and should not be given until intravascular volume has been adequately replaced.
 - 9 Use of a pulmonary artery catheter to assess cardiac function and hemodynamic status may be helpful in select critically ill patients.
 - 10 Electronic fetal heart rate monitoring in the critically ill pregnant patient yields clinically useful information about endorgan perfusion. Fetal hypoxia may lead to changes in the heart rate pattern before the mother becomes overtly hypotensive. In the absence of abnormal changes in the fetal heart rate pattern, significant maternal shock is unlikely.
 - 11 In cases of hemodynamic instability, the maternal condition should be stabilized before delivery is considered for persistent fetal distress. Fetal recovery will likely occur as maternal hypoxia, acidosis, and hypotension are corrected.
 - 12 Perimortem Cesarean section should be initiated within 4 min of cardiac arrest with a goal of delivery of the fetus within 5 min of the initial event.
 - 13 Average blood loss during a vaginal delivery and elective Cesarean section is 500 mL and 1000 mL respectively. No physiologic compromise should be encountered so long as the volume lost at delivery does not exceed this amount.
 - 14 Management of hemorrhage includes: estimation of blood loss; consideration of factors affecting the patient's ability to tolerate blood loss; evaluation for possible hypovolemia and shock; identification of the source of blood loss; restoration of blood volume and oxygen-carrying capacity; and an attempt to prevent further blood loss.
 - 15 Uterine atony is the most common cause of postpartum hemorrhage.
 - 16 The severity and mechanism of blunt traumatic injury during pregnancy does not directly correlate with the incidence or severity of fetomaternal hemorrhage. Relatively minor trauma may result in abruption. A high suspicion for abruption after traumatic injuries is crucial, and a period of continuous fetal monitoring is prudent in most cases of trauma during pregnancy of viable gestational age.
 - 17 The gravid uterus is the most frequently injured organ in cases of penetrating abdominal trauma during pregnancy. In these cases, fetal mortality is high.
 - 18 Infection is a leading cause of morbidity and mortality in the obstetric population, and common causes include endometritis, chorioamnionitis, and pyelonephritis. Treatment of septic shock requires general supportive measures and broad-spectrum antibiotic coverage.
 - 19 If a patient in septic shock fails to improve with supportive measures and broad-spectrum antibiotics, a close examination for abscessed or necrotic tissue must be performed and surgical intervention considered.
 - 20 Clinical assessment of preexisting risk factors for the development of obstetric complications and advance preparation may decrease fetomaternal morbidity and mortality in the event of maternal cardiovascular collapse and shock.

Hypertensive diseases in pregnancy

Frederick U. Eruo and Baha M. Sibai

Approximately 10% of pregnancies are complicated by hypertension. The incidence varies according to the population studied and the criteria used for diagnosis. Preeclampsia accounts for 70% of hypertension in pregnancy, and chronic hypertension accounts for most of the remaining 30%. The quoted figures may be underestimated as the incidence of hypertension is said to have increased by about 40–50% in the past 10 years.^{1,2} This increase is probably due to the increase in obesity in the United States,³ delay of pregnancy until later in life (advanced maternal age), and increased rate of multifetal pregnancy.⁴

Patients with hypertension in pregnancy have higher incidence of eclampsia, abruptio placentae, preterm delivery (very often iatrogenic preterm delivery due to obstetric intervention secondary to hypertension or its complications), disseminated intravascular coagulation (DIC), hemorrhage, pulmonary edema, renal insufficiency, stroke, and death. Apart from being the most common medical complication of pregnancy, hypertensive disorders are associated with significant maternal, fetal, and neonatal morbidity and mortality.^{5,6} African-American women have a fourfold increase in mortality.⁷ Mortality rate is also increased for women over 35 years of age.⁸

Blood pressure measurement

The American College of Obstetricians and Gynecologists (ACOG) defines hypertension in pregnancy as either a systolic blood pressure of ≥ 140 mmHg or a diastolic blood pressure ≥ 90 mmHg observed on two occasions at least 6 hours apart.⁹ Blood pressure is measured with the patient in the sitting position with an appropriately sized blood pressure cuff. The measurement of blood pressure is subject to many inaccuracies. Potential sources of error in blood pressure measurement include faulty equipment, observer bias, improper technique, cuff size, and position of the arm during blood pressure measurement.^{10,11}

Direct intra-arterial blood pressure measurement is the gold standard for blood pressure monitoring and is the preferred method for critically ill patients. However, in clinical practice, the indirect (auscultatory) method is the more convenient and widely accepted technique in use. Of the indirect methods, the use of a mercury sphygmomanometer is the gold standard in clinical practice. An aneroid sphygmomanometer may be used, but it needs to be validated every 6 months for accuracy.¹²

There is controversy regarding the use of Korotkoff phase 4 (muffling of sound) versus phase 5 (disappearance of sound) to measure the diastolic blood pressure. Korotkoff phase 4 measures approximately 5–10 mmHg higher than phase 5 if using the auscultatory technique, or up to 20 mmHg difference if compared with intra-arterial measurement.¹³ It has been suggested that both phases should be measured, but that the phase 5 reading should be used for diagnosis and clinical trials.¹⁴

Classification of hypertensive disorders in pregnancy

Numerous attempts have been made to classify hypertensive disorders of pregnancy. However, it is often difficult to differentiate between preeclampsia (hypertension with proteinuria diagnosed after 20 weeks of gestation), gestational hypertension (elevated blood pressures without symptoms or proteinuria after 20 weeks of gestation), chronic hypertension (elevated blood pressure prior to conception or prior to 20 weeks of gestation), and chronic hypertension with superimposed preeclampsia. The normal second-trimester fall in blood pressure may conceal the presence of underlying chronic hypertension and, unless the patient presents in the first trimester or has a well-documented history of chronic hypertension, accurate classification is very difficult. It is classified as:

- preeclampsia (mild preeclampsia, severe preeclampsia, eclampsia, HELLP syndrome);
- gestational hypertension;

- chronic hypertension;
- chronic hypertension with superimposed preeclampsia.

Preeclampsia

The preeclampsia group includes mild preeclampsia, severe preeclampsia, eclampsia, and HELLP syndrome (hemolysis, elevated liver enzymes, and low platelets). Preeclampsia is the presence of proteinuria with elevated blood pressure (after 20 weeks' gestation) measured on two occasions at least 6 hours apart within 7 days. Mild preeclampsia is systolic blood pressure (BP) > 140 mmHg or diastolic BP > 90 mmHg with proteinuria (Table 38.1). Severe preeclampsia is proteinuria with systolic BP ≥ 160 mmHg or diastolic BP ≥ 110 mmHg or the presence of cerebral or visual disturbances (Table 38.2). Other features of preeclampsia include headache, visual disturbance, persistent visual changes, right upper quadrant pain, epigastric pain, nausea, and vomiting. Some of these features are indicative of severe preeclampsia rather than mild preeclampsia.

Protein excretion in the urine increases in normal pregnancy from approximately 5 mg/100 mL in the first and second trimesters to 15 mg/100 mL in the third trimester. These low levels are not detected by the dipstick technique. Significant proteinuria is defined as > 0.3 g in a 24-hour urine collection or 0.1 g/L (> 2+ on the dipstick), in at least two random samples collected 6 or more hours apart.

There is still confusion in the world literature regarding the true definition of preeclampsia despite the above diagnostic

Table 38.1 Criteria for the diagnosis of mild preeclampsia.

Systolic BP ≥ 140 mmHg or diastolic BP ≥ 90 mmHg on two occasions 6 hours apart after 20 weeks of gestation in a woman known not to have chronic hypertension prior to the pregnancy
Proteinuria ≥ 0.3 g in a 24-hour urine collection or 2+ proteinuria on qualitative examination or urinalysis
Edema and excessive weight gain may be present in preeclampsia but are no longer necessary for the diagnosis of preeclampsia

Table 38.2 Criteria for the diagnosis of severe preeclampsia.

Systolic BP ≥ 160 mmHg on two occasions 6 hours apart
Diastolic BP ≥ 110 mmHg on two occasions 6 hours apart
Proteinuria ≥ 5 g in a 24-hour urine collection
Oliguria of ≤ 500 mL in 24 hours
Cerebral or visual disturbances
Epigastric pain/right upper quadrant pain
Pulmonary edema
Abnormal liver function tests: aspartate aminotransferase (AST) or alanine aminotransferase (ALT) more than twice the upper limit for the laboratory
Thrombocytopenia (platelet count < 100 000/mm ³)

criteria.¹⁵ This is further complicated by problems with urinary protein estimation. The concentration of urinary protein is highly variable, especially if estimated with the dipstick technique. It is influenced by several factors, including contamination with vaginal secretions, blood, or bacteria; urine specific gravity and pH; exercise; and posture.¹⁶

Reported incidence of preeclampsia ranges from 2% to 7% depending on the diagnostic criteria and the population studied. It is principally a disease of primigravidas and rarely presents before 20 weeks' gestation. Early presentation is more likely to be associated with unrecognized renal disease.¹⁷

Several factors have been identified as predisposing to the development of preeclampsia. Risk factors for the development of preeclampsia include diabetes (particularly poorly controlled pregestational diabetes mellitus), obesity, nulliparity or primiparity, extremes of age (more common in teenagers and women with advanced maternal age, i.e., ≥ 35 years old), renal insufficiency or chronic renal disease, preexisting hypertension, personal history of preeclampsia, family history of preeclampsia, molar pregnancy, multifetal gestation, thrombophilia, and fetal hydrops. The risk factors may be present prior to conception (Table 38.3) or may appear during pregnancy (Table 38.4).¹⁸

Eclampsia

Eclampsia is the occurrence of seizures or coma (not attributable to any other cause) in a woman with preeclampsia. Antepartum eclampsia occurs in approximately 75% of cases, with the remaining 25% of cases occurring postpartum. Eclampsia rarely occurs before 20 weeks' gestation.¹⁹ Late postpartum eclampsia is defined as that beginning more than 48 hours postpartum but less than 4 weeks after delivery.²⁰ In one study, late postpartum eclampsia constituted 56% of postpartum eclampsia and 16% of all cases of eclampsia.²⁰

Table 38.3 Preconception risk factors for preeclampsia.

Preconception risk factors for preeclampsia	Frequency of occurrence
Previous preeclampsia	20–30%
Previous preeclampsia at ≤ 28 weeks	50%
Chronic hypertension	15–25%
Severe hypertension	40%
Renal disease	25%
Pregestational diabetes mellitus	20%
Class B/C diabetes	10–15%
Class F/R diabetes	35%
Thrombophilia	10–40%
Obesity/insulin resistance	10–15%
Age > 35 years	10–20%
Family history or preeclampsia	10–15%
Nulliparity/primiparity	6–7%

Courtesy of Sibai.¹⁸

Table 38.4 Pregnancy-related risk factors for preeclampsia.
(magnitude of risk depends on the number of factors)

Unexplained midtrimester elevations in serum AFP, hCG, inhibin A	Twice normal
Abnormal uterine artery Doppler velocimetry	10–30%
Hydrops/hydrops degeneration of placenta	0–30%
Multifetal gestation (depends on the number of fetuses and maternal age)	10–20%
Partner who fathered preeclampsia in another woman	10%
Gestational diabetes mellitus	8–10%
Limited sperm exposure (teenage pregnancy)	8–10%
Nulliparity/primiparity	6–7%
Donor insemination, oocyte donation	Limited data
Unexplained persistent proteinuria or hematuria	Limited data
Unexplained fetal growth restriction	Unknown

Courtesy of Sibai.¹⁸

The reported incidence of eclampsia varies between 0.5% and 0.2% of all deliveries. Eclampsia is associated with multi-organ dysfunction. Factors determining the degree of dysfunction include a delay in the treatment of preeclampsia and the presence of complicating obstetric and medical factors. Eclampsia is associated with a wide spectrum of signs and symptoms, ranging from extreme hypertension, hyperreflexia, proteinuria, and generalized edema to isolated mild hypertension. Some cases present without warning signs or symptoms. A small proportion of cases will occur despite normal blood pressure, but such cases will show other features of preeclampsia (proteinuria, elevated liver enzymes, etc.).¹⁷ Laboratory findings also vary. Serum uric acid and creatinine are usually elevated, and creatinine clearance is reduced. Hemoconcentration, reflected by an increased hematocrit and reduced plasma volume, is common as liver enzymes are found in 11–74% of eclamptic patients. HELLP syndrome complicates approximately 10% of eclampsia and usually occurs in longstanding disease and in patients with medical complications.

Why some women with symptoms of preeclampsia develop convulsions or coma while others do not is unknown. Several mechanisms have been suggested as predisposing factors to the development of eclampsia:

- cerebral vasospasm;
- cerebral hemorrhage;
- cerebral ischemia;
- cerebral edema;
- hypertensive encephalopathy;
- metabolic encephalopathy.

Most women with eclamptic seizures have an abnormal electroencephalogram.²¹ However, electroencephalographic changes are almost always transient and resolve completely. The neurologic and cerebrovascular changes of eclampsia serve as a model for hypertensive encephalopathy, with the occipital and parietal zones most vulnerable. The similar

Table 38.5 Criteria for the diagnosis of HELLP syndrome.*

Hemolysis
Abnormal peripheral blood smear (burr cells, schistocytes)
Elevated bilirubin ≥ 1.2 mg/dL
Increased LDH of more than twice the upper limit of normal for the laboratory
Elevated liver enzymes
Elevated ALT or AST \geq twice the upper limit of normal for the laboratory
Increased LDH more than twice the upper limit of normal for the laboratory
Low platelet count ($< 100\,000/\text{mm}^3$)

*Requires at least two of the abnormalities listed.

LDH, lactate dehydrogenase; ALT, alanine aminotransferase; AST, aspartate aminotransferase.

pathogenetic events of forced vasodilation and altered cerebral autoregulation seen in hypertensive encephalopathy may be operative in eclampsia. However, an additional factor, such as endothelial cell dysfunction, seems to be present in eclampsia. Although routine neuroimaging studies are not advocated for all women with eclampsia, focal neurologic deficits or prolonged coma (atypical eclampsia) require prompt investigation.

HELLP syndrome

Hemolysis, elevated liver enzymes, and low platelet counts have been recognized as complications of preeclampsia or eclampsia for many years.^{22–24} The criteria for the diagnosis of HELLP syndrome (Table 38.5) include: (1) hemolysis: abnormal peripheral blood smear, total bilirubin exceeding 1.2 mg/dL, lactic dehydrogenase (LDH) > 600 U/L; (2) elevated liver enzymes: serum aspartate aminotransferase (AST) > 70 U/L, elevated alanine aminotransferase (ALT) and LDH > 600 U/L; and (3) low platelet count: $< 100\,000/\mu\text{L}$.

The reported incidence of HELLP syndrome in preeclampsia ranges from 2% to 12%, which reflects different diagnostic criteria.²⁵ In the series reported by Sibai,²⁶ women with HELLP syndrome may present with a variety of signs and symptoms, none of which is diagnostic and all of which may be found in women with severe preeclampsia or eclampsia without HELLP syndrome. Nausea, vomiting, and epigastric pain are the most common symptoms.^{25–27} Right upper quadrant or epigastric pain is thought to result from obstructed blood flow in the hepatic sinusoids, which are blocked by intravascular fibrin deposition and capsular distention.

About 15–50% of cases have mild hypertension, about 12–18% have no hypertension, and 13% of cases have no proteinuria.²⁸ As a result, patients are often misdiagnosed as having various medical and surgical disorders, including appendicitis, gastroenteritis, glomerulonephritis, pyelonephritis, viral hepatitis, or even acute fatty liver of pregnancy (AFLP).

Pathogenesis of preeclampsia

A familial factor has been established in the pathogenesis of preeclampsia.²⁹ However, the exact mode of inheritance and the interactions between maternal and fetal genotype have not been elucidated.³⁰

There is evidence that abnormal placental angiogenesis occurs in pregnancies complicated by preeclampsia.³¹ There are reduced serum levels of vascular endothelial growth factor (VEGF) and placental growth factor (PIGF) in women with preeclampsia,^{32,33} coupled with altered expression of angiogenesis-related proteins.³⁴ According to Myatt,³⁵ hypoxia may affect trophoblast invasion and alter villous angiogenesis, leading to a poorly developed fetoplacental vasculature with abnormal reactivity.

An imbalance of prostaglandin metabolism has been implicated in the pathophysiology of preeclampsia.^{36,37} The renin-angiotensin-aldosterone system (RAAS) plays an important role in the control of vascular tone and blood pressure. Angiotensin-converting enzyme (ACE) activity, ACE protein expression, and ACE mRNA expression are higher in preeclamptic placentas than in placentas from uncomplicated pregnancies.³⁸

Gestational hypertension

Mild gestational hypertension is defined as systolic BP ≥ 140 mmHg or diastolic BP ≥ 90 mmHg (without proteinuria) measured on two occasions at least 6 hours apart and no more than 7 days apart after 20 weeks of gestation.³⁹ It is usually mild hypertension, late in onset, often occurs close to term, and occurs intrapartum or within 24 hours of delivery. It often resolves within 10 days of the postpartum period without treatment.

Severe gestational hypertension is defined as sustained systolic BP ≥ 160 mmHg and/or diastolic BP ≥ 110 mmHg measured at least 6 hours apart with no proteinuria.⁴⁰ Women with severe gestational hypertension have higher maternal and perinatal morbidities than those with mild gestational hypertension.^{40,41} Women with mild gestational hypertension may progress to severe gestational hypertension or preeclampsia. The rate of progression from gestational hypertension to preeclampsia is dependent on the gestational age at the time of diagnosis; the rate reaches 50% when gestational hypertension develops before 30 weeks of gestation.⁴²

Latent or transient hypertension was described in the last edition of this text as hypertension occurring antepartum, in labor, or in the first 24 hours postpartum without generalized edema or proteinuria and with a return to normotension within 10 days of delivery. Latent or transient hypertension is gestational hypertension in the intrapartum period but becomes transient hypertension (a retrospective diagnosis) if blood pressure returns to a normal value and no proteinuria is identified 12 weeks postpartum.⁴³ If proteinuria occurs

before 12 weeks' gestation, then the diagnosis will be gestational hypertension with progression to postpartum preeclampsia. If high blood pressure alone persists beyond 12 weeks of the postpartum period, then the patient has chronic hypertension.

Chronic hypertension

Chronic hypertension (CHTN) is diagnosed if there is persistent elevation of blood pressure to at least 140/90 mmHg on two occasions more than 24 hours apart prior to conception, prior to 20 weeks of gestation, or beyond 12 weeks postpartum. Other factors that may suggest the presence of chronic hypertension include the following:

- retinal changes on fundoscopic examination;
- radiologic and electrocardiographic evidence of cardiac enlargement;
- compromised renal function or associated renal disease;
- multiparity with a previous history of hypertensive pregnancies.

It may be difficult to be certain of a diagnosis of chronic hypertension because of significant changes in blood pressure that occur during midpregnancy. Women with mild chronic hypertension show greater decreases in their blood pressure during pregnancy than do normotensive women.⁴⁴

Chronic hypertension occurs in 1–5% of pregnancies. The most common etiology of chronic hypertension is essential or primary hypertension, contributing 90% of CHTN cases, while secondary hypertension accounts for the rest.¹⁷ Causes of chronic hypertension (Table 38.6) include renal diseases (glomerulonephritis, polycystic kidneys, renal artery stenosis, or renovascular disease), systemic lupus erythematosus, polyarteritis nodosa, endocrine disorders (hyperaldosteronism, pheochromocytoma, diabetes mellitus), and coarctation of the aorta.⁴⁵ Most of the secondary causes require specific treatment in addition to antihypertensive therapy. Early diagnosis is important because, if untreated, many of these disorders

Table 38.6 Etiology of chronic hypertension.

Renal factors	Acute and chronic glomerulonephritis Acute and chronic pyelonephritis Polycystic renal disease Renovascular disease
Collagen disease with renal involvement	Lupus erythematosus Periarteritis nodosa Scleroderma
Endocrine factors	Diabetes with vascular involvement Thyrotoxicosis Aldosterone-producing tumors Pheochromocytoma
Vascular system	Coarctation of the aorta

are associated with significant maternal/fetal morbidity and mortality.

In pheochromocytoma, there is increased production of epinephrine and norepinephrine by adrenal tumors or extra-adrenal catecholamine-producing tumors. There is excessive stimulation of adrenergic receptors causing peripheral vasoconstriction and a rise in blood pressure. Diagnosis is based on clinical presentation (high blood pressure not responding to conventional antihypertensives; hypertensive crisis with paroxysmal features and palpitation) and the presence of excess urinary catecholamines or products of catecholamine breakdown [vanilylmandelic acid (VMA), etc.].

Maternal renal artery duplex sonography may be used for initial screening in renovascular disease.⁴⁵ Definitive diagnosis requires more invasive procedures (isotopic renography and plasma renin levels after administration of oral captopril challenge), which are reserved for nonpregnant patients as such tests may have adverse effects on the fetus.

Chronic hypertension in pregnancy may be subclassified into mild hypertension (diastolic BP ≥ 90 to < 110 mmHg or systolic BP ≥ 140 to < 180 mmHg) or severe hypertension (diastolic BP ≥ 110 mmHg or systolic BP ≥ 180 mmHg). For the purpose of clinical management, chronic hypertension in pregnancy may also be divided into a low-risk group (hypertension with no endorgan damage or associated significant comorbidities) or a high-risk CHTN group (hypertension with endorgan damage or associated morbidities). These subdivisions are discussed in detail under the management of chronic hypertension in pregnancy.

Chronic hypertension with superimposed preeclampsia

Chronic hypertension may be complicated by superimposed preeclampsia (or eclampsia), which is diagnosed when there is an exacerbation of hypertension and development of proteinuria that was not present earlier in the pregnancy. Approximately 15–30% of chronic hypertensive women develop superimposed preeclampsia. Conditions for the diagnosis of superimposed preeclampsia on pre-existing chronic hypertension include:

- sudden exacerbation of blood pressure in a woman with previously well-controlled hypertension on antihypertensives;
- new-onset proteinuria (≥ 0.5 g protein in 24-hour urine collection) in a woman with chronic hypertension but no proteinuria prior to 20 weeks' gestation;
- worsening proteinuria in a woman with chronic hypertension and proteinuria prior to 20 weeks' gestation;
- new-onset elevated AST or ALT;
- new-onset thrombocytopenia with a platelet count less than $100\,000/\text{mm}^3$;
- new-onset symptoms of severe preeclampsia (persistent headache, right upper quadrant pain, epigastric pain, scotomata, nausea, and vomiting).

Management of hypertension in pregnancy

Management of preeclampsia

The most effective therapy for preeclampsia is delivery of the fetus and placenta. In pregnancies at or near term in which the cervix is favorable, labor should be induced. There is no need for antihypertensive medication unless the blood pressure is in the severe preeclampsia range. Mild preeclampsia prior to term may be monitored in the hospital or at home with daily fetal kick/movement counts, twice-weekly nonstress tests, and amniotic fluid assessment.

Indications for hospitalization and/or delivery of a patient with mild preeclampsia include:

- worsening maternal or fetal parameters;
- a favorable cervix at term;
- spontaneous rupture of membranes.

Conservative management of mild or severe preeclampsia beyond term is not beneficial to the fetus because uteroplacental blood flow may be suboptimal. After 37 weeks' gestation, labor should be induced as soon as the cervix is favorable.

Severe preeclampsia warrants hospitalization, administration of magnesium sulfate for seizure prophylaxis while antihypertensive medication is instituted for diastolic BP ≥ 110 mmHg or systolic BP ≥ 160 mmHg, and delivery of the fetus (except where conservative management is indicated as discussed below). The therapeutic objective for treatment of severe hypertension is to prevent maternal cerebrovascular accidents and congestive heart failure without compromising cerebral perfusion or jeopardizing uteroplacental blood flow. Profound and rapid reduction in blood pressure may compromise the uteroplacental circulation; therefore, continuous fetal monitoring should be employed. Therapeutic goals include reduction of blood pressure to a level compatible with a decreased risk of cerebrovascular accidents and maintenance of cerebral autoregulation. Accordingly, the goal of initial antihypertensive therapy is to limit the reduction in mean arterial pressure to 20–25% or to a diastolic blood pressure of 100 mmHg.⁴⁶

Parenteral or oral antihypertensive agents (labetalol, hydralazine, nifedipine, sodium nitroprusside, etc.) are used for acute reduction of blood pressure in women with severe preeclampsia or eclampsia. Oral medications are also used for maintenance or chronic therapy (Table 38.7). The choice of agents is dependent on the stage in pregnancy (antepartum, intrapartum, or postpartum), the side-effect profile of the agent in question, the presence of other medical problems (renal insufficiency, diabetes mellitus, pulmonary edema, myocardial ischemia, etc.), and, if postpartum, whether the woman is breastfeeding or not. The different agents used are discussed later under antihypertensive agents.

Table 38.7 Antihypertensive medication in pregnancy.

Class	Medication	Dose	
		Starting dose	Maximum dose
<i>Common drugs for chronic therapy of hypertension</i>			
Central alpha-2 agonist	Methyldopa	250 mg p.o. tid	2 g/day
Calcium channel blocker	Nifedipine	10 mg p.o. qid	120 mg p.o. qid
Alpha- and beta-blocker	Labetalol	100 mg p.o. tid	1200 mg/day
<i>Common drugs for acute therapy of severe hypertension</i>			
Arteriolar dilator	Hydralazine	5–10 mg i.v. every 15–30 min	
Calcium channel blocker	Nifedipine	10–20 mg p.o. every 30 min	
Alpha- and beta-blocker	Labetalol	5–10 mg i.v. per dose, cumulative to 40–80 mg over 20 min (maximum dose is 300 mg)	
Arterial and venous dilator	Nitroprusside	0.2–0.5 µg/kg/min	

Table 38.8 Guidelines for expectant management of severe preeclampsia remote from term.

Management plan	Clinical findings
Expedited delivery (within 72 h)	One or more of the following: Uncontrolled severe hypertension* Eclampsia Platelet count of < 100 000 cells/mL AST or ALT more than twice upper limit of normal with epigastric pain or right upper quadrant tenderness Pulmonary edema Compromised renal function† Persistent severe headache or visual changes
Expectant management	One or more of the following: Controlled hypertension Urinary protein > 5000 mg/24 h Oliguria (< 0.5 mL/kg/h) that resolves with routine fluid and food intake AST or ALT more than twice upper limit of normal epigastric pain or right upper quadrant tenderness

ALT, alanine aminotransferase; AST, aspartate aminotransferase.

*Blood pressure persistently ≥ 160 mmHg systolic or ≥ 110 mmHg diastolic despite maximum recommended doses of two antihypertensive medications.

†Persistent oliguria (< 0.5 mL/kg/h) or rise in serum creatinine of 1 mg/dL over baseline values.

Reproduced from ref. 47.

Conservative or expectant management of severe preeclampsia

Severe preeclampsia or superimposed preeclampsia developing early in pregnancy presents an obstetric dilemma. Delivery is the ultimate cure for maternal disease. However, delivery of infants before 34 weeks of gestation with immature lungs is associated with significant neonatal morbidity and mortality. Therefore, expectant or conservative management of the pregnant woman with severe preeclampsia remote from term (Table 38.8) is a feasible alternative to immediate delivery.⁴⁷

After admission, all women are observed in the labor and delivery unit for 12–24 hours to determine their eligibility for conservative management. Intravenous magnesium sulfate therapy is administered for seizure prophylaxis, glucocorticoid therapy is given for fetal lung maturation, antihypertensive

drug therapy is administered as indicated, and baseline laboratory studies (complete blood count with platelets, serum levels of creatinine, uric acid, total bilirubin, AST, and LDH, and 24-hour urine collection for total protein and creatinine clearance) are obtained. Fetal testing includes a baseline ultrasound examination and biophysical profile.

Once the woman and the fetus are judged to be suitable candidates for expectant management, the magnesium sulfate therapy is discontinued, and the patient is managed on the antepartum ward/floor. Blood pressure is measured every 4–6 hours, platelets every day, and serum AST and ALT every other day. Oral antihypertensive therapy is administered as needed to maintain blood pressure in the range 130–150 mmHg over 80–100 mmHg. Fetal biophysical profiles are obtained daily and ultrasound estimates of fetal weight biweekly. Hospitalization is continued until delivery.

Conservative management in severe preeclampsia at 28–32 weeks of gestation has been shown to prolong pregnancy by an average of 15.4 days (range 4–36 days), to reduce the incidence of admission to the neonatal intensive care unit, and to reduce length of stay in the unit.⁴⁸ Expectant management of severe preeclampsia is beneficial in a select group of women and should be practiced at tertiary care centers or at facilities that have the services of a specialist obstetrician with experience in managing such high-risk patients. Prompt delivery is indicated for the presence of imminent eclampsia, multiorgan dysfunction, fetal distress, or severe preeclampsia developing after 34 weeks of gestation. Mode of delivery is based on obstetric indications.

Management of HELLP syndrome

Delivery is the definitive therapy for HELLP syndrome beyond 34 weeks' gestation or with evidence of fetal lung maturity or fetal or maternal jeopardy. Without laboratory evidence of DIC, steroid therapy may be given to promote fetal lung maturity at gestational age under 34 weeks. During this period of conservative management, maternal and fetal conditions must be continuously assessed.

HELLP syndrome is not an indication for immediate Cesarean delivery. Guidelines similar to those described above for women with severe preeclampsia should be followed. The use of pudendal block or epidural anesthesia is contraindicated because of the bleeding risk. General anesthesia is the method of choice for Cesarean delivery.

Platelet transfusion is indicated either before or after vaginal delivery if the woman is bleeding and the platelet count is less than 20 000/mL. Repeated platelet transfusions are not necessary because consumption is rapid and the effect is transient. Platelet transfusion should be considered before Cesarean delivery if the platelet count is less than 40 000/mL. Six to ten units of platelets can be administered just before tracheal intubation. Generalized oozing from the operative site is common. The bladder flap should be left open, and a subfascial drain should be used for 24–48 hours postpartum to minimize the risk of hematoma formation. The wound may be left open from the level of the fascia, or a subcutaneous drain may be placed and the skin closed. Open wounds are usually closed within 48–72 hours.

After delivery, the woman with HELLP syndrome should be monitored closely in an intensive care facility (labor and delivery recovery unit or medical/surgical intensive care unit) for at least 48 hours. Most women show evidence of resolution of the disease process within 48 hours postpartum. Some (especially those with DIC) may demonstrate delayed resolution or even deterioration. These women are at risk for the development of pulmonary edema from transfusion of blood products, fluid mobilization, and compromised renal function.

HELLP syndrome may also develop in the postpartum period. The time of onset in the postpartum group ranges from a few hours to 6 days, with the majority developing HELLP

syndrome within 48 hours postpartum. Postpartum management is similar to that in the antepartum woman with HELLP syndrome, including the need for antiepileptic prophylaxis. Steroids (dexamethasone or betamethasone) have been suggested in a few studies to improve the hematological parameters and, possibly, the clinical outcome of HELLP syndrome.^{49,50} However, the use of steroids in HELLP syndrome is considered experimental.

Women with delayed resolution of HELLP syndrome (including persistent severe thrombocytopenia) represent a management dilemma. Exchange plasmapheresis with fresh-frozen plasma (FFP) has been advocated.^{51,52} Early initiation of plasmapheresis may result in unnecessary treatment because the majority of these women have spontaneous resolution of their disease.

Women presenting with shoulder pain, shock, or evidence of massive ascites or pleural effusions should have imaging studies of the liver to rule out the presence of subcapsular hematoma of the liver. A ruptured subcapsular liver hematoma resulting in shock is a surgical emergency requiring an acute multidisciplinary approach. Resuscitation should consist of massive transfusion of blood products, correction of coagulopathy with FFP and platelets, and immediate laparotomy. Options at laparotomy include any combination of the following: packing, drainage, surgical ligation of the hepatic artery, embolization of the hepatic artery to the involved liver segment, resection of the involved hepatic segment, and liver transplantation, if indicated.⁵³

Management of eclampsia

The protocol used to manage eclampsia is outlined in Table 38.9. Magnesium sulfate therapy is discussed in detail under antiepileptic medications. Once convulsions have been abolished, arterial blood gas measurements and a chest radiograph should be obtained to insure adequate maternal oxygenation and exclude aspiration. Hypoxemia and acidemia should be corrected and maternal hypertension treated.

The fetal heart rate and uterine activity must be closely monitored. Fetal bradycardia is a common finding during an

Table 38.9 Sibai's protocol for the management of eclampsia.

Convulsions are controlled or prevented with a loading dose of 6 g magnesium sulfate in 100 mL of 5% dextrose in Ringer's lactated solution, given over 15 min, followed by a maintenance dose of 2 g/h. The dose is adjusted according to patellar reflexes and urine output in the previous 4-h period
Induction or delivery is initiated within 4 h after maternal stabilization
Magnesium sulfate is continued for 24 h after delivery or, if postpartum, 24 h after the last convulsion. In some cases, the infusion may be continued for a longer period
Diuretics, plasma volume expanders, and invasive hemodynamic monitoring used only if clinically indicated

eclamptic seizure,⁵⁴ but the rate usually returns to normal once convulsions cease. If bradycardia persists or the uterus is hypertonic, placental abruption should be suspected and evaluated as appropriate. After stabilization of the maternal condition, steps should be taken to deliver the fetus, which is the definitive treatment for eclampsia. The mode of delivery is dependent on the usual obstetric indications. Hemodynamic monitoring with Swan–Ganz catheters is rarely necessary and should be based on the usual indications.⁵⁵

Management of gestational hypertension

Mild gestational hypertension is managed essentially as mild preeclampsia as detailed above, whereas women with severe gestational hypertension are managed as if they had severe preeclampsia. Women with severe gestational hypertension have a higher rate of maternal and perinatal morbidities than those who have mild gestational hypertension or normotensive women.^{40,56,57} The rates of abruptio placentae, small for gestational age (SGA) babies, and iatrogenic preterm deliveries are similar to those in women with severe preeclampsia. Women with gestational hypertension have higher birthweight at delivery, higher rates of induction of labor for maternal reasons, and higher rates of Cesarean delivery than normotensive women.⁵⁸ To all intents and purposes, severe gestational hypertension should be managed just like severe preeclampsia.

Management of CHTN and CHTN with superimposed preeclampsia

Management of secondary hypertension is that of the underlying disease. However, most patients with chronic hypertension have essential hypertension, and the discussion that follows is directed toward this group of patients. The presence of chronic hypertension in pregnancy increases maternal and perinatal morbidity and mortality.⁵⁹ Most of the morbidity and mortality is related to the development of superimposed preeclampsia and abruptio placentae. Maternal and fetal risks can be reduced by proper antepartum surveillance (Table 38.10).

Preconception counseling in women with chronic hypertension provides an opportunity to:

- determine the severity of hypertension and identify any endorgan damage;
- implement prepregnancy lifestyle changes (exercise, weight loss, reduction in sodium intake, etc.) necessary for adequate blood pressure control;
- establish baseline laboratory data that will help in the future diagnosis of superimposed preeclampsia;
- discuss the potential side-effects of antihypertensive drugs.

Laboratory investigation should include the following:

- electrocardiogram (ECG);
- urinalysis, culture, and sensitivity;

Table 38.10 Evaluation of pregnancy complicated by chronic hypertension.

Name:	Date of birth:
Parity: G . . . P . . . :	LMP:
Gestational age:	EDD or EDC:
Ultrasound:	
First trimester ultrasound [for correct dating and nuchal translucence (NT) measurement]:	
Fetal biometry/anatomy ultrasound (at 18–20 weeks):	
Follow-up growth ultrasound at 4-weekly intervals starting in late second trimester	
Fetal testing starting in late second or early third trimester (for patients with renal insufficiency):	
Twice-weekly testing or BPP	
Nonstress test (NST) if there is poor growth	
NST and Doppler studies if IUGR (< 10%)	
Renal evaluation: 24-h urine protein and creatinine clearance, electrolytes, urea, and creatinine levels

Cardiac echocardiography:	
Comments/comorbid conditions:	

Table 38.11 High-risk chronic hypertension in pregnancy.

Maternal age greater than 40 years (may consider age ≥ 35 years)
Duration of hypertension more than 15 years
Blood pressure exceeding 160 over 110 mmHg early in pregnancy
Diabetes mellitus (classes B–F)
Cardiomyopathy
Renal disease
Connective tissue disorders
Consider morbid obesity (weight ≥ 300 lb)

- 24-hour urine collection for total protein and creatinine clearance;
- biochemistry: renal panel (in particular creatinine level), uric acid, lactate dehydrogenase, liver function test;
- hematology: full or complete blood count, prothrombin time (PT), partial thromboplastin time (PTT);
- optional tests (depending on the clinical evaluation/judgment): antinuclear antibody (ANA), VMA and catecholamines, anticardiolipin antibodies (ACA), etc.

Uncomplicated CHTN in pregnancy is labeled low-risk CHTN, whereas the high-risk group (Table 38.11) includes patients with renal disease, diabetes mellitus, etc. The discussion of management focuses on the control of blood pressure and the assessment of fetal and maternal well-being. Most women are seen by a nutritionist and given dietary advice. Daily sodium intake should be restricted to 2 g. The harmful effects of smoking, stress, and caffeine on maternal blood pressure and fetal well-being are emphasized, and frequent rest periods are encouraged.

Women are seen every 2–3 weeks until 34 weeks and then weekly until delivery. At each visit, systolic and diastolic blood pressure should be recorded and the urine tested for the presence of glucose and protein. Evaluation of maternal status includes serial measurements of hematocrit, serum creatinine, and 24-hour urinary excretion of protein. Prompt hospitalization is indicated if there is an exacerbation of hypertension, development of pyelonephritis, or significant proteinuria. An elevation of uric acid > 6 mg/dL may be an early warning sign of superimposed preeclampsia.

Fetal evaluation includes serial growth scans and antepartum fetal heart rate testing from the early third trimester. For those considered high risk, nonstress testing (NST) may commence as early as 28 weeks. Daily fetal movement counts and weekly or biweekly biophysical profiles (BPP) or NSTs are generally employed.

Antihypertensive therapy is restricted to women with severe hypertension. Low-risk pregnancy is allowed to continue to 40–41 weeks' gestation with close monitoring. High-risk pregnancies and women receiving antihypertensive drugs are delivered at or before 40 weeks' gestation.

The outcome in women with chronic hypertension is closely related to the development of superimposed preeclampsia. Sibai and Anderson⁶⁰ studied 44 pregnant women with severe hypertension in the first trimester. Fifty-two percent developed superimposed preeclampsia.

Women with severe chronic hypertension in early pregnancy or underlying renal disease require early referral for antenatal care, intensive fetal and maternal monitoring as described earlier, and delivery in a tertiary care center. Antihypertensive therapy is indicated and should maintain systolic blood pressure between 140 and 150 mmHg and diastolic pressure between 90 and 100 mmHg. Persistent blood pressure levels below these ranges in women who have previously been very hypertensive may jeopardize placental perfusion.

Antiseizure medications in preeclampsia

Parenteral magnesium sulfate (MgSO_4) has become the drug of choice for therapy and prophylaxis of eclampsia (Magpie trial⁶¹). Magnesium causes relaxation of smooth muscle by competing with calcium for entry into cells at the time of cellular depolarization, but its exact mechanism of action in the control of eclamptic seizures is unknown. Central nervous system depression and suppression of neuronal activity are postulated as mechanisms. Additional theories about the efficacy of magnesium sulfate therapy for seizure prophylaxis include its role as a cerebral vasodilator (particularly acting on the smaller diameter vessels). The potential for magnesium to relieve cerebral ischemia through its antagonism of calcium-dependent arterial constriction may explain its antiseizure activity. Conversely, once widespread cerebral vasoconstriction has occurred in severe preeclampsia, the resultant cere-

Table 38.12 Clinical findings associated with increasing maternal serum levels of magnesium.

Serum magnesium level (mg/dL)	Clinical findings
1.5–2.5	Normal level
4–8	Therapeutic range for seizure prophylaxis
9–12	Loss of patellar reflex
15–17	Muscular paralysis, respiratory arrest
30–35	Cardiac arrest

bral ischemia could lower the threshold for seizure activity in those affected areas.⁶²

Most eclamptic convulsions resolve in 60–90 seconds. After the convulsion has ended, an initial intravenous 6-g loading dose of magnesium sulfate should be given over 15–20 min. If another convulsion occurs after the initial loading dose, an additional intravenous bolus of 2 g may be given over 3–5 min. Approximately 10–15% of women have a second convulsion after receiving the loading dose of magnesium sulfate; most women remain free of seizures after the additional 2-g bolus. Maintenance infusion of 2 g/h magnesium sulfate is then begun. Serum magnesium levels may be followed to guide maintenance infusion therapy of magnesium sulfate if there is renal dysfunction. The initial level may be obtained 4 h after the loading dose.

Clinical findings associated with elevated serum magnesium levels will help in monitoring therapy (Table 38.12). The first sign of magnesium toxicity is loss of patellar reflexes (10–12 mg/dL). Other early signs and symptoms of magnesium toxicity include nausea, feeling of warmth, flushing, slurred speech, and somnolence (9–12 mg/dL). Magnesium toxicity should also be considered in women who do not regain consciousness after an eclamptic seizure.

Serum magnesium levels may also be used for monitoring evidence of drug toxicity. Magnesium is excreted by the kidneys; renal dysfunction may result in toxicity. The following guidelines may help to prevent magnesium toxicity:

- monitor hourly urine output;
- evaluate deep tendon reflexes hourly;
- monitor respiratory rate;
- monitor serum magnesium levels regularly.

If magnesium toxicity is suspected, the magnesium infusion should be discontinued, supplemental oxygen administered, and a serum magnesium level obtained. Pharmacologic treatment of magnesium toxicity includes administration of 10 mL of 10% calcium gluconate (1 g in total) as a slow intravenous push. Calcium competitively and briefly inhibits magnesium at the neuromuscular junction. Symptoms of magnesium toxicity may recur if the magnesium level remains elevated. Respiratory arrest secondary to magnesium toxicity requires intubation and assisted ventilation.⁶³

Magnesium sulfate may inhibit uterine contraction, causing uterine atony. Magnesium sulfate therapy appears to prolong bleeding time,^{64,65} to increase blood loss at delivery,⁶⁶ and to be associated with increased postpartum hemorrhage.⁶⁷

Magnesium sulfate may also decrease beat-to-beat variability of the fetal heart rate,⁶⁸ and signs of neonatal hypermagnesemia have been reported after only 24 hours of intravenous therapy.⁶⁹

Women who have recurrent convulsions while receiving therapeutic maintenance magnesium sulfate may be given a short-acting barbiturate, such as sodium amobarbital, in a dose up to 250 mg intravenously over 3–5 min.

Antihypertensive therapy

Treatment of severe hypertension is associated with a reduction in maternal morbidity and mortality.⁷⁰ Antihypertensive therapy does not prevent preeclampsia or abruptio placentae, neither does it improve perinatal outcome.^{71,72}

Central-acting agents (methyldopa, clonidine)

Methyldopa acts by stimulating central alpha-2 receptors. It may also be an alpha-2 blocker acting by a false neurotransmitter effect. The drug is given orally in a loading dose of 1 g followed by maintenance therapy of 1–2 g daily in four divided doses. Peak plasma levels occur within 2 h of an oral dose, and the fall in blood pressure is maximal 4 h after tablet ingestion. Side-effects include drowsiness and a dry mouth. Hepatitis, hemolytic anemia, and a positive Coombs' test have been reported in association with long-term use. Differentiating cholestatic jaundice or abnormal LFT due to methyldopa from elevated liver enzymes resulting from severe preeclampsia might be difficult.

Until recently, methyldopa was the most frequently used antihypertensive agent in pregnancy, probably because of its safety profile. It is no longer the first-line agent because it has a slow onset of action and is not as efficacious as other available antihypertensive agents. In breastfeeding mothers with hypertension requiring medication, when there is difficulty with the choice of antihypertensive agents, methyldopa may be an option.

Clonidine is a powerful alpha-2 adrenergic central stimulant. The usual oral dose in pregnancy is 0.1 (morning) and 0.3 mg/day (bedtime), increasing incrementally to a maximum of 1.2 mg daily. Rebound hypertension has been reported after abrupt cessation of the drug. The safety of clonidine in pregnancy appears to be well established;⁷³ however, it is more likely to be used as a second- or third-line agent. Also, it is a useful alternative in breastfeeding mothers.

Alpha- and beta-blocking agents

Labetalol is a combined alpha- and beta-adrenoceptor blocker. It is probably the most commonly used antihypertensive agent in pregnancy. Parenteral labetalol has a rapid onset of action. The initial intravenous dose is 20 mg with subsequent escalating doses every 20 min (40, 80, 80, and 80 mg) until either a desired effect or a maximum dose of 300 mg is reached. Oral labetalol may also be used for long-term therapy: an initial oral dose of 300 mg daily may be increased to a maximum daily dose of 1200 mg. Side-effects of labetalol therapy include scalp tingling, tremulousness, and headache. Avoid the use of labetalol in women with second-degree heart block.

Other beta blockers (metoprolol, atenolol, oxprenolol) have been studied in pregnancy. Exercise caution with the use of these drugs because of reports of intrauterine growth restriction with the use of atenolol in the first trimester, but not later in pregnancy.⁷⁴ Metoprolol is sometimes used as a last resort in the management of hypertension not responding to other common antihypertensive agents.

Doxazosin, an alpha-blocker, has no role in the management of hypertension in pregnancy. Its role in the nonpregnant population seems to be under scrutiny.⁷⁵

Diuretics

Thiazide diuretics are commonly used to treat hypertension in the nonpregnant population, but their role in pregnancy is highly controversial. Although preeclampsia and eclampsia patients may have edema and appear to be fluid overloaded, they are very frequently intravascularly depleted. Sibai et al.⁷⁶ observed a marked reduction in volume in pregnant women treated with diuretics compared with a control group receiving no medication. Although this effect was reversed after discontinuing the diuretic therapy, plasma volume depletion is associated with a poor perinatal outcome. Consequently, most doctors avoid diuretics in pregnant preeclampsia patients for fear of depleting the intravascular volume. Whereas that may be a concern in the intrapartum period, there is no reason not to use it in the postpartum period, especially if there is pulmonary edema or evidence of fluid overload.

In the postpartum period, there is pooling of fluid from the periphery and the uterus into the circulation, thus increasing the intravascular fluid volume; therefore, the use of diuretics is acceptable. Hopefully, more people will start using diuretics as first-line antihypertensive agents in the postpartum period.

Thiazide diuretics may cause hyperglycemia, thus adversely affecting the control of hyperglycemia in diabetic patients, but this side-effect is unlikely to have a huge impact on outcome when diuretics are used for only a short period. Other side-effects include hyponatremia, hyperuricemia, acute pancreatitis, and fetal thrombocytopenia.

Loop diuretics are useful in patients with signs of fluid overload or pulmonary edema. Prolonged use of loop diuretics may lead to hypokalemia. Therefore, the serum potassium level should be checked if the woman is receiving a loop diuretic for more than a couple of days.

Hydralazine

Hydralazine is a potent vasodilator that acts directly on smooth muscle. It is administered as an intravenous bolus injection. After intravenous administration, the hypotensive effects develop gradually over 15–30 min. The usual bolus dose is 5–10 mg to be repeated every 20–30 min as needed. Maternal side-effects include headache, facial flushing, tachycardia, palpitations, nausea, and vomiting. Mabie et al.⁷⁷ reported fetal distress secondary to hypotension from overtreatment in two of six cases. Chronic administration may be associated with a maternal lupus syndrome and neonatal thrombocytopenia. Oral hydralazine is a weak antihypertensive when used alone and is usually combined with methyldopa or a diuretic.

Sodium nitroprusside

Sodium nitroprusside is a potent arterial and venous dilator used for emergent therapy of patients with hypertensive crisis. It is given as a continuous intravenous infusion because of its immediate onset of action and short duration of action (1–10 min). It is metabolized by the liver and excreted by the kidneys. The initial infusion dose in gravid women should be 0.2 µg/kg/min rather than the usual dose of 0.5 µg/kg/minute, as is standard in nonpregnant patients. This drug should be reserved for hypertensive emergencies because of concerns about thiocyanate toxicity in the neonate.

Calcium channel blockers (CCB)

Calcium channel blockers (CCB) have a very good safety profile in pregnancy and have been used successfully to manage hypertension in pregnancy. They may have a renoprotective effect that might be useful in patients with renal insufficiency. Nifedipine is used extensively in obstetric practice for both blood pressure control and preterm labor with no obvious teratogenic effects documented.^{78,79}

Nifedipine is available orally in both short-acting and extended-release forms. It may improve uteroplacental blood flow and has a tocolytic effect on the uterus. In addition to oral therapy for chronic hypertension in pregnancy, nifedipine may be used for emergent reduction of severe hypertension. The use of sublingual nifedipine in the past for rapid reduction in blood pressure posed significant risks to the mother and fetus; hence, the sublingual route is contraindicated. Exercise caution when using nifedipine in patients on magnesium sulfate as they may have a synergistic action leading to severe hypotension. The maximum daily dose for nifedipine is

120 mg. Common side-effects include headache, flushing, tachycardia, and fatigue.

Although less often used, other CCBs (verapamil and diltiazem) may be used for blood pressure control in patients with cardiac disease. Additional experience with verapamil use in pregnancy is available because of its use in treating arrhythmias in pregnancy.

Angiotensin-converting enzyme (ACE) inhibitors

The chronic use of ACE inhibitors in pregnancy is associated with fetal renal insufficiency/renal failure, fetal growth retardation, oligohydramnios, cranial anomalies, severe fetal hypotension, and death, especially in the second and third trimesters.^{80,81} Postpartum use of ACE inhibitors is indicated for women with diabetic nephropathy and peripartum cardiomyopathy. Women are advised to stop ACE inhibitors prior to conception; however, if exposed to ACE inhibitors in the first trimester, the medication may be stopped without significant damage to the fetus.^{82,83} In summary, ACE inhibitors are contraindicated in pregnancy but may be useful in the postpartum period.

Anesthesia and hypertensive disorders of pregnancy

Exaggerated hemodynamic response

Sudden increase in blood pressure may occur in general anesthesia during either intubation or extubation, leading to a cerebrovascular event. An increase in arterial blood pressure accompanies laryngoscopy performed with or without tracheal intubation. Therefore, blood pressure should be reduced prior to intubation or extubation. This hypertensive response is prevented with a short-acting antihypertensive agent, such as nitroglycerin, sodium nitroprusside, or labetalol.^{84,85} Esmolol, a pure β -receptor antagonist with a rapid onset of action, is a popular agent for blunting the hypertensive response to tracheal intubation in nonpregnant patients. Unfortunately, it crosses the placenta and causes severe fetal bradycardia; hence, it is not recommended in pregnant patients but may be used in postpartum preeclampsia.⁸⁶

Decreased sympathetic activity due to regional anesthesia leads to dilatation of the capacitance vessels that cause hypotension. Adequate intravascular volume repletion (fluid preloading) performed before initiating regional anesthesia avoids this relative hypovolemia. Management of volume status varies according to the severity of the patient's disease. Hypotension can also occur with intravenous administration of antihypertensive medication. This effect is more pronounced if the mother has been in a supine position for a long period; hence, the need to have the patient in a "tilted" position to avoid compression of the vena cava by the uterus.

Difficulty with intubation

Preeclamptic women may have pharyngeal and laryngeal edema rendering intubation and ventilation difficult. A laryngeal mask airway (LMA) may be a useful alternative in cases of difficult airway management and should be anticipated in severe preeclampsia.⁸⁷

Magnesium sulfate interaction with neuromuscular blocking agents

Magnesium decreases the release of acetylcholine from the presynaptic portion of the myometrial junction as well as decreasing the sensitivity of the motor endplate to the effects of acetylcholine. Women receiving magnesium sulfate are more sensitive to the depolarizing and nondepolarizing neuromuscular blocking agents; therefore, the dose of muscle relaxant must be adjusted accordingly.^{84,88} This neuromuscular transmission defect correlates with increased serum magnesium levels and decreased serum calcium levels.

Bleeding problems

Decreased platelet count and function occur in up to 18% of women with preeclampsia.⁸⁴ Epidural anesthesia is safe for women with platelet counts $\geq 100\,000/\mu\text{L}$ in the peripartum period.^{89–91} The rate of fall in platelet count is equally important because a rapid fall in platelet count may be indicative of severe disease. Estimation of bleeding time is no longer deemed necessary as a routine test in severe preeclampsia. It is, however, important to check other indicators of coagulopathy, including prothrombin time (PT), partial thromboplastin time (PTT), and international normalized ratio (INR), especially if there are clinical signs of coagulopathy. If an epidural catheter is already in place, then the platelet count should be checked before removal of the epidural catheter.

Postpartum hemorrhage secondary to uterine atony may be due to magnesium sulfate (a tocolytic agent) and/or anesthetic agents (especially the inhalational agents) used in general anesthesia. Platelet dysfunction or thrombocytopenia, as in HELLP syndrome, will increase the risk of bleeding. Ramanathan et al.⁹² showed that platelet dysfunction is related to the severity of preeclampsia.

Regional anesthesia is now established as the preferred mode of anesthesia for preeclampsia patients as long as there is no contraindication to regional anesthesia such as coagulopathy. Regional anesthesia is the anesthetic of choice in most women with preeclampsia or eclampsia, for some of the following reasons. Epidural analgesia reduces maternal plasma catecholamine levels in laboring women. This may benefit preeclamptic women who are already exhibiting increased vascular reactivity to circulating catecholamines. Compromised intervillous blood flow in preeclamptic women may be improved by lumbar epidural analgesia. In turn, lumbar

epidural analgesia may improve uteroplacental perfusion by reversal of uterine arterial vasospasm.⁸⁴

Prediction and prevention of preeclampsia

Preeclampsia discussion often evokes emotions and controversies, whether it is the etiology, diagnosis, pathogenesis, prediction, prevention, or treatment. Is magnesium sulfate indicated in the management of mild preeclampsia? What is the role of aspirin in the management of preeclampsia? Any role for antioxidants, placental growth factors, etc. in the evaluation of a woman with preeclampsia?

Prediction of preeclampsia

Over 100 clinical, biophysical, and biochemical tests have been recommended to predict or identify women at risk for future development of preeclampsia.^{93–96} The results of the combined data and lack of agreement between serial tests suggest that none of these clinical tests is reliable for use as a screening test.

Numerous biomarkers have been proposed for the prediction of women who are destined to develop preeclampsia. The markers may indicate placental dysfunction,^{96,97} endothelial and coagulation activation,^{98,99} and systemic inflammation.^{43,97} Many of these markers suffer from poor specificity and predictive values and, therefore, are not used in routine clinical practice.

Doppler ultrasound in the second trimester may show abnormal uterine artery velocity waveforms characterized by a high resistance index or by the presence of an early diastolic notch (unilateral or bilateral notch). The presence of these Doppler findings in the second trimester increases the rate of preeclampsia with a 20–60% sensitivity and a 6–40% positive predictive value.^{100–102} A review by Chien et al.,¹⁰³ which included 27 studies with nearly 13 000 patients, claimed that uterine artery Doppler assessment had limited value as a screening tool for preeclampsia.

Prevention of preeclampsia

Magnesium sulfate for the prevention of eclampsia

Magnesium sulfate is now established as the drug of choice for the prevention of eclampsia, having been shown to be superior to placebo or no treatment in the prevention of convulsions in women with severe preeclampsia.^{61,67,104–106} These trials demonstrated that magnesium sulfate prophylaxis, compared with placebo (two trials with a total of 10 795 women), nimodipine (one trial with 1750 women), and no treatment (one trial with 228 women) in the management of severe preeclampsia, is associated with a significantly lower rate of eclampsia. One of the largest trials to date enrolled 10 141 women with preeclampsia in 33 countries (mainly developing

countries).⁶¹ Most of the enrolled patients had severe disease by current United States standards; half of them received antihypertensives prior to randomization; 75% had antihypertensives following randomization. Among the enrolled women, the rate of eclampsia was significantly lower in those assigned to magnesium sulfate. However, of the 1560 women enrolled in the Western world, the rate of eclampsia was 0.5% in the magnesium group versus 0.8% in the placebo group, which was not significant [relative risk (RR) 0.67 within a 95% confidence interval].⁶¹

Two randomized placebo-controlled trials evaluated the efficacy and safety of magnesium sulfate in the management of mild preeclampsia. One study had 135 women⁶⁷ and the other had 222 women,¹⁰⁷ which revealed that magnesium sulfate does not affect the duration of labor, nor does it affect the rate of Cesarean section. Both trials lacked sufficient power to clarify the role of magnesium sulfate in the prevention of convulsions in mild preeclampsia.¹⁰⁸

Aspirin

Several studies of aspirin for the prevention of preeclampsia have been performed. Hauth et al.¹⁰⁹ showed that the incidence of preeclampsia was significantly lower in the aspirin-treated group; however, there were no differences in gestational age at delivery, neonatal birthweight, or frequency of fetal growth restriction or preterm delivery. A subsequent study by Sibai et al.¹¹⁰ showed a reduction in the incidence of preeclampsia by 26% in the aspirin-treated women. However, a significantly higher incidence of abruptio placentae was identified in women receiving aspirin. The CLASP trial,¹¹¹ a multinational, randomized trial involving 9364 women and using low-dose aspirin (60 mg), failed to identify a difference in the incidence of preeclampsia, intrauterine growth restriction, abruptio placentae, or perinatal deaths. The aspirin-treated group did, however, have a lower incidence of preterm delivery. A meta-analysis suggested that low-dose aspirin improved pregnancy outcome in women with persistent elevations in uterine Doppler resistance index at both 18 and 24 weeks of gestation.¹¹² Other studies, however, did not show aspirin

administration to prevent subsequent development of preeclampsia.^{100,102} It thus appears that our hope for low-dose aspirin therapy as an effective prophylaxis for preeclampsia has not materialized, yet.

Oral supplementation with magnesium, zinc, calcium, vitamin C, vitamin E, etc.

Although the early reports of calcium supplementation for the prevention of and reduction in the severity of preeclampsia appeared promising, the results have not been convincing.^{113–117} Zinc supplementation¹¹⁸ and oral magnesium supplementation¹¹⁹ studies did not show any change in the rate of preeclampsia. Fish oil supplementation showed no significant change in the incidence of preeclampsia.¹²⁰ Although Chappell et al.¹²¹ showed improvement in the biochemical indices of preeclampsia after the administration of antioxidants, recent studies indicate that some antioxidants may not necessarily improve the clinical outcome in preeclampsia. Meanwhile, the role of calcium, vitamin E, vitamin C, and other antioxidants remains unclear.^{122,123}

Prospects for the future

Maternal morbidity and mortality related to preeclampsia are principally associated with eclampsia and HELLP syndrome. Fetal morbidity and mortality are associated mainly with second-trimester severe preeclampsia and preterm delivery. Greater understanding of the pathophysiology of preeclampsia is the key to improving both fetal and maternal outcomes. In the present state of knowledge, women with severe disease should be referred to a tertiary center with the experience and facilities to manage maternal complications and provide intensive care for a preterm infant. In the future, it may be possible to identify factors that clearly distinguish between pregnant women at low risk of developing hypertensive complications and those at high risk. This would allow for appropriate antenatal care and maternal–fetal monitoring.

Key points

- 1 Hypertension is the most common medical complication of pregnancy, being present in 8–10% of pregnancies.
- 2 Mild preeclampsia is systolic blood pressure (BP) ≥ 140 mmHg or diastolic BP ≥ 90 mmHg observed on two occasions at least 6 hours apart with proteinuria.
- 3 Severe preeclampsia is proteinuria with systolic BP ≥ 160 mmHg or diastolic BP ≥ 110 mmHg or the presence of cerebral or visual disturbances. Other features of severe preeclampsia include persistent headache, persistent visual changes (scotomata), right upper quadrant pain, epigastric pain, nausea, and vomiting.
- 4 Preeclampsia accounts for 70% of hypertension in pregnancy, and chronic hypertension (CHTN) accounts for most of the remaining 30%.
- 5 Most women with eclamptic seizures have an abnormal electroencephalogram. However, electroencephalographic changes are almost always transient and resolve completely.

- 6 The outcome in women with CHTN is closely related to the development of superimposed preeclampsia and abruptio placentae.
- 7 Patients with hypertension in pregnancy have an increased incidence of eclampsia, abruptio placentae, preterm delivery (mainly iatrogenic preterm delivery due to obstetric intervention secondary to hypertension or its complications), disseminated intravascular coagulation (DIC), hemorrhage, renal insufficiency, pulmonary edema, stroke, and death.
- 8 Hypertension in pregnancy increases perinatal morbidity and mortality including preterm delivery/prematurity and intrauterine growth retardation (IUGR).
- 9 Treatment of severe hypertension is associated with a reduction in maternal morbidity and mortality, but does not prevent preeclampsia or abruptio placentae; neither does it improve perinatal outcome.
- 10 The most effective therapy for preeclampsia is delivery of the fetus and placenta.
- 11 No clinically useful and universally accepted predictive or screening test has been identified for preeclampsia.
- 12 Preconception counseling is very important in the management of patients with CHTN. It is important to establish the etiology and severity of hypertension, to identify endorgan damage, and to achieve adequate blood pressure control prior to conception.
- 13 Calcium channel blockers (diltiazem, nifedipine, etc.) are helpful in patients with CHTN and diabetes mellitus because of their renoprotective effect.
- 14 Angiotensin-converting enzyme (ACE) inhibitors may cause fetal renal insufficiency, oligohydramnios, growth restriction, cranial anomalies, and severe fetal hypotension especially in the second and third trimesters. The ACE inhibitors are contraindicated in pregnancy but may be used in diabetic patients in the postpartum period if they are not breastfeeding.
- 15 Hypertension and diabetes mellitus are both systemic diseases with significant impact on the micro- and macrocirculation leading to nephropathy, retinopathy, cardiac disease, etc. This underscores the need for aggressive control of blood pressure in such women.

Cardiac diseases in pregnancy

Kjersti Aagaard-Tillery and Steven L. Clark

Pregnancy causes significant alterations in the maternal cardiovascular system. The pregnant patient with normal cardiac function accommodates these physiologic changes without difficulty. In the presence of cardiac disease, however, pregnancy may be extremely hazardous, resulting in decompensation and even death. Despite advances in the diagnosis and treatment of maternal cardiovascular disease, such conditions continue to account for 10–25% of maternal deaths.^{1–3} Given an observed increasing prevalence of pregnancies among women with cardiac disease, currently estimated to range between 0.1% and 4%, the need for obstetricians to be well versed in proper counseling and management of these conditions is paramount.⁴ This chapter focuses on the interaction between structural cardiac disease and pregnancy, with an emphasis on the means of achieving optimal maternal and perinatal outcomes.

Counseling the pregnant cardiac patient

The Criteria Committee of the New York Heart Association (NYHA) has recommended a classification of cardiac disease based on clinical function (classes I–IV). Although such a classification is useful in discussing the pregnant cardiac patient, up to 40% of patients developing congestive heart failure and pulmonary edema during pregnancy are functional class I before pregnancy. In one review, the majority of maternal deaths during pregnancy occurred in patients who were initially class I or II.⁵ In general, however, women who begin pregnancy as functional class I or II have a better outcome than those initially in class III or IV.^{6,7} Counseling the pregnant cardiac patient regarding her prognosis for successful pregnancy is further complicated by recent advances in medical and surgical therapy, fetal surveillance, and neonatal care. Such advances render invalid many older estimates of maternal mortality and fetal wastage.

Table 39.1 represents a synthesis of maternal risk estimates for various types of cardiac disease initially developed by Clark et al.⁸ in 1987. Counseling of the pregnant cardiac

patient, as well as general management approaches, were based on this classification. Category I included conditions that, with proper management, were associated with negligible maternal mortality (less than 1%). Cardiac lesions in category II traditionally carried a 5–15% risk of maternal mortality. Patients with cardiac lesions in group III were, and probably remain, subject to a mortality risk exceeding 25%. In all but exceptional cases, this risk is unacceptable, and it is our continued belief that prevention or interruption of pregnancy is generally recommended.

While our initial classification schema has proven useful in grossly predicting mortality risk in the past, a review of more recent data from the United States and Europe suggests the need to selectively revise these estimates; this is summarized in Table 39.2. In some of these current studies, it may generally be said that maternal mortality is almost exclusively seen in patients with pulmonary hypertension, endocarditis, coronary artery disease, cardiomyopathy, and sudden arrhythmia.^{1–3,9–33} deSwiet,¹ reporting on maternal mortality from heart disease in the United Kingdom between 1997 and 1999, found that all deaths could be accounted for from the following entities: puerperal cardiomyopathy (20%), myocardial infarction (14%), aortic dissection (14%), cardiomyopathy and myocarditis (14%), primary pulmonary hypertension (9%), secondary pulmonary hypertension (11%), endocarditis (9%), and dysrhythmia (3%). These authors attribute the changing pattern of heart disease in recent decades to a dramatic reduction in rheumatic heart disease. In support of this hypothesis, a review of maternal mortality in Utah from 1982 to 1994 revealed 13 cardiac deaths, four from pulmonary hypertension (31%), four secondary to cardiomyopathy (31%), two from coronary artery disease (15%), and three (23%) from sudden arrhythmia.³ This is not to imply that the relative risk categories outlined in Table 39.1 are not still valid with respect to the likelihood of maternal complications or that interruption of pregnancy or cardiac surgery before term may not be necessary. The possibility of fetal morbidity and mortality, especially in cases of cyanotic heart disease, also cannot be overlooked. However, it would appear that, with

Table 39.1 Maternal risk associated with pregnancy, by general categorization.

Group	Cardiovascular disorder
Group I: Minimal risk of complications (< 1%)	Atrial septal defect Ventricular septal defect Patent ductus arteriosus Pulmonic or tricuspid disease Corrected tetralogy of Fallot Bioprosthetic valve Mitral stenosis, NYHA classes I and II Marfan syndrome with normal aorta*
Group II: Moderate risk of complications (5–15%)	Mitral stenosis with atrial fibrillation Artificial valve Mitral stenosis, NYHA classes III and IV Aortic stenosis Coarctation of aorta, uncomplicated Uncorrected tetralogy of Fallot Previous myocardial infarction
Group III: Major risk of complications or death (> 25%)	Pulmonary hypertension Coarctation of the aorta, complicated Marfan syndrome with aortic involvement

*Normal aorta, defined as aortic root diameter < 4 cm and no evidence of dissection.

NYHA, New York Heart Association.

appropriate obstetric care, the presence or absence of the above secondary complications or cardiomyopathy appears to play a much more important role in determining ultimate maternal outcome than the primary structural nature of the cardiac lesion itself.⁸ Indeed, the most recent recommendations from the American Heart Association and the American College of Cardiology regarding classification of maternal and fetal risk during pregnancy on the basis of the type of valvular abnormality and NYHA functional class (Table 39.3) note that the absolute risk conferred on a given woman by pregnancy is modified by additional clinical factors.^{34,35}

Congenital cardiac disease

The relative frequency of congenital as opposed to acquired heart disease is changing.^{5,36} With the wide introduction of efficacious penicillin therapy for rheumatic fever, sequent valvular stenosis is relatively uncommon in the United States. Concomitant advances in heart–lung bypass have enabled the surgical correction of many previously fatal congenital cardiac lesions. Thus, patients with congenital cardiac disease now account for the vast majority of pregnant women with heart disease. In a review in 1954, the ratio of rheumatic to congenital heart disease seen during pregnancy was 16:1; the current ratio approximates 1:1.5.^{5,34–37} In the following discussion of specific cardiac lesions, no attempt is made to duplicate existing comprehensive texts regarding physical

Table 39.2 Summary of current revised maternal mortality risks associated with selected cardiovascular disorders.

Group	Cardiovascular disorder	Maternal mortality (%)
Group I: Minimal risk of complications	Atrial septal defect	< 1
	Ventricular septal defect, without pulmonary hypertension	< 1
	Patent ductus arteriosus	< 1
	Pulmonic or tricuspid disease	0–0.5
	Corrected tetralogy of Fallot	0.05–1
	Bioprosthetic valve	1
	Mitral stenosis, NYHA classes I and II	0–1.6
	Marfan syndrome with normal aorta*	0–1.1
Group II: Moderate risk of complications	Mitral stenosis with atrial fibrillation	12–17
	Mechanical valve	1–4
	Mitral stenosis, NYHA classes III and IV	5–7
	Aortic stenosis	2–18
	Coarctation of aorta, uncomplicated	2–5
	Uncorrected tetralogy of Fallot	12–15
	Previous myocardial infarction, remote	2–15
Group III: Major risk of complications or death	Primary pulmonary hypertension	35–50
	Coarctation of the aorta, complicated	> 25
	Marfan syndrome with aortic involvement	50
	Previous myocardial infarction, within 2 weeks of delivery	50

The maternal mortality rates represent a compilation from available and identified references.^{1–4,8–33} As such, they represent varying degrees of disorder severity, a spectrum of patient ages and ethnic background, and additional associated risk factors. They must thus be regarded as generalizable approximations.

*Normal aorta, defined as aortic root diameter < 4 cm and no evidence of dissection.

Table 39.3 Valvular heart lesions stratified by maternal and fetal risk derived from ACC/AHA Guidelines.³⁵

Maternal risk	Lesion	Description
Low maternal and fetal risk	Asymptomatic aortic stenosis	Low mean outflow gradient (< 50 mmHg) Normal LV systolic function (EF > 50%)
	Aortic regurgitation, NYHA I or II	Normal LV systolic function (EF > 50%)
	Mild/moderate mitral stenosis	Mitral valve area > 1.5 cm ² Low gradient (< 5 mmHg) Absence of severe pulmonary hypertension (severe pulmonary hypertension defined as pulmonary pressure > 75% of systemic pressures)
	Mitral regurgitation, NYHA I or II	Normal LV systolic function (EF > 50%)
	Mitral valve prolapse	Absence of mitral regurgitation OR Mild/moderate mitral regurgitation with normal LV systolic function (EF > 50%)
High maternal and fetal risk	Severe aortic stenosis	Valve area <1.5 cm ²
	Aortic regurgitation, NYHA III or IV	Symptomatic per NYHA criteria
	Aortic regurgitation in Marfan syndrome	
	Mitral stenosis, NYHA II, III, or IV	Symptomatic per NYHA criteria
	Mitral regurgitation, NYHA III or IV	Symptomatic per NYHA criteria
	Aortic and/or mitral valve disease, with severe pulmonary hypertension	Resultant severe pulmonary hypertension (severe pulmonary hypertension defined as pulmonary pressure > 75% of systemic pressures)
	Aortic and/or mitral valve disease, with left ventricular systolic dysfunction	Abnormal LV systolic function (EF < 40%)
	Maternal cyanosis	

NYHA, New York Heart Association classification. By functional status, NYHA I is asymptomatic; NYHA II is symptoms with greater than normal activity; NYHA III is symptoms with normal activity; NYHA IV is symptoms at rest.

LV, left ventricular; EF, ejection fraction.

diagnostic, electrocardiographic, and radiographic findings of specific cardiac lesions. (For a comprehensive discussion of diagnostic findings, see Braunwald E, ed. *Heart disease. A textbook of cardiovascular medicine*, 6th edn. Philadelphia: W.B. Saunders, 2001.) Instead, the discussion here focuses on aspects of congenital cardiac disease that are unique to pregnancy. We preface our discussion regarding congenital cardiac lesions with the longstanding acknowledgment that patients at risk of developing right-to-left shunts with increased pulmonary hypertension are at highest risk for unacceptably high maternal and fetal morbidity and mortality; surgical correction prior to the development of increased pulmonary vascular resistance and pulmonary hypertension (Eisenmenger's syndrome) is the greatest single contributor to improved outcomes observed over the preceding four decades.

Atrial septal defect

Atrial septal defect (ASD) is the most common congenital lesion seen during pregnancy and is generally asymptomatic.^{38–42} As a result of the disproportionate number of women with ostium secundum defects being asymptomatic

until the reproductive years, it is not unheard of to have women present with a sentinel ASD diagnosis in pregnancy.⁴³ The two significant potential complications seen with ASD are arrhythmias and ventricular failure.

As a result of pregnancy-associated increases in atrial volume, biatrial enlargement and resultant supraventricular dysrhythmias are occasionally encountered. In general, although atrial arrhythmias are not uncommon in patients with ASD, their onset generally occurs after the fourth decade of life. Thus, such arrhythmias are unlikely to be encountered in the majority of pregnant woman. That said, in patients with ASD, atrial fibrillation is the most common arrhythmia encountered; however, supraventricular tachycardia and atrial flutter also may occur.⁴⁴ Initial therapy is with digoxin; less commonly, propranolol, quinidine, or cardioversion may be necessary.

The hypervolemia and increased cardiac output associated with pregnancy accentuates the left-to-right shunt through the ASD, and thus a significant burden is imposed on the right ventricle. Although this additional burden is tolerated well by most patients, congestive failure and death have been reported with ASD.^{45–47} Thus, peripartum management centers on avoiding vascular resistance changes that increase the degree

Table 39.4 Antibiotic prophylaxis for the prevention of bacterial endocarditis.

Cardiac lesion	Prophylaxis for uncomplicated delivery	Prophylaxis for suspected bacteremia (i.e., chorioamnionitis)
Negligible risk category		
Functional heart murmurs	Not recommended	Not recommended
Mitral valve prolapse without regurgitation	Not recommended	Not recommended
Previous rheumatic fever without valve dysfunction	Not recommended	Not recommended
Previous Kawasaki disease without valve dysfunction	Not recommended	Not recommended
Cardiac pacemakers and implanted defibrillators	Not recommended	Not recommended
Prior coronary bypass graft surgery	Not recommended	Not recommended
Moderate-risk category		
Acquired valve dysfunction (rheumatic fever)	Not recommended	Recommended
Congenital cardiac malformations EXCEPT: repaired ASD, VSD, or PDA, or isolated secundum ASD	Not recommended	Recommended
Hypertrophic cardiomyopathy	Not recommended	Recommended
Mitral valve prolapse with regurgitation or thickened leaflets	Not recommended	Recommended
High-risk category		
Prosthetic cardiac valves	Optional	Recommended
Prior bacterial endocarditis	Optional	Recommended
Complex cyanotic congenital cardiac malformations	Optional	Recommended
Surgically constructed systemic pulmonary shunts/conduits	Optional	Recommended

Adapted from ACOG Practice Bulletin No. 47 Prophylactic Antibiotics in Labor and Delivery, October 2003. These recommendations are based on ACC/AHA guidelines,³⁵ which specifically discourage endocarditis prophylaxis for “routine” vaginal or Cesarean delivery. Given a possible increased risk of endocarditis with complicated deliveries such as retained placenta,⁴⁸ alongside recommendations to give antibiotics before or within 30 min of starting a “complicated” procedure, the decision to hold or administer subacute bacterial endocarditis (SBE) prophylaxis is not necessarily straightforward.³⁵ Thus, many obstetricians may elect to administer prophylactic antibiotics to cover unpredictable complicated deliveries.

of the shunt. In contrast to the high-pressure/high-flow state seen with ventricular septal defect (VSD) and patent ductus arteriosus (PDA), ASD is characterized by high pulmonary blood flow associated with normal pulmonary artery pressures. Because pulmonary artery pressures are low, pulmonary hypertension is unusual. The majority of patients with ASD tolerate pregnancy, labor, and delivery without complication. Neilson and colleagues⁴⁵ reported 70 pregnancies in 24 patients with ASD; all patients had an uncomplicated antenatal and intrapartum course. During labor, placement of the patient in the lateral recumbent position, avoidance of fluid overload, oxygen administration, and pain relief with epidural anesthesia, as well as judicious use of prophylaxis against bacterial endocarditis, are the most important considerations (Tables 39.4 and 39.5).

Ventricular septal defect

VSD may occur as an isolated lesion or in conjunction with other congenital cardiac anomalies, including tetralogy of Fallot, transposition of the great vessels, and coarctation of the aorta. The size of the septal defect is the most important determinant of clinical prognosis during pregnancy. Small defects are tolerated well, whereas larger defects are associated more frequently with congestive heart failure, arrhythmias, or the

development of pulmonary hypertension. In addition, a large VSD is often associated with some degree of aortic regurgitation, which then modifies the risk of congestive failure. Pregnancy, labor, and delivery are tolerated well by patients with uncomplicated VSD. Schaefer and colleagues⁴⁶ compiled a series of 141 pregnancies in 56 women with VSD. The only two maternal deaths were in women whose VSD was complicated by pulmonary hypertension (Eisenmenger’s syndrome). Although very rarely indicated, successful primary closure of a large VSD during pregnancy has been reported.^{47,49} Because of the significance of unrecognized Eisenmenger’s syndrome, careful measurements of pulmonary artery pressures are mandatory in any patient in whom persistent VSD is suspected or in whom the status of a previous repair is uncertain.^{50,51} In general, invasive hemodynamic monitoring is unnecessary. Management considerations for patients with uncomplicated VSD are similar to those outlined for ASD.

Patent ductus arteriosus

Although PDA is one of the most common congenital cardiac anomalies, its almost universal detection and closure in the newborn period make it uncommon during pregnancy.^{52,53} As with uncomplicated ASD and VSD, most patients are asymptomatic, and PDA is generally well tolerated during pregnancy,

Table 39.5 Endocarditis prophylaxis regimens for genitourinary/gastrointestinal procedures.³⁵

Patient group	Agent	Dosage*
High risk	Ampicillin plus gentamicin	Load: Ampicillin 2 g i.v./i.m. Gentamicin 1.5 mg/kg i.v. to a maximum of 120 mg 6 h later: Ampicillin 1 g i.v./i.m. or amoxicillin 1 g p.o.
Ampicillin-allergic high risk	Vancomycin plus gentamicin	Load: Vancomycin 1 g i.v. over 1–2 h Gentamicin 1.5 mg/kg i.v. to a maximum of 120 mg 6 h later: Ampicillin 1 g i.v./i.m. or amoxicillin 1 g p.o.
Moderate risk	Amoxicillin or ampicillin	Amoxicillin 2 g p.o. 1 h before procedure or ampicillin 2 g i.v./i.m.
Ampicillin-allergic moderate risk	Vancomycin plus gentamicin	Load: Vancomycin 1 g i.v. over 1–2 h

*With respect to i.v.- or i.m.-administered ampicillin, gentamicin, or vancomycin, complete infusion within 30 min of starting the procedure.³⁵

labor, and delivery. As with a large VSD, however, the high-pressure/high-flow, left-to-right shunt associated with a large, uncorrected PDA can lead to pulmonary hypertension. In such cases, the prognosis unacceptably worsens. In one study of 18 pregnant women who died of congenital heart disease, three had PDA; however, all these patients had secondary severe pulmonary hypertension.⁴⁷ Management considerations for patients with uncomplicated PDA, without pulmonary hypertension, are similar to those outlined under ASD.

Eisenmenger's syndrome and pulmonary hypertension

Eisenmenger's syndrome develops when, in the presence of congenital left-to-right shunt, progressive pulmonary hypertension leads to shunt reversal or bidirectional shunting as a result of chronically increased pulmonary vascular blood flow with accompanying pulmonary vascular resistance exceeding systemic vascular resistance. Although this syndrome may rarely occur with ASD, VSD, or PDA, the low-pressure and high-flow shunt seen as ASD is far less likely to result in pulmonary hypertension and shunt reversal than is the condition of high-pressure and high-flow symptoms seen with VSD and PDA. Regardless of the etiology, pulmonary hypertension carries a guarded prognosis during pregnancy, although there are published reports suggesting that the greatest risk may be seen in women with Eisenmenger's syndrome.^{54,55} After Eisenmenger's pathophysiology is established, the pulmonary hypertension is permanent, and surgical correction of the defect is unhelpful and may increase mortality.^{33,59}

During the antepartum period, the decreased systemic vascular resistance associated with pregnancy increases both the likelihood as well as the degree of right-to-left shunting. Pulmonary perfusion decreases, with systemic hypotension resulting in hypoxemia with subsequent maternal then fetal deterioration. The peripartum development of systemic hypotension leads to decreased right ventricular filling pressures; in the concomitant presence of a fixed cardiac output state (e.g., pulmonary hypertension), such decreased right

heart pressures may be insufficient to perfuse the pulmonary arterial bed, leading to a sudden and profound hypoxemia and death. While there may exist any number of inciting events resulting in systemic hypotension in pregnancy, it most frequently results from hemorrhage or complications of conduction anesthesia.^{53–61} Thus, avoidance of systemic hypotension is the principal clinical concern in the intrapartum management of patients with pulmonary hypertension of any etiology. This fact is underscored by the longstanding knowledge that the greatest maternal risk occurs in the peripartum period, and most deaths occur between 2 and 9 days postpartum. The precise pathophysiology of such decompensation is unclear, and it is uncertain what, if any, therapeutic maneuvers prevent or ameliorate such deterioration.

Maternal mortality in the presence of Eisenmenger's syndrome ranges from 30% to 60%.^{27,52,59} In their classic review of the subject, Gleicher and colleagues⁵⁵ reported a 39% mortality associated with vaginal delivery and a 75% mortality associated with Cesarean section. These authors' original observations still stand; a more recent review looking at mortality from 1978 to 1996 fails to demonstrate significant improvement in maternal mortality.⁶¹ Eisenmenger's syndrome associated with VSD appears to carry a higher mortality risk than that associated with PDA or ASD. In addition to the previously discussed problems associated with hemorrhage and hypovolemia, thromboembolic phenomena have been associated with up to 43% of all maternal deaths in Eisenmenger's syndrome.⁵⁵ Pitts and colleagues⁵⁸ reported increased mortality associated with prophylactic peripartum heparinization. However, other authors have reported that the use of heparin therapy (with bedrest and supplemental oxygen) may modestly positively influence maternal and fetal outcomes; there are no large trials supporting these findings to date.⁵⁹ Sudden delayed postpartum death, occurring 4–6 weeks after delivery, has also been reported.^{55,60} Such deaths may involve a rebound worsening of pulmonary hypertension associated with the loss of pregnancy-associated hormones, or thromboembolic events.

Because of the high mortality associated with continuing pregnancy,²⁷ pregnancy termination ought to be presented to

the patient as the preferred management of choice for the woman with pulmonary hypertension of any etiology. Pregnancy termination in either the first or the second trimester has long been considered the safer alternative over allowing the pregnancy to progress to term.⁶² Dilation and curettage in the first trimester or dilation and evacuation in the second trimester is the method of choice. Hypertonic saline and F-series prostaglandins (prostaglandin F₂α) are contraindicated, although the careful use of E-series prostaglandins is probably appropriate as long as systemic hypotension is avoided.

For the patient with a continuing gestation, management centers on avoiding increases in pulmonary vascular resistance, maintaining right ventricular preload, left ventricular afterload, and right ventricular contractility. Thus, factors that increase pulmonary vascular resistance ought to be avoided. In general terms, sympathetic agonists (epinephrine and norepinephrine) and conditions resulting in hypoxia or hypercarbia are associated with a poor outcome. Thus, the mainstays of therapy and management continue to be inpatient care in a tertiary care center with experienced providers, with continuous administration of oxygen, use of pulmonary vasodilators, avoidance of hypotension and anemia, and limited use of operative deliveries.^{8,63–68}

With respect to pulmonary vasodilators, recent success with inhaled nitric oxide (iNO) alongside prostacyclin and its analogs has been observed.^{63–68} Administration of iNO via facemask or nasal cannula has been shown to be effective when estimated final alveolar concentrations of 5–40 p.p.m. are reached; great care is taken to avoid accumulation of toxic nitrogen dioxide with the use of continuous monitoring of tidal iNO concentrations using electrochemical monitors (similar to those found in neonatal intensive care unit settings). Given a risk of both maternal and fetal methemoglobinemia, it is also recommended that concentrations should be measured hourly during administration with a goal of < 5 g/dL; in the fetus, postnatal monitoring through the first 48 hours of life is also recommended.^{66–68} High concentrations of methemoglobin can be treated with methylene blue at 2 mg/kg i.v.⁶³ Prostacyclin, a naturally occurring prostaglandin (PGI₂), is a potent vasodilator and inhibitor of platelet aggregation. Infusions of 1–10 ng/kg/min effectively reduce pulmonary vascular resistance, but at the risk of decreasing right ventricular preload. However, its synthetic analog (iloprost) has a minimal effect on systemic vascular resistance, and has been used successfully to reduce pulmonary artery pressures either alone or in combination with iNO.^{64–68} When administered with nebulizers, the systemic effect is minimized; iloprost is administered diluted in 0.9% NaCl (20 µg/2 mL up to six times daily), and prostacyclin at 60 µg/h.^{64,65}

In cyanotic heart disease of any etiology, fetal outcome correlates well with maternal hematocrit; successful pregnancy is unlikely with an initial hemoglobin > 20 g/dL.^{69,70} Thus, we recommend judicious iron therapy and packed red blood cell transfusion to maintain a hematocrit above 24–30%.⁸ Maternal P_aO₂ should be maintained with exogenous oxygen

at a level of 70 mmHg or higher.^{67–69} In addition, third-trimester fetal surveillance with antepartum testing is necessitated as at least 30% of the fetuses are growth restricted,^{55,70} and pregnancy interruption due to fetal deterioration is common.⁷⁰

The issue of pulmonary artery catheterization is controversial. Among some patients with moderate to severe pulmonary hypertension from interatrial shunts, a pulmonary artery catheter will provide useful information.^{8,60} However, we share the concern of other authors that, among those with inter-ventricular shunts, catheter placement is associated with a high rate of complications, including arrhythmias, embolization, and pulmonary artery rupture.⁶⁶ In instances in which pulmonary artery catheterization may be of benefit, simultaneous cardiac imaging with ultrasound may be helpful in catheter placement. If the possibility of right-to-left shunting exists, balloon inflation with carbon dioxide is preferable to that with air in an effort to avoid systemic air embolus associated with the rare occurrence of balloon rupture.

In consideration of catheter placement, it is of note that, during labor, uterine contractions are associated with a decrease in the ratio of pulmonary to systemic blood flow.^{71–73} Pulmonary artery catheterization and serial arterial blood gas determinations thus theoretically allow the clinician to detect and treat early changes in cardiac output, pulmonary artery pressure, and shunt fraction. As point of reference, central hemodynamic assessment references are provided in Table 39.6.⁶ We have used a fiberoptic pulmonary artery catheter in conjunction with an oximeter to detect early changes in mixed venous oxygen saturation during the successful intrapartum management of patients with pulmonary hypertension. Because the primary concern in such patients is the avoidance of hypotension, any attempt at preload reduction (i.e., diuresis) must be undertaken with great caution, even in the face of initial fluid overload. We prefer to manage such patients on

Table 39.6 Reference values with central hemodynamic assessment.

Parameter	Nonpregnant	Pregnant
Cardiac output (L/min)	4.3	6.2
Heart rate (b.p.m.)	71	83
Pulmonary vascular resistance (dyne/cm/s ⁵)	119	78
Systemic vascular resistance (dyne/cm/s ⁵)	1530	1210
Colloid oncotic pressure (mmHg)	21	18
Mean arterial pressure (mmHg)	86	90
Pulmonary capillary wedge pressure (mmHg)	6.3	7.5
Central venous pressure (mmHg)	3.7	3.6

Values are derived from 10 selected patients at 36–38 weeks' gestation, and again at 11–13 weeks postpartum with arterial lines and Swan–Ganz catheters to characterize central hemodynamic values of pregnancy.⁶

the “wet” side (wedge pressure range of 16–18 mmHg), maintaining a preload margin of safety against unexpected blood loss with an *a priori* acknowledged risk of pulmonary edema. Because of the increased risk of significant blood loss and hypotension associated with operative delivery, Cesarean section should be reserved for standard obstetric indications. Similarly, midforceps delivery is not warranted to shorten the second stage, but should be reserved for obstetric indications only.

If surgery is necessary, meticulous attention to hemostasis and surgical technique with an experienced surgical team minimizes the risk of blood loss, hypotension, and death in these patients. Despite expert management, a substantial risk of maternal mortality remains during labor and delivery. Laparoscopic tubal ligation under local anesthesia has also been described in a group of women with various types of cyanotic cardiac disease.⁷⁴

Anesthesia for patients with pulmonary hypertension is controversial. Theoretically, conduction anesthesia, with its accompanying risk of hypotension, should be avoided. Regional techniques for both vaginal (epidural) and Cesarean (spinal) delivery have been described, and successfully used.^{63–68,72–74} To summarize this expanding volume of data, with the concomitant use of systemic vasoconstrictors (ephedrine) and pulmonary vasodilators (iNO and prostacylin analogs), the use of epidural or intrathecal morphine sulfate will be theoretically devoid of any overt effect on systemic blood pressure and thus represents one reasonable approach to the anesthetic management of these difficult patients.

Coarctation of the aorta

Coarctation of the aorta accounts for approximately 9% of all congenital cardiac disease.⁷⁵ The most common site of coarctation is the origin of the left subclavian artery. Associated anomalies of the aorta and left heart, including VSD and PDA, are common, as are intracranial aneurysms in the circle of Willis.⁷⁶ Coarctation is usually asymptomatic. Its presence is suggested by hypertension confined to the upper extremities, although Goodwin⁷⁶ cites data suggesting a generalized increase in peripheral resistance throughout the body. Resting cardiac output may be increased, but increased left atrial pressure with exercise suggests occult left ventricular dysfunction. Aneurysms may also develop below the coarctation, or involve the intercostal arteries, and may lead to rupture. In addition, ruptures without prior aneurysm formation have been reported.^{75,76}

More than 400 patients with coarctation have been reported during pregnancy, with maternal mortality ranging from none to 17%.^{46,75,76} Half the fatalities occur during the first pregnancy. In a review of 200 pregnant women with coarctation of the aorta before 1940, Mendelson⁷⁷ reported 14 maternal deaths and recommended routine abortion and sterilization of these patients.⁷⁷ Deaths in this series were from aortic dissection and rupture, congestive heart failure, cerebrovascular

accidents, and bacterial endocarditis. Six of the 14 deaths occurred in women with associated lesions. In contrast to this historical dismal prognosis, an initial series by Deal and Wooley⁷⁵ in 1973 reported 83 pregnancies in 23 women with uncomplicated coarctation of the aorta. All were NYHA class I or II before pregnancy. In these women, there were no maternal deaths or permanent cardiovascular complications. In a recent series, these findings were confirmed, which suggest that patients with coarctation of the aorta uncomplicated by aneurysmal dilation or associated cardiac lesions who enter pregnancy as class I or II have a good prognosis and a minimal risk of complications or death.^{21,22} Even if uncorrected, uncomplicated coarctation carries with it a risk of maternal mortality of only 3–4%.²² In the presence of aortic or intervertebral aneurysm, known aneurysm of the circle of Willis, or associated cardiac lesions, however, the risk of death may approach 15%; therefore, pregnancy termination must be strongly considered.⁸

Tetralogy of Fallot

Tetralogy of Fallot encompasses the cyanotic complex of VSD, overriding aorta, right ventricular hypertrophy, and pulmonary stenosis. Most cases of tetralogy of Fallot are corrected during infancy or childhood; the vast majority of women may be assumed to have undergone repair in order to survive to reproductive age. Several published reports attest to the relatively good outcome of pregnancy in patients with corrected tetralogy of Fallot.^{7,78–81} In a review of 55 pregnancies in 46 patients, there were no maternal deaths among nine patients with correction before pregnancy. However, in patients with an uncorrected lesion, maternal mortality ranges from 4% to 15%, with a 30% fetal mortality as a result of hypoxia.^{7,80} In patients with uncorrected VSD, the decline in systematic vascular resistance that accompanies pregnancy can lead to worsening of the right- to-left shunt.⁷ This condition can be aggravated further by systemic hypotension as a result of peripartum blood loss. A poor prognosis has been related to prepregnancy hematocrit exceeding 65%, history of syncope or congestive failure, electrocardiographic evidence of right ventricular strain, cardiomegaly, right ventricular pressure in excess of 120 mmHg, and peripheral oxygen saturation of less than 80%.

Pulmonic stenosis

Pulmonic stenosis is a common congenital defect. Although obstruction can be valvular, supraventricular, or subvalvular, the degree of obstruction, rather than its site, is the principal determinant of clinical performance. A transvalvular pressure gradient exceeding 80 mmHg is considered severe and mandates surgical correction.⁸ A compilation (totaling 106 pregnancies) of three series of patients with pulmonic stenosis revealed no maternal deaths.^{45–47} With severe stenosis, right heart failure can occur; fortunately, this is usually less severe

clinically than the left heart failure associated with mitral or aortic valve lesions. Pulmonic stenosis in association with cyanotic congenital lesions has a worse prognosis.

Ebstein's anomaly

Ebstein's anomaly accounts for a rare 1% of all congenital cardiac disease.⁸²⁻⁸⁶ This anomaly consists of apical displacement of the tricuspid valve with secondary tricuspid regurgitation and enlargement of both right atrium and ventricle. In a review of 111 pregnancies in 44 women, no serious maternal complications were noted. Seventy-six percent of pregnancies ended in live births, although there was a 6% incidence of congenital heart disease in the offspring of these women.⁸⁶

Acquired cardiac lesions

By way of introduction, it is often helpful to keep a number of commonly accepted considerations regarding acquired valvular lesions in mind. First, regurgitant lesions are generally better tolerated in pregnancy than stenotic lesions due to pregnancy-associated systemic vascular resistance improving forward flow, and thus limiting the effects of regurgitation (assuming an absence of left ventricular dysfunction). However, in stenotic lesions, increased cardiac output and tachycardia result in an elevation in left atrial pressure (i.e., mitral stenosis) and thus increased incidence of atrial fibrillation and high-output cardiac failure. Second, maternal and fetal risks of acquired cardiac lesions in pregnancy generally vary with the functional classification at pregnancy onset and term. Thus, the common collective wisdom is that women with functional class I or II heart disease have a favorable prognosis in pregnancy (with the notable exception of mitral stenosis; Table 39.3). Moreover, patients who reach term as class I or II usually tolerate properly managed labor without invasive monitoring. Third, because of increasing cardiovascular demand in the high-output state, functional status will deteriorate during pregnancy among functional class II, III, and IV patients.⁵⁻⁷ This is evidenced by the fact that nearly half of all women with acquired valvular lesions will first develop heart failure and pulmonary edema in their third trimester of pregnancy.^{1-3,5}

Acquired valvular lesions are commonly rheumatic in origin, although endocarditis secondary to intravenous drug use ought to be considered as an underlying etiology of acquired right heart lesions. During pregnancy, maternal morbidity and mortality with rheumatic lesions results from congestive failure or arrhythmias with a final common sequelae of pulmonary edema, embolic event, or fatal dysrhythmia. Indeed, pulmonary edema is the leading cause of death in rheumatic heart disease patients during pregnancy.^{1,4-6} Szekely and colleagues⁵ found the risk of pulmonary edema in pregnant patients with rheumatic heart disease to rise with increas-

ing age and with increasing length of gestation. The onset of atrial fibrillation during pregnancy carries with it a higher risk of right and left ventricular failure (63%) than fibrillation with onset before gestation. In addition, the risk of systemic embolization after the onset of atrial fibrillation during pregnancy may exceed that associated with onset in the nonpregnant state.⁵ In counseling the patient with severe rheumatic cardiac disease on the advisability of initiating or continuing pregnancy, the physician must also consider the long-term prognosis of the underlying disease. For up to 44 years, Chesley⁸⁷ followed 134 women who had functionally severe rheumatic heart disease and who had completed pregnancy. He reported a mortality of 6.3% per year but concluded that, in patients who survived the gestation, maternal life expectancy was not shortened by pregnancy. These data would therefore suggest that, in the absence of an acute morbid event, pregnancy has no long-term sequelae for patients who survive the pregnancy.^{62,87}

Pulmonic and tricuspid lesions

Physiologic valvular regurgitation is common during pregnancy, especially with right-sided valves, and the degree of regurgitation progresses as pregnancy advances.⁸⁸ Isolated right-sided valvular lesions of rheumatic origin are uncommon; however, such lesions are seen with increased frequency in intravenous drug abusers, in whom they are secondary to valvular endocarditis. For the reasons reviewed above, pregnancy-associated hypervolemia is far less likely to be symptomatic with right-sided lesions than with those involving the mitral or aortic valves. In a review of 77 maternal cardiac deaths, Hibbard⁴⁷ reported none associated with isolated right-sided lesions. In several recent reviews, congestive heart failure has been noted to occur in less than 2% of women with pulmonic stenosis.⁸⁷⁻⁸⁹ A successful pregnancy has been reported after Fontan repair of congenital tricuspid atresia.⁸⁹ Even after complete tricuspid valvectomy for endocarditis, subsequent pregnancy, labor, and delivery are generally well tolerated. Given the propensity toward pulmonary edema in the puerperium,⁹¹ cautious fluid administration is the mainstay of labor and delivery management in patients with right-sided lesions.⁸⁷⁻⁹¹ In general, invasive hemodynamic monitoring during labor and delivery is not necessary.

Mitral stenosis

Mitral stenosis is the most common rheumatic valvular lesion encountered during pregnancy.⁵⁹ It can occur as an isolated lesion or in conjunction with aortic or right-sided lesions. Severe mitral stenosis (valve area < 1.5 cm²) carries a maternal mortality approximated at 5%.¹¹ Secondary to a severe stenosis, ventricular diastolic filling obstruction yields elevated left atrial pressure with a relatively fixed cardiac output. Marked increases in cardiac output accompany normal pregnancy, labor, and delivery. When the pregnant patient is unable

to accommodate volume fluctuations, right-sided heart failure results in pulmonary edema.

The ability to accommodate an increased cardiac output in patients with mitral stenosis depends largely on two factors.⁵⁹ First, these patients depend on adequate diastolic filling time. However, in instances of stenotic mitral lesions, a rapid and dramatic fall in cardiac output and blood pressure in response to tachycardia will compromise this tenuous filling time. Given that an increase in heart rate of approximately 10 b.p.m. is common in normal pregnancy, labor, and delivery, consideration ought to be given to oral beta-blocker therapy for any patient with severe mitral stenosis who enters labor with even a mild tachycardia. Control of acute-onset tachycardia with an intravenous beta-blocking agent may be employed at the following dosages: propranolol 1 mg i.v. every 2 min; metoprolol 5 mg i.v. over 5 min, repeated in 10 min; esmolol drip at 500 µg/kg i.v. over 1 min with an infusion rate of 50–200 µg/kg/min; or labetalol 20–40 mg i.v. followed by 20–80 mg i.v. every 10 min to a maximum dose of 180 mg.

A second important consideration in patients with mitral stenosis centers on left ventricular preload. In the presence of mitral stenosis, pulmonary capillary wedge pressure fails to accurately reflect left ventricular filling pressures. Such patients often require high-normal or elevated pulmonary capillary wedge pressure to maintain adequate ventricular filling pressure and cardiac output. Any preload manipulation (i.e., diuresis) must therefore be undertaken with extreme caution and careful attention to the maintenance of cardiac output. However, it has long been recognized that potentially dangerous intrapartum fluctuations in cardiac output can be minimized by using epidural anesthesia;⁹² however, the most hazardous time for these women appears to be the immediate postpartum period. Such patients often enter the postpartum period already operating at maximum cardiac output and cannot accommodate the volume shifts that follow delivery. In our series of patients with severe mitral stenosis, we found that a postpartum rise in wedge pressure of up to 16 mmHg could be expected in the immediate postpartum period.⁶⁰ Because frank pulmonary edema generally does not occur with wedge pressures of less than 28–30 mmHg,⁹³ it follows that the optimal predelivery wedge pressure for such patients is 14 mmHg or lower, as indicated by pulmonary artery catheterization.⁶⁰ Such a preload may be approached by cautious intrapartum diuresis with careful attention to the maintenance of adequate cardiac output (Table 39.6). Active diuresis is not always necessary in patients who enter with evidence of only mild fluid overload. In such patients, simple fluid restriction alongside sensible and insensible fluid losses endogenous to labor can result in a significant fall in wedge pressure before delivery.

In a patient with hemodynamically significant mitral stenosis, many of the same management considerations apply as those previously discussed under the section dealing with Eisenmenger's syndrome and pulmonary hypertension. Bedrest with the administration of oxygen and pulmonary

vasodilators to maintain the therapeutic goal of a PO_2 of greater than 70 mmHg are essential. As previously discussed, pulmonary artery catheterization allows the hemodynamic condition to be optimized before the stress of labor. Because pulmonary edema is the major concern in these patients, we recommend incremental diuresis be carried out to approach a wedge pressure of 12–14 mmHg. Such manipulation, however, must be performed with careful attention to maintaining cardiac output; patients with mitral stenosis cannot necessarily tolerate a normal wedge pressure. Thus, wedge pressures of 20 mmHg or more may be necessary to maintain cardiac output and blood pressure.^{8,60} If the pulse rises to more than 100 b.p.m., we recommend the administration of a beta-blocking agent (note the above discussion regarding dosing) to avoid tachycardia and subsequent falls in cardiac output.

Previous recommendations for delivery in patients with cardiac disease have included the liberal use of midforceps to shorten the second stage of labor. In cases of severe disease, Cesarean section with general anesthesia has also been advocated as the preferred mode of delivery. With the aggressive and attentive management scheme presented, we have found that spontaneous vaginal delivery is generally safe and preferable, even in patients with severe disease and pulmonary hypertension.

Mitral insufficiency

Hemodynamically significant mitral insufficiency is usually rheumatic in origin and most commonly occurs in conjunction with other valvular lesions. Fortunately, this lesion is tolerated well during pregnancy, and heart failure is unusual. However, these patients are at risk for the development of atrial enlargement and fibrillation. Given an observed increased risk of developing atrial fibrillation in pregnancy,^{4,5-8} some authors have recommended prophylactic digitalization during pregnancy for patients with significant mitral insufficiency.⁹⁴ That said, the current mainstay of therapy among nonpregnant patients is rate control with anticoagulation;⁹⁵ by extrapolation, we would recommend therapeutic interventions with beta-blocking agents and thromboembolic prophylaxis as outlined previously. In Hibbard's review⁴⁷ of 28 maternal deaths associated with rheumatic valvular lesions, no patient died with complications of mitral insufficiency unless there was coexisting mitral stenosis.

Congenital mitral valve prolapse is much more common during pregnancy than rheumatic mitral insufficiency and can occur in up to 17% of young healthy women. This condition is generally asymptomatic.⁴⁻⁹ The midsystolic click and murmur associated with congenital mitral valve prolapse are characteristic. However, the intensity of this murmur, as well as that associated with rheumatic mitral insufficiency, may decrease during pregnancy because of decreased systemic vascular resistance.⁹⁶ In the largest reported series to date, outcomes of 42 pregnancies from 25 women demonstrated only a single instance of heart failure, which occurred in the context

of severe preeclampsia being managed with intravenous beta-mimetic therapy and glucocorticoids.⁹⁷

Aortic stenosis

Aortic stenosis is commonly congenital in origin, secondary to a bicuspid aortic valve, and thus represents 5% of all congenital cardiac anomalies.^{99,101} In several recent series of pregnancies in women with cardiac disease, no maternal deaths due to aortic stenosis were observed.^{1-5,99-101} In contrast to mitral valve stenosis, aortic stenosis generally does not become hemodynamically significant until the orifice has diminished to one-third or less of normal. Indeed, severe aortic stenosis is defined as a peak gradient > 50 mmHg with a valve area < 1 cm².⁹⁸⁻¹⁰² Given that the major problem experienced by patients with valvular aortic stenosis is maintenance of cardiac output, the relative hypervolemia associated with gestation enables such patients generally to tolerate pregnancy well. This is evidenced by a series of five patients with congenital aortic stenosis demonstrating relatively uncomplicated pregnancies, albeit balloon valvuloplasty was necessary in one case.^{98,99} With severe disease, however, a fixed cardiac output limits adequate coronary artery or cerebral perfusion under conditions of physical exertion. Inadequate cardiac perfusion subsequently results in angina, myocardial infarction, syncope, or sudden death. Thus, among patients with severe aortic stenosis, limitation of physical activity may be necessary.

Consistent with these recommendations is the longstanding observation that delivery and pregnancy termination are the intervals in pregnancy with the greatest risk for inadequate cardiac perfusion.^{4,5,7,98-102} The maintenance of cardiac output is crucial: any factor leading to diminished venous return results in an increase in the valvular gradient with subsequent diminished cardiac output. Indeed, patients with shunt gradients exceeding 100 mmHg are at greatest risk of hemodynamic decompensation. As such, management considerations for the patient with aortic stenosis are similar to those in women with pulmonary hypertension. Of note, because hypovolemia is of greater concern than pulmonary edema, the wedge pressure should be maintained in the range 14–18 mmHg in order to provide a margin of safety against unexpected peripartum blood loss. Hypotension resulting from blood loss, ganglionic blockade from epidural anesthesia, or supine vena caval occlusion by the pregnant uterus may result in sudden death. Pregnancy termination in the midtrimester may be especially hazardous in this regard and has been reported to carry a mortality of up to 40%.⁹⁸ Thus, women who have severe stenosis or symptoms are advised to undergo repair prior to attempting pregnancy in an effort to substantially reduce pregnancy-associated morbidity and mortality.¹⁰⁰⁻¹⁰² That said, there are reports of women with severe aortic stenosis having undergone successful balloon valvuloplasty in pregnancy.¹⁰³ In contrast, open valve replacement is associated with a 30% fetal mortality risk.¹⁰⁴

The cardiovascular status of patients with aortic stenosis is occasionally complicated by the frequent coexistence of ischemic heart disease. In these instances, death associated with aortic stenosis may occur secondary to myocardial infarction rather than as a direct complication of the valvular lesion itself.^{88,99}

Aortic insufficiency

Aortic insufficiency is most commonly rheumatic in origin and, as such, is associated almost invariably with mitral valve disease. The aortic insufficiency is generally tolerated well during pregnancy because the increased heart rate seen with advancing gestation decreases time for regurgitant flow during diastole. In Hibbard's series⁴⁷ of 28 maternal rheumatic cardiac deaths, only one was associated with aortic insufficiency in the absence of concurrent mitral stenosis. If symptomatic, patients respond favorably to diuretics and vasodilators; epidural anesthesia is thus appropriate and reduces the risk of left ventricular failure at delivery.^{33,34}

Peripartum cardiomyopathy

Peripartum cardiomyopathy is defined as cardiomyopathy developing in the last month of pregnancy or the first 6 months postpartum in women without previous cardiac disease and after exclusion of other causes of cardiac failure, as shown in Table 39.7.^{32,105-107} It is therefore a diagnosis of exclusion that should not be made without a concerted effort to identify valvular, metabolic, infectious, or toxic causes of cardiomyopathy.¹⁰⁸ Much of the current controversy surrounding this condition is the result of many older reports in which these causes of cardiomyopathy were not investigated adequately. Other peripartum complications, such as amniotic fluid embolism, severe preeclampsia, and corticosteroid- or

Table 39.7 Clinical parameters defining peripartum cardiomyopathy.

Parameter	Echocardiographic parameters
Cardiac failure in last month of pregnancy, or within 5 months of delivery	
No prior history of cardiac disease	
Absence of clearly identifiable etiology

Echocardiographic parameters as described by Hibbard et al.³²

sympathomimetic-induced pulmonary edema, must also be considered before making the diagnosis of peripartum cardiomyopathy.¹⁰⁸ However, prior to concluding a definitive etiologic role for beta-agonists, it must be considered that sympathomimetic agents may unmask rather than induce an underlying peripartum cardiomyopathy.¹⁰⁹ To date, there remains no definitive proven association between tocolytic therapy and peripartum cardiomyopathy.

The incidence of peripartum cardiomyopathy is estimated at between 1 in 1500 and 1 in 4000 deliveries in the United States.^{29–31,110} An incidence as high as 1% has been suggested in women from certain African tribes.¹¹⁰ However, idiopathic heart failure in these women may be primarily a result of unusual culturally mandated peripartum customs involving excessive sodium intake, as such, and may represent simple fluid overload.¹¹⁰ In the United States, the peak incidence of peripartum cardiomyopathy occurs in the first postpartum month and appears most frequently among older, multiparous, black females.^{105,108,110} Other suggested risk factors include twinning and pregnancy-induced hypertension.^{28–31,108–111} In some cases, a familial recurrence pattern has been reported.

The condition is manifest clinically by increasing fatigue, dyspnea, and peripheral or pulmonary edema. As most women in the last trimester of pregnancy manifest these conditions, suspicion for a cardiomyopathy should arise with paroxysmal nocturnal dyspnea, chest pain, nocturnal cough, new regurgitant murmurs, pulmonary crackles, and hepatomegaly.⁹⁴ Physical examination reveals classic evidence of congestive heart failure, including elevated jugular venous pressure, rales, and an S3 gallop. Cardiomegaly and pulmonary edema are found on chest radiograph, and the electrocardiogram often demonstrates left ventricular and atrial dilation and diminished ventricular performance, with the reported observance of inverted T waves, Q waves, and nonspecific ST segment changes. In addition, up to 50% of patients with peripartum cardiomyopathy may manifest evidence of pulmonary or systemic embolic phenomena. The diagnosis rests on the echocardiographic finding of new left ventricular systolic dysfunction during a limited period around parturition (Table 39.7).³² Overall mortality ranges from 25% to 50%.^{29–31,108–111}

The histologic picture of peripartum cardiomyopathy involves nonspecific cellular hypertrophy, degeneration, fibrosis, and increased lipid deposition. Although some reports have documented the presence of a diffuse myocarditis, the common collective wisdom suggests that peripartum cardiomyopathy may represent a type of myocarditis arising from an infectious (viral), autoimmune, or idiopathic process.^{106,108,111} Its existence as a distinct entity is supported primarily by epidemiologic evidence suggesting that 80% of cases of idiopathic cardiomyopathy in women of childbearing age occur in the peripartum period.¹¹² Such an epidemiologic distribution could also be attributed to an exacerbation of underlying subclinical cardiac disease related to the hemodynamic changes accompanying normal pregnancy.^{29,31}

However, as such changes are maximal in the third trimester of pregnancy and return to normal within a few weeks postpartum, such a pattern does not explain the peak incidence of peripartum cardiomyopathy occurring, in most reports, during the second month postpartum. Nevertheless, the diagnosis of peripartum cardiomyopathy remains primarily a diagnosis of exclusion and cannot be made until underlying conditions, including chronic hypertension, valvular disease, and viral myocarditis, have been excluded.

Therapy includes digoxin (dosed to achieve a serum level of 1–2 ng/dL), diuretics (furosemide 20–40 mg orally daily), fluid and sodium restriction (2 L/day and 4 mg/day, maximum, respectively), and prolonged bedrest.^{28–33,105–111} In refractory cases or with clear evidence of systolic dysfunction, we employ concomitant afterload reduction with vasodilators (25–100 mg of oral q.i.d. hydralazine being the drug of choice peripartum, with either long-acting nitroglycerin or 5–10 mg of oral daily amlodipine as second-line agents) or use epidural regional analgesia approximating delivery. In general, because of the adverse effects of negative inotropic agents, other calcium channel blockers ought to be avoided. In recent years, angiotensin-converting enzyme inhibitors (enalapril 5–20 mg oral twice daily) have been the mainstay of treatment postpartum; breastfeeding women should be counseled accordingly. Early endomyocardial biopsy to identify a subgroup of patients who have a histologic picture of inflammatory myocarditis and who may be responsive to immunosuppressive therapy has been suggested.¹¹³ It is of note that patients with poor cardiac function (EF < 40%) are at increased risk of thromboembolism; we recommend anticoagulation with unfractionated heparin (5000–7500 units s.c.) or low-molecular-weight enoxaparin (40 mg s.c. daily) during pregnancy, and consideration of warfarin in the postpartum interval.

When peripartum cardiomyopathy occurs in the last trimester of pregnancy, delivery is indicated. The mode of delivery should be based on obstetric indications. Indeed, the advantages of vaginal delivery over Cesarean section are evident: minimal blood loss, greater hemodynamic stability, and decreased pulmonary and thromboembolic complications. In addition, regional epidural analgesia has the distinct advantage of reducing both preload and afterload, as well as minimizing fluctuations in cardiac output associated with labor.⁹⁴ In instances of obstetrically indicated Cesarean delivery, we and others⁹⁴ recommend careful monitoring of fluid balance with central monitoring in an effort to clearly define and monitor the central venous pressure.

A notable feature of peripartum cardiomyopathy is its tendency to recur with subsequent pregnancies. Several reports have suggested that the prognosis for future pregnancies is related to heart size. Patients whose cardiac size returned to normal within 6–12 months had an 11–14% mortality in subsequent pregnancies; patients with persistent cardiomegaly had a 40–80% mortality.^{28–31} Recently, persistent decreased contractile reserve has been demonstrated in women who have

recovered from peripartum cardiomyopathy.^{30,107} Thus, pregnancy is contraindicated in all patients with persistent cardiomegaly accompanying left ventricular dysfunction; the 11–14% risk of maternal mortality with subsequent pregnancy seen in patients with normal heart size would seem, in most cases, to be unacceptable as well.

Idiopathic hypertrophic subaortic stenosis

Idiopathic hypertrophic subaortic stenosis (IHSS) or hypertrophic cardiomyopathy (HCM) is an autosomal dominant condition with variable penetrance, generally characterized by left ventricular hypertrophy with reduced left ventricular size and compliance. IHSS manifests clinically in the second or third decade of life; thus, its sentinel presentation is likely to occur during pregnancy. Detailed physical and echocardiographic diagnostic criteria have been described elsewhere.^{113,114} IHSS is unique among the hypertrophies in that the left ventricular hypertrophy involves the septum to a greater extent than the free wall, resulting in obstruction to left ventricular outflow and secondary mitral regurgitation, the two principal hemodynamic concerns of the clinician.^{113–116} Although the increased blood volume associated with normal pregnancy should enhance left ventricular filling and improve hemodynamic performance, this positive effect of pregnancy is counteracted by the fall in arterial pressure and vena caval obstruction common in the last trimester of pregnancy. In addition, tachycardia resulting from pain in labor and Valsalva with active maternal efforts in the second stage of labor diminish left ventricular filling and aggravate the relative outflow obstruction. Thus, it may be generally surmised that reduction of preload and afterload in IHSS patients results in an increase in the outflow gradient with a concomitant reduction in left ventricular filling. As such, regional analgesia is relatively contraindicated, although reports of its use are observed.¹¹⁵

The keys to successful management of the peripartum period in patients with IHSS involve avoidance of hypotension (resulting from conduction anesthesia or blood loss), control of tachycardia, conduction of labor in the left lateral recumbent position, and avoidance of maternal Valsalva with the use of forceps or vacuum. As with most other cardiac diseases, Cesarean section of IHSS patients should be reserved for obstetric indications only.

Despite the potential theoretical risks, maternal and fetal outcome in IHSS patients is generally good. In a report of 54 pregnancies in 23 patients with IHSS, no maternal or neonatal deaths occurred.¹¹⁴ Although beta-blocking agents were once used routinely in patients with IHSS, they are currently reserved for patients with angina, recurrent supraventricular tachycardia, or occasional beta-blocker-responsive arrhythmias. In these patients, we recommend antibiotic prophylaxis against subacute bacterial endocarditis.

Marfan syndrome

Marfan syndrome is an autosomal dominant disorder resulting from multiple lineage-specific mutations in the fibrillin gene on chromosome 15; the weakness results in skeletal, ocular, and cardiovascular abnormalities. Among the cardiovascular manifestations, mitral valve prolapse, mitral regurgitation, aortic insufficiency, and aortic root dilation with a marked propensity toward aortic root dissection are common. The most common cause of death among women under 40 years of age with Marfan syndrome is an aortic complication, and 50% of aortic aneurysm ruptures in these women occur during pregnancy.⁷⁷ Rupture of splenic artery aneurysms also occurs more frequently during pregnancy.⁷⁷ In addition, 60% of patients with Marfan syndrome have associated mitral or aortic regurgitation.¹¹⁷ Thus, patients are followed prior to and during pregnancy for aortic root diameter, as it may predict the risk of aortic dissection or rupture. Generally, the longstanding recommendation for replacement of the ascending aorta in asymptomatic patients is recommended when the root diameter exceeds 5.5 cm.¹¹⁷

Although some authors believe that pregnancy is contraindicated in any woman with documented Marfan syndrome, prognosis is best individualized and should be based on echocardiographic and computed tomography (CT) assessment of aortic root diameter and postvalvular dilation.^{23–25,117} It is important to note that enlargement of the aortic root is not demonstrable by chest radiograph until dilation has become pronounced.¹¹⁷ Women with an abnormal aortic valve or aortic dilation may have up to a 50% pregnancy-associated mortality; women without these changes and with an aortic root diameter of less than 40 mm have a mortality of less than 5%.^{23–25} Even in patients meeting these echocardiographic criteria, however, special attention must be given to signs or symptoms of aortic dissection because even serial echocardiographic assessment is not invariably predictive of complications.^{118–120} In counseling women with Marfan syndrome, the genetics of this condition and the shortened maternal lifespan must be considered, in addition to the immediate maternal risk.^{23–25}

Gestational management hinges on aggressive control of hypertension with beta-blocker therapy; utilization of labetalol (an alpha- and beta-antagonist) has the added advantage of controlling mean arterial blood pressure in a rapid fashion, alongside its ability to decrease pulsatile pressure on the aorta.¹¹⁹ In instances of aortic root dilation approximating 5 cm, we and others^{33,120} would recommend Cesarean delivery to minimize episodic hypertension that may precipitate aortic root dissection. If Cesarean section is performed, retention sutures should be used because of generalized connective tissue weakness.

It is worthy of mention that type IV Ehlers–Danlos syndrome similarly bears an equivalent risk of aortic root dissection and should be managed accordingly.¹²⁰

Myocardial infarction

Coronary artery disease is uncommon in women of reproductive age; therefore, myocardial infarction in conjunction with pregnancy is rare and occurs in less than 1:10 000 pregnancies.¹²¹ In a review of 68 reported cases, myocardial infarction during pregnancy was associated with a 35% mortality rate.¹²² Only 13% of patients were known to have had coronary artery disease before pregnancy. Two-thirds of the women suffered infarction in the third trimester; mortality for these women was 45%, compared with 23% in those suffering infarction in the first or second trimesters. Thus, it appears that the increased hemodynamic burden imposed on the maternal cardiovascular system in late pregnancy may unmask latent coronary artery disease in some women and worsen the prognosis for patients suffering infarction.²⁷ Fetuses from surviving women appear to have an increased risk of spontaneous abortion and unexplained stillbirth.

Women with class H diabetes mellitus face risks beyond those imposed by their cardiac disease alone. Although successful pregnancy outcome may occur, maternal and fetal risks are considerable. Such considerations, as well as the anticipated shortened lifespan of these patients, make special counseling of such women of major importance.¹²⁴

In the largest series published to date, Roth and Elkayam¹²³ reviewed 125 cases of myocardial infarction during pregnancy or within 3 months of delivery; 78 occurred antepartum, 17 peripartum, and 30 postpartum. Among these cases, 43% were attributed to coronary atherosclerosis, with coronary thrombus without atherosclerosis in 21%, coronary artery dissection in 16%, and acute or coronary aneurysm in 4%. Maternal mortality in this series was 21%, and fetal mortality was 13%. Mode of delivery was not associated with maternal mortality.

Antepartum care of women with prior myocardial infarction centers on efforts to minimize myocardial oxygen demands. Diagnostic radionuclide cardiac imaging during pregnancy results in a fetal dose of no more than 0.8 rad and thus does not carry the potential for teratogenesis.⁶² If cardiac catheterization becomes necessary, the simultaneous use of contrast echocardiography may reduce the need for cineangiography and thus reduce radiation exposure to the fetus.¹²⁵ In women with angina, nitrates have been used without adverse fetal effects. Delivery within 2 weeks of infarction is associated with increased mortality; therefore, if possible, attempts should be made to allow adequate convalescence before delivery. If the cervix is favorable, cautious induction under controlled circumstances after a period of hemodynamic stabilization is optimal. Labor in the lateral recumbent position, the administration of oxygen, pain relief with epidural anesthesia, and shortening of the second stage to reduce myocardial oxygen demands with assisted vaginal delivery are important management considerations; Cesarean delivery is reserved for obstetric indications. Having six or

more pregnancies has been associated with a small but significant increase in the risk of subsequent coronary artery disease.¹²⁶

Anticoagulation

Anticoagulation in the patient with an artificial heart valve or atrial fibrillation during pregnancy is controversial and has been the focus of many recent and comprehensive reviews.^{127–131} The key issue involves the lack of consensus on an ideal agent for anticoagulation during pregnancy.

Warfarin (coumadin) is relatively contraindicated at all stages of gestation because of its association with fetal warfarin syndrome (warfarin embryopathy, characterized by nasal hypoplasia and stippled epiphyses) in weeks 6–12, and because of its theoretical relationship to fetal intracranial hemorrhage and secondary brain scarring at later stages. In addition, there are reports suggesting that central nervous system and ocular abnormalities may be associated with warfarin exposure during the second and third trimesters.^{127–131} Several studies have suggested that the presumed risk of warfarin embryopathy beyond the first trimester has been overstated; one deficiency in these studies is a lack of detailed neonatal neurologic evaluation and follow-up.¹³² Thus, although the risk of embryopathy when warfarin derivatives are taken between weeks 6 and 9 is historically estimated to be between 8% and 30%, recent reports suggest an anomaly rate of 3.9% of all pregnancies and 7.4% of live births,¹²⁸ with prospective studies supporting a rate of 10.2%;¹³¹ the frequency of intracranial hemorrhage in fetuses whose mothers receive warfarin after the first trimester is unknown. Several series from outside the United States have reported on the use of warfarin in pregnant patients with prosthetic valves, and demonstrated a 2% incidence of embryopathy.¹³⁵ Thus, while one can debate the precise risk of embryopathy based on prospective or retrospective acquired data, this risk unequivocally exists.

Balancing the fetal risks with warfarin therapy are the maternal risks with heparin and low-molecular-weight heparin therapy. In sum of a large body of data, there are now multiple series comparing maternal thromboembolic events in patients receiving unfractionated heparin, which demonstrate a two- to fourfold increased risk of treatment failure with maternal mortality from thrombosed valves.^{127–131} However, as noted by Nassar et al.,¹³² the risk of valve thrombosis relies on many factors, including type, number, and position of the valve with higher risk in mitral valves, arrhythmias, previous thrombosis, and adequacy of anticoagulation. In addition, it is suggested that bileaflet valves (St Jude valves) may actually have a lowered thrombogenic potential, albeit one study did not support such findings.¹³⁶

Reported and hypothesized treatment failures with unfractionated heparin led both cardiologists and obstetricians to employ low-molecular-weight heparin (LMWH) for prosthetic valve prophylaxis. However, this too is fraught with

Table 39.8 Treatment approaches for women with mechanical heart valves.

Approach	Dosing regimen	Therapeutic parameters
Adjusted-dose unfractionated heparin throughout pregnancy	Adjusted dosage s.c. every 12 h	Maintain midinterval aPTT at a minimum of twice control OR anti-factor Xa heparin level of 0.3 U/ml
Adjusted-dose LMWH throughout pregnancy	Adjusted dosage s.c. every 12 h	Maintain peak anti-factor Xa heparin levels (4 h post injection) > 0.8 U/mL
Heparin or LMWH in adjusted dose (as above) through the 12th week of gestation, then warfarin until 36 weeks, followed by reinitiation of adjusted-dose heparin or LMWH (as above)	As above, with warfarin after 12 weeks daily	Target INR 2.5–3.5 with warfarin therapy Otherwise as above

INR, international normalized ratio; aPTT, activated partial thromboplastin time.

controversy and limitations. Both the Food and Drug Administration (FDA) and the American College of Obstetricians and Gynecologists (ACOG) warn against the use of enoxaparin and other LMWHs during pregnancy, citing risk of thrombosis.¹³⁸ Understandably, many clinicians were thereafter frustrated with the elimination of potentially acceptable therapeutic options. This frustration prompted a flurry of reports, most notably the Report and Recommendations of the Anticoagulation in Prosthetic Valves and Pregnancy Consensus Report (APPCR) Panel and Scientific Roundtable.¹²⁷ This panel of experts ultimately came to the consensus opinion that “There is a substantial body of published, peer-reviewed, trial- and cohort study-based evidence, institutional data sets, and expert clinical experience/opinion to support safe and effective use of enoxaparin for anticoagulation management of non-pregnant patients with prosthetic mechanical heart valves. There are insufficient data to reliably predict, compare clinical outcomes, or to confirm the safety or effectiveness of enoxaparin, UFH, or warfarin in pregnant patients with mechanical heart valves. In light of the predictable, published, and problematic aspects encountered with each of the aforementioned anticoagulants currently available in the armamentarium for pregnant patients with mechanical valves, the Panel felt strongly that while concerns about efficacy and safety were justified for all agents (i.e., warfarin, heparin, and LMWH [enoxaparin]), the available literature and index cases did not support selective, asymmetrical warning language in the case of enoxaparin.”¹²⁷

In essence, a choice between fetal and maternal risks must be made, and neither choice is considered ideal. That said, two approaches may be termed “acceptable.”^{127–131,139} One involves substitution of heparin or enoxaparin for warfarin from the time pregnancy is diagnosed until 12 weeks’ gestation, followed by warfarin until 32 weeks, at which time heparin or enoxaparin is reinstituted until delivery. The second approach involves using adjusted-dose subcutaneous heparin or enoxaparin throughout pregnancy. We recommend dosage regimens as outlined in Table 39.8, with acknowledgment of the paucity of data supporting these recommendations. Given

the controversies outlined above, with their ensuing medicolegal implications, the patient must be involved in this choice and thoroughly informed of the risks and benefits of either approach.

Patients with bioprosthetic or xenograft valves are not usually treated with anticoagulants during pregnancy. This fact makes the bioprosthetic valve the ideal choice of prosthesis for young women of childbearing age.¹³⁹ Patients with a bioprosthetic valve who are in atrial fibrillation or have evidence of thromboembolism, however, should be anticoagulated and rate controlled accordingly.⁹⁵

Cardiovascular surgery

There are numerous reports of cardiovascular surgery during pregnancy, most of which are favorable; they include successful correction of most types of congenital and acquired cardiac disease (as reviewed above). Early reports of closed mitral valve commissurotomy during pregnancy were also favorable and indicated a maternal death rate of 1–2% and perinatal loss in the region of 10%.^{4,8} This procedure has been replaced by open valvuloplasty with equally good results.

Initial reports of cardiopulmonary bypass during pregnancy were not nearly as favorable, indicating a fetal wastage of up to 33%.^{140,141} Initiation of cardiopulmonary bypass is generally followed by fetal bradycardia, which may be correctable by high flow rates.¹⁴² With the use of continuous electronic fetal heart rate monitoring, flow rate can be adjusted to avoid or correct fetal hypoperfusion and bradycardia, thus reducing fetal mortality to less than 10%. High-flow/high-pressure normothermic perfusion and continuous electronic fetal heart rate monitoring appear to be optimal for the fetus.⁸ Maternal mortality is highly dependent on the specific nature of the procedure being performed and does not appear to be increased significantly by pregnancy. Successful pregnancy after heart transplantation has been reported. Principles of counseling and management for these complex patients have been summarized previously.⁸

Key points

- 1 Normal physiologic changes of pregnancy may mimic cardiac disease.
- 2 Despite (1), suspected cardiovascular abnormalities must be worked up aggressively in pregnancy.
- 3 Most maternal deaths in developed countries due to cardiac disease are secondary to cardiomyopathy, ischemic heart disease, endocarditis, pulmonary hypertension, and arrhythmia.
- 4 Women with cardiac disease should seek preconception counseling.
- 5 Women with pulmonary hypertension, complicated or unrepaired aortic coarctation, and Marfan syndrome with a dilated aortic root should be counseled toward pregnancy termination.
- 6 Women with ischemic cardiac disease or prior peripartum cardiomyopathy should also be encouraged to consider pregnancy termination.
- 7 No method of anticoagulation is ideal or risk free in patients with mechanical valves during pregnancy.
- 8 Any woman with suspected pulmonary hypertension must have a definitive diagnosis as soon as possible, usually via right heart catheterization.
- 9 With the exception of conditions listed in (5) and (6) above, prepregnancy NYHA classification is prognostic of how the woman will tolerate pregnancy.
- 10 In women with cyanotic heart disease, fetal deterioration is a very common cause of early delivery.
- 11 Most valvular insufficiency is tolerated well during pregnancy.
- 12 In patients with significant mitral stenosis, the risks of pulmonary edema due to peripartum volume shifts must be weighed against the risks of falling cardiac output if active diuresis is considered during labor.
- 13 Patients with pulmonary hypertension incur intrapartum risk primarily from conditions resulting in hypovolemia or reduced venous return to the heart.
- 14 Patients with obstructive congenital cardiac disease have up to a 10% risk of a cardiac defect in their fetus.
- 15 The postpartum period is the time of greatest risk of pulmonary edema in women with mitral stenosis.
- 16 The major hemodynamic considerations complicating pregnancy in women with heart disease are increased intravascular volume, decreased systemic vascular resistance, increased tendency for pathologic clot formation, and hemodynamic fluctuations during the peripartum period.
- 17 The need for endocarditis prophylaxis during uncomplicated vaginal delivery in women with structural heart disease is controversial, but is recommended by many authorities.
- 18 Even in most forms of severe cardiac disease, forceps or vacuum delivery should be reserved for standard obstetric indications.
- 19 With proper management, many women with cardiac disease can expect successful pregnancy.
- 20 Management of significant cardiac disease in pregnancy should be a team effort, involving obstetrics, cardiology, maternal–fetal medicine, and anesthesia specialists.

Maternal pulmonary disorders complicating pregnancy

Steven L. Clark and Calla Holmgren

Pregnant women are afflicted by the same respiratory ailments as nonpregnant women, but these conditions are complicated by the physiologic alterations of pregnancy. Certain lung diseases, such as asthma, are common in women of childbearing age and may often be seen in pregnant women. However, asthma and other pulmonary diseases may first manifest during pregnancy or change their course during gestation. In this chapter, we first review diagnostic techniques for lung disease, including history and physical examination, pulmonary function tests, arterial blood gases, and radiographic tests. We then summarize the physiologic alterations of the respiratory system during pregnancy. Specific respiratory illnesses are discussed, including those found in women with chronic disease as well as those found in women who were previously normal.

Diagnostic techniques

History and physical examination

Most common respiratory disorders lead to symptoms such as shortness of breath, exercise intolerance, cough, sputum production, wheezing, chest tightness, fever, chills, night sweats, or hemoptysis. A careful history should elicit information about medications, smoking history, and prior respiratory illness. Physical examination should be carried out with particular attention to the duration of the expiratory phase, the use of accessory muscles, and the presence of rales, rhonchi, wheezes, pleural rubs, signs of pleural effusions, consolidation, and chest wall abnormalities. Taken together, these aspects of the history and physical examination provide the necessary database for the care of patients with pulmonary disease during pregnancy. If the patient has been pregnant in the past, the presence of respiratory symptoms during the previous pregnancy should be noted and compared with the patient's usual respiratory symptoms when not pregnant.

Dyspnea is the most common respiratory complaint during pregnancy, with as many as 60–70% of previously normal women having this symptom at some time during pregnancy.

The complaint usually begins in the first or second trimester but is most prevalent at term.¹ It is not usually due to underlying lung disease, but appears to result from the subjective perception of hyperventilation that normally accompanies pregnancy. With increased progesterone levels in pregnancy, the volume of air taken into the lungs with each breath (tidal volume) increases, giving a sensation of hyperventilation. This occurs despite a lack of change in breathing frequency. As the woman acclimatizes to this new sensation, her perception of dyspnea is reduced, and dyspnea stabilizes as the pregnancy progresses. Maximum dyspnea seems to correlate with the time of lowest arterial carbon dioxide tension, which suggests a potential role for hypocarbia in mediating this symptom.

Arterial blood gases

Arterial blood sampling provides valuable data about maternal oxygenation and acid–base status. Because of the well-documented risks of fetal hypoxia with decreasing maternal oxygenation, arterial blood gas data should be obtained when any serious acute respiratory complaint is present. Interpretation of acid–base abnormalities is greatly aided by reference to base nomograms, such as the one shown in Figure 40.1.² In a normal pregnant female, arterial blood gas measurements usually show a compensated respiratory alkalosis due to maternal hyperventilation.

The pH generally ranges from 7.40 to 7.47, and the partial pressure of arterial carbon dioxide is 25–32 mmHg.^{3–6} The partial pressure of arterial oxygen (P_aO_2) may be as high as 106 mmHg in early pregnancy, decreasing during pregnancy but remaining at 100 mmHg, or slightly higher, at term. In patients at moderate altitude, partial pressure of oxygen (PO_2) values are lower, averaging 88 mmHg.⁶ The measured arterial O_2 tension represents the partial pressure of O_2 dissolved in blood, but is only an indirect reflection of the blood's O_2 content. Calculating the O_2 content of blood requires a knowledge of the amount of O_2 dissolved in the blood, the maximum amount of O_2 able to be carried per gram of hemoglobin, the

Figure 40.1 Nomogram showing bands for uncomplicated respiratory or metabolic acid-base disturbances in intact subjects. Each “confidence” band represents the mean \pm standard deviation for the compensatory response of normal subjects or patients to a given primary disorder. Ac, acute; acid, acidosis; alk, alkalosis; chr, chronic; met, metabolic; resp, respiratory. (Modified from Arbus.) (Reprinted from ref. 2, with permission.)

hemoglobin concentration, and the O_2 saturation of hemoglobin.

$$O_2 \text{ content} = [(\text{hemoglobin [Hb]} \text{ (g/dL)} \times 1.39 \text{ mL } O_2/\text{g Hb}) \times (O_2 \text{ saturation})] + [(0.003 \text{ mL } O_2/100 \text{ mL of blood}) \times P_{aO_2} \text{ (mmHg)}]$$

As the equation shows, 1 g of fully saturated Hb can combine with 1.39 mL of O_2 . Because normal blood has approximately 15 g of Hb per 100 mL, the maximal O_2 -carrying capacity is usually approximately 20.8 mL of O_2 per 100 mL of blood. The O_2 saturation of Hb is usually taken from the oxyhemoglobin dissociation curve (Fig. 40.2)⁷ and is affected by such variables as pH, partial pressure of carbon dioxide (PCO_2), temperature, and the amount of 2,3-diphosphoglycerate (DPG) present. The amount of dissolved O_2 is calculated by applying Henry's law, which states that the amount of dissolved gas is proportional to its partial pressure. For each 1 mmHg of partial pressure of O_2 , 0.003 mL of O_2 is dissolved per 100 mL of blood (0.003 mL O_2 per 100 mL of blood). Thus, the dissolved O_2 content of arterial blood with a P_{aO_2} of 100 mmHg is 0.3 mL of O_2 per 100 mL of blood.

The adequacy of alveolar gas exchange depends on the matching of ventilation and blood perfusion within various regions of the lung. Mismatching of ventilation and perfusion

Figure 40.2 Anchor points of the oxygen dissociation curve. The curve is shifted to the right by an increase in temperature, PCO_2 and 2,3-DPG and a fall in the pH. The oxygen content scale is based on a hemoglobin concentration of 14.5 g per 100 mL. (Reprinted from ref. 7, with permission.)

is responsible for most of the defective gas exchange in pulmonary diseases. The adequacy of alveolar gas exchange can be assessed by calculating the alveolar–arterial O_2 tension gradient and, if the alveolar O_2 tension (P_{AO_2}) greatly exceeds the P_{aO_2} , then alveolar gas exchange is abnormal. Ideal P_{aO_2} is calculated as follows:

$$P_{aO_2} = F_{IO_2} \times (PB - 47) - P_aCO_2/0.8$$

F_{IO_2} = fractional percentage of inspired O_2 ; PB = barometric pressure; 47 = water vapor pressure; P_aCO_2 = arterial blood tension of carbon dioxide; 0.8 = respiratory quotient.

This equation states that a patient's P_{aO_2} equals the tension of O_2 in inspired air minus the amount of O_2 taken up in the lung in exchange for carbon dioxide. This latter exchange relationship, the respiratory quotient, is equal to 0.8 of the volume of carbon dioxide released in exchange for every volume of O_2 delivered. P_{aO_2} , obtained from blood gas measurement is subtracted from P_{AO_2} to obtain a measure of the (A–a) O_2 gradient.

In the nonpregnant patient, the (A–a) O_2 gradient varies with age, but a prediction formula for the expected range of normal is not applicable during pregnancy. In one study, the mean (A–a) O_2 gradient in normal pregnant women in the supine position during the third trimester was 20 mmHg, whereas in the sitting position it decreased to 14.3 mmHg.⁸ In another study of normal obstetric patients, P_{aO_2} increased by 13 mmHg when changing from a supine to a sitting position, and arterial PCO_2 decreased by 2 mmHg, leading to a net decrease in the (A–a) O_2 gradient of 10 mmHg.⁹ The increased gradient noted in the supine position may be the result of

decreased cardiac output attributable to decreased venous return from compression of the inferior vena cava by the uterus.^{8,10}

On the other hand, a more recent study performed at moderate altitude showed no effect of position or oxygenation in normal pregnant women.⁵

Because most acute lung diseases are accompanied by an increased (A–a) O₂ gradient, the gradient should be assessed with the pregnant patient in the upright position and should be considered abnormal if it exceeds 25 mmHg. Blood gas analysis should be accompanied by calculation of the gradient because, given the usual decreased P_{CO}₂ of pregnancy, on casual observation, a “normal” P_aCO₂ can be seen even with an abnormally increased (A–a) O₂ gradient.

Pulmonary function tests

Normal respiratory physiology is altered in pregnancy, and these changes must be considered when evaluating tests of lung function. In the terminology of pulmonary function testing (Table 40.1), a volume is a single discrete component of the lung. Four such volumes exist: tidal volume (TV), residual volume (RV), inspiratory reserve volume (IRV), and expiratory reserve volume (ERV). The term capacity refers to a sum of volumes. Except for RV, each of the volumes defined can be recorded and measured by simple spirometry. RV, the volume of gas remaining in the thorax at the end of a maximal exhalation, can be measured only by indirect methods (e.g., helium dilution, nitrogen washout, or body plethysmography). The enlarging fetus and the increased concentration of circulating hormones during pregnancy account for the changes in pulmonary function seen with gestation. The hyperventilation of pregnancy is characterized by an increased depth of breathing (TV increases from 450 to 600 mL) rather than a higher respiratory rate.¹¹ Minute ventilation is increased in excess of the rise in O₂ consumption associated

with pregnancy and is thought to be due to a progesterone-mediated increase in sensitivity to carbon dioxide. In one study, at term, minute ventilation was 48% higher than normal, whereas oxygen consumption increased by only 21%.¹² Vital capacity generally remains unchanged because there is an increase in inspiratory capacity but a decrease in ERV. In the second half of pregnancy, a slight reduction in functional residual capacity (FRC) (18%), RV, and total lung capacity (TLC) occurs, caused by compression of the resting lung by the elevated intra-abdominal pressure secondary to uterine enlargement.¹³ Typical pulmonary volumes and capacities and the modifications caused by pregnancy are shown schematically in Figure 40.3. In women with a moderate deficiency of serum protease inhibitor, forced expiratory volume (FEV), forced vital capacity (FVC), and other tests of pulmonary function increase with increasing numbers of children.¹⁴

Abnormal spirometry is usually classified as fitting a pattern of either obstruction or restriction. Normal spirometric lung values are within 20% of a predicted normal, which is based on a patient's age, sex, height, and weight. Flow rates are preserved in both large and small airways during a normal pregnancy.

A restrictive pattern is present when TLC is less than 80% of the predicted normal. With restrictive disease, air flow rate, expressed by volume of air expired in 1 s from maximum inspiration (FEV) as a percentage of FVC (FEV₁ per FVC), can be increased to more than 85%. Restrictive ventilatory defects are caused by skeletal, neuromuscular, pleural, interstitial, and alveolar diseases that lead to a reduction in lung volume or chest wall expansion. Sarcoidosis and chest wall deformity are the most common restrictive lung diseases seen in women of childbearing age.

An obstructive pattern is present when the FEV/FVC ratio is less than 75% and FEV is less than 80% of the predicted value, indicating a reduction in air flow rates. Lung volumes

Table 40.1 Pulmonary parameters.

Lung volumes	Description
Tidal volume (TV)	The volume of air inhaled or exhaled with each normal breath
Residual volume (RV)	The volume of air remaining in the lungs after a vital capacity maneuver
Inspiratory reserve volume (IRV)	The maximal additional volume of gas that can be inhaled after a tidal breath is inhaled
Expiratory reserve volume (ERV)	The maximal volume of gas that can be exhaled after a tidal breath is exhaled
Total lung capacity (TLC)	The volume of air in the lungs at maximal inspiration
Vital capacity (VC)	The maximum amount of air that can be exhaled after a maximal inspiration to TLC
Inspiratory capacity (IC)	The maximal volume of gas that can be inspired from the resting expiratory level
Functional residual capacity (FRC)	The volume of air remaining in the lungs after a tidal volume exhalation
Forced vital capacity (FVC)	The volume of air exhaled during a rapid forced expiration starting at full inspiration
<i>Other measurements made by spirometry</i>	
Forced expiratory volume in 1 s (FEV)	The volume of air expelled in 1 s during a forced expiration starting at full inspiration
Minute ventilation (MV)	The amount of air exhaled per minute, measured under resting conditions
Peak expiratory flow rate (PEFR)	The peak rate (L/min) of a forceful expiration of a vital capacity

Figure 40.3 Alterations in pulmonary volumes and capacities associated with pregnancy. (Reprinted from ref. 11, with permission.)

may be normal, or they may be increased if air is trapped as a result of early airway closure. Asthma is the most common obstructive airway disease encountered in pregnancy.¹⁵ Other obstructive lung diseases include cystic fibrosis, bronchiectasis, and emphysema. The diffusing capacity of the lung, which reflects the amount of O_2 that can be taken up by the pulmonary capillary blood, is either unchanged or increased during pregnancy. Diffusing capacity has been reported to be most elevated in the first trimester^{16,17} as a result of the increase in capillary blood volume that accompanies pregnancy. Diffusing capacity may also be increased in asthmatic patients because relative pulmonary hypertension, secondary to hypoxemia, results in redistribution of pulmonary blood flow to the upper lobes, where alveoli have higher ventilation-perfusion ratios.¹⁸

When a patient with known lung disease seeks advice about the risks of pregnancy, pulmonary function studies should be obtained. These studies combined with other clinical data can be used to make an objective assessment of the patient's risks during pregnancy. However, no strict guidelines can be given as to the level of pulmonary function that will prohibit a safe pregnancy. A patient with a vital capacity less than 1 L generally has significant difficulties. If the FEV exceeds 1 L in a woman with obstructive disease, she does not ordinarily experience dyspnea at rest, even at term. Resting ventilation during pregnancy increases less in patients with lung disease than in normal subjects.¹⁹ Although patients with obstructive lung disease vary widely in their tolerance of pregnancy, most women with restrictive disease tolerate pregnancy well. Studies in patients with lung disease resulting from lung resection have shown the potential for normal pregnancy and fetal development. Indeed, even intrapartum lung resection has

been carried out when necessary without adverse outcome.²⁰ In view of these data, women with respiratory disease that is unlikely to worsen during pregnancy, an FEV of greater than 1 L, and no dyspnea at rest can generally undertake pregnancy safely.

When a pregnant patient must undergo general anesthesia and serious lung disease is suspected, ideally, pulmonary function should be assessed. Postoperative respiratory complications of atelectasis, inadequate secretion clearance, infection, and respiratory failure are more likely to occur when the FEV is less than 2 L. A higher FEV is required to undergo uncomplicated surgery than is needed to tolerate pregnancy alone because of an expected reduction in lung function in the immediate postoperative period. Both spinal and epidural anesthesia impair cough effectiveness as well as most other respiratory variables during pregnancy.²¹

Radiographic testing

Radiologic evaluation is a cornerstone of pulmonary medicine. Chest radiography performed on a pregnant patient may expose the fetus to 8–36 mrad.^{22,23} Chest fluoroscopy exposes the fetus to approximately 70 mrad, an estimate that varies depending on the operator, shielding, and reason for fluoroscopy.²² Technetium-99m, a radionuclide frequently used in lung scanning, has a short half-life (6 h), is rapidly excreted, emits no beta rays, and is attached to macroaggregates of human albumin with a particle size of approximately 20 μm , which does not cross the placenta. Fetal radiation exposure has been estimated to range between 500 mrad and 1 rad,²² and thus poses no hazard to the developing fetus. If at any time during pregnancy, the health of the mother or fetus would

be compromised by failure to perform a radiologic examination, the examination should be performed, and every care should be taken to shield the fetus from scatter radiation and from the direct beam when appropriate. Although available data are not conclusive, both epidemiologic and laboratory studies indicate that some levels of radiographic exposure can be harmful to the developing human. Irradiation *in utero* may increase the risk of childhood leukemia and other malignancies by 40–50%.^{22,24} Experimental studies show that doses as low as 5 rad can kill the early embryo, cause neural and skeletal malformations, and impair several aspects of behavior, including learning ability and emotional response to varied stimuli.²³ Obvious malformations are particularly associated with irradiation during the period of major organogenesis, which extends from approximately week 2 through week 9 after conception.²⁵ Taking into account the greatest oncogenic risk, the overall risk of any adverse effect from exposure to 1 rad is estimated to be 0.1%,²⁶ a risk that is thousands of times smaller than the risks of spontaneous abortion, malformation, or genetic disease.²² Fetal exposure to less than 5 rad is considered insufficient reason to recommend termination of a desired pregnancy.^{23,25,26}

When chest radiographs are performed in the pregnant patient, normal findings differ from those seen in nonpregnant women of childbearing age. The diaphragm may be elevated 4 cm at term, but there is a compensatory increase in anteroposterior diameter. The subcostal angle increases from 68.5° to 103.5° from early to late pregnancy.²⁷ Also, lung markings may be increased, giving a false impression of mild congestive heart failure. Hughson and colleagues reported that pleural effusions frequently occurred in the first 24 h after delivery²⁸ and that, in the absence of symptoms or signs of illness, no intervention was necessary. A subsequent prospective ultrasound study of 50 women within 1–45 h of delivery found only one patient with a pleural effusion, a patient who was also in pulmonary edema.²⁹ The results of this study suggest that postpartum pleural effusions may not be a normal occurrence.

Maternal–fetal oxygen exchange

Fetal O₂ delivery depends on maternal respiratory function, hemoglobin concentration, and cardiac output. During pregnancy, plasma volume increases by 30 mL/kg (from 40 to 70 mL/kg), and red cell volume increases from 25 mL/kg to 30 mL/kg.³⁰ As a result, even though erythrocyte mass is increased, there is a decrease in hemoglobin concentration to a value as low as 10.5–11.0 g/dL. Maternal cardiac output, however, is enhanced by 30–40% early in the second trimester because of an increase in stroke volume, left ventricular compliance, and heart rate, along with a reduced systemic vascular resistance (Table 40.2).³¹ The net result of these physiologic changes is to ensure a high rate of O₂ delivery to the gravid uterus.

Table 40.2 Hemodynamic alterations in pregnancy.

Plasma volume	++
Red cell volume	+
Hemoglobin	–
Hematocrit	–
Stroke volume	+
Left ventricular compliance	+
Heart rate	+
Systemic vascular resistance	–
Cardiac output	+++

+++, greatly increased; ++, increased; +, slightly increased; –, slightly decreased; –, decreased.

In a woman with no pulmonary disease who is breathing room air, arterial blood typically has a P_{aO_2} of 91 mmHg and a PCO_2 of 36 mmHg. In the fetal umbilical vein, a simultaneous blood gas typically shows a PO_2 of 32 mmHg and a PCO_2 of 50 mmHg. The same woman breathing 100% O₂ would raise her P_{aO_2} to 583 mmHg, and the PO_2 of the umbilical vein would increase from 32 to 40 mmHg, thereby illustrating a large shunt effect.³² Experimental data in sheep demonstrate that the O₂ tension in the fetal umbilical vein is always less than that in the uterine arteries at all levels of maternal oxygenation.³² Increases in the concentration of inspired O₂ result in the expected rise in O₂ tension in the maternal arteries, but not in large increases in the O₂ tension of the fetal umbilical veins. The fetus is sensitive to large shifts in O₂ delivery caused by a fall in cardiac output. With complete interruption of O₂ supply to the umbilical vein, the fetus has only a limited O₂ reserve. In the normoxic fetus, the effects of maternal administration of nasal cannula or standard mask O₂ on fetal O₂ saturation are negligible.^{33,34}

Blood pH is an important determinant of uterine blood flow, and the finding of an acute, uncompensated respiratory alkalosis in a pregnant female signals possible compromise of fetal oxygenation. In one study of women at term, hyperventilation during inspiration of room air was associated with an increase in maternal O₂ tension from 91 to 100 mmHg, but fetal scalp O₂ tension fell from 25 to 19 mmHg because of a reduction in maternal carbon dioxide tension from 25 to 19 mmHg. Maternal inhalation of 95% O₂ and 5% carbon dioxide restored the fetal O₂ tension to a normal level.³⁵ These data and studies in sheep have suggested that maternal alkalosis can result in decreased fetal O₂ tension because of reduced uterine blood flow due to hypocarbia-induced vasoconstriction of uterine arteries. This effect occurs because of the mechanical effects of hyperventilation causing decreased maternal venous return and because of a shift in the maternal oxyhemoglobin dissociation curve to the left, thereby impairing O₂ transfer to the fetus. In the studies by Wulf and colleagues, fetal O₂ delivery was compromised when maternal pH exceeded 7.6 and PCO_2 was 15 mmHg.³²

Asthma

Approximately 1–4% of pregnancies are complicated by bronchial asthma.¹⁵ During the past decade, the prevalence, morbidity, and mortality of asthma have all increased. In about 0.05–2% of cases, asthma presents as a life-threatening event. In general, data suggest that the severity of asthma during pregnancy improves in about one-third of women, remains stable in one-third and worsens in one-third of patients. In addition, there appears to be a tendency for the course of asthma to be similar in subsequent pregnancies.³⁵ The working group on Asthma and Pregnancy of the National Institutes of Health concluded that undertreatment, principally because of unfounded fears of fetal effects of medication, is the major problem in asthma management during pregnancy in the United States.^{36,37}

Traditionally, asthma treatment relied on symptomatic therapy with bronchodilators. This reflected the view of asthma as an intermittent illness that is primarily a bronchospastic event. However, recent pathophysiologic insights have defined more clearly the dominant role of chronic airway inflammation in bronchial hyperreactivity and exacerbations of reversible airway obstruction. Thus, asthma is now viewed as a chronic process characterized by acute exacerbations. Control of inflammation should minimize or eliminate the acute exacerbations and dramatically decrease morbidity and mortality from the illness.

Pathogenesis

Asthma is a lung disease involving airway obstruction that is partially or completely reversible and involves both airway inflammation and airway hyperresponsiveness to a variety of stimuli, including environmental irritants, viral respiratory infections, cold air, and exercise.¹⁵ Several mechanisms have been proposed to explain airway hyperresponsiveness in asthma, including airway inflammation, abnormalities in bronchial epithelial integrity, alterations in autonomic neural control of airways, changes in intrinsic bronchial smooth muscle function, alterations in the volume and composition of the airway liquid lining layer, defects in control of bronchial blood flow, and abnormal airway geometry.¹⁵ Airway inflammation is thought to be a key factor in airway hyperresponsiveness, even in individuals with mild asthma. Cellular infiltrates of eosinophils, neutrophils, lymphocytes, mast cells, and macrophages are present. During an asthmatic attack, the release of inflammatory mediators leads to migration and activation of more inflammatory cells, destruction of the epithelial cell layer integrity, abnormalities of autonomic neural control of airway tone, changes in mucociliary function, and increased airway smooth muscle responsiveness.¹⁵ Desquamation of epithelial cells and alteration in their barrier function as a consequence of the airway inflammatory process can lead to increased permeability to inhaled allergens and other pro-

voking agents, impaired mucociliary clearance, impaired metabolism of peptide hormones, impaired regulation of the bronchial fluid lining layer, and increased response to cholinergic stimulation.¹⁵ Although airway smooth muscle is clearly hypertrophic in asthma, it does not show increased constriction to pharmacologic stimulation. However, there may be impaired relaxation characteristics of the airway smooth muscle *in vivo*. Narrowing of the airway lumen may also occur through the development of bronchial mucosal edema, inflammatory cellular infiltrates, excess mucus and fluid, and smooth muscle hypertrophy or constriction. This narrowing may contribute to airway hyperresponsiveness.¹⁵

Exacerbations of asthma manifest as acute or subacute episodes of progressively worsening shortness of breath, cough, wheezing, or chest tightness. Exacerbations are characterized by decreases in expiratory air flow and an increase in FRC, leading to increased work in breathing, use of accessory muscles of respiration, hypoxemia because of mismatching of ventilation and perfusion, hypercapnia due to respiratory muscle failure, increases in pulmonary vascular resistance, and the development of negative pleural pressures associated with lung hyperinflation manifested by pulsus paradoxus.¹⁵ In an acute asthma exacerbation, maternal P_{aO_2} falls. Because the fetus operates on the steep portion of the O_2 dissociation curve (normal fetal venous P_{aO_2} is close to 33 mmHg), decreases in maternal P_{aO_2} below 60–70 mmHg result in a rapid and profound decrease in fetal O_2 saturation and fetal hypoxia. Careful monitoring of the fetal heart rate is essential in the late second or third trimester in a clinically unstable or marginally hypoxic mother.¹⁵

Effects on pregnancy

Two large epidemiologic studies have clearly defined the potential adverse effects of maternal asthma on pregnancy and the infant. One study described pregnancy outcomes in 381 women with asthma compared with a control population of 112 530 pregnant women with no medical illness.³⁸ There was a statistically significant increase in preterm births and low birthweights, decreased mean birthweight, and increased neonatal mortality in the pregnancies of women with asthma compared with control pregnancies. These investigators also found a statistically significant increase in hyperemesis gravidarum, vaginal hemorrhage, preeclampsia, and induced and complicated labors in the women with asthma compared with normal control subjects. No increased incidence of congenital malformations was found. Another study compared pregnancy outcomes between 277 women with asthma and the entire cohort population of 30 861 women.³⁹ A statistically significant increase in perinatal mortality was found in the pregnancies of women with asthma compared with the control women. Subsequent studies have reported increases in low birthweight infants, chronic hypertension, and preeclampsia in the pregnancies of women with asthma compared with those of women without asthma.^{40–42}

The mechanism(s) of the potential adverse effects of asthma on pregnancy and the infant have not been fully defined. However, good asthma control is perhaps the most important factor in improving maternal and fetal outcomes.³⁷ Acute exacerbations of asthma are associated with maternal hypoxia as well as hypocapnia and alkalosis, factors that may further impair fetal oxygenation.³⁷ Relative hypoxia in high-altitude pregnancies is associated with lower infant birthweight, and chronic hypoxia seen in women with cyanotic heart disease is associated with both fetal growth restriction and prematurity.¹⁵ Lower mean birthweights occur in infants whose mothers are hospitalized for asthma during pregnancy compared with infants whose mothers did not require emergency therapy for asthma.¹⁵ In addition, diminished pulmonary function is associated with decreased birthweight and asymmetric growth restriction in infants of asthmatic mothers.¹⁵

Another recent study suggests that asthma morbidity during pregnancy is related to the original severity classification of mild, moderate, or severe based on the 1993 National Asthma Education Program Working Group on Asthma recommendations.⁴² In this investigation, 1793 patients with asthma were evaluated throughout pregnancy. Exacerbations during pregnancy occurred in 12.6% of patients initially classified as mild, in 25.7% of patients classified as moderate, and in 51.9% of patients classified as severe. Although the course of asthma may change during pregnancy, with up to 30% of patients manifesting an increasing severity classification during pregnancy,⁴² experience in a previous pregnancy often predicts the course of asthma in a subsequent gestation. The condition of women with severe asthma before pregnancy is more likely to deteriorate during pregnancy. The variable effect of pregnancy on the course of asthma appears to be more than random fluctuations in the natural history of the disease because the changes generally revert to the prepregnancy level of severity within 3 months postpartum.^{15,43}

Effective management of asthma in pregnant women relies on four components:

- 1 patient education;
- 2 avoidance or control of environmental precipitating factors;
- 3 objective assessment of maternal lung function and fetal well-being;
- 4 pharmacologic therapy.^{15,37}

Patient education is an invaluable component of treating asthma during pregnancy. The key educational messages are that none of the drugs commonly prescribed for asthma during pregnancy is associated with significant teratogenic effects and that control of maternal symptoms (and thus fetal hypoxia) is vital to fetal and maternal well-being. This awareness often improves compliance with therapeutic recommendations and enhances fetal oxygenation in pregnant women who are justifiably concerned about the potential adverse effects of drugs taken during pregnancy. Other educational components are the nature of the disease, specifically identification of triggers, and proper utilization of medications prescribed for asthma. Written guidelines may be necessary for some patients.

Known environmental precipitants of asthma attacks should be eliminated. Cigarette smoke, either primary or secondary, is perhaps the most common of such agents. Animal dander is also highly allergenic; sensitive individuals should remove pets from their environments. An alternative strategy involves the use of 3% tannic acid shampoo to render such dander less allergenic. Mites are ubiquitous in most mattresses and in household dust, and mite feces is one of the most potent environmental allergens known. Thus, the patient's mattress should be enclosed in an airtight cover, and she should wear a mask or leave the house for 1 h after cleaning, vacuuming, or dusting (preferably performed by someone else!). Household filters in the heating and cooling systems should be changed regularly. When specific allergens have been identified, immunotherapy may be considered and is safe during pregnancy. Other common asthma triggers to avoid include sulfite food additives, aspirin, and beta-blockers.³⁷

Another preventive measure to be considered in women with a history of asthma is influenza vaccination. Since 1998, the American College of Obstetricians and Gynecologists and the Centers for Disease Control (CDC) have recommended influenza vaccination for all pregnant women who will be in the second and third trimester during influenza season. It is also recommended at all stages of pregnancy for women with chronic medical conditions such as asthma.⁴⁴ One population-based study by Hartert et al. in 2003 found that, after evaluating eight influenza seasons, those patients with asthma accounted for half of all respiratory-related hospitalizations.⁴⁵ With women in later stages of pregnancy being at increased risk of serious influenza-related maternal morbidity, particularly with underlying respiratory disease, patients with asthma should be strongly encouraged to be vaccinated.

Objective measurements of lung volumes or flow rates are essential for assessing and monitoring the severity of asthma in order to recommend appropriate therapy and to identify asthma attacks early in their course. This practice allows treatment even before the patient becomes overtly symptomatic. Such measures are desirable because both patient and physician perceptions of asthma severity are often insensitive or inaccurate.⁴⁴ Furthermore, objective measures of lung function differentiate asthma from other causes of dyspnea during pregnancy. The single best measure of pulmonary function for assessing the severity of asthma is the FEV. However, the peak expiratory flow rate (PEFR) correlates well with FEV and can be measured reliably with inexpensive, portable peak flowmeters. Because PEFR reflects only large airway function, its measurement may not be sufficient to diagnose or fully evaluate the severity of asthma. Nevertheless, patient PEFR monitoring at home is valuable for giving insight into the course of asthma throughout the day. Such monitoring is important for assessing circadian variation in pulmonary function (an indication of airway hyperresponsiveness), detecting early signs of deterioration (often before symptoms appear), and assessing response to therapy (Table 40.3).^{15,37}

In general, pregnant women with moderate to severe asthma should make daily PEFR measurements at home with a peak flowmeter. Ideally, the measurements should be made and recorded twice a day, in the morning on rising and approximately 12 h later. These records should be brought to each prenatal visit. Predicted values of PEFR are in the range 380–550 ml³/min for women, and these values do not change during pregnancy. Rather than use the predicted value, however, it is often better to establish a personal best PEFR for each patient after a period of monitoring when the asthma

is well controlled. This is most easily performed by administering a “burst” of corticosteroids (such as prednisone, 40 mg p.o., tapering over the course of 1 week). Recommendations for adjustments in asthma therapy may then be based on deviations from this personal best level.

Early sonography provides a benchmark for progressive fetal growth. Sequential sonographic evaluations of fetal growth are indicated in the second and third trimesters if asthma is moderate or severe or if fetal growth restriction is suspected. Antepartum fetal surveillance in the third trimester should be used as needed to ensure fetal well-being. Daily maternal assessment of fetal activity in the late third trimester should be encouraged.^{15,37}

Because asthma is an airway disease, inhalation therapy is generally preferable to systemic treatment. Aerosolized medications deliver the drug directly to the airways, minimizing systemic side-effects. Inhaled β_2 -agonists, by themselves, are usually sufficient therapy for mild, intermittent asthma (Table 40.4).³⁷ If symptoms disappear and pulmonary function normalizes with inhaled β_2 -agonists, they can be used indefinitely as needed. However, their use on a daily basis, or even more often than three times a week, usually indicates a need for anti-inflammatory therapy.^{15,37} The category of moderate asthma includes patients who, before treatment, have symptoms that are not controlled or that are poorly regulated by episodic administration of a β_2 -agonist. Some patients have frequent (more than three times a week) symptomatic exacerbations of asthma. Others do not have acute exacerbations and can regulate symptoms by modulating their lifestyle, even though

Table 40.3 Status asthmaticus: warning signs of fatal attack.

Previous or recurrent episodes of status asthmaticus, especially previous intubation
FVC <1.0L; FEV ₁ <0.5L; PEFR <100L/min
Little or no response to bronchodilator therapy at 1h (Δ FEV ₁ of <400mL; Δ PEFR of <60mL/min)
Altered consciousness
Unequivocal central cyanosis; arterial PO ₂ of <50mmHg
PCO ₂ of >45mmHg
Pulsus paradoxus
Echocardiographic abnormalities
Presence of pneumothorax or pneumomediastinum

FEV₁, forced expiratory volume in 1 second; FVC, forced vital capacity; PEFR, peak expiratory flow rate.

Table 40.4 Drugs and dosages for asthma and associated conditions preferred for use during pregnancy.

Drug class	Specific drug	Dosage
Anti-inflammatory	Cromolyn sodium	2 puffs q.i.d. (inhalation) 2 sprays in each nostril b.i.d.–q.i.d. (intranasal for nasal symptoms)
	Beclomethasone	2–5 puffs b.i.d.–q.i.d. (inhalation) 2 sprays in each nostril b.i.d.–q.i.d. (intranasal for allergic rhinitis)
	Prednisone	Burst for active symptoms: 40mg/day, single or divided dose for 1 week, then taper for 1 week. If prolonged course is required, single morning dose on alternate days may minimize adverse effects
Bronchodilator	Inhaled β_2 -agonist	2 puffs every 4h as needed
Antihistamine	Theophylline	Oral: Dose to reach serum concentration level of 8–12mg/mL
	Chlorpheniramine	4mg by mouth up to q.i.d. 8–12mg sustained-release b.i.d.
	Tripelennamine	25–50mg by mouth up to q.i.d. 100mg sustained-release b.i.d.
Decongestant	Pseudoephedrine	60mg by mouth up to q.i.d. 120mg sustained-release b.i.d.
	Oxymetazoline	Intranasal spray or drops up to 5 days for rhinosinusitis
Cough	Guaifenesin	10mL by mouth q.i.d.
Antibiotics	Dextromethorphan	
	Amoxicillin	3 weeks therapy for sinusitis

This table presents drugs and suggested dosages for the home management of asthma and associated conditions. Drugs and dosages for the treatment of exacerbations in the emergency department or hospital are presented in the full report of the working group.

From ref. 37, with permission.

their pulmonary function (FEV or PEFR) is 60–80% of the predicted range.^{15,37}

Inhaled anti-inflammatory agents are the primary therapy for moderate asthma. Choices include cromolyn sodium or inhaled corticosteroids, which provide effective asthma control with minimal side-effects at recommended doses. However, suppression of symptoms and PEFR improvement are often not maximal until 2–4 weeks of treatment. A spacer, used to bypass the oropharynx during the administration of aerosolized medication, should be considered not only to reduce oropharyngeal candidiasis but also to improve respiratory tract penetration and reduce systemic effects. A short tapering course of oral corticosteroids is indicated when asthma is not controlled by a combination of bronchodilators, cromolyn sodium, and inhaled corticosteroids. Such deterioration of asthma may be characterized by a reduction in PEFR of 20% or more from normal values that fails to respond to inhaled bronchodilators, by greater intolerance of exercise, or by the development of nocturnal symptoms. At the end of this course, oral corticosteroids can be stopped; if asthma symptoms do not recur and pulmonary functions remain normal, no additional oral steroid therapy is necessary. However, if this burst of prednisone does not control symptoms, is effective for less than 10 days, or must be repeated frequently, the patient has severe asthma and needs additional therapy.^{15,37}

Leukotriene modifiers, such as montelukast (Singulair) and zafirlukast (Accolate), are available for the treatment of asthma. The cysteinyl leukotrienes (LTC₄, LTD₄, and LTE₄) are produced by way of arachidonic acid metabolism and are released by mast cells and eosinophils. They then bind to leukotriene receptors in the human airway, causing airway edema, smooth muscle contraction, and altered cellular activity. Leukotriene modifiers bind to these leukotriene receptors, inhibiting the actions of leukotriene at the level of the mast cell and eosinophil. These medications are pregnancy category B and may be continued during pregnancy.³⁷

Sustained release theophylline or a long-acting oral agonist once a day in the evening may be helpful for the patient with primarily nocturnal symptoms. Otherwise, oral theophylline is generally not used in current clinical practice. Asthma not controlled on maximal doses of bronchodilators and inhaled anti-inflammatory agents is classified as severe, and these patients may also need oral corticosteroids on a routine basis. Although the prolonged use of high doses of oral corticosteroids may be associated with increased risk of gestational diabetes and maternal adrenal insufficiency, use of these agents is justified in women with chronic severe asthma to avoid potentially fatal attacks.

Several risk factors for fatal asthma have been identified, and these include the following:

- a history of intubation for asthma;
- two or more hospitalizations for asthma within 1 year;
- three or more emergency room visits for asthma within 1 month;
- recent withdrawal from systemic corticosteroids;

- history of syncope or seizure associated with an asthmatic attack;
- previous admission to a hospital intensive care unit for asthma;
- coexisting psychiatric disease or psychosocial problems.

Individuals with one or more of these risk factors require especially intensive patient education, close monitoring, and prompt treatment of exacerbations.⁴⁸

For symptomatic exacerbations with PEFR above 80% of baseline, the patient administers two puffs of a β_2 -agonist inhaler every 20 min for up to 1 h if needed. If the response is good (PEFR of more than 70%), two puffs every 3–4 h are given for 6–12 h. If the response is not good (PEFR of less than 70%), the patient must begin or increase a dose of inhaled or systemic corticosteroids. If the PEFR is less than 50% of baseline, the patient is instructed to seek immediate medical attention. It is important to emphasize to patients that they should not delay seeking medical help if an asthma exacerbation is severe, if therapy does not give rapid improvement, if sustained improvement is not achieved, or if there is further deterioration.³⁷

The emergency management of acute, severe asthma in pregnancy involves several initial steps:

- 1 Administer O₂ to maintain a P_{aO_2} as near normal as possible but at least above 60 mmHg or O₂ of at least 95%.
- 2 Perform baseline arterial blood gases, continuous pulse oximetry, and intensive fetal monitoring for late second- or third-trimester fetuses.
- 3 Obtain baseline pulmonary function tests (FEV or PEFR).
- 4 Administer an inhaled β -agonist, such as albuterol, 2.5 mg in 2–3 mL of diluent with a pressure-driven nebulizer, every 20 min for up to three doses. Alternately, terbutaline sulfate, 0.25 mg, is administered subcutaneously every 20–30 min for up to three doses.

Further management is based on clinical response and improvements in pulmonary function testing. If these maneuvers improve the PEFR to more than 70% of baseline, the patient may be discharged, often with a short course of oral corticosteroids. For a PEFR that is 40–70% of baseline, the β -agonist therapy is continued (at intervals as frequent as every hour in patients without heart disease) and methylprednisolone, 80 mg every 6 h, is initiated. If the initial response results in a PEFR less than 40% of baseline, the patient should be admitted to hospital. A PEFR of less than 25% or PCO_2 of more than 35 mmHg suggests imminent respiratory failure. The patient should be admitted to an intensive care unit, where intravenous aminophylline may be added and nebulized beta-agonist therapy intensified. Intubation may be necessary if deterioration continues^{15,37,43} (see Table 40.3).

Other obstructive lung disorders

Severe emphysema due to α_1 -antitrypsin deficiency and cystic fibrosis (CF) can occur in women of childbearing age. Care of

these patients is primarily supportive, with attention to the physiologic parameters of lung function and oxygenation discussed earlier. As noted, the effect of pregnancy on these diseases and the effect of these diseases on fetal outcome are more variable than with restrictive lung disorders. This is true primarily because pulmonary function can deteriorate rapidly as a result of the respiratory infections that frequently complicate these diseases.

A National Institutes of Health study followed 129 pregnancies in CF patients and found only 86 viable infants, leading the investigators to conclude that CF patients have greatly increased fetal wastage.⁴⁹ In the study, there were six spontaneous abortions, 25 therapeutic abortions, and 11 perinatal deaths. Ten of the perinatal deaths occurred in infants born at less than 37 weeks' gestation. Premature labor occurred in 26 of the 129 pregnancies, and infant mortality was 18% within 24 months of delivery.

The authors recommended that pregnancy be avoided unless the potential CF mother was clinically healthy. Published studies relate the severity of maternal disease at the onset of pregnancy more than the effects of CF on pregnancy to outcomes.^{50,51} Factors such as pancreatic insufficiency, nutritional status, and low Taussig score were predictors of poor prognosis in pregnancy. Any woman with pulmonary hypertension should not undertake pregnancy.⁵⁰ A reasonable set of guidelines is to advise against pregnancy in any CF patient with a vital capacity (VC) of less than 50% of predicted, hypoxemia, pulmonary hypertension, or pancreatic insufficiency. The absence of pancreatic insufficiency may identify a subgroup more able to tolerate pregnancy.⁵² A recent study showed that women with CF, after adjusting for demographic differences, who became pregnant did not have worse survival.⁵³

Bronchial drainage, antibiotic therapy, prophylactic immunization (including annual influenza vaccine administration), and optimal nutritional and psychosocial care are essential components in the care of the CF patient contemplating pregnancy. Respiratory infections may be responsible for increased fetal and maternal mortality during pregnancy. Although the use of continuous antibiotic prophylaxis is controversial, therapy for acute exacerbations accompanied by a change in sputum character is effective.⁵⁴ Therapy is often given intravenously with antibiotics directed against *Pseudomonas aeruginosa* and *Staphylococcus aureus*, which commonly infect CF patients. Antibiotic therapy can be guided further by the results of sputum cultures. Most pregnant women with CF can successfully breastfeed, maintaining their own weight and supporting the growth of a healthy infant.⁵⁵

Patients with α_1 -antitrypsin deficiency or bronchiectasis are managed using the same principles. All should be regarded as high-risk patients, and serial spirometries and blood gas analyses are indicated.

Aspiration of stomach contents

The aspiration of low-pH liquid stomach contents into the tracheobronchial tree, with subsequent chemical pneumonitis, was first described in women undergoing labor and delivery. This syndrome is most likely to develop if aspirated material has a pH of less than 2.5, but some reports suggest that some degree of respiratory dysfunction can occur even if the pH of the aspirate is higher.^{56,57} Other syndromes that can result from aspiration are bronchial obstruction by an aspirated foreign body and bacterial pneumonia from aspiration of oropharyngeal bacteria. Foreign body aspiration is managed by bronchoscopic removal, whereas aspiration pneumonia is treated with antibiotics, chosen on the basis of whether the event occurred out of hospital, shortly after admission, or during a prolonged hospitalization.⁵⁸

In the pregnant patient, the acid aspiration syndrome is encountered more frequently and can lead to maternal mortality.⁵⁹ The pregnant woman is vulnerable to this problem because increased circulating progesterone levels tend to relax the esophageal sphincter and because the gravid uterus can compress the stomach and elevate intragastric pressure. Labor itself delays gastric emptying and, in one study, 55% of intrapartum patients had more than 40 mL of liquid gastric juice and 42% had a pH of less than 2.5.⁶⁰ Forceful abdominal manipulation and obtundation during anesthesia also add to the risk of aspiration.

In aspiration pneumonitis, there is generally a delay of at least 6–8 h before the first appearance of signs and symptoms such as bronchospasm, tachycardia, hypotension, tachypnea, cyanosis, and frothy pink sputum. Treatment of acid aspiration is supportive with O₂ and mechanical ventilation if needed. If aspiration is observed, endotracheal suctioning should be performed, but saline lavage is not indicated and may even serve to spread the acid to uninvolved areas. Bronchodilators may be used to control bronchospasm, and the prophylactic use of broad-spectrum antibiotics should be considered. Corticosteroids have been used in the treatment of witnessed gastric aspiration, but are of unproven benefit.

Prophylaxis of aspiration should always be undertaken in the pregnant patient undergoing surgery, with antacids given during labor to raise the gastric pH to more than 2.5 and thus reduce the chance of a dangerous aspiration. One study found that the risk of serious aspiration of gastric fluid with a pH of more than 2.5 could be reduced with the use of 30 mL of antacid given every 3 h after the onset of labor.⁶¹ Gibbus and colleagues have demonstrated that adverse pulmonary reactions may result from aspirating antacid particles; thus, the use of nonparticulate agents is preferred.⁶² Recently, various combinations of oral nonparticulate antacids and H₂-receptor blockers have been advocated as a convenient prophylactic regimen for patients about to undergo elective or emergency Cesarean section, but no particular combination appears to be clearly superior.⁶² Additional prophylactic measures include

limiting oral intake to essential medications once labor has started, nasogastric evacuation of a distended stomach, selection of regional anesthesia when possible, use of a cuffed endotracheal tube, and use of cricoid pressure during intubation.

Bacterial pneumonia

Pneumonia of all etiologies is a relatively common cause of maternal mortality. It has been reported in 0.1–0.84% of all pregnancies, with a mortality rate of 3.5–8.6%,⁶³ although antibiotics and modern obstetric care have improved the prognosis.⁶⁴ *Streptococcus pneumoniae* is the most common infectious agent implicated in antepartum pneumonia, and other common bacterial pathogens include *Mycoplasma pneumoniae* and *Haemophilus influenzae*.⁶⁴ *Legionella pneumoniae* and *Listeria monocytogenes* have rarely been reported to cause respiratory failure in pregnancy.^{65–67}

Pneumococcal pneumonia classically begins with the abrupt onset of shaking chills, fever, pleuritic chest pain, cough productive of purulent sputum, and shortness of breath. The physical examination often shows signs of consolidation, such as dullness to percussion, tactile fremitus, and egobronchophony. A chest radiograph usually reveals evidence of lobar consolidation, but bronchopneumonia may also occur. Laboratory examination may reveal a polymorphonuclear leukocytosis in the range of 12 000–25 000 cells/mL, but a normal white blood cell count can also be seen, especially in patients with overwhelming infection and bacteremia. A sputum specimen for culture and Gram's stain should generally be obtained and may demonstrate Gram-positive encapsulated cocci in pairs and short chains. Blood cultures are positive in approximately 20–30% of patients and should be collected before the administration of antibiotics.

Although penicillin U has long been considered the antibiotic of choice, recent evidence suggests that penicillin nonsusceptibility is found in nearly 40% of strains of *Streptococcus pneumoniae* causing disease in adults.^{68,69} Given this, any gravid patient thought to have bacterial pneumonia should be admitted to the hospital and started on a third-generation cephalosporin and a macrolide (e.g., azithromycin) until sputum culture reveals the causal organism and sensitivities. Once established, antibiotic treatment can be tailored to the responsible organism. This will typically lead to defervescence within 48 h. Once the patient is afebrile for 48 h, parenteral antibiotic therapy can be discontinued and oral cephalosporin continued for 10–14 days.⁶⁹

Mycobacterium pneumoniae produces symptoms similar to a viral infection, with a flu-like syndrome, interstitial infiltrates, and alveolar filling. Small pleural effusions are common, and approximately 50% of affected patients have cold agglutinins in their serum. Because tetracycline is relatively contraindicated in pregnancy, erythromycin is the drug of choice. *Haemophilus influenzae* pneumonia may have a gradual rather than an abrupt onset and may be clinically indistinguishable from *S. pneumoniae*. It is infrequently seen

in young adults unless the patient has a history of chronic obstructive lung disease or is an alcoholic. Sputum Gram's stain usually shows abundant neutrophils and pleomorphic coccobacillary Gram-negative organisms. The chest radiograph may show either bronchial or lobar consolidation, and pleural effusions are common. Again, because the occurrence of ampicillin resistance may be significant,⁷⁰ the patient should be managed as stated above with susceptibility testing performed on all culture isolates and antibiotic therapy tailored appropriately.

Influenza

Although the exact mortality rate from influenza during pregnancy is not known, during the 1918 influenza epidemic, maternal mortality with the illness varied from 30% to 50%.^{71,73} In one study from the 1957 epidemic, pregnancy increased mortality ninefold in the 20- to 29-year age group.⁷³ In a review of all deaths due to influenza from 1957 through 1960, 1–11% occurred in pregnant patients.⁷³ These deaths were concentrated late in the third trimester and early puerperium and were more likely to occur with increased maternal age. In more recent studies, 39–60% of asymptomatic pregnant women had serologic evidence of recent influenza infection, and up to 35% of pregnant symptomatic women had no serologic evidence of recent influenza infection.^{71,74,75} Because earlier studies were based on the clinical diagnosis of influenza, the conclusion that pregnancy predisposes to infection or to an enhanced severity of illness is controversial.⁷¹

Influenza usually begins abruptly with systemic symptoms, such as headache, fever, chills, myalgia, and malaise accompanied by an upper respiratory illness. In an uncomplicated case, complaints of a sore throat and cough may persist for a week or more. Physical findings may be minimal, but reddened engorgement of the mucous membranes and a postnasal discharge can be seen along with mild cervical adenopathy. The chest examination may be normal but can reveal rhonchi, wheezes, and scattered rales. Occasionally, the disease can progress rapidly to fulminant cardiopulmonary failure, or it can be complicated by secondary bacterial or mixed viral–bacterial pneumonia involving *Streptococcus*, *Staphylococcus*, or *H. influenzae*.

Amantadine, an oral antiviral agent active against influenza A, can be used therapeutically and prevents 70–90% of experimentally produced and natural infections. It is not effective in treating infections due to influenza B. If used within 48 h of the onset of symptoms, amantadine shortens the duration of the illness by up to 50%, reduces fever, and hastens the resumption of normal activities.^{76,77} If given concomitantly with an influenza vaccine, it can protect the patient for the 2–3 weeks necessary for immunity to develop during exposure to an epidemic. Other antivirals, such as zanamivir and oseltamivir, may reduce the duration of uncomplicated influenza A and B. No clinical study has been conducted regarding the safety or efficacy of any of these antiviral med-

ications during pregnancy. Because safety during pregnancy has not been adequately established, the Committee on Obstetric Practice recommends that these medications be used only if the practitioner thinks the “potential benefits justify the potential risks.”⁷⁶

Although influenza virus can cross the placenta, it has not been isolated from fetal blood,⁷¹ and transplacental passage does not appear to cause congenital defects. Fetal abnormalities, such as circulatory defects, central nervous system malformations, cleft lip, and childhood cancer, have been attributed to influenza, but most investigators have concluded that no influenza-induced congenital syndrome exists.^{71,78} Influenza vaccine may be administered appropriately in pregnant women in any trimester with standard indications for such immunization. Because increased mortality from infections usually occurs late in pregnancy, vaccination can often be delayed until the middle of the second trimester if necessary.⁷⁹

Viral pneumonia

Other life-threatening viral pneumonias can develop in the pregnant patient, including varicella pneumonia, which may accompany chickenpox and can range from a mild to a rapidly fatal illness. In pregnancy, varicella is rare; however, if pneumonia develops, mortality is high, ranging from 30% to 40% in some series.^{80–82} Varicella pneumonia has been associated with an increased incidence of premature labor.⁸² The pneumonia can be completely asymptomatic but, in its severe form, it is accompanied by tachypnea, high fever, cough, dyspnea, and pleuritic chest pain. The chest examination may be unimpressive and correlates poorly with the severity of the pneumonia, but the chest radiograph usually shows extensive bilateral, peribronchial, fluffy, nodular infiltrates, which are more prominent when the skin eruption is maximal.⁸² In severe cases, rapid pulmonary deterioration requiring intubation can occur within a matter of hours. Maternal varicella infection in any trimester of pregnancy can be associated with infrequent, but possibly lethal, congenital anomalies. If the maternal infection occurs within 5 days of delivery, the infant is at risk of fatal disseminated infection. Given the high mortality rate associated with varicella pneumonia occurring in pregnancy and the lack of demonstrated human fetal toxicity, it is recommended that any gravid patient with varicella pneumonia be admitted to the hospital for parenteral therapy with acyclovir. The dose is 500 mg/m² every 8 h and should be continued until symptoms of the illness resolve.^{83,84} An important consideration of varicella pneumonia during pregnancy is the issue of prevention. Patients considering pregnancy should be questioned regarding their history of varicella and, if unsure, titers should be drawn to confirm immunity. If the patient is not immune, then the varicella vaccine can be given prior to pregnancy. If the patient is not immune, but exposed to varicella peripartum, many authors have recommended administration of varicella zoster immune globulin.⁸⁵

Fungal pneumonia

Cryptococcus neoformans, *Blastomyces dermatitidis*, and *Sporothrix schenckii* have rarely been reported as causing serious respiratory infection in pregnancy. The clinical course and outcome are generally the same in pregnant and nonpregnant patients.⁸⁶ It has been estimated that coccidioidomycosis occurs in less than 1 in every 1000 pregnancies.⁸⁷ However, infection in pregnancy, particularly during the second and third trimesters, increases the rate of disseminated infection from 0.2% to more than 20%.⁸⁷ It has been suggested that 17 β -estradiol has a stimulatory effect on the fungus and may be responsible for the increased risk of dissemination associated with pregnancy.⁸⁸ Maternal mortality rate from disseminated coccidioidomycosis approaches 100%, a rate approximately twice that seen in nonpregnant patients,⁸⁷ and dissemination is associated with increased fetal prematurity and mortality.⁸⁷

Symptomatic pulmonary coccidioidomycosis manifests as cough, fever, chest pain, malaise, and occasionally hypersensitivity reactions. Chest radiography may show an infiltrate, hilar adenopathy, or pleural effusions. The peripheral blood count may show eosinophilia. The diagnosis is made by serologic testing and by culture and wet smear examination of sputum, urine, and pus. Dissemination should be suspected in the setting of rapidly progressive respiratory failure with a clinical picture similar to miliary tuberculosis.⁶⁵

Amphotericin B has been used to treat cryptococcoses, blastomycosis, and disseminated coccidioidomycosis in pregnancy.^{86,87} It crosses the placenta and can be found in both amniotic fluid and fetal blood. Although use in pregnancy has not been well studied, normal, full-term infants have been born to patients who received amphotericin B in the first trimester.⁸⁸ Its use is associated with anemia; thus, serial hematocrits must be followed.

Pneumocystis carinii pneumonia

Pneumocystis carinii pneumonia is the most common opportunistic infection affecting the lungs of patients with acquired immunodeficiency syndrome (AIDS).^{89–92} It can be confused with atypical mycobacterial infection, cryptococcoses, and histoplasmosis. Clinically, *P. carinii* pneumonia manifests with fever, dyspnea, and nonproductive cough, which may have an insidious onset followed by a rapid progressive deterioration. Arterial blood gases usually demonstrate hypoxemia with an increased alveolar–arterial gradient and respiratory alkalosis, and the chest radiograph classically shows bilateral diffuse infiltrates beginning in the perihilar regions and lower lung fields that progress to involve the entire parenchyma. Diagnosis is made by specific staining of sputum, bronchial aspirates, or material obtained by bronchoscopically performed bronchoalveolar lavage or biopsy.

There are several case reports of *P. carinii* pneumonia (PCP) complicating pregnancy^{90–92} and evidence to suggest that PCP

has a more aggressive course during pregnancy, with increased morbidity and mortality. Because of the current level of asymptomatic human immunodeficiency virus (HIV) infection and because women of childbearing age represent a significant portion of some of the groups at risk for AIDS, the number of infected mothers will continue to increase. In one published case series of 22 pregnant women with PCP, 60% of these patients required mechanical ventilation and 11 patients died of pneumonia. These patients were treated with a variety of regimens, but the treatment of choice in pregnant women with AIDS and *P. carinii* pneumonia is trimethoprim-sulfamethoxazole (SXT).⁹² Concomitant use of steroids is controversial. Studies of *in utero* exposure to SXT failed to show an increase in prematurity, hyperbilirubinemia, or kernicterus.⁹³ Patients should be monitored for drug toxicity, such as rash, fever, neutropenia, thrombocytopenia, and hepatitis. Nausea and vomiting may occur and can exacerbate hyperemesis gravidarum. Pentamidine is an alternative therapy, but its use has not been studied in pregnancy.

In patients who cannot tolerate trimethoprim-sulfamethoxazole, pentamidine may be required because of the life-threatening risk of withholding treatment from the mother.⁹⁴ If pentamidine is used, the mother should be closely monitored for hypoglycemia. Aerosolized pentamidine, because of poor systemic absorption and decreased systemic side-effects, has been advocated as safe, effective prophylaxis for *P. carinii* pneumonia.⁹⁵ Treatment of even mild cases of *P. carinii* pneumonia with aerosolized pentamidine may be effective, but some investigators have discouraged this therapy because of a concern about treatment failure.⁹⁶ Pyrimethamine-sulfadoxine has been used as prophylaxis, and no fetal malformations have been associated with its use. However, because it is a folate antagonist, it should be used cautiously. Prophylaxis against PCP with trimethoprim-sulfamethoxazole is known to be very effective, with rates of prevention of 90–95%.⁹⁶ Given this, in pregnant patients with known HIV-positive status, prophylaxis should be strongly considered.

Amniotic fluid embolism

Amniotic fluid embolism (AFE) is a devastating, pregnancy-specific condition in which both maternal and fetal death is the most probable outcome.⁹⁷ It is one of the principal causes of maternal death in developed countries. In a high percentage of survivors, profound neurologic impairment is seen. Although an immunologic basis for this syndrome (similar to anaphylaxis) has been postulated and discussed for decades, a recent report from the national AFE registry provided direct support for the anaphylactoid nature of this condition, based on marked clinical similarities between a large series of patients with AFE and patients with both septic and anaphylactic shock.⁹⁷

Clinically, AFE manifests by the sudden development of hypoxia, hypotension, or cardiac arrest and disseminated

Table 40.5 Signs and symptoms found in patients with amniotic fluid embolism.

Sign or symptom	No. of patients	%
Hypotension	43	100

intravascular coagulation (DIC). All components of the full AFE syndrome are not invariably present. AFE occurs as fetal tissue enters the maternal circulation and incites the reaction described above, probably via the release of various endogenous mediators. This most commonly occurs during labor but, in susceptible maternal-infant pairs, it has clinical onset at the time of Cesarean section with roughly the same frequency as the Cesarean rate in the general population.⁹⁷

In the past, a pattern of hypertonic uterine contractions was implicated in the genesis of AFE.⁹⁸ This theory has been clearly rejected on statistical, clinical, and theoretical grounds.^{98,99} Uterine hypertonicity, similar to that seen with eclamptic seizures, is a response to hypoxia and stress-induced norepinephrine release, and is an early manifestation of impending hemodynamic collapse.¹⁰⁰ Fetal bradycardia commonly precedes maternal physiologic manifestations. Commonly observed clinical signs and symptoms are outlined in Table 40.5.⁹⁷

There is currently no way to predict or prevent AFE. Treatment of the mother is supportive and involves the administration of O₂ in response to clinical hypoxia, preload and inotropic support of falling blood pressure, and blood component replacement for DIC with clinical hemorrhage. With the development of lethal cardiac dysrhythmia, standard basic and advanced cardiac life support protocols should be instituted.

In the presence of maternal cardiac arrest, maternal survival without profound neurologic impairment is rarely achieved.⁹⁷ However, a clear relationship exists between arrest-to-delivery interval and neonatal outcome (Table 40.6).⁹⁷ Thus, expeditious perimortem Cesarean section should be initiated on the diagnosis of maternal cardiac arrest, regardless of its etiology, assuming the gestation has advanced to the point of fetal via-

Table 40.6 Cardiac arrest-to-delivery interval and neonatal outcome in amniotic fluid embolism.

Interval (minutes)	Survival (no. of subjects)	Intact survival (no. of subjects)
< 5	3/3	2/3 (67%)
5–15	3/3	2/3 (67%)
16–25	2/5	2/5 (40%)
26–35	3/4	1/4 (25%)
36–54	0/1	0/1 (0%)

bility.⁹⁷ When maternal hemodynamic or respiratory instability exists short of frank arrest, the situation becomes far more complex, and valid generalizations about fetal intervention are not possible.

The diagnosis of AFE is a clinical one based on physiologic manifestations and must be made after the exclusion of other conditions, such as myocardial infarction and pulmonary thromboembolism. The presence of a consumptive coagulopathy, although not required for the diagnosis of AFE, supports its diagnosis because acute consumptive coagulopathy in obstetrics is limited to AFE and placental abruption.^{97,98,101} Further, because placental abruption provides a classic opportunity for admixture of placental thromboplastin and other tissue of fetal origin with the maternal circulation, these two entities commonly occur together, with clinical manifestations depending on the maternal response to the fetal tissue.¹⁰² Because some fetal debris is commonly found in the maternal circulation, the presence or absence of histologic pulmonary findings is not sufficient by itself to make the diagnosis of AFE, nor does its absence rule this syndrome out in the presence of appropriate clinical manifestations.^{98,99}

Venous air embolism

Venous air embolism may account for as many as 1% of maternal deaths,⁶⁵ with risk factors being the performance of surgery, intravenous infusions, and central venous catheter placement. However, because the venous sinuses of the uterus are particularly susceptible to the entry of air during pregnancy, air embolism can occur during normal labor, delivery of a placenta previa, criminal abortions using air, orogenital sex,¹⁰³ and insufflation of the vagina during gynecologic procedures.^{103,104} Maternal mortality associated with a clinically significant event exceeds 90% in untreated cases.¹⁰⁵ The severity of a venous air embolism depends on the amount and rate of air entry. Small amounts of venous air are clinically undetectable, but accidental bolus injections of 100–300 mL³ of air have been reported to be fatal.¹⁰³ However, there are reports of patients surviving infusions of up to 1600 mL³.^{105,106}

Embolization of a large bolus of venous air to the right ventricle results in mechanical obstruction to the forward flow of

blood in the pulmonary artery outflow tract.¹⁰⁷ In addition, the pumping action of the right ventricle acting on blood and air may produce platelet damage and fibrin formation, resulting in fibrin emboli that lodge in the pulmonary vascular bed. Maldistribution of pulmonary blood flow may result in ischemia or hyperperfusion, with the hyperperfused areas being susceptible to developing interstitial and alveolar edema. Areas that are initially ischemic may also become abnormally permeable once perfusion is restored.¹⁰⁷ In animal models, the permeability pulmonary edema after venous air embolism has been related to leukocyte production and the release of toxic O₂ metabolites.¹⁰⁸ Paradoxical embolization can occur if there is an atrial septal defect, resulting in arterial ischemia or occlusion.¹⁰⁹

The patient initially presents with a feeling of faintness, dizziness, fear of impending doom, dyspnea, cough, diaphoresis, and substernal chest pain.

Physical examination may reveal a state of altered consciousness, cyanosis, tachypnea, wheezing, tachycardia, hypotension, elevated jugular venous pressure, gallop rhythm, and an evanescent “mill wheel” or “waterwheel” murmur heard over the precordium.^{65,109} Paradoxical embolism may be evidenced by bubbles in the retinal arterioles, marble-like skin (air in superficial dermal vessels), and possibly stroke or myocardial infarction.¹⁰⁹ A blood gas test characteristically reveals hypoxemia, and there may be an associated metabolic acidosis. Chest radiography may occasionally demonstrate air in the right side of the heart or the main pulmonary artery, and the electrocardiogram may show signs of right heart strain, ischemia, or arrhythmia.^{65,109} Therapy must be instituted promptly, and the patient should be placed in the left lateral decubitus position to minimize obstruction to the right ventricular outflow tract.

Administration of 100% O₂ promotes removal of nitrogen from the air bubble and results in more rapid absorption of the embolus. Nitrous oxide is highly soluble and, in a patient receiving general anesthesia, it should be discontinued because it can increase the size of the air embolus.¹⁰⁶ In the presence of cardiovascular collapse, closed chest compression and aspiration of air from the right side of the heart via venous catheterization or transthoracic puncture have been suggested, although actual improved survival of pregnant women so treated has not been demonstrated. Hyperbaric O₂ may be useful in the setting of cerebral venous air embolism, and anticoagulation has been suggested to minimize the formation of fibrin microemboli.^{106,107} Mechanical ventilation may be necessary to treat permeability pulmonary edema.

Adult respiratory distress syndrome

Adult respiratory distress syndrome (ARDS) is the final common pathway of pathophysiologic changes occurring in the lungs as a consequence of a variety of acute bodily insults that reach the lung directly or via the vasculature (Table 40.7).

Table 40.7 Causes of adult respiratory distress syndrome in pregnant women.

Abruptio placentae
Air embolism
Amniotic fluid embolism
Aspiration
Bacterial pneumonia
Blood transfusion
Carcinomatosis
Dead fetus syndrome
Diabetic ketoacidosis
Drugs (narcotics, barbiturates)
Fat embolism
Fractures
Fungal and <i>Pneumocystis carinii</i> pneumonia
Head trauma
Inhaled toxin
Intra-abdominal abscess
Lung contusion
Nonthoracic trauma
Pancreatitis
Preeclampsia, eclampsia
Seizure
Septic abortion
Septicemia
Shock
Tocolytic therapy with sympathomimetics and glucocorticoids
Tuberculosis
Uremia

Clinically, patients present with marked respiratory distress, tachypnea, hypoxemia refractory to O₂ therapy, “stiff” non-compliant lungs that require high pressures to achieve inflation, and diffuse bilateral interstitial and alveolar infiltrates on chest radiograph.¹¹⁰ The central pathophysiologic event in ARDS is injury to the alveolar–capillary membrane, either directly or via mediators delivered by the pulmonary vasculature, which results in increased vascular permeability and non-cardiogenic pulmonary edema. Severe hypoxemia results from both increased shunting of unoxygenated blood and impaired ventilation and perfusion matching in the alveoli, with an arterial PO₂ of typically less than 50–60 mmHg despite an inspired O₂ concentration of 60% or more.¹¹¹ To make the diagnosis of ARDS, chronic pulmonary disease and left heart failure (cardiogenic pulmonary edema) must be excluded, and an appropriate precipitating event should be present. Right heart catheterization is often required to demonstrate that the pulmonary capillary hydrostatic pressure is not elevated,¹¹² but the data thus obtained should be assessed in the light of the expected decrease in colloid oncotic pressure during pregnancy and in the immediate postpartum period.¹¹³ Mortality in patients with ARDS continues to exceed 50%, a figure that has remained fairly constant over the last 20 years.¹¹⁴

In the pregnant patient, ARDS can be associated with many of the factors that complicate pregnancy and delivery, includ-

ing septicemia, AFE, aspiration of stomach contents, eclampsia, septic abortion, venous air embolism, abruptio placentae, blood transfusion (with white blood cell agglutination in the pulmonary circulation), dead fetus syndrome (with DIC), drug overdose (narcotics, barbiturates, aspirin), fat embolism (after long bone fracture), hemorrhagic shock, seizures, and overwhelming pneumonia. The incidence of ARDS in pregnancy is unknown but, in one general hospital respiratory care unit, 9.5% of all patients carried this diagnosis, and it is estimated that more than 150 000 cases occur annually in the United States.¹¹⁵

Pathophysiology

Except in cases of direct damage to the alveolar–capillary membrane (e.g., via inhaled toxins, aspiration, invasive organisms), the specific mechanisms that initiate lung injury in ARDS are generally incompletely understood. Multiple humoral and cellular mediators contribute to the intense inflammatory response that characterizes ARDS. These mediators include polymorphonuclear leukocytes, alveolar macrophages, platelets, free fatty acids, arachidonic acid metabolites (prostaglandins, leukotrienes, thromboxane A), fibrin-derived peptides, and tumor necrosis factor.^{111,116–119} Initial injury to the alveolar–capillary membrane results in increased endothelial cell permeability and noncardiogenic pulmonary edema.^{111,120,121} This capillary leak is the earliest finding in ARDS and results in the accumulation of protein-rich fluid in the extravascular space of the lung, initially in the interstitium and later in the alveolar sacs. Alveolar type I epithelial cells are injured, the alveolar basement membrane is denuded, and the alveolar space fills with red blood cells, leukocytes, macrophages, and cell debris. Damage to the epithelium results in the loss of surfactant and alveolar collapse. Early hyaline membranes composed of protein, fibrin, and cellular debris can be seen.¹²²

Morphologically, epithelial cell injury is more obvious than endothelial cell injury, which may indicate a greater reparative capacity of the endothelial cells.¹²² After 24–96 h, the early exudative phase of injury is followed by a cellular proliferative phase, with repopulation of the alveolar basement membrane by alveolar type 2 cells. The hyaline membrane begins to organize, and morphologic evidence of endothelial injury is more obvious.¹²² This phase is present from the third to the 10th day and is followed by a fibrotic proliferative phase as the hyaline membranes undergo fibrosis.

Clinical presentation

Clinically, the patient with ARDS of any etiology may go through four clinical stages:

- 1 injury;
- 2 apparent stability;
- 3 respiratory insufficiency;
- 4 terminal stage.

The initial injury may occur without outward clinical signs and usually lasts for 6 h or more. Next, the patient develops dyspnea associated with rapid shallow breathing and a persistent cough. Approximately 12–24 h after injury, the chest radiograph may begin to show bilateral infiltrates that coalesce into a diffuse haze, representing perivascular fluid accumulation, interstitial edema, and alveolar edema. As the disease progresses, mechanical ventilation is usually required because the pulmonary edema and localized atelectasis have resulted in ventilation–perfusion mismatching and an increased alveolar–arterial O_2 gradient that is resistant to high inspired O_2 concentrations.¹¹¹ Other physiologic derangements include an increase in physiologic dead space, frequently exceeding 60% of each breath and resulting in significant carbon dioxide retention, despite the presence of a very high minute ventilation. Narrowing and obstruction of the pulmonary vessels, primarily caused by edema fluid, results in “stiff” lungs and is often associated with a high pulmonary arterial pressure despite a low or normal capillary hydrostatic pressure.

Therapy

Corticosteroids, in doses up to several grams of methylprednisolone over 24 h, have been widely used in the treatment of full-blown ARDS without good evidence that they are effective.¹²³ However, although corticosteroids have not been shown to be effective in treating “early ARDS,” there is some evidence to suggest that their use in the management of “late ARDS” is useful. The ARDS Net group recently completed enrollment in a randomized, double-blind trial comparing corticosteroid with placebo treatment in severe, late ARDS, a study which suggested the usefulness of corticosteroids. The use of corticosteroids and mineralocorticoids to treat patients who are in shock that might be caused by or accompanied by adrenal insufficiency is warranted. Surfactant, a complex substance containing phospholipids and apoproteins, is used to treat RDS in premature infants, but there are some data to suggest that, when instilled by way of bronchoscopy, it may be useful in the treatment of ARDS.^{124,125} Efforts to identify pharmacologic agents effective in enhancing lung repair or blocking mediators of lung injury in ARDS have been largely unsuccessful. Nonsteroidal anti-inflammatory drugs, such as ibuprofen, meclofenamate, and indomethacin, have been studied *in vitro* and in animals and have shown some promise.^{126,127}

The care of a patient with ARDS is primarily supportive, with the mainstays of therapy being supplemental O_2 and the application of positive end-expiratory pressure (PEEP). Despite the lack of any clear evidence that its use improves mortality rates, PEEP is almost universally employed because it improves oxygenation and can reduce O_2 needs below potentially toxic concentrations.¹²⁸ The early application of PEEP (prophylactic PEEP) cannot prevent the development of ARDS.¹²⁹

Reversible causes of ARDS, such as occult intra-abdominal or pelvic abscesses, should be sought because early surgical intervention and antimicrobial therapy may be life-saving. Patients with abruptio placentae, dead fetus syndrome, and septic abortion often have accompanying DIC. These patients should undergo delivery of the fetus or evacuation of the uterus as soon as the coagulopathy has been addressed and the patient is surgically stable.

Mechanical ventilation

Ventilator therapy should be instituted when refractory hypoxemia is present and should be considered at the earliest recognition of ARDS-related symptoms to ensure fetal well-being. With correction of hypoxemia and respiratory alkalosis, fetal O_2 delivery can often be maintained at an adequate level. Pregnant patients with ARDS should be placed in the left lateral decubitus position, with the right buttock and hip elevated approximately 15°, or with the uterus manually displaced to the left, to maximize venous return. Continuous external fetal heart monitoring should be instituted when appropriate, and pulse oximetry can permit continuous monitoring of arterial oxygenation. Periodic blood gas determinations should be obtained to check acid–base status.

When indicated, volume-cycled mechanical ventilation is begun, using 100% O_2 , at a respiratory rate of 10–12 breaths/min. Traditionally, a TV of 10–15 mL/kg was utilized, but a National Institutes of Health (NIH)-sponsored ARDS Net trial compared the outcomes of 861 patients with ARDS at a TV of 6 versus 12 mL/kg. They found an overall 22% reduction in mortality rate, more ventilator-free days, and more organ failure-free days in the low tidal volume group.¹²⁹ The maternal pH should be maintained in the normal pregnancy range of 7.4 to 7.47, with an arterial CO_2 between 25 and 32 mmHg. Under normobaric conditions, the F_{IO_2} , initially set at 1.0, can be continued for up to 24 h without the threat of pulmonary O_2 toxicity.¹²⁸ An F_{IO_2} of 0.5 can be administered indefinitely without adverse sequelae. In ARDS, the increased work of breathing caused by noncompliant lungs and the increased airway resistance caused by bronchial edema and possibly bronchospasm can be relieved using the continuous mandatory ventilation mode of mechanical ventilation, which allows the respiratory muscles to rest completely, thereby reducing O_2 consumption. Use of the continuous mandatory ventilation mode may require sedation or paralysis to maximize ventilation and minimize patient O_2 requirements and discomfort. Should a vaginal delivery of the fetus be contemplated while the patient is intubated, withdrawal of sedation and a change of respirator mode to intermittent mandatory ventilation is probably warranted to allow the patient to assist in the delivery effort.¹³⁰

If the maternal arterial O_2 saturation cannot be maintained at or above 90%, with an F_{IO_2} of 0.6 or less, then PEEP should be added. PEEP recruits atelectatic areas for gas exchange that would otherwise collapse during expiration and which are

difficult to expand due to the loss of surfactant and structural derangements. The result is an increase in systemic arterial O_2 tension and in the lung's FRC and compliance.^{131–133} The use of PEEP is not without pitfalls, however, as it can overdistend alveoli, thereby decreasing compliance and increasing the risk of pneumothorax. The most important adverse effect is to decrease cardiac output by impeding venous return to the right side of the heart, particularly when the blood volume is low.¹³⁴ Application of PEEP is accomplished by titrating upward from levels of 5 cmH₂O and checking P_aO_2 15–30 min later. By following serial arterial blood gases or using a pulse oximeter, PEEP can be increased until either the required $F_I O_2$ is less than 0.6 or cardiac output declines. Generally, levels of more than 15 cmH₂O are not required, but values as high as 20 cmH₂O may occasionally be necessary to provide an appreciable increase in arterial O_2 . Applying PEEP at high levels may lead to retention of excessive lung water. If PEEP is then decreased, this lung water can flood alveoli and lead to a deterioration in gas exchange, which is not easily reversible by simply raising levels of PEEP.¹³⁵ This problem can be avoided by starting PEEP at low levels and then gradually increasing as needed.¹²⁹

An optimal PEEP has been defined as a level that increases oxygenation without significantly reducing cardiac output and, consequently, O_2 delivery. Studies have shown that this level correlates with maximal pulmonary compliance.¹³⁴ Use of a pulmonary artery catheter permits the calculation of maximal pulmonary compliance or “best PEEP” by direct sampling of the mixed venous O_2 saturation (S_vO_2) and measuring the cardiac output by the thermodilution method. The S_vO_2 reflects the balance between tissue O_2 delivery and tissue O_2 utilization and declines with inadequate tissue perfusion. The normal average value for S_vO_2 is 73%, with saturations of less than 60% considered low. Because of the altered pulmonary capillary permeability inherent in ARDS, an increase in pulmonary capillary blood pressure that would be well tolerated by a healthy individual may cause life-threatening pulmonary edema in a patient with ARDS. Therefore, the ultimate goal of fluid management in ARDS is to maintain adequate maternal and fetal tissue O_2 delivery while keeping pulmonary microvascular pressures as low as possible, a task made easier with the use of a pulmonary artery catheter to measure pulmonary capillary wedge pressure and cardiac output serially. Units of packed red cells are given to patients who are anemic and who would benefit from the increased O_2 -carrying capacity provided by blood transfusion.

Therapy of ARDS in the pregnant patient is complicated because a cardiac output sufficient to supply maternal needs may not be adequate for placental perfusion. Additionally, vasopressor drugs often used to increase cardiac output may have deleterious effects on uterine blood flow. Given the lack of available information on the effects of hemodynamic and pharmacologic manipulation on uterine blood flow in the critically ill patient, it seems prudent to lower intravascular volume only to a level tolerated by the circulation and to avoid excessive pharmacologic manipulation. External fetal heart

rate monitoring is a useful adjunct in assessing fetal O_2 delivery.¹³⁰

After the initiation of therapy for ARDS, the patient may begin to show signs of improvement, with less impairment of gas exchange and increases in lung compliance and S_vO_2 . If the $F_I O_2$ can be reduced to less than 0.5 and PEEP can be reduced to 5 cmH₂O, consideration should be given to weaning the patient from mechanical ventilation. Most patients who are successfully weaned require supplemental O_2 for several days or more after mechanical ventilation is discontinued.

Complications

Therapy of ARDS requires knowledge not only of the disease process and its management but also of associated complications. Table 40.8 lists complications resulting from intubation

Table 40.8 Complications associated with adult respiratory distress syndrome.

<i>Pulmonary</i>
Pulmonary emboli
Pulmonary barotrauma
Pulmonary fibrosis
Pulmonary complications of ventilatory and monitoring procedures
Mechanical ventilation
Right main stem intubation
Alveolar hypoventilation
Swan–Ganz catheterization

and mechanical ventilation and emphasizes that this severe disease can involve many organ systems in addition to the lungs. Two specific complications, pulmonary barotrauma and infection, merit special attention.

Pulmonary barotrauma is common. In one series of ARDS patients, 38% of the group was found to have pneumomediastinum or pneumothorax.¹³⁶ Pneumothorax may cause further deterioration in gas exchange, and tension pneumothorax may produce life-threatening pulmonary and cardiovascular deterioration. Factors that have been implicated as predisposing to these complications include high inflation pressures resulting from poor lung compliance, large TVs, and high levels of PEEP. Approximately two-thirds of all critically ill patients have respiratory tract colonization with Gram-negative bacteria, and Brodie and colleagues found concurrent pneumonia in a majority of patients with ARDS.¹³⁷ Intravenous catheters, endotracheal tubes, bladder catheters, and intra-arterial cannulae can all be sources of infection. Respiratory assistance devices and medical personnel are other potential sources of infection.^{138,139}

Infection can be both an important etiologic factor in ARDS and a secondary complication that increases mortality. Ashbaugh and Petty,¹⁴⁰ in a retrospective review of 51 patients with ARDS, reported a mortality of 70% in patients who acquired respiratory infection, in contrast to a fatality rate of 40% in patients without respiratory tract infection. Seidenfeld

et al.¹⁴¹ found a mortality of more than 70% in ARDS patients with infection, whereas mortality was only 20% when patients were free from infection.

Pneumonia in the setting of ARDS is notoriously difficult to diagnose. In one study, although 58% of patients with ARDS had histologic evidence of pneumonia,¹²⁶ 36% of these cases were not clinically detected, and 20% of those without pneumonia were incorrectly given this diagnosis. Fever, leukocytosis, and focal infiltrates may be present in ARDS patients, independent of the presence of pneumonia. The relatively recent development of the bronchoscopically directed, protected specimen brush may help to make this diagnosis in complicated patients.¹⁴²

In addition to pneumonia, other infections may complicate the course of ARDS. Nasotracheal and large nasogastric tubes predispose to bacterial sinusitis by blocking ventilation and drainage of the sinuses. Sinus infections are particularly likely to occur in patients who have underlying disorders of the nasal passages and in those who have sustained either facial trauma or trauma due to instrumentation. Parenteral empiric antibiotics should cover both Gram-positive and nosocomial Gram-negative organisms, and patients may benefit from a topical nasal decongestant. Other complications of ARDS include airway trauma from translaryngeal intubation¹⁴³ and persistent pulmonary function abnormalities (both small airways disease and reduced diffusion).^{144,145}

Key points

- 1 Normal respiratory physiology is altered in pregnancy, and these changes must be considered when evaluating tests of lung function.
- 2 When a patient with known lung disease seeks advice about the risks of pregnancy, pulmonary function studies should be obtained.
- 3 If at any time during pregnancy, the health of the mother or fetus would be compromised by failure to perform a radiologic examination, the examination should be performed and every care should be taken to shield the fetus from scatter radiation and from the direct beam when appropriate.
- 4 Chest radiographs performed in the pregnant patient have normal findings that differ from those seen in nonpregnant women of childbearing age. The diaphragm may be elevated 4 cm at term, but there is a compensatory increase in anteroposterior diameter. The subcostal angle increases from 68.5° to 103.5° from early to late pregnancy. Lung markings may be increased, giving a false impression of mild congestive heart failure.
- 5 Because the fetus operates on the steep portion of the O₂ dissociation curve (normal fetal venous P_aO₂ is close to 33 mmHg), decreases in maternal P_aO₂ below 60–70 mmHg during an acute asthma exacerbation can result in rapid and profound decrease in fetal O₂ saturation and fetal hypoxia.
- 6 Good asthma control is perhaps the most important factor in improving maternal and fetal outcomes.
- 7 Effective management of asthma in pregnant women relies on four components: patient education, avoidance or control of environmental precipitating factors, objective assessment of maternal lung function and fetal well-being, and pharmacologic therapy.
- 8 It is reasonable to advise any patient with cystic fibrosis against pregnancy if there is evidence of a VC of less than 50% of predicted or of hypoxemia, pulmonary hypertension, or pancreatic insufficiency. The absence of pancreatic insufficiency may identify a subgroup more able to tolerate pregnancy.
- 9 Bronchial drainage, antibiotic therapy, prophylactic immunization (including annual influenza vaccine administration), and optimal nutritional and psychosocial care are essential components in the care of the CF patient contemplating pregnancy.

- 10 In aspiration pneumonitis, there is generally a delay of at least 6–8 hours before the first appearance of signs and symptoms such as bronchospasm, tachycardia, hypotension, tachypnea, cyanosis, and frothy pink sputum.
- 11 Prophylaxis of aspiration should always be undertaken in the pregnant patient undergoing surgery and during labor to raise the gastric pH to more than 2.5 and thus reduce the chance of a dangerous aspiration.
- 12 *Streptococcus pneumoniae* is the most common infectious agent implicated in antepartum pneumonia, but other common bacterial pathogens include *Mycoplasma pneumoniae* and *Haemophilus influenzae*.
- 13 Gravid patients thought to have bacterial pneumonia should be admitted to hospital and started on a third-generation cephalosporin and a macrolide.
- 14 Influenza vaccine may be appropriately administered in pregnant women in any trimester.
- 15 Amantadine, an oral antiviral agent active against influenza A, can be used therapeutically and prevents 70–90% of infections.
- 16 Given the high mortality rate associated with varicella pneumonia occurring in pregnancy, it is recommended that any gravid patient with varicella pneumonia be admitted to the hospital for parenteral therapy with acyclovir.
- 17 *Pneumocystis carinii* pneumonia (PCP) is the most common opportunistic infection affecting the lungs of patients with acquired immunodeficiency syndrome (AIDS) and prophylaxis against PCP with trimethoprim–sulfamethoxazole is known to be very effective, with rates of prevention of 90–95%.
- 18 Amniotic fluid embolism (AFE) is a devastating, pregnancy-specific condition in which both maternal and fetal death is the most probable outcome.
- 19 The diagnosis of AFE is clinical, based on physiologic manifestations, and is made after exclusion of other conditions, such as myocardial infarction and pulmonary thromboembolism.
- 20 Clinically, the patient with ARDS of any etiology may go through four clinical stages: injury, apparent stability, respiratory insufficiency, terminal stage.
- 21 The care of a patient with ARDS is primarily supportive, with the mainstays of therapy being supplemental O₂ and the application of positive end-expiratory pressure (PEEP).

Diabetes mellitus in pregnancy

Carol J. Homko, Zion J. Hagay, and E. Albert Reece

Diabetes mellitus is a heterogeneous disorder characterized by hyperglycemia, which is a result of relative or absolute insulin deficiency. It is estimated that diabetes mellitus affects approximately 4 million women of childbearing age in the United States.

Peel, in an excellent historic review of diabetes and pregnancy, noted that, before 1856, there were few reports of pregnancy-complicated diabetes.¹ At that time, diabetes was a disease with a dismal prognosis, and infertility was common in women with diabetes. The advent of insulin brought about a dramatic change in the overall outlook for diabetics and their reproductive potential. A dramatic fall in maternal mortality from 45% to just over 2% was observed shortly after the introduction of insulin in 1922.² A decline in perinatal mortality was achieved more gradually, however, and must be credited to a number of developments. Infant survival can be credited to a better understanding of metabolism in diabetic patients, a recognition of the need for stringent metabolic control to achieve glucose levels that are as close as possible to nondiabetic values to insure a better pregnancy outcome, the improvement in neonatal intensive care units, new techniques for fetal surveillance, and devices for self-monitoring blood glucose. In fact, perinatal mortality rates have been reduced remarkably, from approximately 15–20% in the 1960s to approximately 2–3% at present.^{2–4} Furthermore, if mortality secondary to major congenital malformations is excluded, then perinatal mortality rates in well-controlled diabetics approximates that of nondiabetics. Unresolved problems remain, however, such as macrosomia and congenital anomalies.

At present, there is no doubt that the goal in treating diabetic patients is not only a reduction in perinatal mortality but also decreases in perinatal and maternal morbidity.

Classification

Diabetes during pregnancy is still generally classified using the original system proposed by Priscilla White almost 40 years ago.⁵ White's classification relates the onset of diabetes, its duration, and the degree of vasculopathy to the outcome of pregnancy. Because there were differences and some confusion in the interpretation of class A diabetes, particularly when the

patient required insulin for therapy, a revision made by Hare and White proposed that class A diabetes should include women known to have diabetes before pregnancy and who are treated with diet alone.⁶ Thus, White's class A classification includes only patients with pregestational diabetes and defines gestational diabetes as a completely separate group.

Practically speaking, women with pregnancies complicated by diabetes mellitus may be separated into one of two groups:

- 1 Gestational diabetes: women with carbohydrate intolerance of variable severity, with onset or first recognition during the present pregnancy.

- 2 Pregestational diabetes: women known to have diabetes before pregnancy.

Table 41.1 presents the classifications that include these two groups.⁷

Epidemiology and etiology

Significant advances in the understanding of genetic features of diabetes mellitus have been achieved in the last 20 years.⁸ Because diabetes mellitus is a heterogeneous disorder rather than a single disease, the different types of diabetes should be distinguishable from each other. To improve differentiation of the various forms of diabetes, the National Diabetes Data Group (NDDG) was updated in 1997 by the Expert Committee on The Diagnosis and Classification of Diabetes Mellitus (see Table 41.2).⁹

Ninety percent of all pregnant diabetic patients have gestational diabetes mellitus (GDM), whereas type 1 (insulin-dependent diabetes) and type 2 (noninsulin-dependent diabetes) account for the remaining 10%.¹⁰ The clinical distinction between the ketosis-prone type 1 and the nonketosis-prone type 2 has been recognized by clinicians for many years, but the two types were thought to represent differences in the expression of a single disease.¹¹ Twenty years ago, it was discovered that type 1 is a human leukocyte antigen (HLA)-linked disorder, whereas type 2 is not, and thus they are two different diseases genetically.^{12–14} In general, type 1 and type 2 can be distinguished from each other using clinical criteria or islet cell antibody (ICA) studies (Table 41.3).

Type 1 accounts for 6–10% of all cases of diabetes in the

Table 41.1 Classification of diabetes in pregnancy.

Pregestational diabetes:				
Class	Age of onset (years)	Duration (years)	Vascular disease	Therapy
A	Any	Any	No	Diet only
B	> 20	< 10	No	Insulin
C	10–19	10–19	No	Insulin
D	Before 10	> 20	Benign retinopathy	Insulin
F	Any	Any	Nephropathy	Insulin
R	Any	Any	Proliferative retinopathy	Insulin
H	Any	Any	Heart disease	Insulin
Gestational diabetes:				
Class	Fasting glucose level		Postprandial glucose level	
A-1	< 105 mg/dL		and	< 120 mg/dL
A-2	> 105 mg/dL		and/or	> 120 mg/dL

Based on the American College of Obstetricians and Gynecologists (ACOG), Technical Bulletin no. 92 (Chicago), May 1986, with modifications.

Table 41.2 Classification of glucose intolerance.

	Nomenclature	Old name(s)
Type I	Type 1 diabetes	Insulin-dependent diabetes Juvenile-onset diabetes
Type II	Type 2 diabetes	Noninsulin-dependent diabetes Maturity-onset diabetes
Type III	Other specific types	Secondary diabetes
Type IV	Gestational diabetes mellitus	

From ref. 9.

general population.^{15,16} It has an increased prevalence rate in white people but is rare in certain ethnic groups (e.g., Japanese, Chinese, and Eskimos).^{17,18} The prevalence of type 1 in Europe and the United States is estimated to be in the range of 0.1–0.4% in various age groups younger than age 30 years.¹⁹

In contrast, type 2 is the most common form of diabetes observed in the general population. It has a peak incidence at age 65 years, with 80% of cases appearing after age 40 years.^{18,19} However, in recent years, type 2 diabetes has been steadily increasing among younger individuals and, as a result, in many parts of the world, including the United States, the number of pregnancies complicated by type 2 diabetes is actually exceeding those with type 1 diabetes. A study of diabetes prevalence in the United States found that, while the overall prevalence of type 2 diabetes increased by 33% from 1990 to 1998, the prevalence in individuals aged 30–39 years

increased by 70%.^{5,20} In 1994, type 2 diabetes accounted for approximately a third of all cases of diabetes in teenagers and as many as half of all new cases of diabetes in certain populations.²¹

Genetics of type 1 diabetes mellitus

In the past few years, it has become increasingly clear that autoimmunity plays a key role in type 1 diabetes.^{22–24} It is currently believed that type 1 diabetes mellitus is actually a slow process in which insulin-secreting cells are gradually destroyed, leading to islet cell failure and hyperglycemia.

The exact mechanism of the inheritance of type 1 diabetes is not known. Formerly, it was suggested that the risk of inheriting diabetes in offspring with one affected parent was in the range of 1–6%.^{25–27} Based on recent information,²⁸ it has become clear that type 1 diabetes is transmitted less frequently to the offspring of diabetic mothers (1%) than to children of diabetic fathers (6%). This preferential paternal transmission rate may be related to greater transfer of DR₄ alleles to the offspring of DR₄ fathers than to the offspring of DR₄ mothers.²⁹ Family studies have shown that the estimated risk of type 1 diabetes in offspring in a family with one affected sibling but unaffected parents is 5–6%.^{30,31}

Genetics of type 2 diabetes mellitus

There are clear genetic and immunologic differences between type 1 and type 2 diabetes. Type 2 diabetes is not linked to HLA, and no specific genetic markers have been found. Furthermore, type 2 diabetes does not seem to be an autoimmune

Table 41.3 Predominant characteristics of type 1 and type 2 diabetes.

Characteristic	Type 1	Type 2
Prevalence	0.1–0.5%	5–10%*
Weight at onset	Nonobese	Often obese
Age at onset	Usually young, < 30 years	Usually older, > 40 years
Seasonal variations	Yes	No
Insulin level	Low or absent	Variable
Ketosis	Most often	Unusual
MHC gene associations	HLA-DR ₄ , HLA-DR ₃ , HLA-DQ	No
Twin studies	30–50% concordance	80–100% concordance
Anti-islet cell antibodies	Positive in 70% of individuals with new type 1	No

MHC, major histocompatibility complex.

*Prevalence in Western countries.

or endocrine disease. Currently available information indicates that type 2 diabetes occurs when there is both impaired insulin secretion and insulin antagonism.³²

For relatives of individuals with type 2 diabetes, the empiric risk of developing the disease is much higher than it is for relatives of type 1 diabetics (Table 41.4). The risk of transmitting type 2 diabetes to first-degree relatives is almost 15%, and as many as 30% have impaired glucose tolerance.¹⁶ When both parents have type 2 diabetes, the chance of developing the disease is much higher, reaching 60–75%.¹⁹

Genetics of gestational diabetes mellitus

Historically, GDM was believed to be a variant of type 2 diabetes; however, available data now support the concept that GDM is a heterogeneous disorder representing, at least in part, patients who are destined to develop either type 1 or type 2 diabetes in later life.^{33,34} The exact percentage difference of each subgroup is unknown, but it appears that most GDM cases represent a preclinical state of type 2 diabetes. Immunologic studies have shown that as many as 30% of GDM patients may have circulating ICAs,³⁵ and anti-ICAs have been found in many patients with pretype 1 diabetes.^{36–39} Furthermore, it has been shown that GDM patients who were ICA positive had a higher prevalence of HLA-DR₃ or -DR₄ than those who were ICA negative. More than half the patients who were ICA positive developed type 1 diabetes within an 11-year period after the diagnosis of GDM.

Metabolic changes in normal and diabetic pregnancies

Insulin secretion and insulin resistance in normal pregnancy

Insulin is the major hormonal signal regulating metabolic

Table 41.4 Empiric risk for offspring of parents with type 1 and type 2 diabetes developing diabetes.

Affected parent(s)	Empiric risk estimate of offspring
<i>Type 1 diabetes</i>	
Mother	1%
Father	6%
Parents unaffected, sibling affected	Overall 5–6% No. of haplotypes shared: 1 haplotype = 5% 2 haplotypes = 13% No haplotypes = 2%
Both parents affected	33%
<i>Type 2 diabetes</i>	
MODY	50%
Obese	7%
Nonobese	15%
Both parents affected	60–75%

MODY, maturity-onset diabetes of youth.

responses to feeding and tissue use of carbohydrates; it is also the major glucose-lowering hormone. It is produced by the B cells of the pancreas and is secreted into the hepatic portal circulation, from which it reaches and acts on the liver and other peripheral tissues (i.e., muscle and fat). Insulin suppresses endogenous glucose production by inhibiting hepatic glycogenolysis and gluconeogenesis. On the other hand, it stimulates glucose uptake and fuel storage of glycogen and triglyceride in the liver, muscle, and adipose tissue (Table 41.5).⁴⁰

During pregnancy, fasting values of insulin rise from roughly 5 mU/L to approximately 8 mU/L until term (Fig. 41.1).^{41,42} The increase in insulin release in response to a glucose load becomes pronounced by the third trimester.^{41,43–45} Data show that the release of insulin in response to a challenge with oral or intravenous glucose in the last trimester of

Table 41.5 Summary of the metabolic effects of insulin.

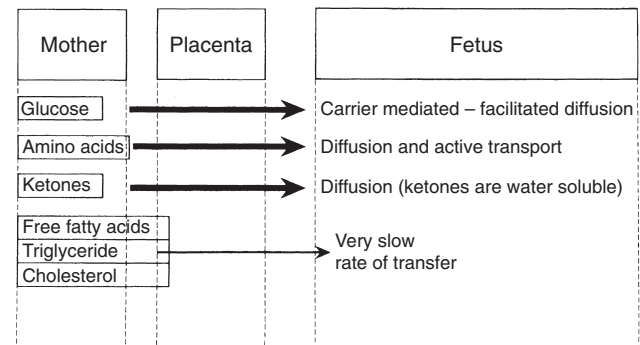

Target tissue	Enhances glucose and amino acid uptake Increases glycogen synthesis Converts glucose into fatty acids Inhibits glyconeogenesis
Muscle	Enhances glucose and amino acid uptake Increases glycogen synthesis
Adipose tissue	Increases glucose and amino acid transport Increases fatty acid synthesis Inhibits release of fatty acids from fat stores “Fat-sparing effect” is enhanced by glucose utilization in many tissues
Central nervous system	Has little or no effect on uptake or metabolism of glucose
All tissues	Increases protein synthesis Inhibits protein catabolism

From ref. 40.

**Figure 41.1** Plasma insulin in normal pregnancy and postpartum after overnight fast. Basal insulin levels are increased in the last half of pregnancy. (Modified from ref. 71.)

pregnancy is approximately 1.5–2.5 times greater than it is in nonpregnant women.^{43,46} In the first trimester of pregnancy, insulin action is enhanced by estrogen and progesterone; thus, an increase in peripheral glucose use leads to lower fasting plasma glucose levels,⁴⁷ a decrease that may explain the clinical observation of increased episodes of hypoglycemia experienced by pregnant diabetic patients in early pregnancy.

Late pregnancy is characterized by accelerated growth of the fetoplacental unit, rising plasma concentrations of several diabetogenic hormones including human placental lactogen and estrogens, and increasing insulin resistance. Several investigators^{48–50} have demonstrated increased first- and second-phase insulin release during late gestation as well as increased plasma insulin/glucose ratios. Buchanan and colleagues,⁴⁹ using the minimal model technique, found that peripheral insulin sensitivity was reduced to approximately one-third of normal during late gestation. Similar findings have been reported by Catalano et al.⁴⁸ and Ryan et al.,⁵⁰ both using the eug-

**Figure 41.2** Transplacental transfer of maternal fuels to the fetus (for details, see text).

lycemic–hyperinsulinemic clamp technique. They reported decreases of 50% and 33%, respectively, in insulin-stimulated glucose uptake, indicating peripheral insulin resistance during the third trimester of pregnancy. In another publication, Catalano et al.⁵¹ observed a 30% increase in basal hepatic glucose output despite elevated basal serum insulin levels, suggesting hepatic insulin resistance. Our own investigations,^{52,53} in overweight women using the insulin clamp technique, have demonstrated a 40% reduction in insulin-stimulated glucose uptake during the third trimester of pregnancy compared with the postpartum period. In addition, we found that, after 2 h of hyperinsulinemia, endogenous glucose production was significantly less inhibited during the third trimester when compared with either the second trimester or the nonpregnant state. Thus, there appears to be general agreement that the second half of pregnancy is associated with increasing insulin resistance in the periphery (muscle and, in obese women, also at the hepatic level).

Placental transfer of nutrients

The placenta is a complex organ that has an important function in the transfer of gases and nutrients between mother and fetus. Fetal growth is controlled by various factors and depends on the uptake of nutrients and oxygen by the placenta and on their transfer to the fetus. The availability of nutrients to the fetus depends principally on the maternal metabolic state. Placental transfer of the principal nutrients is discussed briefly here (Fig. 41.2).

Glucose

Experimental studies have provided evidence that the process of transplacental glucose transfer involves a carrier-mediated active transport system.^{54,55} In this process of facilitated diffusion, the net result is that fetal blood glucose levels are 15–20% lower than maternal levels. It is believed that this difference in blood glucose levels between maternal and fetal blood is a result of placental use of glucose. It has been shown that the placenta contains insulin receptors, but their role is

not yet clear.⁵⁶ The fetus seems to be protected from very high maternal glucose levels. In fact, it has been found that the placental transport system of glucose is saturated when maternal glucose levels are maintained up to approximately 250 mg/dL. It is not possible to increase fetal plasma glucose levels above this threshold.^{57,58}

Amino acids

Placental transfer of amino acids is an active process. Amino acids are transferred against a concentration gradient; in the fetus, amino acid levels are three to four times higher than those in the maternal blood. However, the concentration of amino acids in the placenta is higher than that in either fetal or maternal blood.⁵⁹

Metabolism in the diabetic pregnancy

Islet cells function completely differently in type 1 than in type 2 diabetes. It is therefore unsurprising that there is a difference in insulin secretion between the two forms of diabetes. C peptide, which is the connecting peptide between the A and B chains of insulin, was found to be higher in pregnant women with type 2 diabetes than in normal control subjects. However, C-peptide release in type 2 diabetes was lower after meals.⁶⁰ This may indicate impaired effectiveness of insulin in target tissues and pancreatic B-cell dysfunction in patients with type 2 diabetes.

In type 1 diabetes, C-peptide levels were found to be very low or almost undetectable, which may indicate no residual B-cell function.⁶¹ It has also been shown that, in patients with type 1 diabetes, the increase in insulin requirement is almost 40%, whereas in type 2 it can be much higher, reaching as high as 100%.⁶² For several years, it has been known that maternal fuel levels other than that of glucose can be abnormal in diabetic pregnant patients. Metzger and colleagues⁶³ have shown that plasma triglyceride levels are elevated in obese pregnant patients with GDM and type 2 diabetes. Skryten and colleagues⁶⁴ reported higher than normal plasma triglyceride concentrations in pregnant patients with type 1 diabetes during the third trimester. However, this has not been confirmed in more recent studies.⁶⁴

Metzger et al.⁶³ reported that plasma free fatty acid (FFA) levels tend to be higher in patients with gestational diabetes than in normal pregnant patients. Furthermore, FFA levels were also found to be elevated in pregnant patients with type 1 diabetes. A correlation between these concentrations and neonatal birthweight was reported.⁶⁵ In yet another study, high-density lipopolysaccharide (HDL) cholesterol concentrations were found to be low in type 2 diabetes and not significantly changed in women with type 1 diabetes compared with nondiabetic pregnant control subjects.⁶⁶

In summary, the metabolic disturbances in diabetic pregnant patients are expressed in increased concentrations of circulating metabolic fuels, including carbohydrate, protein, and fat. This increased circulating maternal level can be transferred to

the fetus and may contribute to the development of fetal macrosomia.^{64,67}

Gestational diabetes mellitus

Definition and incidence

GDM is defined as carbohydrate intolerance of variable severity with onset or first recognition during the present pregnancy.⁶⁸ This means that the glucose intolerance may have antedated the pregnancy but was not recognized by the patient or physician. The incidence of GDM varies in different study populations and is estimated to occur in 3–5% of pregnant women.⁶⁹ The likelihood of developing gestational diabetes is significantly increased among certain subgroups, and these include women with a family history of type 2 diabetes, advancing maternal age, obesity, and nonwhite ethnicity.

Screening for gestational diabetes

In the United States, screening for gestational diabetes mellitus consists of a 50-g oral glucose load, followed 1 h later by a plasma glucose determination. The screen is performed without regard to the time of day or interval since the last meal. It is recommended that screening be carried out at 24–28 weeks' gestation in average-risk women not known to have diabetes mellitus. Women deemed to be a high risk for GDM should be tested as soon as possible. This approach is endorsed by the American College of Obstetricians and Gynecologists (ACOG),⁷ the Expert Committee on the Diagnosis and Classification of Diabetes Mellitus,⁹ and the Fourth International Workshop Conference on Gestational Diabetes Mellitus.⁶⁸

However, there is a lack of agreement among clinicians and experts as to whether screening should be selective or universal. This controversy is apparent from the varying recommendations from different but related professional organizations. The ACOG⁷ recommended selective screening in 1986 but made no definite recommendations in 1994. The American Diabetes Association recommended universal screening until 1997.⁷⁰ At that time, the Fourth International Workshop Conference on GDM⁶⁸ took a stand that there appears to be a low-risk group in whom screening may not be cost-effective. They defined low-risk women as those possessing all of the following characteristics: < 25 years of age, of normal weight, without a history of abnormal glucose metabolism or poor obstetric outcome, and with no first-degree relative with diabetes.

A value of plasma venous glucose between 130 and 140 mg/dL has been recommended as a threshold to indicate the need for a full diagnostic oral glucose tolerance test (OGTT). Lowering the threshold to 130 mg/dL increases the sensitivity of the test but increases the number of diagnostic tests performed and, therefore, increases the cost per case diagnosed. When the plasma glucose screening test results are

Table 41.6 Incidence of a positive glucose tolerance test among 96 gravidas with 50-g, 1-h screening test values > 134 mg/dL (plasma, glucose oxidase).

Screening test result (mg/dL)	Incidence of gestational diabetes (%)
135–144	14.6
145–154	17.4
155–164	28.6
165–174	20.0
175–184	50.0
> 185	100.0

From ref. 73.

> 185 mg/dL, patients are gestational diabetics and no further testing is required (Table 41.6).

Diagnosis

The diagnosis of GDM is, in most cases, based on an abnormal result of an OGTT during pregnancy. A minority of cases are diagnosed on the basis of high fasting glucose levels during pregnancy, in which case the OGTT does not have to be performed. The OGTT is administered under standard conditions: 100 g of glucose is given orally in at least 400 mL of water after an overnight fast of 8–14 h. The patient should have at least 3 days of unrestricted diet with more than 150 g of carbohydrates and should be at rest during the study. Diagnosis requires that at least two of four glucose levels of the OGTT meet or exceed the upper limits of normal values. The normal upper limit was determined by O'Sullivan and Mahan as two standard deviations (SD) above the mean for each of four glucose values of 752 pregnant patients undergoing 100-g OGTT.²⁷ Their criteria for the OGTT in pregnancy are the most widely used in the United States. O'Sullivan and Mahan studied whole blood using the Somogyi–Nelson method, which has been shown to identify other saccharides in addition to glucose.⁷¹ The NDDG⁷² has modified O'Sullivan's data for plasma values by increasing whole blood values by 15% because plasma glucose values are approximately 15% higher than those in whole blood.

Further modifications of O'Sullivan's criteria were proposed by Carpenter and Coustan, who took into consideration not only the change in the medium tested (whole blood versus plasma), as had been done by the NDDG, but also the changes in methodology.⁷³ Currently, the most widely used methods of glucose measurement in plasma are the glucose oxidase, or hexokinase, assay. These new methodologies are more specific for glucose and have been shown to result in approximately 5-mg/dL lower values than the less specific Somogyi–Nelson method. Thus, the criteria of Carpenter and Coustan for oral glucose tolerance testing are stricter.⁷³ Whole blood and plasma glucose criteria of the OGTT used for the diagnosis of GDM are presented in Table 41.7.

Table 41.7 Oral glucose tolerance test (100-g) values for the diagnosis of gestational diabetes (mg/dL).

	O'Sullivan (ref. 71)	NDDG (ref. 72)	Carpenter and Coustan (ref. 73)
Fasting	90	105	95
1-h	165	190	180
2-h	145	165	155
3-h	125	145	140

Long-term maternal outcome of gestational diabetes

Several investigators have shown that patients with GDM are at increased risk of developing diabetes years after pregnancy.⁷⁴ O'Sullivan et al.,⁷⁵ in a long-term study of the outcome of women with GDM, has shown the development of overt diabetes at 20 years after pregnancy to be as high as 20%, and 50% had impaired glucose tolerance.

It is recommended, therefore, that women with GDM be followed postpartum to detect diabetes early in its course. They should be evaluated at the first postpartum visit by a fasting plasma glucose test and by a 2-h OGTT (30, 90, and 120 min) using a 75-g glucose load. The criteria of the NDDG⁷² for the diagnosis of diabetes mellitus in nonpregnant adults include a fasting plasma glucose level of more than 140 mg/dL on more than one occasion, or a 75-g, 2-h OGTT in which the 2-h value and at least one other value are more than 200 mg/dL. The criteria for the diagnosis of impaired glucose tolerance are the following: fasting plasma glucose below 140 mg/dL, a 2-h value between 140 and 200 mg/dL, and at least one other value of 200 mg/dL or more.

Pregestational diabetes mellitus

Congenital anomalies in infants of diabetic mothers

The frequency of major congenital anomalies among infants of diabetic mothers has been estimated at 6–10%, which represents a two- to fivefold increase over the frequency observed in the general population.⁷⁶ Congenital malformations in fetuses of diabetic patients are now responsible for approximately 40% of all perinatal deaths, replacing respiratory distress syndrome (RDS) as the leading cause of infant death.⁷⁷ These malformations usually involve multiple organ systems (Table 41.8), with cardiac anomalies being the most common, followed by central nervous system and skeletal malformations.⁷⁸

Pathogenesis of diabetes-associated congenital anomalies

Both clinical and experimental studies agree that diabetes-associated birth defects occur after disruption of developmental processes during organogenesis and are associated with abnormal metabolism, which is thought to be related mostly to hyperglycemia.^{79,80} *In vivo* studies in which rats were made diabetic by streptozotocin or alloxan therapy resulted in fetal anomalies.^{81,82} These studies suggest a cause and effect relationship between altered glucose metabolism and congenital anomalies; however, the target site of action remains unknown. Studies in our laboratory at Yale on diabetes-related teratogenesis focused on the mechanism and possible target site of action.^{82,83} Using the *in vitro* rodent conceptus culture system, we conducted studies of glucose-induced embryopathy. In all cases of embryopathy, concomitant characteristic yolk sac changes were observed in both gross and microscopic examinations. These findings support our hypothesis that the yolk sac is the primary target site for the adverse metabolic effect of diabetes and that embryonic malformations occur as a secondary phenomenon to the primary yolk sac damage. Factors other than hyperglycemia have been implicated in diabetes-associated birth defects, including ketone bodies, hypoglycemia, low levels of trace metals, and somatomedin-inhibiting factors.^{84,85}

A correlation between maternal oxygen free radicals produced in excess in patients with diabetes mellitus and the induction of fetal anomalies has been suggested in the past few years. *In vitro* studies demonstrated that the addition of

oxygen free radical-scavenging enzymes to culture medium protects embryos against glucose-induced maldevelopment and growth impairment. More recently, Hagay et al.⁸⁵ demonstrated the role of oxygen free radicals in the genesis of diabetic embryopathy *in vivo* in an animal model. Mice used in this study produced elevated levels of copper or zinc superoxide dismutase (SOD), a key enzyme in the metabolism of free oxygen radicals. This enzyme was found to elicit a protective effect against diabetes-associated embryopathy. Although this finding has yet to be verified in humans, it provides important information for designing interventions effective in the prevention of diabetic embryopathy.

Prevention of fetal anomalies

Clinical studies suggest that euglycemia during organogenesis is critical in the prevention of congenital anomalies.⁸⁶ Several investigators have recruited diabetic women before pregnancy and attempted to place them under tight glycemic control before conception.⁸⁶⁻⁹⁰ These studies are summarized in Table 41.9.

Periconceptional care

Management of the pregnant diabetic woman is a complex task that ideally begins before conception. Prepregnancy clinics for diabetics were initiated in Edinburgh in 1976. In such clinics, physicians have the opportunity to explain to the patient and her partner the practice of diabetes care during pregnancy, in particular the need for stringent glycemic control. At the initial visit, the patient's general medical status is assessed, and signs of retinopathy, nephropathy, hypertension, and ischemic heart disease are looked for. The patient undergoes ophthalmologic evaluation, electrocardiography, and kidney function tests.⁹¹ Optimization of blood glucose control should be achieved before a woman is advised to become pregnant. It is generally recommended that women achieve a glycosylated hemoglobin level that is less than 1% above the upper limit of normal. Women should receive appropriate contraceptive therapy while preparing for pregnancy. For women who are not already following an intensive diabetes regimen, an extensive period of education and the institution of self blood glucose monitoring is also necessary.

Diabetes management during pregnancy

Diabetes during pregnancy has been associated with increased perinatal mortality, an increased rate of Cesarean sections, significant risk of macrosomia, and other neonatal morbidities, including serious birth trauma, hypoglycemia, hypocalcemia, polycythemia, and hyperbilirubinemia.^{92,93} Management is therefore directed toward reducing perinatal mortality and morbidity, a goal that may be achieved by maintaining close surveillance of the mother and fetus and stringent glucose control.

Table 41.9 Summary of selected clinical studies using a program of preconceptional metabolic control to prevent diabetes-associated birth defects.

Investigator (year)	No. of patients	Malformation rate (%)	Glucose control achieved	No. of patients	Malformation rate (%)	Glucose control achieved
<i>Control group</i>			<i>Study group</i>			
Pedersen et al. (1979)	284	14.1	Inadequate	363	7.4	Improved
Miller et al. (1981)	58	22.4	HbA _{1c} > 8.5%	58	3.4	HbA _{1c} ≤ 8.5%

Diet

Diet therapy is considered a standard treatment for diabetes mellitus. The goals of diet therapy are to provide adequate maternal and fetal nutrition, appropriate gestational weight gain, and to minimize glucose excursions. For women with pregestational diabetes, guidelines suggest that diet composition be based on an individualized nutrition assessment.⁹⁴ In GDM, it is generally accepted that carbohydrate levels should not exceed 40–45% of total calories. Restricted saturated fats and cholesterol and increased dietary fiber are suggested. Most patients are instructed on how to maintain a diet that consists of three meals and one to three snacks, the last snack usually being taken at bedtime. The bedtime snack should be composed of complex carbohydrates with proteins to maintain adequate blood glucose levels during the night, thereby avoiding nocturnal hypoglycemia.

Patient weight gains are assessed at each visit to the clinic, and caloric intake is adjusted accordingly. The aim is to prevent weight reduction and its associated ketogenic risk while ensuring optimal weight gain. It is desirable to increase weight by 2–4 lb (0.9–1.7 kg) in the first trimester and 0.5–1.0 lb (200–450 g) per week thereafter until term. A total

weight gain of 22–30 lb (10–13 kg) during normal and diabetic pregnancy is recommended.⁹⁵

It is generally agreed that pregnancy is not the time for weight reduction; however, excessive weight gain should be firmly discouraged. Dietary advice to the obese pregnant diabetic patient is a matter of controversy. Several authors have indicated that caloric restriction in obese pregnant patients is contraindicated.⁹⁵ However, there are data to show that modest caloric restriction (25–30 kcal/day), especially for the morbidly obese patient, is not associated with ketonuria or elevated plasma ketone concentrations.^{96,97}

Insulin administration

Insulin is the only pharmacological therapy currently recommended to treat diabetes during pregnancy. The goal of insulin therapy is to achieve blood glucose levels that are nearly identical to those observed in healthy pregnant women. Therefore, multiple injections of insulin are usually required in women with pre-existing diabetes. Human insulin is the least immunogenic of all insulins and is exclusively recommended in pregnancy. The rapid-acting insulin analogs with peak hypoglycemic action 1–2 h after injection offer the potential for

Table 41.10 General guidelines for insulin administration.

Regimen no.	Prebreakfast insulin	Prelunch insulin	Predinner insulin	Bedtime insulin	Comments
I. Two-injection scheme	NPH + regular or rapid-acting analog; 2:1	–	NPH + regular or rapid-acting analog	–	Give two-thirds of the total dose as prebreakfast dose and one-third as predinner dose Disadvantage: predinner NPH may cause nocturnal hypoglycemia (1–3 AM) and may not be effective in controlling the early morning glucose level
II. Three-injection scheme	NPH + regular or rapid-acting analog; 2:1	–	Regular or rapid-acting analog	NPH	This regimen may be more effective than regimen I. By changing the administration of NPH to bedtime, nocturnal hypoglycemia may be prevented and early morning glucose control may be achieved
III. Four-injection scheme	NPH + regular or rapid-acting analog	Regular or rapid-acting analog	Regular or rapid-acting analog	NPH	This is the most effective regimen. We use it as an alternative to regimen II. Here the dose of insulin given at bedtime replaces basal daily insulin requirements. This regimen (with a rapid-acting analog) works especially well for patients with morning sickness or erratic schedules

NPH, neutral protamine Hagedorn.

improved postprandial glucose control. Studies support their safety during pregnancy and ability to improve blood glucose control. Insulin requirements may change dramatically throughout the various stages of gestation. In the first trimester, the maternal insulin requirement is approximately 0.7 U/kg of body weight/day.⁹⁸ This is increased in the third trimester to 1.0 U/kg/day. There are several different approaches to insulin administration, as outlined in Table 41.10. We prefer to use the three-injection scheme, which permits better control of the fasting blood glucose levels while minimizing the risk of middle-of-the-night hypoglycemia.⁹⁹

In addition, continuous subcutaneous insulin infusion pumps have also been shown to be effective during pregnancy. Insulin therapy delivered by a subcutaneous infusion pump more closely resembles that of physiologic insulin release. Insulin pumps deliver a continuous basal rate of insulin infusion with pulse-dose increments before meals. Published studies have demonstrated that comparable glucose control and pregnancy outcomes can be achieved by both conventional insulin therapy and pump therapy.^{100,101} However, Gabbe¹⁰² reported that HbA1c levels were significantly lower 1 year after delivery in women who elected to remain on pump therapy after delivery compared with women who had continued to use conventional insulin treatment. Therapy guidelines for converting patients to pump therapy are provided in Table 41.11.

Insulin therapy should be initiated in all women with GDM who fail to maintain euglycemia with diet. We start women on a daily insulin dose of 20 U of neutral protamine Hagedorn (NPH) and 10 U of regular insulin daily. Insulin doses are

Table 41.11 Guidelines for insulin schedule for patients converting to pump therapy.

Use the same total daily dose of insulin that the patient received with conventional therapy
Fifty percent of the daily insulin dose is given as a constant basal rate
The remaining 50% is divided into three doses, each administered as a bolus before each meal:
20% before breakfast
15% before lunch
15% before dinner

adjusted according to blood glucose levels, and an evening injection is added if fasting hyperglycemia persists. Some investigators have advocated the use of prophylactic insulin in GDM to reduce the risk of macrosomia. However, the advantages of this therapy must be weighed against the disadvantages of no treatment.

Although the current data demonstrate a relationship between metabolic control and neonatal complications, maternal glycemia may not be the sole parameter of optimal control. In women with gestational diabetes, Buchanan and colleagues^{103,104} have suggested the use of fetal ultrasound to identify pregnancies at risk of fetal macrosomia and related morbidity. They have found that a fetal abdominal circumference < 75th percentile for gestational age obtained in the late second trimester or early third trimester can distinguish pregnancies at low risk from those at high risk of producing

large for gestational age (LGA) infants. Their data suggest that maternal glucose concentrations alone may not accurately predict which fetuses are at high risk of excessive fetal growth and support the use of fetal criteria to direct metabolic therapies in GDM.

Self-monitoring of blood glucose

Self blood glucose monitoring has become the mainstay of management for pregnancies complicated by diabetes mellitus. A variety of small, battery-powered blood glucose reflectance meters are currently available for home use. Accurate readings depend on performing the test correctly; however, most of the newest models are less technique dependent. Some models are extremely sophisticated, having memories that permit the storage of results with the day and time they were collected, whereas others can even be downloaded onto a personal computer. All women should be seen by a qualified nurse educator for an individualized assessment to insure that her technique is accurate. Ongoing education is also important to help the woman make necessary changes to her treatment plan to maintain euglycemia throughout gestation.

Although it has been shown that, in general, self-monitored blood glucose levels correlate very well with automated laboratories, reports have shown that sometimes patients falsely report blood glucose levels both during and outside pregnancy. These findings are worrisome as accurate information is essential for optimal management of the pregnancy complicated by diabetes. Therefore, verified blood glucose determinations (i.e., the utilization of blood glucose meters with memory) are recommended to enhance the reliability and accuracy of self-monitored blood glucose results.

Blood glucose measurements should be obtained at least four times a day (fasting and 1–2 h after meals) in women with gestational diabetes and five to seven times a day in women with pre-existing diabetes. In addition to this regular monitoring, patients should also test whenever they feel symptoms of either hyperglycemia or hypoglycemia. Detailed record keeping is useful to help identify glucose patterns. Daily urine ketone testing should be performed to insure early identification of the development of starvation ketosis or ketoacidosis. Ketone testing should also be performed any time the blood glucose level exceeds 200 mg/dL, during illness, or when the patient is unable to eat.

Blood glucose levels are measured in both fasted and postprandial states. A recent randomized controlled trial compared the efficacy of preprandial and postprandial glucose determinations in reducing the incidence of neonatal macrosomia and other complications in women with gestational diabetes.¹⁰⁵ Women requiring insulin treatment were randomly assigned to have their diabetes managed according to the results of preprandial self blood glucose monitoring or postprandial monitoring, which was performed 1 h after meals. Both groups had similar success in achieving blood glucose targets and demonstrated similar degrees of adherence to the

monitoring schedule. Nevertheless, the women in the postprandial monitoring group received significantly more insulin and achieved a greater decrease in glycosylated hemoglobin values during treatment than those in the preprandial monitoring group. In addition, there was significantly less macrosomia and neonatal hypoglycemia among the offspring of the mothers in the postprandial monitoring group. These data suggest that adjustment of insulin therapy according to the results of postprandial blood glucose values improves glycemic control and pregnancy outcomes. Previous studies in pregnant women with pregestational diabetes have also found that postprandial blood glucose levels are better predictors of fetal macrosomia than are fasting blood glucose levels.^{106,107}

In conclusion, the target ranges for blood glucose during pregnancy should be based on maternal plasma glucose levels in normal pregnancy. The logical approach is to achieve as near normal glucose levels as possible without undue severe hypoglycemia. Current recommendations are that whole blood glucose levels should not exceed 95 mg/dL in the fasted state and 120 mg/dL after meals.

Oral agents

Traditionally, insulin therapy has been considered the gold standard for management because of its efficacy in achieving tight glucose control and the fact that it does not cross the placenta. As GDM and type 2 diabetes are characterized by insulin resistance and relatively decreased insulin secretion, treatment with oral hypoglycemic agents that target these defects is of potential interest. However, because of concerns regarding transplacental passage and, therefore, the possibility of fetal teratogenesis and prolonged neonatal hypoglycemia, these agents are not currently recommended in pregnancy.

There are no randomized controlled trials on which to draw conclusions regarding the teratogenicity of these oral agents. However, most retrospective studies and the published clinical experience have not demonstrated an increased risk of malformed infants among women treated with oral hypoglycemic agents.^{108–110} Rather, the data indicate that the increased risk of major congenital anomalies appears to be related to maternal glycemic control during the periconceptual period. These studies and currently available data on the use of both metformin and sulfonylureas in pregnancy have also failed to demonstrate an increased risk of neonatal hypoglycemia and other neonatal morbidities. To date, there has only been one randomized controlled trial to test the effectiveness and safety of sulfonylurea therapy (glyburide) in the management of women with GDM.¹¹¹ Both the insulin- and the glyburide-treated women were able to achieve satisfactory glucose control and had similar perinatal outcomes. Glyburide was not detected in the cord serum of any infant in the glyburide group.

In summary, based on the currently available data, it would appear that glyburide could be safely and effectively utilized

in the management of GDM. More intensive investigation regarding the safety and feasibility of oral agents in pregnancies complicated by type 2 diabetes is necessary.

Antepartum assessment

Maternal assessment

Ophthalmologic and renal function tests, including creatinine clearance and total urinary protein excretion, are performed in each trimester or more often, if indicated. In patients with vasculopathy, an electrocardiogram is performed at the initial visit and repeated, if clinically indicated. In patients in White's class H, the electrocardiogram is performed routinely in each trimester. The echocardiogram is performed at enrollment and repeated in the pregnancy, depending on the initial findings. It is extremely important to detect early signs of pregnancy-induced hypertension; therefore, an assessment of blood pressure and the signs of proteinuria and edema formation is essential. It is estimated that approximately 25% of all diabetics develop preeclampsia during pregnancy. The highest incidence is seen among patients with vasculopathy.¹¹² In many cases, differentiation between pregnancy-induced hypertension and chronic hypertension is very difficult. In patients with diabetic nephropathy, the diagnosis of preeclampsia may be challenging. We have used a number of factors as adjunctive clues: acute increase in blood pressure, the elevation of fibrin split products, liver function test abnormality, or thrombocytopenia. Most helpful is the increase in fibrin split products as a reasonably sensitive marker of underlying consumptive coagulopathy. We recognize that this is less than ideal but, at the present time, it is the best diagnostic aid available.

Fetal surveillance

All pregnancies complicated by diabetes require extra assessment. The use of ultrasonography provides essential information about the fetus. A first-trimester scan is used to date the pregnancy and to establish viability and fluid volume status. A second-trimester scan is repeated at 18–20 weeks' gestation to rule out fetal anomalies. Subsequent ultrasound evaluations are then performed at 4- to 6-week intervals to assess fluid volume and fetal growth. Because diabetic patients are at risk of growth aberrations (intrauterine growth restriction and macrosomia), this frequency is recommended to identify states of altered growth.

Fetal macrosomia

Macrosomia, arbitrarily defined as fetal weight in excess of 4000 g, or a birthweight above the 90th percentile for gestational age, occurs in approximately 10% of all pregnancies. Almost 30% of all diabetics deliver infants weighing more than 4000 g.¹¹³ Gabbe and colleagues¹¹⁴ reported an incidence of macrosomia of 20% and 25% in GDM and type 1 patients respectively.

Fetal macrosomia is thought to be related to maternal hyperglycemia which induces fetal hyperglycemia and hyperinsulinemia. Fetal hyperinsulinemia results in enhanced glycogen synthesis, lipogenesis, increased protein synthesis and, thus, fetal organomegaly and fat deposition.

Macrosomic fetuses have higher rates of perinatal morbidity and mortality, a result caused mainly by the traumatic delivery. These fetuses are at increased risk of severe fetal asphyxia due to head and neck birth trauma. Shoulder dystocia is common in macrosomic fetuses; therefore, infants of diabetics experience more shoulder dystocia than those of nondiabetics. Disproportional growth of the body compared with the head is believed to be the cause of shoulder dystocia. Acker and associates¹¹⁵ reported the incidence of shoulder dystocia in nondiabetic offspring weighing 4000–4499 g as 10% and in those weighing 4500 g or more as 22%. Among the offspring of diabetics, the incidence is much higher, and in infants with birthweights of 4000–4499 g and 4500 g or more, the incidence doubles, reaching 23.1% and 50% respectively.

It has been suggested that Cesarean section should be employed to deliver diabetic mothers of babies of 4000 g or more.¹¹⁵ In our institutions, primary Cesarean section is performed if the estimated fetal weight is 4500 g or more. In cases of estimated fetal weight of 4000–4500 g, the mode of delivery is determined individually for each patient and is based on the clinical assessment of the pelvis and the past history (e.g., birthweight of previous babies). In such cases, midpelvic instrumental delivery should be avoided as much as possible.

Antepartum fetal testing

In pregnant diabetic patients, stillbirth occurs with increased frequency, particularly in the third trimester.¹¹⁶ Therefore, a program of fetal monitoring should be initiated, usually at 32–33 weeks. Currently, in most medical centers, outpatient protocols for antepartum fetal surveillance include either once- or twice-weekly nonstress tests (NSTs), once-weekly oxytocin challenge tests (OCTs), or biophysical profiles.¹¹⁷ Which is the best test remains controversial because controlled, prospective randomized studies comparing the various methods of antepartum fetal assessment are lacking. Many investigators have concluded that the NST is simple, inexpensive, and reasonably reliable. Therefore, the NST is most widely used for pregnancies complicated by diabetes mellitus.^{117,118}

Gabbe and colleagues¹¹⁴ observed no intrauterine fetal death within 1 week of a negative contraction stress test (CST) in 211 metabolically well-controlled type 1 patients. This observation suggests that a negative CST in metabolically controlled patients predicts fetal survival for 1 week. The high incidence of false-positive CSTs (50%) and the potential unnecessary intervention as a result of these false-positive findings are major disadvantages.

The biophysical profile has been shown to have a lower false-abnormal test rate than either the CST or NST.¹¹⁹ Golde and Plan¹¹⁷ have demonstrated that a biophysical score of 8 is

reliable in predicting good fetal outcome in diabetics, which is comparable to the reliability of reactive NSTs.

Sadovsky¹²⁰ has shown that maternal evaluation of fetal movements has a very low false-negative rate and that patients with decreased fetal movements of less than 10 in 12 h may show severe fetal compromise. Therefore, further testing is necessary in cases of decreased fetal movements. Maternal assessment of fetal activity seems to be not only a practical approach toward evaluation of fetal condition but a simple, inexpensive, and valuable screening technique. Patients with diabetes are instructed to count fetal movements, beginning as early as 28–29 weeks of gestation, and to report any decrease in fetal movements so that further testing can be initiated if necessary.

A large body of evidence shows that maternal glucose control is the most important factor in improved perinatal mortality and morbidity rates. Therefore, any method of fetal surveillance is ineffective unless strict control of maternal diabetes is maintained.¹¹⁷ In fact, the need for elective intervention resulting from abnormal antepartum fetal testing in diabetics in good metabolic control is very low compared with patients in poor metabolic control.¹²¹ Several investigators reported an intervention rate of 1–5%, based on abnormal fetal testing in pregnant type 1 patients.^{122–124} In one report, no intervention for abnormal fetal testing was required in 82 type 1 patients.¹²⁵ Drury and colleagues¹²⁴ have shown that, when strict maternal metabolic control is achieved, antepartum fetal testing can be used less frequently and that, despite limited use of antepartum testing, the perinatal mortality was low, approaching 3%.

In summary, in recent years, management protocols using strict metabolic control consistent with various techniques of antepartum surveillance have allowed more diabetic patients to deliver at term and to achieve good fetal outcome similar to that of the general obstetric population.

Timing and mode of delivery

In recent years, there has been a significant change in the attitude of obstetricians and perinatologists toward the mode and timing of delivery of type 1 and type 2 pregnant patients. It is now recognized worldwide that, if the pregnant diabetic patient and her fetus are under stringent metabolic control and antepartum surveillance, delivery may be safely delayed in most cases until term or the onset of spontaneous labor.^{114,126}

Management during labor and delivery

During labor and delivery, it is necessary to maintain maternal euglycemia to avoid neonatal hypoglycemia. Induced maternal hyperglycemia during labor in diabetics is associated with neonatal hypoglycemia.^{127,128} Soler and associates¹²⁷ have demonstrated that mean glucose levels of more than 90 mg/dL during labor are associated with higher rates of neonatal

episodes of hypoglycemia. Therefore, the goal should be to maintain glucose levels of 70–90 mg/dL during labor.

Caloric and insulin requirements in diabetic patients during labor have been studied extensively.¹²⁹ Investigators have documented a decrease in insulin requirement, particularly in the first stage of labor, with constant glucose requirement during this time. Jovanovic and Peterson,¹²⁹ using an artificial pancreas (Biostator) for 12 type 1 patients during labor, have demonstrated the lack of insulin requirement during the first stage of labor, despite a constant and continuous glucose infusion rate of 2.5 mg/kg/min. In another study by Golde and colleagues,¹³⁰ 48% of type 1 patients undergoing induction of labor required no insulin therapy.

Therefore, in patients undergoing induction of labor, the morning insulin doses should be withheld and glucose levels determined once every hour with a home glucose meter. In well-controlled patients, 1 U of insulin/h and 3–6 g of glucose/h are usually required to maintain a glucose level of 70–90 mg/dL. If the initial glucose level is between 80 and 120 mg/dL, 10 U of regular insulin can be added to 1000 mL of 5% dextrose in 0.5% normal saline or 5% dextrose 5% and Ringer's lactate, and administered at an infusion rate of 125 mL/h. If initial glucose levels are less than 70 mg/dL, it is recommended that, initially, 5% dextrose in water without insulin at a rate of 100–120 mL/h be given throughout labor.

If the patient presents in spontaneous labor and has already taken her morning intermediate-acting insulin, additional insulin may not be required throughout labor and delivery, but a continuous glucose infusion will be necessary (125 mL/h of 5% dextrose in water).

When an elective Cesarean section is planned for a diabetic patient, the procedure should be scheduled early in the morning, when glucose levels are usually in the normal range because of the action of the intermediate-acting insulin dose given the night before. Infusion without glucose is preferred (i.e., normal saline), and glucose levels are monitored frequently. If the patient is under regional anesthesia, it is easier to detect signs of hypoglycemia.

After delivery, a dramatic decrease in the insulin requirement is almost the rule because of a significant decrease in the level of placental hormones that have anti-insulin action. At this time, there is no need for stringent glucose control, and glucose levels of less than 200 mg/dL are satisfactory. In the first few days after delivery, it is preferable to give regular insulin subcutaneously before each meal on the basis of plasma glucose levels. After the patient is able to eat regular meals, she may receive one-half of the prepregnancy dosage of insulin, usually divided into two daily injections.

Maternal complications

Diabetic women have a markedly higher risk of a number of pregnancy complications. Because of a paucity of data on maternal complications during diabetic pregnancy, the exact

relative risk for each complication is not known. Complications that have been reported to be more frequent in diabetic pregnancy include spontaneous abortion, preterm labor, pyelonephritis, polyhydramnios, and hypertensive disorders. Also directly related to metabolic control are hypoglycemia and diabetic ketoacidosis (DKA). These complications, together with the vascular alterations and the higher Cesarean section rate, contribute to the higher maternal morbidity and mortality among diabetic pregnant patients.

Maternal mortality

The advent of insulin in 1922 and its widespread introduction in 1935 brought about a dramatic fall in the maternal mortality rate from 45% to just over 2%.² Together with improved medical and obstetric care, the maternal mortality rate has decreased to as low as 0.5%.¹³¹ More recently, a mortality rate of 0.11% was reported among 2584 pregnant diabetic patients.¹³² Causes or events related to maternal death among diabetics include acute myocardial infarction during Cesarean section,¹³³ sepsis, hemorrhage, ketoacidosis, hypoglycemia, and anesthetic and hypertensive complications.¹³¹ Maternal mortality seems to be highest (approaching 65%) among patients with coronary artery disease.¹³⁴

Diabetic ketoacidosis

In recent years, the incidence of DKA during pregnancy has decreased significantly. Cousins,¹³² in a review of a large number of studies, found an incidence of 9.3% of DKA among 1508 diabetics. Ketoacidosis has been reported to occur in pregnant diabetic patients more rapidly and at lower blood glucose levels than in nonpregnant patients. It may be precipitated by stress, infection (e.g., urinary tract), or omission of insulin because of patient neglect. The use of beta-sympathomimetic agents in pregnant diabetics may induce DKA.¹³⁵

Omission of insulin or insulin deficiency in type 1 pregnant patients results in hyperglycemia and glucosuria. Osmotic diuresis results in urinary potassium, sodium, and water losses. Hyperglycemia is aggravated because, as a consequence of hypovolemia, there is an increase in the secretion of glucagon and catecholamines.^{136,137} Lipolysis consequent to insulin deficiency leads to increased hepatic oxidation of fatty acids, with the formation of ketone bodies (acetone, β -hydroxybutyrate, and acetoacetate), which leads to the production of metabolic acidosis (Fig. 41.3).

The following are some general guidelines for the treatment of DKA:

- 1 Insert two intravenous lines; obtain blood to assess levels of glucose, serum electrolytes and ketones, and arterial blood gases; and administer oxygen by face mask. Frequently assess the clinical status and follow urinary output. Repeat blood and urinary testing often.
- 2 Patients with DKA require simultaneous correction of fluid and electrolyte imbalance and treatment of hyperglycemia and acidosis.

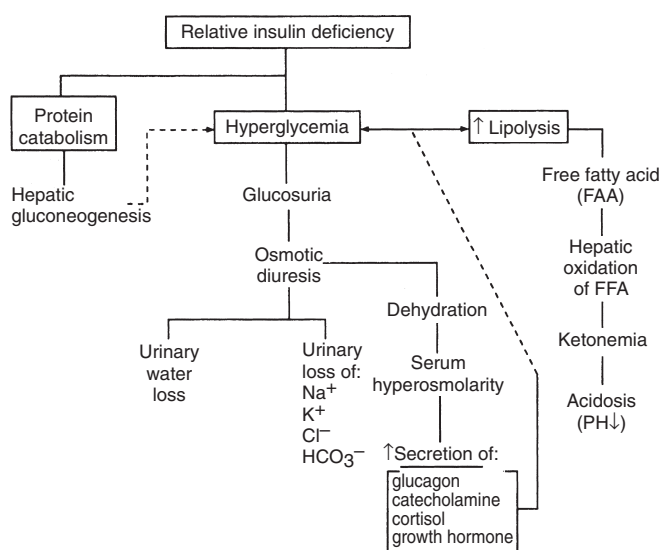

Figure 41.3 Metabolic alterations in diabetic ketoacidosis.

- Replacement of fluid. The average fluid deficit is 3–5 L. It is therefore necessary to administer 1000–2000 mL of isotonic saline rapidly during the first hour. If hypernatremia is present, 0.45% sodium chloride is preferred. After the first hour, 300–500 mL/h is given, depending on hemodynamic status. Normal saline is given to hypotensive patients in larger amounts. In these cases, a central line may be necessary.
- Insulin therapy. Administer an initial bolus of 10–20 U of regular insulin intravenously. Follow this with a constant infusion of approximately 10 U/h (Add 50 U of regular insulin per 500 mL of normal saline.) Larger doses of constant regular insulin infusion of 12–20 U/h may be required if acidosis does not begin to respond within 3 h or if plasma glucose level does not fall by 30%.
- Glucose administration. To reduce the risk of hypoglycemia and cerebral edema, change the intravenous solution to 5% dextrose when the plasma glucose level reaches 200–250 mg/dL, and simultaneously decrease the rate of the insulin infusion.
- Potassium administration. Hyperkalemia is usually present on administration. At this point, potassium administration is not required and, in fact, may be dangerous or even lethal because hyperkalemia may rapidly reach cardiotoxic levels. Potassium administration is usually started after 3–4 h of insulin therapy, when potassium begins to fall to normal or low levels. It is given by adding 40 mEq of potassium chloride per 1000 mL of normal saline at a rate of 10–20 mEq/h, as needed. It should be stressed that, when potassium is administered, it is given with extreme caution, and that potassium and urinary output are monitored carefully.
- Bicarbonate administration. Add 44 mEq of sodium bicarbonate to 1 L of 0.45% saline and administer intra-

venously only if arterial pH is less than 7.1 or serum bicarbonate is less than 5 mEq. If the pH is less than 7, the sodium bicarbonate dose should be doubled (88 mEq). Bicarbonate administration should be terminated if arterial pH has been corrected to 7.2. Alkali administration in DKA is still controversial because this therapy might aggravate tissue hypoxia.

Hypoglycemia

The goal of very stringent glycemic control during diabetic pregnancy places the patient at increased risk for hypoglycemic episodes. Coustan and associates¹⁰¹ observed a high frequency of both symptomatic and biochemical hypoglycemia. Forty-five percent of type 1 patients treated with multiple daily insulin injections had severe hypoglycemia requiring hospitalization or emergency room care.

Pyelonephritis

Pedersen¹³⁸ reported a 6% incidence of pyelonephritis in diabetic pregnant patients, including it as one of the “prognostic bad signs of pregnancy” because it is associated with higher perinatal mortality and morbidity. Cousins¹³² reported an incidence of pyelonephritis of 2.2% among 356 class B and C diabetics, and 4.9% among 264 class D, E, and R diabetics in an extensive literature review. In no study, however, was a nondiabetic control group used for comparison. It appears that, in recent years, there has been a reduction in the frequency of pyelonephritis in diabetic pregnancy.¹³⁹ However, this reduction has not been confirmed statistically.¹³² Nevertheless, it is our practice to perform serial urine cultures at least once in each trimester of pregnancy and to treat asymptomatic bacteriuria vigorously in diabetic pregnant patients because, if left untreated, it may result in frank pyelonephritis.

Polyhydramnios

Polyhydramnios occurs commonly in diabetics, with a reported incidence that varies from 3% to 32%.¹³² Although this condition can be associated with central nervous system and gastrointestinal abnormalities, in almost 90% of diabetics with polyhydramnios, no etiology can be found.¹⁴⁰

The etiology of polyhydramnios in diabetics is not clear. Suggested mechanisms include increases in amniotic fluid osmolality caused by increases in glucose load, decreased fetal swallowing, high gastrointestinal tract obstruction, and fetal polyuria secondary to fetal hyperglycemia. Experimental work, however, has not provided strong evidence for any of these explanations.¹⁴¹ Although the most likely reason for the higher fluid volume is increased fetal urine production in diabetics, this was not demonstrated by sequential estimation of bladder volume over time.¹⁴²

Preterm labor

Earlier studies have found that the incidence of prematurity in diabetic pregnancies is three times higher than that in nondi-

abetics.¹⁴³ This high rate was attributed in part to the higher rate of iatrogenic preterm delivery. In a study by Miodovnik and colleagues,¹⁴⁴ the rate of spontaneous preterm labor was 31.1% in type 1 patients, a rate that is three to four times more than that reported in the general obstetric population. The authors found two factors to be significantly associated with premature labor: premature rupture of membranes and previous history of preterm labor and delivery. Furthermore, patients with poor glycemic control during the second trimester of pregnancy had increased rates of preterm delivery. Interestingly, polyhydramnios was not significantly associated with preterm labor in this study.

Magnesium sulfate is considered the drug of choice in diabetic patients with premature labor because it has no effect on diabetic control. In contrast, beta-sympathomimetic tocolytic agents or glucocorticosteroids have been reported to induce hyperglycemia and ketoacidosis.¹³⁹ Therefore, treatment with both medications in diabetics requires great caution, intensive monitoring of glucose levels, and treatment with intravenous insulin infusion as needed.

Spontaneous abortions

The rate of spontaneous abortion in pregestational pregnant diabetic patients varies considerably between reports, ranging from 6% to 29%.¹⁴⁵ Most studies are retrospective and do not have nondiabetic control groups for comparison. Kalter,¹⁴⁶ in an extensive literature review of the years 1950–1986, concluded that the incidence of spontaneous abortion in diabetic women is similar to that in nondiabetic women, approaching 10%. However, a prospective study reported from Cincinnati, Ohio, showed a significantly higher rate of spontaneous abortions among pregnant type 1 patients than among pregnant nondiabetic women (30% vs 15%).¹⁴⁷ Furthermore, the same group demonstrated in another study that the higher rate of spontaneous abortions in type 1 women was associated with poor glycemic control in the early postconceptional period, as reflected by high levels of HbA_{1c} early in pregnancy.¹⁴⁸ The latter findings were confirmed by the results of the Diabetes in Early Pregnancy Study.¹⁰⁶

Diabetic retinopathy

Diabetic retinopathy is usually classified as background simple diabetic retinopathy and proliferative diabetic retinopathy. The characteristic lesions of diabetic retinopathy are presented in Table 41.12.

Microaneurysms alone are not usually associated with severe loss of vision but, when maculopathy is present with either macular edema or macular ischemia, serious loss of vision can occur. The most serious condition, however, is proliferative retinopathy, which carries a high risk of blindness. It is believed that background retinopathy represents an early stage of the disease: as it worsens, it leads to proliferative retinopathy, which, when developed, is usually associated with the characteristic lesions of background retinopathy.¹⁴⁹

Table 41.12 Characteristic lesions of diabetic retinopathy.*Background diabetic retinopathy*

Microaneurysms

Small vessel obstruction, soft exudates, intraretinal microvascular abnormalities

Venous abnormalities

Retinal hemorrhages

Hard exudates

Disk edema

Maculopathy

Proliferative diabetic retinopathy

Neovascularization

Fibrous deposition

Vitreous hemorrhage

Retinal detachment

Pregnancy and progression of diabetic retinopathy

Investigators have reported controversial findings on the role of pregnancy in the development and progression of diabetic retinopathy. Most recent reports have shown that, in some diabetic patients, pregnancy is associated with progression of diabetic retinopathy from minimal to marked deterioration of the retina.^{150–153} However, many changes during pregnancy have proved to be reversible, and many patients have experienced regression of their lesion after delivery.

Tight metabolic control in pregnancy and diabetic retinopathy

Studies in nonpregnant type 1 patients investigated the effect of glycemic control on the progression of diabetic retinopathy.^{154,155} These studies have shown that progression of diabetic retinopathy was significantly higher over an 8-month period compared with a control group with proper metabolic control.^{154,155} After 2 years of follow-up, no statistical significance was found between the rates of progression of retinopathy in the two groups. The authors suggest that caution should be used and that one should avoid achieving good glycemic control too rapidly in type 1 patients with retinopathy and poor glycemic control.

Principal management of diabetic retinopathy in pregnant diabetics

Diabetic retinopathy occurring during pregnancy should be treated in essentially the same manner as in the nonpregnant state.¹⁴⁹ Laser treatment can be used safely during pregnancy, when indicated. It is recommended that diabetic patients undergo careful retinal examination before conception and be treated with laser photocoagulation before pregnancy, if necessary. It is our practice to perform ophthalmoscopy every trimester in pregnant type 1 patients and even more frequently in patients with documented retinopathy before pregnancy.

The preferred mode of delivery in patients with active proliferative retinopathy remains controversial. In the past, the performance of Cesarean section was suggested to avoid the Valsalva maneuver and the risk of vitreous hemorrhage.^{156–158}

Today, however, most investigators do not recommend Cesarean delivery in patients with active neovascularization because it has been found that vitreous hemorrhages during childbirth are extremely rare.¹⁵⁸ Furthermore, there are no data to show any advantage of Cesarean section over vaginal delivery in patients with proliferative retinopathy.

Diabetic nephropathy

Diabetic nephropathy is a disease that develops slowly and appears on average 17 years after the onset of type 1 diabetes. Background retinopathy complicates almost all these pregnancies, and proliferative retinopathy affects approximately 35–65% of patients.^{159,160}

The prevalence of diabetic nephropathy in type 1 pregnant patients is estimated at 6%.¹³⁸ Five evolutionary stages of nephropathy in diabetics have been described for type 1 diabetes:¹⁶¹

- 1 early hypertrophy or hyperfunction;
- 2 glomerular lesions without clinical disease;
- 3 incipient nephropathy characterized by microproteinuria;
- 4 overt nephropathy characterized by macroproteinuria;
- 5 endstage diabetic renal disease.

In type 1 diabetes, renal insufficiency eventually occurs in all patients who exhibit macroproteinuria, whereas in type 2 diabetes, deterioration occurs in only 10% of cases.¹⁶² A diagnosis of diabetic nephropathy in pregnancy is made if there is persistent proteinuria of more than 300 mg/day in the first half of pregnancy in the absence of urinary tract infection.¹⁶⁰

Several studies examining fetal outcome and maternal risks in women with diabetic nephropathy suggest that most patients have an increase in proteinuria during the course of pregnancy.^{159,163} Reece and colleagues¹⁶⁰ reported an increase in third-trimester proteinuria that exceeded 3.0 g/day in 70% of the pregnancies studied. Kitzmiller and colleagues¹⁵⁹ also found increasing proteinuria in the third trimester, with almost 60% exceeding 6.0 g/day in the third trimester.

Acute worsening of hypertension is very common in patients with diabetic nephropathy and occurs in almost 60% of cases. In the report by Reece and colleagues,¹⁶⁰ hypertension during pregnancy developed in 32% of women who began pregnancy with normal blood pressure levels. However, after delivery, changes in renal function, proteinuria, and hypertension returned to values observed in the first trimester. Based on a 9-year follow-up study, the long-term maternal course was judged to be consistent with the expected course of diabetic nephropathy in nonpregnant women.

Many investigators have shown that the likelihood of a successful fetal and neonatal outcome in patients with diabetic nephropathy is comparable to that of type 1 patients without overt renal disease.^{105,109} Fetal survival has been reported to exceed 90% when contemporary methods of fetal and maternal care are applied.^{159,160,163} Perinatal mortality and morbidity in patients with diabetic nephropathy may be attributed to the higher incidence of early delivery (31%), a higher incidence of low birthweight infants (21%),¹⁵⁹ and an increased

incidence of fetal distress and preeclampsia. Therefore, pregnant patients with diabetic nephropathy require an intensive program of maternal and fetal evaluation, adequate bedrest during pregnancy, assessment of renal function and retinal status at regular intervals, blood pressure monitoring, and treatment of hypertension, when required, using methyldopa, arteriolar vasodilator, or beta-blockers. In patients on antihypertensive medications before pregnancy, the same regimen is continued during pregnancy (with the exception of diuretics and ace inhibitors, which should be discontinued). A modest sodium restriction (1500 mg of Na) in all patients with significant proteinuria (> 500 mg/dL) is suggested to reduce the rate of edema formation.

Morbidity of the infant of the diabetic mother

In the last decade the perinatal morbidity rate in pregnancies complicated by diabetes mellitus has been remarkably reduced. However, severe neonatal morbidity in infants of diabetic mothers is still a problem that may affect even infants delivered at term.^{164,165} The following sections briefly discuss the most common neonatal morbidities.

Hypoglycemia

Hypoglycemia is diagnosed when plasma glucose levels are less than 35 mg/dL and 25 mg/dL in term and preterm infants respectively. Infants of diabetic mothers in unsatisfactory glycemic control often develop hypoglycemia during the first few hours of life. The reported incidence ranges from 25% to 40% of infants of diabetic mothers. Poor glycemic control during pregnancy and high maternal plasma glucose levels at the time of delivery increase the risk of occurrence, particularly if the patients have been delivered by Cesarean section.¹⁶⁶

Because prolonged and severe hypoglycemia may be associated with neurologic sequelae, initiation of treatment is advised in all neonates of diabetic mothers with plasma glucose levels of less than 40 mg/dL. The most efficient means of therapy for hypoglycemia is continuous dextrose infusion at a rate of 4–6 mg/kg/min. The use of a bolus of a hypertonic glucose infusion should be avoided to prevent later rebound hypoglycemia.¹⁶⁷ Occasionally, hypoglycemia may persist beyond the second day of life and may require the use of glucocorticoids.^{168,169}

Hypocalcemia and hypomagnesemia

There is a significant increase in the incidence of hypocalcemia and hypomagnesemia in infants of diabetic mothers.^{170,171} The incidence of neonatal hypocalcemia, defined as calcium levels at or below 7 mg/dL, has been reported to approach 20% in a group of infants with a mean gestational age at delivery of 38 ± 0.2 weeks.¹⁷² Serum calcium levels in infants of diabetic mothers are lowest on the second to third days of life. The etiology of hypocalcemia in neonates of diabetic mothers is not yet clear, but some evidence shows that it is associated with “relative” neonatal hypoparathyroidism.¹⁷³ It has also been

postulated that magnesium deficiency may contribute to hypoparathyroidism and hypocalcemia in infants of diabetic mothers.¹⁶⁷

Polycythemia

Polycythemia is diagnosed when the venous hematocrit exceeds 65%. This condition has been reported to affect one-third of neonates of diabetic mothers in the first few hours of life.¹⁷⁴ The mechanism responsible for polycythemia in these babies may be related to chronic intrauterine hypoxia that leads to an increase in erythropoietin and a consequent increase in red blood cell production.

Usually, polycythemia is associated with hyperviscosity of the blood, which may impede the velocity of blood flow and increase the risk of microthrombus formation in multiple organs.^{175,176} Kidneys, adrenals, and lungs are the most commonly affected organs. Clinically, infants with polycythemia appear plethoric. Some of these infants have convulsions, respiratory distress, tachycardia, congestive heart failure, and hyperbilirubinemia. The treatment of polycythemia consists of partial exchange transfusion with a volume expander (e.g., plasma) to reduce the hematocrit to approximately 55%.¹⁷⁷

Respiratory distress syndrome (RDS)

RDS was considered a common neonatal morbidity in the infants of diabetic mothers in the past. However, the incidence has dramatically decreased with the initiation of strict glycemic control. Factors contributing to the development of RDS in these infants are preterm deliveries, delayed fetal lung maturation, and a high rate of elective Cesarean section.

In poorly controlled diabetic patients, the reason for the increased risk of RDS seems to be related to the inhibitory effect of high fetal insulin levels on surfactant phospholipid synthesis and secretion and possibly to decreased prolactin levels.^{178,179}

Hyperbilirubinemia

Infants of diabetic mothers have a higher incidence of hyperbilirubinemia than do infants of nondiabetic mothers matched for gestational age.¹⁸⁰ The mechanism of this increased risk of jaundice is not clear. Early treatment of polycythemia may further reduce the risk of hyperbilirubinemia.

Cardiomyopathy

Infants of diabetic mothers have a higher risk of hypertrophic types of cardiomyopathy and congestive heart failure.¹⁸¹ The incidence of cardiomyopathy in neonates of diabetic mothers is not known. According to one study, 10% of infants of diabetic mothers may have evidence of myocardial and septal hypertrophy. The characteristic findings in echocardiography are generalized myocardial hypertrophy with disproportionate hypertrophy of the interventricular septum. Infants of diabetic mothers with severe cardiomyopathy may develop left ventricular outflow tract obstruction with reduced cardiac output and congestive heart failure.^{182,183} The natural history

of cardiomyopathy in infants of diabetic mothers is different from other types of cardiomyopathy in that there is a complete regression of hypertrophic changes to normal after several months.^{181,184} Several studies have demonstrated a strong correlation between the risk of cardiomyopathy in infants of diabetic mothers and poor maternal diabetic control.^{182,185,186}

Conclusion

The diagnosis of diabetes mellitus during pregnancy has certain implications for the well-being of both the mother and

the fetus. Advances in medical and obstetric care have dramatically improved the outlook for women with diabetes and their offspring. However, both mother and child remain at increased risk for a number of complications. Research indicates that the majority of these complications are associated with hyperglycemia. The achievement and maintenance of euglycemia has therefore become the major focus of management.

Key points

- 1 Diabetes mellitus is a heterogeneous disorder characterized by hyperglycemia. It is estimated that diabetes mellitus affects approximately 4 million women of childbearing age in the United States.
- 2 Diabetes mellitus is generally classified into the following categories: type 1, type 2, and GDM. The prevalences of type 1, type 2, and GDM are all increasing.
- 3 The development of insulin resistance during late pregnancy is a normal physiologic adaptation that shifts maternal energy metabolism from carbohydrate to lipid oxidation and thus spares glucose for the growing fetus.
- 4 Screening for gestational diabetes mellitus consists of a 50-g oral glucose load, followed 1 h later by a plasma glucose determination. The screen is performed without regard to the time of day or interval since the last meal.
- 5 This screening should be carried out at 24–28 weeks' gestation in average-risk women not known to have diabetes mellitus.
- 6 Current research studies indicate that optimization of blood glucose control in the periconceptual period can dramatically reduce the rate of congenital malformations in the offspring of women with diabetes.
- 7 All diabetic women of childbearing age should be counseled regarding the importance of preconception care and planning of their pregnancies.
- 8 Women with diabetes and their offspring are at greater risk of a number of pregnancy-related complications.
- 9 Strict blood glucose control prior to conception and throughout gestation can reduce and/or eliminate the excess risk for both mother and baby.
- 10 The achievement of euglycemia requires frequent daily self blood glucose determinations in both the fasted and the postprandial states.
- 11 Subcutaneous insulin pump therapy can be a safe and effective means of glucose control in pregnant women with diabetes.
- 12 The introduction of new rapid-acting insulin analogs has expanded our options for the treatment of diabetes during pregnancy.
- 13 Serial ultrasound measurements need to be performed during pregnancy to identify infants at risk of excessive fetal growth.
- 14 Most clinicians institute some form of antenatal surveillance based on diabetes classification, existence of comorbidities, and degree of glycemic control.
- 15 Hypertensive complications are more common in women with diabetes than in their nondiabetic counterparts.
- 16 Diabetic ketoacidosis is one of the most significant complications in pregnancy and requires both timely and aggressive treatment.
- 17 Pregnancy *per se* is an independent risk factor that accelerates retinopathy.
- 18 Macrosomic fetuses have higher rates of morbidity and mortality, a result caused mainly by traumatic delivery.
- 19 Euglycemia should be maintained during labor and delivery to reduce the risk of neonatal hypoglycemia.

Endocrine disorders in pregnancy

Fred H. Faas

In this chapter on endocrine disorders in pregnancy, changes in endocrine function that occur during normal pregnancy will be reviewed. Following this, those endocrine disorders whose diagnosis, course, or treatment are affected by pregnancy will be discussed. This chapter is intended to present a practical review of these issues and will emphasize the most common dilemmas facing the practicing clinician. The diagnostic and therapeutic areas of confusion or controversy will be reviewed in the greatest detail to provide the information necessary for decisions in patient management.

Endocrine changes associated with a normal pregnancy

There are a number of endocrine changes that occur during normal pregnancy. Although the mechanisms for these changes are not always understood, they presumably occur for the health of the mother and her developing offspring. The known mechanism(s) of these changes and the importance to the physician of understanding these changes will be reviewed. Some of these changes occur through the existing maternal endocrine system, and some occur as a result of effects of placental hormones on the maternal endocrine system. For additional information on this subject, see Chapters 5 and 9.

Pituitary

Lactotroph hyperplasia causes an increase in pituitary size in normal pregnancy, mainly due to estrogen stimulation of the pituitary lactotrophs. Prolactin levels rise progressively during pregnancy in preparation for lactation. Prolactin levels rise to 100–300 ng/mL by late pregnancy, levels in the range of those seen in pituitary prolactinomas in the nonpregnant patient^{1,2} (see Fig. 42.1). The new diagnosis of a prolactinoma in a pregnant patient is not a common problem, as substantial prolactin elevations typically result in amenorrhea and infertility. However, it is important to be aware that prolactin levels are

normally elevated during pregnancy to avoid confusion in diagnosis. For the management of patients during pregnancy with known pituitary prolactinomas prior to pregnancy, see the section in this chapter on Prolactinomas under Pituitary disorders.

Cortisol and adrenocorticotrophic hormone (ACTH) levels rise normally during pregnancy as a result of large rises in corticotropin-releasing hormone (CRH), derived from the fetal-placental unit^{3–5} (see Table 42.1). CRH levels can be detected in maternal plasma at levels averaging at least 100 times those in nonpregnant plasma.³ Estrogen-induced increases in cortisol-binding globulin increase total plasma cortisol without affecting plasma free cortisol. However, total and free plasma cortisol, ACTH and 24-h urine free cortisol all increase during normal pregnancy. Twenty-four-hour urine free cortisol levels average three times higher than those in the nonpregnant state.³ Thus, pregnancy is a normal physiologic state of mild hypercortisolism, which on occasion has corresponding clinical features of mild hypercortisolism. Interestingly, it has been suggested that activation of the hypothalamic-pituitary-adrenal axis during pregnancy, resulting from the large rises in CRH derived from the fetal-placental unit, combined with the central suppression of maternal hypothalamic CRH secretion, might explain the increased vulnerability to affective disorders during the postpartum period.⁶ A practical implication of these changes in the hypothalamic-pituitary-adrenal axis during and immediately after pregnancy is that diagnosis of Cushing syndrome, particularly the ACTH-dependent type, should be made with caution during this time period. Unless there is a profound clinical situation indicating severe Cushing syndrome, diagnostic evaluation is best deferred until after delivery.

Salt and water metabolism

The renin-aldosterone system is a major determinant of sodium balance in pregnancy, as in the nonpregnant state. Salt retention occurs during pregnancy accompanied by a rise in renin and aldosterone levels, producing a form of secondary

Figure 42.1 Changes in serum prolactin during pregnancy and in the postpartum period. Data shown in the figure were derived from the data from refs 1 and 2.

Figure 42.2 Plasma renin activity and aldosterone levels during pregnancy in normotensive and hypertensive women. Reprinted from ref. 7.

hyperaldosteronism. Renin and aldosterone levels may increase to three or four times the levels in the nonpregnant state⁷ (see Fig. 42.2). Interestingly, in gestational hypertension, this effect is dampened. In general, unless there is an urgent

clinical situation, diagnostic evaluation of hyperaldosteronism is better delayed until the postpartum period, although a very low renin activity level during pregnancy might suggest primary hyperaldosteronism.

Table 42.1 Mean concentrations of CRH, ACTH, cortisol, and urine free cortisol in pregnant and nonpregnant women.

Study group	CRH (pg/mL)	ACTH (pg/mL)	Serum cortisol (μg/dL)	Urine free cortisol (μg/24 h)
Nonpregnant	< 41	1.3 ± 0.4	9.2 ± 4.0	29 ± 1
21–24 weeks' gestation	158 ± 5	8.2 ± 1.8	15.4 ± 1.9	–
25–28 weeks' gestation	315 ± 50	11.4 ± 0.9	23.7 ± 3.1	–
29–32 weeks' gestation	705 ± 115	15.0 ± 0.9	31.9 ± 5.0	–
22–34 weeks' gestation	–	–	–	89 ± 14
33–36 weeks' gestation	2060 ± 490	16.4 ± 3.2	36.7 ± 5.4	–

In normal pregnancy, there is a decrease in plasma osmolality to a level of about 10 mOsmol/kg below normal.^{8,9} This seems to result from a new steady-state setpoint caused by a decrease in the osmotic thresholds for both thirst and vasopressin suppression, similar to that seen in the syndrome of inappropriate antidiuretic hormone secretion (SIADH).

Calcium metabolism

A detailed discussion of changes in calcium and bone mineral metabolism occurring during pregnancy is beyond the scope of this chapter. One new area of interest related to calcium metabolism and pregnancy is the importance of parathyroid hormone-related peptide (PTHrP) in pregnancy. PTHrP, the protein responsible for causing humoral hypercalcemia of malignancy in many patients, has been found to be necessary for development of the fetal skeleton. In fact, in animal models, absence of PTHrP results in severe abnormalities and an incompletely developed fetal skeleton.¹⁰ PTHrP is also instrumental in the transport of calcium in the lactating mammary gland.¹¹ The calcium receptor present in non-parathyroid tissues appears to be partially regulated by PTHrP. Increasing blood levels of PTHrP during pregnancy further suggest that it plays an important role during normal pregnancy. The practical implications of changes in PTHrP levels in normal pregnancy are unknown at this time.

There is an obvious need for increased available calcium in the mother for the developing fetal skeleton. Calcium homeostasis appears to be attained by more efficient intestinal calcium absorption and by renal calcium conservation during pregnancy and lactation.¹² Although total calcium levels may fall during pregnancy due to hemodilution, ionized calcium levels remain normal. It has been suggested that the increased calcium needed for infant growth during pregnancy and lactation may come in part from the maternal skeleton. Regarding the need for maternal dietary calcium during pregnancy, it has been the standard practice for many years to give pregnant women supplemental calcium with vitamin D, usually 400 IU of vitamin D daily. Serum 25(OH)vitamin D levels are considered the best measure of endogenous vitamin D status.

Although 1,25(OH)vitamin D levels increase during pregnancy, 25(OH)vitamin D and parathyroid hormone levels are typically normal during pregnancy. It has been recognized in recent years that vitamin D deficiency is an increasingly common condition in healthy nonpregnant adults, particularly in dark-skinned people. There is evidence that severe vitamin D deficiency may cause rickets and affect fetal growth. A better understanding of vitamin D requirements and vitamin D levels in normal pregnant women taking usual amounts of dietary calcium and vitamin D is needed. Although the dose of dietary vitamin D necessary during pregnancy has not been determined scientifically, it may be as much as 1000 IU daily or more.^{13,14} One concern is the possibility that increased intake of vitamin D in association with the hypercalciuria that often occurs in pregnancy may increase the frequency of kidney stones during pregnancy, although the dose of vitamin D necessary to elevate serum 25(OH)vitamin D levels and cause hypercalciuria is likely to be much higher than this (see the section on Vitamin D deficiency below).

Thyroid

Thyroid-binding globulin (TBG) levels increase during pregnancy as a result of increased estrogen levels, and lead to increases in total thyroxine (T₄) and total triiodothyroxine (T₃), but this increase in TBG does not affect free thyroid hormone or thyroid-stimulating hormone (TSH) levels. However, there is often a transient rise in free T₄ (although usually within the normal range) during the first trimester of pregnancy associated with a mild decrease in TSH due to the high circulating human chorionic gonadotropin (hCG) levels (see section below on hCG). This requires different normal ranges for TSH during each trimester of pregnancy. In some cases, these changes may be more pronounced and may be considered an abnormal change in thyroid function during pregnancy rather than “normal.” This has been referred to as gestational transient thyrotoxicosis. This syndrome may also overlap with the transient thyrotoxicosis associated with hyperemesis gravidarum (see section below on Thyrotoxicosis). In addition to changes in thyroid hormone levels, an increase in thyroid size sometimes occurs during pregnancy,

which may be related to a relative iodine deficiency (see section below on Goiter).

Placental/fetal hormones affecting the maternal endocrine system

These hormones are discussed in more detail in other sections of this book. Here, the emphasis will be on effects they may have on the maternal endocrine system.

Human chorionic gonadotropin

hCG is a glycoprotein, a unique gonadotropin produced by the syncytiotrophoblast of the placenta. It is an analog of luteinizing hormone (LH) with the same alpha subunit but a different beta subunit. Although its main function is maintenance of the corpus luteum, the fetal testis is a target organ for hCG. It is largely responsible for the early development of the fetal testis and for testosterone production prior to fetal LH control. The main effect of this hormone relevant to maternal endocrine function is the well-documented thyrotropic effect which, in cases of trophoblastic disease, can cause hyperthyroidism in the mother. Not only can hCG have a thyrotropic effect, but there is recent evidence that the hCG molecule from women with trophoblastic diseases displays enhanced thyrotropic activity compared with that from normal pregnant women.¹⁵ This thyrotropic effect in normal women causes a mild lowering of TSH early in pregnancy, recognized by most laboratories, which report lower normal ranges of TSH during pregnancy. It is important that this be recognized and taken into consideration when considering the diagnosis of hyperthyroidism in the mother, another fairly common condition that is discussed in more detail below.

Thyrotropin-releasing hormone

Thyrotropin-releasing hormone (TRH) is produced by the placenta and enters the maternal and fetal circulation.^{16,17} However it seems to be more important in fetal thyroid function than in maternal thyroid function.

Human chorionic somatomammotropin (human placental lactogen)

Human chorionic somatomammotropin, also known as human placental lactogen, is a polypeptide that has a structure very similar to that of human growth hormone. Its major function is to provide the nutritional needs of the fetus during pregnancy. The role of this hormone in pregnancy relates more to its metabolic properties than to its somatotropic or lactogenic effects.¹⁷ Its major effect on the maternal endocrine system relates to its effect on carbohydrate and fat metabolism, playing a role in the shift of energy metabolism from

carbohydrate to fat during pregnancy. Despite these effects, it probably does not play a major role in altering glucose and insulin levels during pregnancy.

Placental growth hormone

There is a placental growth hormone variant synthesized by the syncytiotrophoblast and secreted into the circulation during pregnancy, the levels of which relate to fetal growth.¹⁷ This also results in increased insulin-like growth factor (IGF)-1 levels during pregnancy¹⁸ (see Fig. 42.3). Although there is a specific antibody for measuring the placental growth hormone variant, some commercial growth hormone assays may measure this along with the maternal pituitary growth hormone. Thus, elevated growth hormone and IGF-1 levels may confuse the diagnostic evaluation of a patient with a possible growth hormone-secreting pituitary tumor during pregnancy.

Insulin-like growth factor

IGF-1 is a peptide that is important for fetal and placental growth during pregnancy.^{18,19} It is bound by a family of binding proteins. IGFBP-1, IGFBP-4, and perhaps others are synthesized by the endometrium and placenta. They probably

Figure 42.3 Placental growth hormone (GH) and IGF-1 levels during pregnancy. The lines shown represent the mean and 95% confidence interval. Reprinted with minor changes from ref. 18.

play an important part in the insulin–glucose homeostasis system during pregnancy (see Chapter 5).

Endocrine disorders of pregnancy

There are a variety of endocrine disorders which, when associated with pregnancy, have unique aspects of importance to the mother, newborn, or both that may alter the usual diagnostic or therapeutic strategies.²⁰ In some instances, the disease is more likely to occur or may be worsened by the pregnancy; in some, changes resulting from the pregnancy and/or the associated alterations in metabolism influence the diagnostic evaluation; and, in some, the treatment strategy of the endocrine disorder may require alterations to avoid detrimental effects on the fetus.

Thyroid disorders

Thyroid disorders in pregnancy are relatively common in the general population and are much more common than previously thought because of increased screening and the increased sensitivity of current diagnostic techniques. Overt hypothyroidism and hyperthyroidism have clearly been shown to have detrimental effects on the pregnancy and the fetus. It is more difficult to establish the risk to the fetus of untreated mild hypothyroidism or hyperthyroidism. Although there is no clear consensus on thyroid screening of all pregnant women,²¹ thyroid disease is sufficiently common that all pregnant women should be screened with a serum TSH antibody. This is mainly to detect overt biochemical hypo- or hyperthyroidism that has been overlooked clinically. Some have recommended adding free T₄ and thyroid thrombopoietin (TPO) antibodies to the screen, but this should probably be reserved for patients with an abnormal TSH level or a family history of autoimmune thyroid disease. Several comprehensive reviews of thyroid disorders in pregnancy have been published.^{20–25} This review of thyroid diseases during pregnancy will emphasize the practical management issues.

Goiter

Thyroid size has historically been said to increase in pregnancy. However, objective studies have shown that this only occurs in the presence of iodine insufficiency.²⁶ It seems that marginal iodine insufficiency is enough of a stimulus to cause thyroid enlargement during pregnancy, whereas a normal iodine intake is adequate to maintain normal thyroid size. Such an increase in thyroid size can be prevented by as little as 100 µg of supplemental dietary iodine daily, an amount easily consumed by simply using iodized salt.

Thyrotoxicosis

The term thyrotoxicosis is used for an increased metabolic state associated with excess thyroid hormone levels from any source. Hyperthyroidism is the term reserved for thyrotoxi-

sis due to thyroid gland hyperfunction, i.e., Graves' disease or toxic nodular goiter. Although both thyroid hyperfunction and hypofunction may be associated with infertility, these conditions are not uncommonly seen in pregnancy.

Thyrotoxicosis is the most frequent thyroid disorder in the pregnant patient and is the most difficult to evaluate and manage. Being certain that one is dealing with hyperthyroidism as the cause of thyrotoxicosis may be difficult as performing a radioactive iodine uptake is contraindicated in pregnancy. Silent thyroiditis (postpartum thyroiditis) may occur during late pregnancy and may cause transient thyrotoxicosis. This may be difficult to differentiate from Graves' hyperthyroidism, again, because a radioactive iodine uptake cannot be done. If the patient is sufficiently symptomatic and the diagnosis is not clear during pregnancy, antithyroid drug therapy may be instituted, which will be beneficial for Graves' hyperthyroidism but not for the thyrotoxicosis due to silent thyroiditis. Painful subacute thyroiditis is no more likely to occur in the pregnant than in the nonpregnant state. This condition is recognized by the presence of an enlarged, painful, tender thyroid gland, sometimes with fever, and may be associated with transient thyrotoxicosis. It is generally self-limiting and resolves in a few weeks. Another potentially difficult differential diagnosis is the transient gestational thyrotoxicosis of hyperemesis gravidarum. In hyperemesis gravidarum, biochemical thyrotoxicosis is commonly seen. Such patients usually do not have supporting clinical features of thyrotoxicosis, and free T₄ and TSH generally return to normal by 15–20 weeks of gestation with free T₄ preceding TSH in the return to normal²⁷ (Fig. 42.4).

Figure 42.4 Mean free T₄ levels by gestation. *Mean free T₄ levels established in the normal population. †Mean free T₄ levels in women with hyperemesis gravidarum. Reprinted from ref. 27.

Even after hyperthyroidism is established as the probable cause of thyrotoxicosis, management is complicated by the fact that the antithyroid drugs propylthiouracil (PTU), methimazole (MMI), and carbimazole cross into the fetal circulation readily whereas thyroid hormone does so less readily. A unique study in patients with thyroid hormone resistance has shown that high maternal thyroid hormone levels *per se* are detrimental to the fetus.²⁸ Inadequate treatment of maternal hyperthyroidism is associated with prematurity, low birthweight infants, small for gestational age infants, and stillbirths. It is less certain whether there is an increase in congenital malformations. Uncontrolled maternal hyperthyroidism in the last trimester may result in transient central hypothyroidism in the newborn, presumably due to suppression of fetal TSH and impaired maturation of the fetal hypothalamic–pituitary–thyroid system.²⁹ Diagnosis requires a T₄ as well as a TSH determination in the newborn. The hypothyroidism may last for weeks to months and may require treatment of the infant. On the other hand, aggressive treatment of maternal thyrotoxicosis may cause fetal goiter, fetal hypothyroidism, and the associated consequences of either fetal loss or impaired intellectual development.

Radioactive iodine therapy is contraindicated in hyperthyroidism in the pregnant mother, although in the few reports in which this was done inadvertently, the results were for the most part not catastrophic.^{30,31} The greatest risk appears to be if radioactive iodine is given late in the first trimester, at the time of fetal thyroid development and high sensitivity to radioactive iodine. Thus, surgical thyroidectomy or antithyroid drug therapy are the only two therapeutic options for hyperthyroidism in pregnancy. The main indication for surgical thyroidectomy is the hyperthyroid patient who cannot tolerate thionamide therapy or whose hyperthyroidism cannot be adequately controlled with thionamides. Thus, in the vast majority of patients, therapy with a thionamide, either PTU or MMI in the United States or carbimazole in Europe, has become the preferred therapy.

In view of the risks of untreated or undertreated hyperthyroidism as well as overtreatment of hyperthyroidism, one must always evaluate the risk/benefit ratio of treating maternal hyperthyroidism on a case by case basis. In the newly diagnosed hyperthyroid woman, beta-blockers such as propranolol are effective in controlling symptoms and signs of hyperthyroidism in a short period of time and appear to be safe. However, long-term treatment with beta-blockers, particularly during the third trimester is not recommended, as there have been reports of neonatal morbidity and mortality associated with such long-term use, although it is always difficult to know whether it is the beta-blocker therapy or the underlying condition that might be responsible for any fetal effects. In extremely severe maternal hyperthyroidism, short-term therapy with stable iodine may be helpful and appears to be safe. Chronic maternal iodine therapy may be associated with fetal goiter or hypothyroidism.

Even though there are no well-controlled studies of various treatment regimens using thionamides for hyperthyroidism in

the pregnant mother, the standard treatment recommendation is to treat the mother with a thionamide. The dose should be sufficient to keep the free T₄ level in the upper normal or mildly elevated range, which is usually accompanied by a low or suppressed TSH. This approach balances minimizing the risk of overt hyperthyroidism to fetal development and survival while at the same time avoiding the risk of excessive thionamide therapy, which may affect fetal thyroid development and function and fetal survival. PTU has traditionally been preferred over MMI because PTU was thought to cross the placenta less well and because of reports of cutis aplasia and other possible congenital abnormalities in the infant related to MMI therapy. However, a recent study has questioned the evidence for this advantage of PTU over the other thionamides and has emphasized the importance of individualization of the thionamide dose.³² As such a large experience with successful outcomes has been developed using PTU, this continues to be the main antithyroid drug used by most endocrinologists treating hyperthyroidism in pregnancy. A pregnant woman who has hyperthyroidism should be monitored at 4- to 6-week intervals during the pregnancy.

As the third trimester approaches, one must be aware that hyperthyroidism in the mother frequently improves, allowing dose reduction or discontinuation of antithyroid drug therapy. There is evidence that improvement is associated with a decline in thyroid-stimulating antibodies and TSH-binding inhibitory immunoglobulins during pregnancy.³³ As symptomatic Graves' hyperthyroidism commonly recurs in the postpartum period, either continuation of low-dose antithyroid therapy during the third trimester or careful frequent monitoring during the postpartum period with reinstitution of antithyroid therapy as soon as biochemical hyperthyroidism recurs may prevent clinically symptomatic hyperthyroidism during this time.³⁴

In addition, early in the third trimester is an appropriate time to measure TSH receptor-stimulating antibodies and/or thyroid-stimulating immunoglobulins in the mother.^{35,36} These antibodies cross the placenta and can produce transient hyperthyroidism in the infant. It should be emphasized that all women with a history of Graves' disease, even if not hyperthyroid during the present pregnancy, may have these circulating antibodies and should have them measured early in the third trimester of the pregnancy. Transient hyperthyroidism in the infant occurs in about 17% of patients with high levels of thyroid-stimulating immunoglobulins,³⁶ and the risk relates to the antibody titer³⁶ (Fig. 42.5). TSH receptor-blocking antibodies may also be present, which can lead to transient fetal hypothyroidism. It is probably not necessary to measure blocking antibodies routinely, but one can obtain a TSH level in the newborn, as is done routinely. Several recent studies have demonstrated the value of ultrasonographic monitoring of fetal thyroid size during thionamide therapy, which might be an indicator of either fetal Graves' disease or fetal hypothyroidism.³⁷ In one study, umbilical blood sampling was done in patients with positive thyroid-

Figure 42.5 Maternal thyroid-stimulating immunoglobulin values and pregnancy outcomes in 35 pregnancies. There are 29 data points in the bar with normal outcomes. Solid figures of similar shape represent different pregnancies from the same mother. Reprinted from ref. 36.

stimulating or -blocking antibody levels for diagnosis of fetal hyperthyroidism or hypothyroidism, treated with maternal thionamide therapy in the former instance or T_4 injection into the amniotic sac in the latter case.³⁸ Whether such an aggressive approach is justifiable remains to be determined.

Regarding continued management during the postpartum period, an advantage of PTU over MMI is that it appears to be secreted in breast milk in lower concentrations. Daily doses of PTU of up to 600 mg have been shown to have no significant affect on the infant's thyroid hormone level.²² Current evidence supports the view that breastfeeding with either of the thionamides appears to be safe for the infant. Thus, PTU can be continued or reinstituted during breastfeeding. In such a case, it would always be reasonable to check the infant's TSH levels after several months to be absolutely certain that fetal thyroid function has not been affected. Obtaining a radioactive iodine uptake and administering radioactive iodine therapy should be withheld until breastfeeding has been completed.

Hypothyroidism

Hypothyroidism is most commonly due to primary thyroid gland failure resulting from radioactive iodine treatment of hyperthyroidism, surgical thyroidectomy, or idiopathic primary hypothyroidism, often related to underlying Hashimoto's thyroiditis. Rarely, hypothyroidism may be due to underlying pituitary disease. This is unlikely as patients with pituitary hypothyroidism usually have pituitary hypogonadism and are unlikely to achieve a pregnancy. Primary hypothyroidism may be diagnosed prior to pregnancy or may be first diagnosed during pregnancy. Gestational hypothyroidism is linked to fetal cognitive development and an increased rate of fetal death. This relationship has been most clearly established for severe hypothyroidism and, as one might expect, less well established for mild hypothyroidism. Worldwide, iodine defi-

ciency is a common cause of hypothyroidism and may be more common in Western societies than previously thought. It is readily preventable by small supplemental doses of dietary iodine.³⁹ There is an increasing consensus that clinical and subclinical maternal hypothyroidism requires early detection and treatment.³⁹ In addition to screening pregnant women with a TSH antibody for the presence of primary hypothyroidism, any woman on replacement L-thyroxine therapy should have their TSH and free T_4 levels monitored periodically during pregnancy as L-thyroxine requirements often increase during pregnancy. This has recently been carefully studied with the finding that the average increase in T_4 requirement in pregnant women is nearly 50% during the first half of pregnancy.⁴⁰ Therefore, because of the known importance of maternal thyroid function for normal fetal cognitive development, and the fact that increased T_4 requirements may occur as early as the fifth week of pregnancy, it has been recommended that treatment be initiated as soon as pregnancy is confirmed. Patients should be given about a 30% increase in their thyroid hormone dose and then be monitored and have their T_4 dose adjusted as necessary.⁴⁰

Postpartum thyroid disease

In the postpartum period (up to 1 year postpartum), one must be sensitive to the possibility of silent thyroiditis (postpartum thyroiditis), generally manifest as transient thyrotoxicosis, sometimes followed by transient hypothyroidism.⁴¹ This may easily be overlooked in the mother going through emotional changes following pregnancy and the many responsibilities in caring for a newborn. In the thyrotoxic phase, this can be confirmed by demonstrating high free T_4 and free T_3 levels with a suppressed TSH level. If the mother is not breastfeeding, a low radioactive iodine uptake may be helpful in making the diagnosis. This transient thyrotoxicosis may be followed by a transient phase of hypothyroidism in up to 40% of patients. Recovery of normal thyroid function usually occurs (Fig. 42.6),

Figure 42.6 Clinical pattern of postpartum thyroid dysfunction in three women studied weekly for 30 weeks postpartum. FT3, free T₃; FT4, free T₄; RAIU, percent radioactive iodine uptake at 24 h; TPOAb, thyroid peroxidase antibodies. The top part of the figure shows hormone levels from a patient with transient hyperthyroidism developing 8–9 weeks postpartum; the middle part of the figure is from a patient with transient hyperthyroidism developing 22–24 weeks postpartum; and the lower part of the figure is from a patient developing modest transient hyperthyroidism followed by severe transient hypothyroidism. Note the significant rise in anti-TPO antibody. Reprinted from ref. 56.

although long-term follow-up of such patients indicates that permanent hypothyroidism is common.⁴² Beta-blocker therapy is appropriate during the hyperthyroid phase for the symptomatic patient.

Fetal thyroid disease

Fetal primary hypothyroidism is now usually detected through fetal screening at birth. Transient fetal hyperthyroidism usually occurs in conjunction with maternal Graves' hyperthyroidism (see above). An excellent detailed review of this topic is available.²³

Pituitary disorders

Prolactinoma

The pituitary gland normally enlarges during pregnancy owing to lactotroph hyperplasia.⁴³ The most common potentially serious therapeutic problem associated with pituitary gland disorders and pregnancy is the coexistence of a pituitary prolactin-producing tumor and pregnancy. This is being seen with increasing frequency, as the diagnosis of a prolactinoma is made during the evaluation of infertility in a woman with amenorrhea and galactorrhea. An elevated serum prolactin level leads to a pituitary magnetic resonance image (MRI), which demonstrates a pituitary tumor, most commonly a microadenoma (< 1 cm) but occasionally a macroadenoma (> 1 cm). Although this can be a gratifying situation in which infertility is very treatable, before therapy with a dopamine agonist such as bromocriptine or cabergoline, the physician should discuss the potential risks and benefits to the mother and fetus of a pregnancy resulting from dopamine-induced fertility. Such fertility is a result of lowering of the serum prolactin, with cessation of galactorrhea and resumption of menses. The physician is then faced with optimal management of this woman during her pregnancy. A large experience from a single center in patients with pregnancy and a coexisting prolactinoma has been published.⁴⁴

If a microprolactinoma was known to be present before the pregnancy, there is a very small risk of significant tumor growth requiring therapy during the pregnancy. Although it appears that bromocriptine is likely to be safe when taken during pregnancy, it is recommended that it be stopped as soon as the pregnancy is recognized. In a recent review, only 1.4% of over 300 patients with microprolactinomas had symptomatic tumor enlargement defined by headaches and/or visual field disturbance, and none required surgery.⁴⁵ Any documented visual field disturbance or significant increase in headaches would indicate the need for a follow-up MRI during the pregnancy. Although some authors have indicated that there is no value in monitoring prolactin levels in such patients because of the normal rise in prolactin during pregnancy (Fig. 42.1), it would seem reasonable to monitor prolactin levels periodically. If a substantial rise in serum prolactin occurs beyond that expected from the pregnancy, a follow-up MRI of the pituitary might be considered

even in the absence of increasing headaches or visual field disturbance.

In the occasional patient with a macroprolactinoma diagnosed prior to pregnancy, most endocrinologists would advise against any attempt at pregnancy until the tumor showed substantial regression following medical therapy or surgical resection. The problem with doing a surgical resection in such a patient is that there is a significant risk of postoperative hypogonadotropic hypogonadism, making it much more difficult for the woman to conceive. When a pregnancy occurs in a patient with a diagnosed macroprolactinoma, one must undertake frequent follow-up including regular visual field determinations by a neuro-ophthalmologist and a follow-up MRI during the pregnancy. The risk of significant symptomatic tumor enlargement during pregnancy is about 25%, and the risk seems to be greater in patients with no prior therapy compared with those with prior surgical or radiation therapy.⁴⁵ There is little information available on the incidence of tumor enlargement following first shrinkage of the tumor with dopamine agonist therapy followed by a pregnancy. In all patients with a present or prior macroprolactinoma, one must weigh up the advantages and disadvantages of discontinuing dopamine agonist therapy against those of continuing or initiating dopamine agonist therapy. The data available suggest that both bromocriptine and cabergoline are safe when given during pregnancy, although there are much less data available for use throughout pregnancy compared with use of these drugs only early in pregnancy. As there are more data available for bromocriptine than for cabergoline, when the decision is made to use dopamine agonist therapy, it is preferable to use bromocriptine. One helpful point in making this decision is the size of the tumor and the amount of suprasellar or lateral extension of the tumor. If the tumor is less than 2 cm and not overtly impinging on the optic apparatus, it would seem reasonable to discontinue the dopamine agonist therapy, as in a patient with a microprolactinoma, and observe carefully. On the other hand, for a large tumor or one that is pressing on the optic chiasm or invading the cavernous sinus, it would seem reasonable to continue dopamine agonist therapy throughout the pregnancy and follow carefully with visual field determinations and MRI. If the tumor enlarges substantially during pregnancy or visual field abnormalities occur, one must be prepared to undertake surgical decompression of the tumor.

Other pituitary tumors

Pituitary tumors other than prolactinomas have no particularly association with pregnancy, but may coexist with pregnancy. This includes secretory and nonsecretory pituitary tumors. Nonsecretory tumors are not commonly seen in pregnancy as the frequent hypopituitarism present in such patients makes pregnancy unlikely. Secretory pituitary tumors such as pituitary Cushing disease and acromegaly have occasionally been seen in pregnancy, although the frequently associated infertility makes this situation uncommon.⁴⁴⁻⁴⁶ These diseases

are not more likely to occur during pregnancy. However, they each have special diagnostic problems, and great caution should be exercised in making these diagnoses in a pregnant patient.

Regarding acromegaly, the placental growth hormone variant secreted into the circulation during pregnancy may not be distinguished from the normal adult growth hormone in clinical growth hormone assays and may give a falsely high serum growth hormone level. Maternal IGF-1 levels also normally rise during pregnancy¹⁷ (Fig. 42.3). In the absence of unequivocal dramatic clinical features, the diagnosis of acromegaly or a growth hormone-secreting tumor should be delayed until the postpartum period. If a patient with known acromegaly becomes pregnant, there might be a greater problem with hypertension and diabetes than in the nonacromegalic patient. Therapeutically, as the potential fetal effects of octreotide during pregnancy have not been clearly established, and as bromocriptine is in general only modestly effective, such patients are probably best left untreated until the pregnancy is complete. The only major exception would be an increase in tumor size during pregnancy with pressure symptoms on the optic apparatus, making surgical therapy a consideration during the pregnancy.

Regarding Cushing syndrome of any type, particularly pituitary Cushing disease, once again it is best to delay biochemical evaluation until the postpartum period. This is because, as indicated above, urine free cortisol, plasma cortisol, and ACTH levels normally increase during pregnancy (Table 42.1), making diagnostic studies difficult to interpret, including dexamethasone suppressibility. The exception would be a patient with dramatic catabolic features of Cushing syndrome or a patient with ACTH-independent Cushing syndrome with a low ACTH due to an adrenal tumor. If profound pituitary Cushing disease is thought to be present, one should treat any resulting hypertension or diabetes, deferring definitive therapy until the postpartum period.

Hypopituitarism

Patients with partial hypopituitarism who become pregnant should simply be monitored carefully. If they require cortisol replacement due to ACTH deficiency, one might consider a slightly higher replacement dose of 30 mg of hydrocortisone daily in divided doses rather than the usual 15–20 mg daily as cortisol levels typically increase during normal pregnancy. Patients with diabetes insipidus may experience worsening of their condition during pregnancy related to increased clearance of arginine vasopressin by the increased levels of vasopressinase known to exist in pregnancy.²⁰ As desmopressin is resistant to vasopressinase, this is probably the preferred therapy in the rare case in which diabetes insipidus is present.

Lymphocytic hypophysitis

Lymphocytic hypophysitis is an uncommon inflammatory autoimmune disorder of unknown etiology occurring with increased frequency in the postpartum period or rarely in late

pregnancy.^{47,48} It usually presents with symptoms of a mass effect including headaches, visual field disturbances, and a sellar/suprasellar mass visualized on MRI. Anterior pituitary hormonal deficiencies and hyperprolactinemia occur in approximately half of such patients. Diabetes insipidus is frequently present. The main differential diagnosis is between an inflammatory mass and a pituitary macroadenoma. The other inflammatory disorders in the differential diagnosis include granulomatous diseases, most commonly sarcoidosis. The Tolosa-Hunt syndrome may also have similar MRI characteristics, but is usually differentiated clinically by the presence of orbital pain and cranial nerve palsies. There are certain MRI characteristics suggestive of an inflammatory process. If these MRI characteristics are present, the diagnosis is often made clinically without histological confirmation. The presence of diabetes insipidus is supportive of the diagnosis of an inflammatory etiology as this rarely occurs in patients with a pituitary adenoma. Although a female preponderance is described in patients diagnosed with lymphocytic hypophysitis, this depends on the definitions used and the institutional experience. In one center reporting 16 patients with primary hypophysitis, 13 of whom had histological verification of the diagnosis, half were male.⁴⁹ In this series, two had had a recent pregnancy and one occurred in late pregnancy. Lymphocytic hypophysitis often improves spontaneously or responds to glucocorticoid therapy, although persistent partial hypopituitarism is common. Surgical therapy may be required because of the mass effect, which at the same time provides tissue to document the diagnosis. If one discovers a new symptomatic pituitary mass during late pregnancy or in the postpartum period, particularly if associated with diabetes insipidus, the likelihood is that this is an inflammatory hypophysitis rather than a pituitary macroadenoma.

Sheehan syndrome

Although Sheehan syndrome does not occur during pregnancy, it is a complication of pregnancy. Sheehan syndrome is infarction of the pituitary gland postpartum, which was originally described as resulting from hypotension following massive bleeding at or around the time of delivery. Current information indicates that, although it still usually occurs following severe postpartum vaginal bleeding, it may occur in the absence of massive bleeding, presumably secondary to vasospasm, thrombosis, or vascular compression of the anterior pituitary. The enlarged pituitary gland of pregnancy may be more susceptible to such events. Typically, the key to diagnosis is the history of bleeding, the failure to lactate in the postpartum period, and failure of the resumption of menses. This syndrome may occasionally present similarly to pituitary apoplexy. Most commonly, it is insidious in its presentation and, although imaging may show an enlarged nonhemorrhagic pituitary gland if the patient presents early, more commonly imaging shows an empty sella by the time the diagnosis is made. The newer as well as the older aspects of this disease have been reviewed recently.⁵⁰ Any patient with an obstetric

hemorrhage and prolonged hypotension following delivery should have hormonal evaluation of possible hypopituitarism and be treated with stress doses of steroids until cortisol levels measured prior to treatment are available. If the diagnosis is in question, the patient can gradually be tapered off steroids after clinical improvement and undergo formal testing with a metyrapone test as well as assessment of other pituitary endorgan hormones.

Adrenal gland disorders

Congenital adrenal hyperplasia

Although pregnancy in a woman with congenital adrenal hyperplasia is a matter that the obstetrician and endocrinologist do not deal with often, it presents some special issues, namely that of prenatal diagnosis and possible early therapeutic intervention.⁵¹ The congenital adrenal hyperplasias are a group of disorders involving enzymatic defects of adrenal steroid biosynthesis usually inherited as a recessive trait. As more than 95% of such patients who achieve pregnancy will be those with the 21-hydroxylase deficiency, this is the only disorder reviewed here. 21-Hydroxylase deficiency may be either the salt-losing type or the classic virilizing type. Such patients are typically managed with glucocorticoids in doses adequate to maintain 17-hydroxyprogesterone, androstenedione, and testosterone levels in the normal or near normal range. Although fertility is often decreased in such patients, patients who are able to be well controlled biochemically and those with milder disease often menstruate regularly and are fertile. Monitoring the adequacy of steroid hormone therapy during pregnancy is complicated by the fact that 17-hydroxy-

Figure 42.7 The luteal phase (LP) reference interval for 17-hydroxyprogesterone, 0.8–8.7 nmol/L, is shown in the shaded area at the left. Changes in maternal serum concentrations of 17-hydroxyprogesterone during pregnancy. Data are from 60 women who had hormone levels measured at three different times during the pregnancy. The solid lines correspond to the mean and central 95th percentile values. Reprinted from ref. 2.

progesterone levels rise substantially during normal pregnancy (Fig. 42.7). Total testosterone levels rise, but free testosterone levels are unchanged during gestation and may be used as a guide to the adequacy of steroid hormone suppression. Although many authors do not recommend a change in steroid hormone doses during pregnancy in such patients, in view of the normally increased cortisol levels during pregnancy, it would seem reasonable to treat such patients with slightly higher steroid doses, i.e., 30 mg of hydrocortisone daily in divided doses in contrast to the more usual 15–20 mg daily in adrenal insufficiency. There is insufficient data to provide much information on pregnancy outcomes in such patients.

Prenatal diagnosis of 21-hydroxylase deficiency in the fetus is now possible, raising possible therapeutic decisions and ethical concerns. A detailed discussion of these issues is beyond the scope of this chapter. However, such decisions must be made after detailed counseling of the parents by someone trained in genetic counseling, informing them of the potential risks of the procedure, the probability of the fetus being affected, and the risks and benefits of identifying an affected fetus.⁵¹ Such counseling should take into consideration the parents' moral and religious values. Optimal treatment to prevent virilization in the affected female fetus requires administration of glucocorticoids, preferably dexamethasone, prior to the seventh week of gestation followed by chorionic villus sampling at 10 weeks.⁵² If genotyping demonstrates that the fetus is a male or unaffected female, dexamethasone is tapered and discontinued over a 1-week period. Depending on the parents' genetics, the chances of the fetus being an affected female are fairly small. This results in the unnecessary exposure of the majority of fetuses to dexamethasone, which has an undetermined long-term effect. This issue is currently under intensive study.⁵² An alternative approach is to evaluate the fetal perineum and adrenal glands by ultrasound as soon as possible and, if there appears to be an affected female fetus, therapy can be started at that time. Although this approach is probably much less effective than earlier treatment, it may have some benefit.⁵¹

Endocrine hypertension in pregnancy

As hypertension in pregnancy is extremely common, the most difficult decision is deciding when one should look for correctable causes of hypertension in the pregnant woman. This is a decision that must be individualized and must be made by the patient's obstetrician. A detailed review of the endocrine causes of hypertension in pregnancy is available.⁵³ Some of the most serious causes are discussed here in more detail.

Adrenal gland tumors

Although any adrenal gland tumor including benign secretory or nonsecretory tumors of the adrenal cortex, adrenal cortical carcinoma, or pheochromocytoma may occur or be diagnosed during pregnancy, there is nothing to indicate that these occur with an increased frequency in pregnancy. The main issue to

consider is whether such disorders require any special diagnostic or therapeutic considerations because of the pregnancy. Other than the biochemical diagnostic studies used to diagnose an adrenal gland disorder, the only safe abdominal radiologic studies to identify such a lesion are an MRI or ultrasound. In a pregnant woman who is thought to have a benign nonsecretory tumor of the adrenal gland, a definitive diagnosis should be delayed until the postpartum period unless a very large tumor is present and an adrenal carcinoma is suspected. In such a case, intervention should be carried out with a laparoscopic adrenalectomy immediately unless the tumor is too large to approach by this technique. An androgen-secreting tumor is unlikely because of the usual associated infertility.

Primary hyperaldosteronism

In primary hyperaldosteronism, the primary diagnostic difficulty relates to the fact that aldosterone levels rise during normal pregnancy (Fig. 42.2). A suppressed renin level during pregnancy, which does not normally occur, is a clue that primary hyperaldosteronism might be present, but is insufficient to make the definitive diagnosis. Therefore, unless there is a pressing clinical situation, definitive diagnostic procedures should be delayed until the postpartum period. Spironolactone is contraindicated as medical therapy. Hypokalemia is best managed simply by potassium replacement. If the hypertension cannot be adequately controlled by other drugs that are acceptable during pregnancy, and if the diagnosis seems clear, consideration can be given to a laparoscopic adrenalectomy during the second trimester.

ACTH-independent Cushing syndrome

In Cushing syndrome resulting from a cortisol-producing adenoma, cortisol levels are of limited value for diagnosis as they normally rise substantially during pregnancy (Table 42.1). However, a suppressed ACTH level may be of value. As in primary hyperaldosteronism, most patients can simply be followed through their pregnancy without specific treatment, but with treatment of their hypertension. If they have evidence of severe Cushing syndrome with catabolic features, a laparoscopic adrenalectomy may be performed during the second trimester.

Pheochromocytoma

Although the presence of a pheochromocytoma during pregnancy is rare, proper diagnosis and management is vital. The diagnosis of pheochromocytoma is usually not complicated by the presence of the pregnancy because urine catecholamines, metanephrines, and vanillylmandelic acid (VMA) are generally normal in the pregnant patient who is not unduly stressed. The benefit of medical management in such a patient far outweighs the unknown possible risk to the fetus resulting from the use of appropriate pharmacotherapy. The patient should be treated with alpha blockade, using a drug such as phenoxybenzamine, and beta blockade as necessary. Timing of adrenalectomy for this condition in pregnancy is controver-

sial. If the patient is relatively stable, it is probably best to delay resection of the pheochromocytoma until the fetus is viable. However, if any threat to the mother's health ensues, surgical therapy should be undertaken at that time.

Renovascular hypertension

Although renovascular hypertension is not a primary endocrine disorder, this may become a consideration in the pregnant women with accelerated hypertension. Although aldosterone and renin levels are of limited value because of the increases that occur in normal pregnancy (Fig. 42.2), and many of the usual diagnostic techniques such as nuclear medicine scans and angiography are contraindicated in pregnancy, ultrasound Doppler blood flow of the renal arteries and MRI may be helpful. Beta-blocker therapy is the preferred medical therapy. If possible, definitive therapy of renal artery stenosis with angioplasty or renal artery bypass should be delayed until the postpartum period.

A pregnant woman, recently seen at our institution and screened for renovascular hypertension with an ultrasound during the second trimester, was found to have a 6 × 8-cm adrenal tumor. Endocrine evaluation indicated that the tumor was secreting cortisol, as demonstrated by a very high 24-h urine free cortisol level of 1300 µg/24h and a low plasma ACTH level of 7 pg/mL. It was possibly also secreting aldosterone, but this evaluation was complicated by the known increase in aldosterone levels during pregnancy. A decision was made for her to undergo an open adrenalectomy immediately because of the size of the tumor and uncontrolled hypertension. This was done near the end of the second trimester. The tumor was an adrenal carcinoma. Unfortunately, intrauterine death of the fetus occurred 1 month later at 27 weeks. The patient was followed for the next 3 years with no signs of anatomical or biochemical recurrence of her tumor and thus is one of the few patients likely cured of an adrenal carcinoma because of early diagnosis and immediate therapy.

Addison's disease

If a patient with Addison's disease becomes pregnant, management should be the same as in the nonpregnant state except that it may be best to use hydrocortisone doses at the higher end of usual replacement therapy such as 30 mg daily in divided doses rather than the 15–20 mg daily commonly used; this is because of the increase in urine and plasma cortisol levels seen during normal pregnancy. The dosage of mineralocorticoid therapy may also decrease during pregnancy because of the secondary hyperaldosteronism occurring with pregnancy.

Disorders of calcium metabolism

Vitamin D deficiency

As indicated above, vitamin D requirements during pregnancy have not been clearly established. Nutritional rickets may be more common than previously thought.¹³ Even though 25(OH)vitamin D levels are typically normal during preg-

nancy, adequate vitamin D intake is likely important during pregnancy, and may be even more important in the postpartum period while the mother is nursing. A recent study has indicated that mothers taking 2000–4000 IU of supplemental vitamin D daily while nursing during the first few months after birth do not develop high serum levels of 25(OH)vitamin D. Furthermore, such doses are safe for both the mother and the infant and increase the infant's 25(OH)vitamin D levels to 25–30 ng/dL, ensuring an adequate nutritional status for both mother and infant.¹⁴

Hyperparathyroidism

Hyperparathyroidism, a common endocrine disorder, may occur coincidentally with pregnancy. As the mean age of patients with primary hyperparathyroidism is substantially older than the mean age of pregnancy, these two conditions do not coincide frequently. However, primary hyperparathyroidism in pregnancy has not been reported as frequently as one might expect. This may be due to masking of hypercalcemia by the physiologic hypoalbuminemia that occurs with pregnancy causing a lower than expected total calcium, although the ionized calcium level accurately reflects the hypercalcemia.

When primary hyperparathyroidism occurs with pregnancy, there may be more complications from the hyperparathyroidism than expected.⁵⁴ An increased incidence of maternal and fetal complications has been reported. Nephrolithiasis is reported to occur in hyperparathyroidism associated with pregnancy more frequently than in the nonpregnant state because of the hypercalciuria that occurs in pregnancy. Pancreatitis is also reported to be a more common complication during pregnancy than in the nonpregnant state. Regarding fetal complications, the most common fetal complication is neonatal hypocalcemia. This is presumably due to suppression of the fetal parathyroid glands by the maternal hypercalcemia. This can generally be managed successfully, although neonatal deaths have been reported.

Regarding management of the hyperparathyroidism, one must weigh up the risks of uncontrolled hyperparathyroidism against the benefits and risks of parathyroidectomy. Some have recommended that, if the total serum calcium is less than 12 mg/dL, attempts should be made at conservative management with hydration and decreasing calcium intake.⁵⁴ In patients whose calcium is greater than 12 mg/dL, parathyroidectomy should be considered. Intravenous pamidronate therapy may be safe, but there are significant concerns about potential effects on the fetus, and it should not be used unless there is life-threatening hypercalcemia. As surgical parathyroidectomy in large numbers of patients using current standard techniques with ultrasound-guided localization and intraoperative parathyroid hormone assays by an experienced parathyroid surgeon have only been published in recent years in the nonpregnant patient, this procedure will likely be shown to be safely used with increasing frequency in the pregnant patient undergoing surgery during pregnancy. The most important decision if surgery is contemplated is to identify an

experienced parathyroid surgeon. Preoperative sestamibi parathyroid scans should probably not be done although they may be safe.

Hypoparathyroidism

Patients with idiopathic or surgical hypoparathyroidism who become pregnant should be managed just as if they were not pregnant with sufficient doses of calcitriol and calcium to keep the serum calcium in the low normal range.⁵⁵ As total calcium levels may be falsely low in pregnancy, monitoring the ionized calcium is probably preferable during pregnancy if a reliable ionized calcium assay is available.

Summary

In this chapter, the endocrine changes that occur during

normal pregnancy have been reviewed, emphasizing the impact of these changes on the diagnosis and treatment of various endocrine disorders in pregnancy. Substantial increases in ACTH, cortisol, prolactin, renin, aldosterone, and IGF-1 occur during normal pregnancy. These changes complicate the diagnosis of Cushing syndrome, primary hyperaldosteronism, acromegaly, and pituitary prolactinoma. In addition, the diagnosis and treatment of common thyroid disorders occurring in pregnancy that present special problems have been reviewed as well as treatment of pregnant women with a pituitary prolactin-producing tumor. Other issues such as dealing with the pregnant woman with congenital adrenal hyperplasia have been discussed. It is hoped that this review will make the physician better able to diagnose and treat the pregnant woman with an endocrine disorder.

Key points

- 1 Lactotroph hyperplasia causes pituitary size to increase during pregnancy, and prolactin levels may rise to values as high as > 10 times the upper limit of normal for the nonpregnant state.
- 2 Corticotropin-releasing hormone derived from the fetal-placental unit appears in the maternal circulation at very high levels, causing maternal increases in ACTH and true free cortisol levels.
- 3 Diagnosis of Cushing syndrome during pregnancy should be made with caution.
- 4 Plasma osmolality decreases by about 10 mOsm/kg, and renin and aldosterone levels increase three- to fourfold during normal pregnancy.
- 5 Diagnoses of abnormalities in salt and water metabolism, i.e., hyperaldosteronism, are complicated by the normal changes occurring during pregnancy.
- 6 Maternal vitamin D requirements during pregnancy and lactation may be greater than previously thought.
- 7 Normal pregnancy causes a mild lowering of TSH levels because of the thyrotropic effect of the high chorionic gonadotropin levels.
- 8 Pregnancy-adjusted normal ranges for TSH should be taken into consideration when diagnosing or managing disorders of thyroid function during pregnancy.
- 9 A placental growth hormone variant is secreted during normal pregnancy, which suppresses maternal pituitary growth hormone and increases maternal IGF-1 levels.
- 10 Diagnosis of growth hormone deficiency or excess during pregnancy must take into consideration the effects of secretion of the placental growth hormone variant.
- 11 As maternal hypothyroidism or hyperthyroidism may have adverse fetal effects, pregnant women should have their TSH level determined early in pregnancy.
- 12 Thyrotoxicosis during pregnancy due to Graves' hyperthyroidism may be difficult to distinguish from thyroiditis or hyperemesis gravidarum.
- 13 Hyperthyroidism during pregnancy should be treated with antithyroid drugs in doses sufficient to achieve adequate control of maternal hyperthyroidism without causing fetal hypothyroidism.
- 14 Pregnant women with present or past Graves' disease should be screened during the early part of the third trimester for TSH receptor antibodies to determine the fetal risk for neonatal thyrotoxicosis.
- 15 Pregnant women being treated with L-thyroxine for hypothyroidism should be monitored frequently during pregnancy as a 30–50% increase in L-thyroxine requirement is commonly seen.
- 16 Women with amenorrhea and galactorrhea may have a pituitary prolactin-producing tumor, and fertility can be restored by treatment with a dopamine agonist such as bromocriptine.
- 17 Patients with a microprolactinoma who become pregnant after taking a dopamine agonist should have the dopamine agonist stopped as soon as they learn of their pregnancy because the growth of the microprolactinoma during pregnancy is very small.

- 18 In the unusual patient with a macroprolactinoma who becomes pregnant, the therapeutic decision must be individualized, weighing up the risks and benefits of continuing dopamine agonist therapy against follow-up therapy.
- 19 The postpartum period, a time when the mother is dealing with the physical and emotional stresses of a new baby, is a time when thyroiditis commonly occurs, which may present as transient thyrotoxicosis or hypothyroidism.
- 20 Presentation with headaches and amenorrhea in the postpartum period should lead one to entertain the possible diagnoses of lymphocytic hypophysitis or Sheehan's syndrome.
- 21 Pregnancy in a woman with congenital adrenal hyperplasia presents special ethical issues regarding possible prenatal diagnosis and/or therapeutic intervention in a potentially affected infant.

Gastrointestinal diseases complicating pregnancy

Washington Clark Hill and Alfred D. Fleming

Pregnancy can complicate almost any gastrointestinal disease. The pregnant woman may enter pregnancy with a gastrointestinal disorder, or it may develop during pregnancy. The physiologic effects of pregnancy may cause gastrointestinal disturbances such as nausea, vomiting, hyperemesis gravidarum, and esophageal reflux. Conversely, gastrointestinal disorders such as ruptured appendix, gallbladder, and inflammatory bowel disease may affect the course of pregnancy. New findings and diagnostic advances warrant revisiting key features of acute nonobstetric abdominal pain in pregnancy.¹ This chapter discusses the various gastrointestinal diseases complicating pregnancy and their effect on the fetus and mother.

Diseases within the gastrointestinal tract

Nausea, vomiting, and hyperemesis gravidarum

Nausea with or without vomiting is an especially common symptom during early pregnancy and the most common gastrointestinal complaint. It usually occurs during the first trimester of pregnancy and, by mid-second trimester, most women no longer complain of these symptoms. It occurs in approximately 60–80% of pregnancies. In its mildest form, it is referred to as morning sickness, which is unpleasant and distressing, both physically and psychologically, but requires no particular therapy. Approximately 1–2 per 1000 pregnant patients may experience some morning sickness throughout their entire pregnancy. It is unknown why some patients experience no morning sickness and others are bothered by it all the time.

The cause of nausea and vomiting during pregnancy is also unknown. The smooth muscles of the stomach do relax during pregnancy, and this physiologic change may play some role. The role of human chorionic gonadotropin (hCG) has been studied; however, a clear correlation between maternal serum hCG levels and the severity of morning sickness has not been demonstrated.² Patients with high levels of hCG, as in mul-

tiple gestation or hydatidiform moles, may or may not experience exaggerated nausea and vomiting throughout pregnancy.

The management of nausea and vomiting during pregnancy is primarily supportive. Therapeutic regimens include reassurance, physical and psychological support, frequent small meals, the avoidance of foods that are unpleasant or that may initiate symptoms, adequate hydration and fluid intake, and selective, occasional use of antiemetics. There is no ideal antiemetic currently available for the treatment of morning sickness. Until 1983, Bendectin was available; this drug was a combination of doxylamine succinate (10 mg) and pyridoxine (10 mg). Bendectin, which had been approved by the Food and Drug Administration (FDA) for the treatment of nausea and vomiting in pregnancy, was removed from the market by the pharmaceutical company in 1983, primarily because of litigation. There was no evidence that Bendectin was teratogenic.^{3–7} When symptoms require treatment, both pyridoxine and doxylamine are still available over the counter as Unisom (25 mg). Several studies have shown that pyridoxine alone may be effective in treating patients with severe nausea and vomiting in the hospital or as an outpatient.^{8,9} Antiemetic therapy should be used when supportive measures are not effective. Other antiemetics that have also been used successfully in the treatment of nausea and vomiting in pregnancy include the phenothiazines, trimethobenzamide, metoclopramide, and diphenhydramine.

Hyperemesis gravidarum is the abnormal condition of pregnancy associated with pernicious nausea and vomiting. Hyperemesis is both infrequent and uncommon. These patients experience persistent intractable nausea and vomiting associated with weight loss, fluid and electrolyte imbalance, ketonuria, and ketonemia. Electrolyte imbalance may include decreased sodium, potassium, and chloride, and metabolic alkalosis. The patient usually becomes clinically dehydrated and may even develop jaundice, hyperpyrexia, and peripheral neuritis. Recurrent hyperemesis gravidarum has caused recurrent first-trimester jaundice.¹⁰ Wernicke's encephalopathy has even been reported in patients with hyperemesis gravidarum.¹¹ If the patient is not appropriately treated, there may be a

failure of the mother and fetus to increase their weight. A patient with hyperemesis gravidarum who has abnormal electrolyte, renal, or liver test results should be promptly hospitalized for fluid management. Outpatient, hospital, or home therapy consisting of intravenous fluid hydration with pyridoxine, 100 mL/L, can be sufficient along with supportive care. The management of hyperemesis in the home can be both safe and efficacious.¹² Furthermore, successful therapy can be achieved at a significantly reduced cost. However, when the patient's condition does not improve, hospitalization with appropriate electrolyte, caloric, and fluid management is necessary, if not mandatory.

Refractory hyperemesis gravidarum has been successfully treated with corticosteroid therapy. Corticosteroids are effective in suppressing symptoms of intractable hyperemesis, decreasing the length of hospitalization, and allowing normal maternal nutrition. The exact mechanism of action of corticosteroids is unclear. It has been assumed that they act directly on a vomiting center in the brain. The safety of corticosteroid therapy early in pregnancy has been established by its use in other disorders. Corticosteroid therapy should be considered not as a first-line therapy but when: (1) all other causes of vomiting have been excluded; (2) vomiting has been prolonged and associated with dehydration; (3) the risks and benefits of the treatment have been clearly explained to the patient; and (4) intravenous fluid replacement and conventional antiemetics have failed. Studies have established the efficacy and safety of corticosteroid therapy for refractory hyperemesis. Methylprednisolone in tapering doses is the drug of choice. The use of droperidol and diphenhydramine in the management of hyperemesis gravidarum has been reported but is now used infrequently.¹³ Levine and Esser¹⁴ have reported the safe and effective use of first-trimester total parenteral nutrition in the management of hyperemesis gravidarum, which was initiated in the hospital and was continued in the patient's homes. Hsu and colleagues¹⁵ have reported that enteral feeding via nasogastric tube seems to be effective as an alternative for relieving intractable nausea and vomiting and providing adequate nutrition support.

The role of psychosocial stressors, such as an undesired pregnancy, in the etiology of nausea, vomiting, and hyperemesis gravidarum has been only partially studied. It is believed that psychological factors contribute to excessive nausea and vomiting during pregnancy. Several studies have shown that these symptoms occur more frequently in women with undesired pregnancies or negative relationships with their mothers or partners.^{15,16}

Although most patients with pernicious nausea and few patients with hyperemesis gravidarum have transient hyperthyroidism,¹⁷ thyroid evaluation should be part of the workup of these patients. Whether the hyperthyroidism is a cause of hyperemesis or is present because of the condition is controversial and a difficult differential diagnosis. Whether or not antithyroid medication is necessary in the treatment of transient hyperthyroidism occurring in hyperemetic pregnancies has in the past been controversial. However, Goodwin and

coworkers,¹⁸ in the largest series of hyperemesis subjects studied prospectively with respect to thyroid function, show that hyperthyroidism in these patients is common, self-limited, and requires no therapy.

Most patients with hyperemesis gravidarum improve with appropriate medical therapy. Maternal mortality is rare, but has been reported when severe metabolic abnormalities go untreated, esophageal tears (Mallory–Weiss syndrome) occur, or hematemesis develops. Intrauterine fetal demise can also occur in severe cases. The association of nausea and vomiting in pregnancy with other pregnancy outcomes has been investigated by several authors. Women admitted on multiple occasions for hyperemesis had significantly lower birthweight infants.¹⁹ Although nausea and vomiting in early pregnancy may be a bothersome and a common symptom, there is no consistent or significant effect from this gastrointestinal disorder on pregnancy outcome, good or bad.²⁰

Oral cavity complications of pregnancy

Many pregnant women enter pregnancy with poor dental care. They may not have seen a dentist since their own childhood. Their teeth are in poor condition, and numerous cavities and gingivitis are present owing to poor dental hygiene. They should be urged to practice good oral hygiene and referred and encouraged to see a dentist because dental care is not prohibited during pregnancy. Pregnant women are no more susceptible to tooth decay than the nonpregnant patient. There is no agreement that normal pregnancy causes a decreased or increased incidence of caries. Rather, the worsening of dental caries during pregnancy is due to poor dental hygiene. This may not be true for the diabetic pregnancy where the prevalence of gingivitis is higher.²¹

The chemical and mineral composition of human teeth has not been shown to be changed by pregnancy or lactation. Pregnancy does not cause gingivitis; it is caused by bacteria.²² The increase in gingival vascularity can result in accentuated gingival hyperplasia or enlargement, which is commonly referred to as pregnancy gingivitis. The incidence of this common oral condition during pregnancy is unknown, but it probably occurs in at least one-half of pregnant women. Once the hormonal changes of pregnancy decline, the exaggerated gingivitis due to pregnancy decreases. Pregnancy does not increase the amount of oral calculus present on the teeth. When oral hygiene is poor, calculus may, however, lead to mild, moderate, or severe gingivitis and other periodontal disease. Bleeding from the gingivae, a common complaint of pregnant women, due to pregnancy gingivitis, requires no treatment.²² Gingivitis due to poor dentition and hygiene is treated by good cleaning of the teeth and by meticulous dental care. There is no basis for delaying dental care during pregnancy, and patients who require treatment should obtain it promptly. Prenatal care should, but frequently does not, include a good examination of the teeth by a dentist who may then consult with the obstetrician about the best treatment plan.

Pregnancy tumor is a granuloma that forms as a result of exaggerated gingival enlargement during pregnancy.²³ It appears as a localized enlargement of the hyperplastic gingivae or pedunculated growth. Pregnancy tumors are pyogenic granulomas because they result from nonspecific inflammatory gingivitis secondary to poor oral hygiene, associated with deposits of plaque and calculus on the teeth. The poor teeth and gums adjacent to these lesions are responsible for the local irritation resulting in the pregnancy tumor. These predisposing inflammatory factors, along with the hormonal effects of pregnancy on the gingival tissues, predispose to the development of pregnancy tumors. They occur in approximately 1–5% of pregnant women. The tumors are typically painless, pedunculated, lobulated, red owing to their vascularity, and soft with a smooth surface. Consultation with a dentist is indicated. The treatment for pregnancy tumor is complete surgical excision.²² The adjacent teeth should be cleaned aggressively to remove debris, plaque, and calculus. If the tumor is not completely removed, it may recur, and recurrence during a future pregnancy is not uncommon.

The treatment of dental problems associated with pregnancy is rarely contraindicated and, when several guidelines are used, may be performed safely.²⁴ If the treatment is necessary but elective, it is best delayed until the second trimester, when there is the least risk of teratogenesis. Emergency treatment should be obtained whenever indicated. Fillings, extractions, and crowns can be safely performed during pregnancy. The supine hypotensive syndrome, which occurs most frequently during the third trimester, can be avoided by keeping the patient turned toward her side while she is in the dental chair.

Radiographs, which are often necessary to establish a proper dental diagnosis, may be taken safely during any stage of pregnancy. The maternal abdomen should be shielded with a lead apron. Using fast X-ray film, the exposure time is minimized. There is no harm to the fetus when dental radiographs are taken with the necessary precautions, good techniques, and today's modern equipment.²⁵ Dental procedures may cause pain. Efforts should be made by the dentist to reduce the pain and stress of the treatment. Although the dentist may be concerned, a local or topical anesthetic is usually recommended and is safe for both mother and fetus. The smallest amount necessary to achieve satisfactory anesthesia should be used. When incorporated with a vasoconstrictor such as epinephrine, the anesthetic's effect is prolonged, blood loss decreased, and the dosage of anesthesia is minimized. Lidocaine and mepivacaine combined with epinephrine have become the local anesthetics of choice for dental work during pregnancy. Low doses of intravenous medications may be used, but should be titrated to an acceptable level before administering the local anesthesia.²⁴ Inhalation or general anesthesia should be reserved for those patients who are hospitalized and require extensive dental surgery. The anesthesia should be administered by an anesthetist or anesthesiologist who is familiar with the risks of the procedure.²⁶ It is best,

whenever possible, to avoid the use of an inhalational anesthetic for dental procedures during pregnancy. Laboring patients with oral jewelry should remove the hardware before receiving anesthesia for safety reasons.²⁷

Most dental procedures require no antibiotics. When antibiotics are necessary, tetracycline should not be given to the pregnant woman.²⁸ Penicillin, frequently used by the dentist for treatment or prophylaxis therapy, is safe to use during pregnancy and would be the drug of choice.²⁸ There is now evidence that maternal periodontal disease and incident progression are significant contributors to obstetric risk for preterm delivery.²⁹

Reflux esophagitis

The esophagus is a fibromuscular tube that connects the oral pharynx and the stomach. It is predominantly an interthoracic organ, although a small portion of the esophagus is located beneath the diaphragm. The function of the esophagus is to move food from the oral pharynx to the stomach. The esophagus also prevents or helps to prevent the movement of air from the oral pharynx to the stomach and the movement of food from the stomach into the oral pharynx, called gastroesophageal reflux. Peristalsis carries food into the stomach. At the distal end of the esophagus is the lower esophageal sphincter, consisting of circular muscle fibers approximately 2 cm in length. Normally, the lower esophageal sphincter is in a state of tonic contraction, thus preventing gastroesophageal reflux. Heartburn is really a symptom of reflux esophagitis. Heartburn is a common, bothersome complaint during pregnancy and occurs in as many as 70% of pregnant patients. A quarter of pregnant patients experience some degree of heartburn daily.³⁰ The symptoms of heartburn include burning and substernal discomfort radiating to the back of the neck. Heartburn is usually more severe after meals and is aggravated by recumbent positions. The pain is not limited to substernal discomfort, but may also be epigastric, between the shoulders or, rarely, generalized chest pain. Usually, the symptoms of reflux esophagitis occur in the last trimester, but they can occur at any time during pregnancy.³¹ They subside after 36 weeks of gestation and improve, as expected, postpartum with the decrease in the size of the uterus.

The exact cause of heartburn and reflux esophagitis of pregnancy remains unknown and controversial.³⁰ It probably occurs as a result of some degree of gastroesophageal reflux favored by the decreased gastric emptying time during pregnancy and by the increased intra-abdominal pressure created by the enlarged uterus. The differential diagnosis of esophageal reflux includes cardiac symptoms, peptic ulcer disease, and hiatal hernia. Treatment of reflux esophagitis during pregnancy consists primarily of neutralizing the acid material that is being refluxed into the esophagus, thereby decreasing gastroesophageal reflux.^{31,32} Symptomatic strategies include dietary modification. Foods and drinks such as chocolate, caffeine, peppermint, and alcohol may actually

decrease the lower esophageal sphincter pressure. Fatty or spicy foods aggravate the symptoms and are to be avoided. The avoidance of recumbency, particularly immediately after eating a meal, is likewise to be avoided. Elevation of the head of the bed while reclining may provide symptomatic relief. A variety of antacids have been prescribed for heartburn. All these over-the-counter preparations neutralize gastric acid, which is responsible for the symptoms. In the nonpregnant patient, the lower esophageal sphincter pressure has been elevated with a variety of medications, including metoclopramide.³³ The use of this and similar drugs, although safe, should be avoided except in severe cases. The histamine H₂ receptor antagonists and/or the proton pump inhibitors can also be prescribed for severe and persistent symptoms.³⁰ Prolonged esophageal reflux can result in complications such as peptic esophageal stricture, hemorrhagic esophagitis, gastrointestinal bleeding, and hemorrhage. Ulceration of the esophageal mucosa can also occur with significant bleeding. The symptoms of reflux esophagitis can be so severe or difficult to treat that esophagoscopy, parenteral hyperalimentation, and parenteral nutrition are necessary.³⁰ These procedures may be performed safely, when necessary, during pregnancy for this and other gastrointestinal diseases complicating pregnancy.

Peptic ulcer disease

An ulcer is a defect that occurs in the gastrointestinal mucosa and extends through the muscularis mucosa. The stomach, pylorus, or duodenum are the usual sites for ulcers. However, they may occur in the esophagus as a result of gastroesophageal reflux. Benign ulcers of the upper gastrointestinal tract are caused by a number of factors including the action of hydrochloric acid and pepsin on the gastrointestinal mucosa.^{34,35} Because of the action of acid and pepsin, these defects are called peptic ulcers. Factors known to play a role in the development of peptic ulcer are infections of the stomach and nonsteroidal inflammatory drugs.³⁴ Ulcerations of the stomach affect both sexes equally and are less common than duodenal ulcer disease, which is twice as common in men as in women.³⁴ The development of peptic ulcer disease during pregnancy is uncommon and rare. Patients who have peptic ulcers before pregnancy frequently experience fewer symptoms during pregnancy and may even become totally asymptomatic. This is the primary reason why complications of ulcer disease, such as perforation, bleeding, and pyloric stenosis, are quite rare during pregnancy. The exact cause of the decrease in symptoms remains unknown. There was a recurrence in 50% of the patients by 3 months and in 75% of patients by 6 months after delivery. There are no conclusive studies regarding gastric acid secretion changes during pregnancy. Studies to date have shown conflicting data, with some showing no change and others a slight decrease in gastric acid secretion.³⁵

The symptoms of peptic ulcer disease are quite similar to

those of reflux esophagitis.³⁰ The diagnosis during pregnancy may therefore be delayed. The most common symptom of peptic ulcer disease is complaints of heartburn or dyspepsia. The patient may experience nausea and vomiting, which is a common complaint of pregnancy. She may also have anorexia, bloating, or epigastric pain and discomfort. Patients with duodenal ulcer disease more frequently have epigastric pain than those with gastric ulcers. There are no typical physical findings. When presenting to her obstetrician, the patient may already have taken antacids and found that they may have helped her symptoms. Peptic ulcer disease is diagnosed by the visualization of the ulcer by radiography or endoscopy. Although the upper gastrointestinal series is sometimes used to diagnose peptic ulcer disease in a nonpregnant patient, esophagoscopy when necessary should be used in the pregnant patient. This is usually not necessary except in the patient who has symptoms that do not respond to antacids. However, patients with persistent and serious gastrointestinal signs and symptoms from peptic ulcer disease or other disorders may require endoscopy during pregnancy. Gastrointestinal endoscopy, both esophagogastroduodenoscopy and colonoscopy, has been used safely in the diagnosis and treatment of pregnant patients. Not only may the procedure be useful, but it may be necessary in making an accurate and early diagnosis.³⁴

Complications of peptic ulcer disease rarely occur during pregnancy, because in most cases the disease does not worsen. Complications that can occur include perforation, hemorrhage or other bleeding, pyloric stenosis, and gastrointestinal obstruction.³⁴ When serious complications occur, they should be managed as in the nonpregnant patient. By doing so, there is less maternal and fetal mortality. There is disagreement in the literature as to whether or not a Cesarean section should be performed at the time of an emergency gastric resection. The decision to perform a Cesarean section would depend on the gestational age of the fetus. The experience of most clinicians is not to perform an emergency Cesarean before the peptic ulcer surgery. Patients who have had previous peptic ulcer disease surgery are at no increased risk for complications during future pregnancies.³⁵

Lewis and Weingold⁷ have extensively reviewed the use of gastrointestinal drugs during pregnancy and lactation. The treatment of peptic ulcer disease consists primarily of the use of antacids, which are safe to use during pregnancy.^{7,36} The usual recommended dose is 15–30 mL 1–3 h after meals and at bedtime. Antacids neutralize acid that has been secreted by the gastrointestinal lining. In most cases, antacids improve symptoms. A combination of magnesium trisilicate and aluminum hydroxide is found in most antacid preparations. Sodium bicarbonate should not be used as an antacid during pregnancy, because it can lead to the absorption of large amounts of sodium. Sucralfate is a mucosal-protective aluminum hydroxide salt that has been used in the nonpregnant patient to enhance mucosal defense. Some investigators have suggested that sucralfate forms a shield over the ulcer crater.

There has been no adverse fetal or maternal effect of this drug when used during pregnancy.^{7,36}

Patients with peptic ulcer disease should avoid a diet of foods that cause discomfort. Some authorities suggest that milk, which is frequently included in the diet of the pregnant patient, stimulates acid secretion and should be taken in moderation. Other dietary modification is not necessary, although bedtime snacks are to be avoided. Smoking, which should be avoided in both pregnant and nonpregnant woman, and alcohol should certainly be eliminated from the diets of these patients. Patients who are smokers and have a previous history of peptic ulcer disease are at highest risk for ulcer disease during pregnancy.³⁴ Aspirin and the nonsteroidal and inflammatory drugs such as indomethacin, which is used for tocolysis, can produce gastric irritation and, with prolonged use, gastric and duodenal ulcers; their use should be avoided in patients with active or a history of peptic ulcer disease.^{32,34}

Histamine H₂ blockers such as cimetidine, famotidine, nizatidine, ranitidine, and others are second-line therapy for peptic ulcer disease. They do cross the placenta, but no teratogenic risk has been detected from their use during the first trimester.^{30,35} H₂ receptors are located on parietal cells of the gastrointestinal lining. Their stimulation results in the production of histamine. H₂ receptor antagonists decrease the production of histamine. Histamine H₂ blockers are a mainstay in the medical therapy of peptic ulcer disease. There are several concerns about the use of cimetidine during pregnancy. It is an antiandrogen and has produced gynecomastia and impotence in a small number of male animals and male users.^{30,35} Its effect on the H₂ receptors in the uterine myometrium has not been well studied, but no adverse effect on uterine activity has been reported. Cimetidine does cross the placenta. No teratogenicity has been linked to the use of cimetidine during pregnancy.^{7,36} However, its use is and should be reserved for those patients who have symptoms refractory to antacid therapy. There are no data to support the discontinuation of cimetidine during pregnancy in patients prescribed it before conception.

Ranitidine, famotidine, and nizatidine are other H₂ receptor antagonists that have been used for ulcer therapy during pregnancy without maternal or neonatal complications.^{30,35} The newest antisecretory agents are the proton pump inhibitors omeprazole, lansoprazole, esomeprazole, pantoprazole, and rabeprazole. These drugs suppress gastric acid secretion by a direct inhibitory effect on the gastric parietal cell. They are potent agents that promote faster healing of peptic ulcers. The use of these drugs during pregnancy has been limited.^{30,35} The use of proton pump inhibitors during pregnancy does not present a teratogenic risk when used in recommended doses. Increased maternal or fetal morbidity is not caused by peptic ulcer disease.

Acute intestinal obstruction

Intestinal obstruction is a serious complication of pregnancy that is occurring with increasing frequency. The incidence is approximately 1 in 2500 to 1 in 3500 pregnancies.³⁷ There has been an increasing incidence because of the increasing number of abdominal surgeries performed on women. Matthews and Mitchell³⁸ noted three time periods during pregnancy when obstruction is likely to occur: (1) during the fourth and fifth months, when the enlarging uterus is no longer a pelvic organ; (2) during the eighth and ninth months, when the fetal head descends into the pelvis; and (3) during the puerperium, when there is a marked change in the size of the uterus. Acute intestinal obstruction is most common in the third trimester, less common in the second, and least likely in the first trimester.^{39,40}

The most common cause of intestinal obstruction in the pregnant and nonpregnant woman is adhesions.^{37,39} More than half of intestinal obstructions are secondary to adhesions that are usually, but not always, due to prior abdominal surgery. Previous laparotomy for appendectomy or gynecologic surgery is the most frequent preceding operation.^{37,40} Intussusception and hernias are less common causes of intestinal obstruction during pregnancy.³⁹

Volvulus usually involves the sigmoid colon rather than the small intestine or cecum and is the second most common cause of intestinal obstruction during pregnancy.⁴⁰ Sigmoid volvulus is usually treated by surgery. Goldthorp⁴¹ determined that 80% of intestinal obstruction cases caused by past appendectomy adhesions occurred during the first pregnancy after the operation. Spontaneous small bowel obstruction associated with a spontaneous triplet gestation has been reported by Ludmir and co-workers. Their patient had no predisposing factors, a delayed diagnosis, delivered preterm, and required surgery to alleviate the obstruction. The authors emphasized the importance of considering the diagnosis of intestinal obstruction when nausea, vomiting, and an overdistended abdomen occur during pregnancy.

The diagnosis of intestinal obstruction in pregnancy is not easy.^{39,40,42} As with appendicitis, delay in diagnosis is not uncommon. This can result in perforated or strangulated bowel, preterm labor, and increased maternal and fetal mortality. The classic triad of presenting symptoms in intestinal obstruction is abdominal pain, vomiting, and constipation. All these are common symptoms during normal pregnancy. The physician must have a high index of suspicion for the presence of acute intestinal obstruction. Pain, although usually present, may be constant, colicky, mild, severe, diffuse, or localized. Preterm labor or increased uterine contractions may be present. Physical examination may or may not reveal guarding or rebound tenderness. Abdominal distention can easily be missed in late pregnancy because of the normally large uterus and abdomen. When present, it usually indicates large bowel rather than small bowel obstruction. Bowel sounds may be normal, absent, or high pitched with rushes. Physical examination, however, can be completely nondiagnostic. The white

blood cell count is usually not helpful because it is normally elevated in pregnancy. If there is considerable delay in diagnosis and the patient is not appropriately treated, then third spacing of fluids occurs. This results in dehydration, electrolyte imbalance, hypotension, oliguria, fever, tachycardia and, eventually, shock and death.

Diagnosis, once expected clinically, can be made by limited radiographic studies showing bowel distention, intraluminal fluid levels, and decreased gas in the large bowel.^{39,40} The concern of obtaining radiographic studies during pregnancy should be tempered by the increased maternal and fetal mortality associated with delayed or misdiagnosis. Radiographic or serial studies showing dilated, gas-filled loops of bowel with air–fluid levels is diagnostic.

Treatment of intestinal obstruction during pregnancy is the same as in the nonpregnant patient.^{42,43} Exploratory laparotomy is the treatment of choice. Before surgery, close attention must be paid to correction of fluid and electrolyte imbalance, maintenance of adequate urinary output, administration of blood and blood products, and fetal monitoring. Antibiotics may be indicated. A vertical abdominal incision should be made to provide adequate exposure. Care should be taken by the operating surgeon to avoid manipulating, touching, or tugging on the pregnant uterus, because this could result in preterm labor. If labor occurs while the patient is in surgery, tocolysis should be initiated. The prophylactic use of tocolytic therapy before, during, or after surgery has not been proven and remains debatable.³⁷ When surgery occurs at term, a well-repaired abdominal incision will tolerate labor without difficulty. At the time of surgery, a Cesarean section should be performed only for obstetric reasons and not because the abdomen is open. Vaginal delivery can occur without difficulty following abdominal surgery. There do not appear to be many, if any, clinical indications for the use of a long intestinal tube rather than surgery to treat obstruction.

Maternal and fetal mortality from undiagnosed cases of intestinal obstruction have decreased over the years.^{37,38} Because this is a disease of the third trimester, preterm labor and neonatal death can cause significant fetal mortality.³⁹ This should be reduced with early diagnosis and aggressive operative treatment. It is good, therefore, for the clinician to remember that an abdominal scar on a pregnant woman with abdominal pain should raise the suspicion of acute intestinal obstruction.^{38,42}

Inflammatory bowel disease

The term inflammatory bowel disease refers to a group of idiopathic chronic inflammatory diseases of the intestinal tract.^{44,45} The two most commonly seen during pregnancy are ulcerative colitis and Crohn's disease, also called regional enteritis. Both these disorders are not uncommon in women during their reproductive years and are frequently seen either before or during pregnancy.^{34,44–48}

The pathologic features of these two diseases distinguish and differentiate them.^{34,44} Ulcerative colitis is an inflammatory ulcerative pathologic process involving the mucosal lining of the colon and/or rectum. It is characteristically not transmural. A typical biopsy of ulcerative colitis lesions shows diffuse mucosal ulceration and a chronic inflammatory response consisting of polymorphonuclear cells, lymphocytes, and plasma cells. There may be abscesses of the mucosa. The mucosal lining is edematous and replaced by a chronic inflammatory infiltrate. As this chronic process continues over time, the bowel may become thickened. Areas of stricture, fibrosis, and stenosis develop. Intestinal obstruction and toxic dilation of the colon with resultant perforation can complicate ulcerative colitis.⁴⁹

Crohn's disease, on the other hand, is an inflammatory disease that may involve any area of the gastrointestinal tract, but the distal small intestine, colon, and anal rectal regions are most often affected. The pathologic process is transmural, and the granulomatous enteritis involves all layers of the bowel, mesentery, and lymph nodes. The inflammatory process consists primarily of plasma cells and lymphocytes. The bowel that is affected is edematous, thickened, hyperemic and ulcerated. There may be adhesions of the involved portion with other loops of intestine. Intestinal obstruction, perforation, and fistula formation between loops of bowel can result. The nearby mesentery lymphadenopathy is present. The chronic inflammatory process is more granulomatous than in ulcerative colitis. Granulomas, multinucleated giant cells, and chronic ulcerations may be present. Skipped areas are common and characteristically found in removed bowel affected by regional enteritis. These are unaffected areas of the bowel located next to diseased areas.

These two disorders share a common cause, clinical findings, and management.^{34,44} Ulcerative colitis and Crohn's disease may be so similar clinically that a specific diagnosis of the type of inflammatory disease present cannot be made. They can be characterized as chronic disorders that go through periods of quiescence and exacerbation, making differentiation even more difficult.

The effect of inflammatory bowel disease on fertility has been studied by several authors. Most reports show that ulcerative colitis does not affect or alter female fertility.^{45,50} Numerous reports have shown and there is general agreement that fertility is decreased in patients with Crohn's disease.⁴⁵ This is probably due to the chronic pelvic adhesions that occur as a result of the inflammatory process. The activity of the disease process also affects fertility. Although it is decreased during exacerbations, there is also a decrease in fertility when the disease is quiescent. Improved and reduced fertility after the removal of intestine affected by regional enteritis has been reported.⁴⁵

Ulcerative colitis and regional enteritis can affect pregnancy. The earliest and most extensive report is by Abramson et al.,⁵¹ who reviewed the effect of ulcerative colitis on pregnancy. This report suggests that the best prognosis for pregnancy is in

those patients who had inactive disease at the time of conception or whose active disease is limited to early pregnancy. In general, a good prognosis can be expected, and ulcerative colitis does not adversely affect fetal outcome. Brostrom⁵² has suggested that pregnancy, if planned, should be encouraged when the patient is in remission, although the disease or its standard treatment does not seem to dangerously affect the patient, fetus, or the newborn infant. The more inactive the disease at the time of conception, the better the prognosis for a more favorable pregnancy outcome.⁵³

The effect of Crohn's disease on pregnancy is similar. Numerous investigators have concluded that there is little or no decrease in the live birth rate.^{45,48} Adverse pregnancy outcome, as reflected by prematurity, stillbirths, spontaneous abortion, or congenital anomalies, does not appear to be increased. The route of delivery may be affected by inflammatory bowel disease. Cesarean section has been recommended if severe perineal fistulas or scarring, which can occur as a complication of Crohn's disease, are present. Patients who have recently had a proctocolectomy to promote healing of perineal disease should also be delivered by Cesarean section. However, in a small study by Rogers and Katz⁵⁴ of 17 women whose pregnancies were complicated by Crohn's disease, the mode of delivery was not protective against worsening perineal disease. Active disease at the onset of pregnancy tends to remain active, and quiescent disease tends to remain quiescent.⁵⁴ Cesarean section is not indicated in patients simply because they have had successful restorative surgery for inflammatory bowel disease. However, the full clinical picture, including gestational and fetal age, should be assessed.⁴⁵

The clinical manifestations of inflammatory bowel disease depend on the area of the gastrointestinal tract involved.^{34,44} Some symptoms occur with both diseases or are more common with one or the other. Symptoms occurring with both these diseases may include soft stools, rectal bleeding, diarrhea, abdominal pain, weight loss, and urgency of defecation. Rectal bleeding is more common in ulcerative colitis. Abdominal pain, diarrhea, weight loss, fever, and rectal bleeding are the most frequent symptoms occurring in ulcerative colitis. The symptoms of Crohn's disease are most frequently episodic abdominal pain, fever, diarrhea, and weight loss. Perineal fistulas and scarring are more commonly present with regional enteritis and occur in one-third to one-half of the patients with this disease.

The clinical features and presentations of these two disorders can be quite similar, requiring sigmoidoscopy, colonoscopy, radiography, and histologic examination of a biopsy to tell the difference.^{34,44} The endoscopic techniques are safe during pregnancy and have replaced radiography in making a diagnosis.^{55,56} Extraintestinal manifestations of the inflammatory bowel diseases occur in both the pregnant and the nonpregnant patient.^{34,44,47} These include nutritional and metabolic abnormalities, hematologic abnormalities, skin and mucous membrane lesions, arthritis, and eye and renal complications. Hepatic and biliary complications can also occur

with the development of sclerosing cholangitis and gallstones. Systemic complications and manifestations have been reported to occur all over the body.⁴⁴ Local complications requiring surgical and gastroenterologic intervention can occur, depending on the severity of the disease. These complications include stricture, stenosis, bleeding, malignancy, abscess formation, perforation, fistulas, and perineal problems.

There is little evidence to suggest that pregnancy has an effect on inflammatory bowel disease. The clinical course of ulcerative colitis can be worsened when pregnancy occurs when the disease is active. The risk of exacerbation of ulcerative colitis in pregnant patients is approximately 50%, not dissimilar from that in the nonpregnant patient. One-third of patients who conceive while their colitis is inactive have an exacerbation during their pregnancy. The worst prognosis for the pregnant woman, according to Nielsen and colleagues,⁵⁷ occurs when the patient develops ulcerative colitis for the first time during pregnancy. The maternal mortality rate under those circumstances was 15%. Pregnancy should therefore be avoided if possible while the disease is active; one-third of pregnant patients experience worsening of their disease, and less than a half show remission or improvement. Pregnancy has little or no effect on Crohn's disease, and the overall maternal prognosis is good. When an exacerbation in inflammatory bowel disease occurs during pregnancy, it most frequently happens during the first trimester or the postpartum period.

Inflammatory bowel disease is treated by both medical and surgical measures during pregnancy. In general, the treatment is the same as in the nonpregnant patient,^{34,44} with several special considerations.^{34,44} The mainstay of medical therapy for both ulcerative colitis and Crohn's disease is the use of mesalamine preparations, sulfasalazine, and corticosteroids. Mesalamine is more efficacious in the treatment of ulcerative colitis than in regional enteritis. The corticosteroids most frequently used are prednisone, hydrocortisone, and prednisolone. Metronidazole, azathioprine, and 6-mercaptopurine have also been used in the medical therapy of inflammatory bowel disease. These three agents have possible teratogenic effects, and their use during pregnancy must be carefully evaluated and weighed against their expected benefit.^{36,58} Metronidazole has been shown to be effective in the management of inflammatory bowel disease, particularly Crohn's disease for perineal fistula. Although efficacious, it should be used during pregnancy and postpartum only in severe and unusual cases because, although not teratogenic, its use is of concern.^{7,36,58} Mesalamine is now the most commonly used drug in the treatment of inflammatory bowel disease and is safe to use during pregnancy (FDA risk category B; see Tables 43.1 and 43.2). It does not appear to pose a teratogenic risk when used at recommended doses. Azathioprine is also indicated for treatment and maintenance of remission of Crohn's disease, but is regarded as unsafe in pregnancy (category D). Remicade can be used in patients with Crohn's disease unresponsive to the above drugs. Although there are limited data for its use in pregnancy, it is a category B drug.^{58,59}

Corticosteroid therapy has been used in both these diseases to suppress the inflammatory response present in the bowel.^{34,44,47} It is also frequently used in treating exacerbations of Crohn's disease. Doses of prednisone range from 40 to 60mg daily for a period of several weeks to a month. Some pregnant patients who have been unable to be weaned from corticosteroids may enter pregnancy on a low dose. The continuation of their medication or even the institution of corticosteroid therapy during pregnancy is not contraindicated.^{7,58,59} The mother may experience the usual side-effects of corticosteroid therapy, but there are no adverse effects on the fetus from the use of corticosteroids during pregnancy. Breastfeeding is likewise not contraindicated in the mother on corticosteroid therapy.^{58,59} None of the drugs used to treat inflammatory bowel diseases is associated with poor pregnancy outcome.⁶⁰

Medical management should include nutritional assessment and treatment, as in any patient with a chronic disease.^{34,44} Adequate calories should be provided to help prevent weight loss. Parenteral nutrition, sometimes required in the management of some of the other gastrointestinal complications of pregnancy, is infrequently needed in these patients. If medically necessary to provide adequate caloric intake, total parenteral nutrition may be used safely during pregnancy.^{47,61} General therapeutic measures include antidiarrheal drugs such as codeine, opium, paregoric, and diphenoxylate with atropine (Lomotil). As in the treatment of hyperemesis gravidarum, the patient should have the opportunity to discuss the psychological factors of pregnancy or other aspects of her life, which may be playing a part in the precipitation of inflammatory bowel disease.

Inflammatory bowel disease may require surgical treatment of ulcerative colitis including total proctocolectomy with construction of an ileostomy or ileoanal pullthrough.^{34,45} Indications for surgery include perforation (with or without abscess formation), massive bleeding, and carcinoma of the colon. Patients who develop toxic megacolon and do not respond to other therapy may also be candidates for this surgical therapy. The procedure should not be done during pregnancy, because the surgery would not only be difficult to perform as the pregnant uterus enlarges, but could also initiate preterm labor.⁴⁹ Patients with ulcerative colitis who have been treated with surgery before pregnancy have no increased risk during their pregnancy. Care of the ileostomy is not hampered by pregnancy. There is no evidence that the enlarging uterus interferes with the function of the ileostomy. Vaginal delivery is not contraindicated and should be encouraged. The performance of a Cesarean section for obstetric indications only is recommended, with draping of the ileostomy out of the surgical site.

Surgical therapy for Crohn's disease or regional enteritis is the same as for ulcerative colitis.^{34,44} Intractability of symptoms is the most frequent indication for surgery. Perianal complications such as fistulas may also lead to total proctocolectomy with ileostomy or some other variation of this surgery. As with ulcerative colitis, there is a high recurrence rate of the disease

with an internal anastomosis. Unlike ulcerative colitis, Crohn's disease is not cured by total proctocolectomy; there is a recurrence rate as high as 80% in 5 years. Surgery for both these disorders should be performed during pregnancy only after intensive medical therapy has failed.^{45,62} The interested reader is referred to several other extensive and recent reviews of inflammatory bowel disease in pregnancy.⁴⁵⁻⁴⁸

Appendicitis

Appendicitis is the most common cause of an acute abdomen during pregnancy. The incidence during pregnancy has been reported to vary from 1 per 1000 to 1 per 2000 pregnancies, with an average incidence of 1 per 1500 deliveries. There appears to be no increased frequency during any particular trimester.⁶³ Appendicitis occurring postpartum is fortunately rare as it is particularly difficult to diagnose because peritonitis is a less prominent finding. During pregnancy, the usual symptoms and physical changes may delay the diagnosis or confuse the clinical picture of appendicitis. This delay in diagnosis can be further compounded by the commonly experienced nausea, vomiting, and abdominal discomfort of pregnancy and the displacement of the appendix upward by the enlarging uterus (Fig. 43.1). Additionally, the usual elevation in the white blood cell count during pregnancy and the elevated sedimentation rate may also delay the diagnosis. Unfortunately, pregnant women have a higher mortality rate

Figure 43.1 Change in the position of the appendix during pregnancy.

when they develop appendicitis. This is primarily because of procrastination in diagnosis and treatment, with resultant perforation of the appendix and peritonitis.^{39,63} Therefore, in pregnancy the frequent association of appendicitis with peritonitis is caused by a delay in diagnosis.

The pregnant woman with appendicitis has symptoms and signs similar to those in the nonpregnant patient, but may not experience abdominal rigidity, rebound, or similar signs of peritonitis. Abdominal pain is present, but usually not at McBurney's point. This is because of the change in the position and direction of the appendix during pregnancy.^{39,63,64} As pregnancy advances, the cecum is displaced toward the iliac crest, thus moving the appendix laterally, superiorly, and posteriorly. The abdominal pain of appendicitis is typically mild at onset. During pregnancy, it is even less severe. It may be intermittent or colicky, due to a fecalith within the appendix. The pain is followed within an hour or two by anorexia, nausea, and vomiting, symptoms frequently seen during a normal pregnancy. The temperature may be normal, or there may be a low-grade fever. An increasing left shift in the differential may be helpful in making the diagnosis. The urinalysis is usually not helpful other than in excluding the diagnosis of urinary tract infection.

To reduce both maternal and perinatal mortality associated with appendicitis during pregnancy, the diagnosis must be made promptly. These adverse sequelae are obviated by prompt operative exploration when appendicitis is suspected and prevention of appendiceal perforation. A delay in diagnosis appears to increase with gestational age.^{39,63} The diagnosis must be suspected in the pregnant patient who experiences persistent right-sided abdominal pain and atypical gastrointestinal symptoms. The removal of a normal appendix may occur in half the cases and should not be criticized, because such an operation rate may be necessary to detect the case with minimal or unusual symptoms, thus decreasing fetal and maternal mortality.^{39,63,65} An uncomplicated appendectomy does not increase the risk of preterm labor. However, the presence of peritonitis and a perforated appendix more frequently results in preterm labor and preterm birth. If in doubt, the appendix should be removed, especially during pregnancy.^{42,65}

The differential diagnosis of appendicitis during pregnancy includes threatened abortion, ectopic pregnancy, pelvic inflammatory disease, pyelonephritis, placental accidents, twisted ovarian cyst, pancreatitis, gallbladder disease, degenerating fibroids, ruptured corpus luteum, chorioamnionitis, infarcted omentum, and the difficult-to-diagnose "round ligament syndrome." Both computed tomography (CT) and magnetic resonance imaging (MRI) are helpful and safe during pregnancy in the diagnosis of acute appendicitis. The clinician or radiologist or emergency room physician should not hesitate to use them when they are indicated. The use of laparoscopy and graded compression sonography in the differential diagnosis of acute appendicitis in the nonpregnant patient may be helpful. Sonography can be helpful in the diagnosis of a

postappendectomy abscess. The diagnosis of appendicitis in pregnancy must always be considered when a pregnant patient presents with abdominal pain. The most frequent condition misdiagnosed as appendicitis is pyelonephritis.

Appendectomy is the treatment of choice for appendicitis during pregnancy. It is the most frequent nonobstetric procedure performed during pregnancy. Laparoscopic appendectomy is now as safe as open surgery in pregnancy. It is becoming the standard of care for appendicitis and cholelithiasis management during pregnancy.⁶⁶ Some surgeons still suggest the use of a transverse muscle-splitting incision directly over the point of maximum tenderness. When necessary, this incision can be extended without much difficulty. During the operation, the uterus should be manipulated as little as possible. The left lateral position with uterine displacement should be used to minimize the chance of the development of supine hypotension. There is no need for drainage of the incision if the appendix is unruptured and the incision can be primarily closed. Antibiotics are indicated when the appendix is perforated or there is extensive inflammation. There are no data to indicate that tocolysis reduces the incidence of uterine contractions or preterm labor. The routine usage of such agents in these circumstances cannot be recommended. When the diagnosis is made in the third trimester, there are few, if any, indications for a simultaneous Cesarean delivery, except in the presence of obstetric indications. On occasion, a patient presents with appendicitis in labor. Vaginal delivery is not precluded, with minilaparotomy and appendectomy immediately postpartum. This scenario presumes the patient is not in acute distress from a possible perforation.

The complication rate with rupture of the appendix can be very high, including fetal loss and maternal morbidity. When the diagnosis is made promptly and procrastination in treatment does not occur, fetal loss is lowered.^{42,63} Prophylactic appendectomy at the time of Cesarean section has been studied prospectively by Parsons and colleagues,⁶⁷ who found that this procedure does not add to the risk of elective Cesarean section. Nevertheless, most elective Cesarean sections performed today are not accompanied by an incidental appendectomy, even though they may be safe.

Pregnancy after operation for morbid obesity

Pregnant patients today are more obese than in the past. Over the past 30 years, patients who are morbidly obese have been undergoing a variety of surgical bypass operations to induce weight loss.⁶⁸ Seventy-five percent of these patients are women and therefore may be seen after their bypass pregnancy. There are basically two types of bypass operations: the older jejunoileal and the more recently developed gastric techniques. The jejunoileal bypass results in weight loss by bypassing approximately 90% of the small bowel, which decreases the area of the bowel available for absorption of food.^{68,69} In performing the jejunoileal shunt, an end-to-end or end-to-side anastomosis of the jejunum is accomplished.

A newer procedure, the gastric bypass, involves altering the stomach in some manner to produce a slower, as well as a physiologically better tolerated, weight loss. This can be accomplished by a variety of techniques.⁶⁸ The gastric procedures have less long-term morbidity and mortality, making the jejunoileal bypass operation now obsolete.⁶⁸

Successful pregnancy after jejunoileal bypass continues to occur.⁶⁹ Knudsen and Kallen studied delivery of women who, before pregnancy, had undergone an intestinal bypass operation. The infants born to these women had an increased rate of low birthweight, short gestation, and also growth retardation. In their study, there was no distinct difference between these infants, whether they were conceived less than 24 months or more than 24 months after the operation. A previous report by Stenning et al.⁷⁰ had suggested that pregnancy not long after the procedure could result in fetal loss and a complicated maternal course.

Most pregnant women with a jejunoileal bypass tolerate pregnancy quite well. It has been recommended that they receive supplemental iron, folic acid, vitamin B12, and a prenatal vitamin–mineral preparation.⁶⁷ Pregnancy is not contraindicated after jejunoileal bypass,⁷¹ but a 2-year interval before pregnancy is undertaken has been suggested so that the patient will not become pregnant during the highest phase of weight loss and to allow the weight loss to plateau. The longer the interval from surgery to pregnancy, the better the prognosis for both mother and newborn.⁷⁰ Pregnancies after gastric restrictive operations are usually well tolerated by both the mother and the fetus. However, complications reported have included severe maternal and fetal electrolyte imbalance, other nutritional deficiencies, and gastrointestinal hemorrhage during pregnancy.⁷² Total parenteral nutrition may be necessary in some patients who have previously undergone a jejunoileal bypass when they have evidence of intrauterine growth retardation and inadequate absorption of nutrients.⁷²

Because of long-term complications, including persistent electrolyte abnormalities, the jejunoileal bypass procedure is no longer performed. Gastric restrictive operations have now developed as the operations of choice for the patient who is morbidly obese.⁶⁸ These include gastropasty, gastric stapling, and gastric bypass techniques. It has been recommended that a woman undergoing one of these procedures does not become pregnant for at least 1 year because, during that year, significant postoperative metabolic changes occur in the patient. Even after 1 year, severe iron deficiency anemia resulting from malabsorption can complicate pregnancy that occurs after gastric bypass surgery. Pregnancy after at least 1 year has for the most part been uncomplicated, and the patient may actually benefit from the weight loss that has occurred before conception.⁶⁸

Constipation

A decrease in the frequency of stools, painful defecation, increased straining, or increased consistency of the stool is usually thought of as constipation. A patient may complain of

being constipated if she experiences any of these symptoms, but a patient's perception of being constipated may differ considerably from that of her physician. Constipation is a common symptom of pregnancy, particularly in late pregnancy. Levy and coworkers⁷³ interviewed 1000 healthy postpartum women about their bowel habits before and during pregnancy. In 54.6%, there was no change in the bowel frequency during pregnancy. Increased frequency occurred in 34.4%, and only 11% experienced a decreased frequency. Five percent of the subjects actually reported diarrhea of 2–8 weeks' duration in the last trimester. Ninety percent of the women interviewed experienced either no change or an increase in bowel frequency during pregnancy, contrary to the generally accepted view that constipation is frequent in pregnancy. Why pregnancy may cause constipation remains unclear and unknown.

The prevention and treatment of constipation during pregnancy should consist mainly of nutrition counseling, increasing fluid intake, daily exercise, and dietary modification to increase the fiber content.^{74,75} If these measures are unsuccessful, then mild laxatives, bulk-producing substances, and stool softeners may be used. These preparations should be used sparingly and are not usually necessary. Castor oil may initiate preterm uterine contractions and preterm labor and is not recommended. Laxatives most commonly recommended are the bulk-forming preparations containing fiber (e.g., Metamucil, Citrucel, and Konsyl) because no systemic absorption occurs. The use of excess laxatives by patients to induce labor should not be condoned. The stool softener dioctyl sulfosuccinate may be used to make the stool softer and able to be passed with less straining. No teratogenic effects have been reported from the use of these common laxatives, stool softeners, or bulk-forming preparations.^{58,59} Lewis and Weingold⁷ have suggested that they be used cautiously in the breastfeeding patient because they may be transmitted to the infant. Constipation may result in the development of hemorrhoids and, less commonly, rectal prolapse. These can usually be treated by topical ointments or sprays, stool softeners, sitz baths, and over-the-counter preparations such as Preparation H. When hemorrhoids develop during the puerperium after vigorous pushing, they may become thrombosed. Incision after local anesthesia may be necessary and beneficial. Rectal bleeding should be evaluated as in the nonpregnant patient.

Diarrhea

Diarrhea occurs during pregnancy at an incidence up to 34%. Although it is not a common occurrence, it may be due to drugs, malabsorption, osmotic diarrhea, food poisoning, and infections, particularly viral. When persistent, routine evaluation or consultation with a gastroenterologist is indicated;⁷⁵ evaluation is the same as in the nonpregnant patient and flexible sigmoidoscopy is safe. Most diarrhea that occurs during pregnancy is nonspecific and can be managed with a variety of nonsystemic and systemic medications. Nonsystemic med-

ications are preferable and should be tried initially. These include kaolin with pectin (Kaopectate) and stool-bulking agents. These substances are not absorbed from the gastrointestinal tract and therefore can cause no systemic side-effects or cross the placenta. Systemic medications frequently prescribed include loperamide (Imodium), diphenoxylate atropine (Lomotil), and bismuth subsalicylate (Pepto-Bismol). All these systemic therapies have been used during pregnancy. No teratogenic effects have been demonstrated from their use.^{58,59}

Diseases adjacent to the gastrointestinal tract

Gallbladder disease

Classically, the female patient with gallbladder disease has been described as “fair, fat, forty, and fertile.”³⁹ Gallbladder disease is uncommon during pregnancy. It may present as cholelithiasis or acute cholecystitis.

Cholelithiasis

Pregnancy predisposes to gallstones, increasing the risk of cholesterol gallstone formation by causing incomplete emptying of the gallbladder, particularly in late pregnancy, leaving a large residual volume because of decreased gallbladder contractility. The decreased gallbladder motility is theorized to result from the high progesterone levels present in the second and third trimesters of pregnancy that stimulate progesterone receptors and decrease mobility. The risk of developing gallstone disease increases in association with increasing parity, particularly among younger women, and most stones develop during the second and third trimester.³⁹ Older women have a decreased risk of developing gallstones.

The exact incidence of cholelithiasis during pregnancy in female patients is unknown, because many gallstones are asymptomatic. It has been reported that 2.0–5.3% of asymptomatic women undergoing routine obstetric ultrasound examinations have cholelithiasis.⁷⁶ Consequently, approximately 0.05% of pregnant women will develop symptomatic cholelithiasis and 40% of these women will require surgery.⁷⁷ When asymptomatic gallstones are found incidentally during a prenatal ultrasound examination, no therapy is indicated. The authors advise the patient that she has cholelithiasis and to seek follow-up evaluation after her pregnancy. There is no evidence that asymptomatic gallstones become symptomatic at a higher or lower frequency during pregnancy. Gallstones create a problem by passing through or becoming impacted in the biliary tract, producing colic. It has been estimated that one-half of asymptomatic silent stones will cause a problem during a patient's life. The most common complication of cholelithiasis is choledocholithiasis. This occurs in approximately 15–25% of patients with gallstones. The incidence of choledocholithiasis and biliary colic does not appear to be affected by pregnancy. The presence of gallstones

may also lead to the development of acute and chronic cholecystitis.

Biliary colic, which is due to choledocholithiasis, is a form of chronic cholecystitis in which the gallstones become impacted or pass through the biliary tract and is the most common symptom that gallstones produce during pregnancy. It affects 15% of patients with cholelithiasis.³⁴ The pain is due to the passage of the gallstones from the gallbladder into the cystic duct or the common bile duct. This produces a spasm of the gallbladder or the biliary duct involved. The pain is in the right upper quadrant and moderate to severe. It may be cramping or steady. The pain may come on abruptly, particularly after eating a fatty meal. It does not usually last more than a few hours. Although biliary colic is most frequently present in the right upper quadrant, it may also be epigastric, colicky, or steady in intensity. Unlike appendicitis, the pain of biliary colic is not altered in location or character. The patient may also experience nausea, vomiting, and, if cholangitis is present, fever. Jaundice may be present, although gallstones account for only 5% of the causes of jaundice during pregnancy. Depending on where the stone becomes impacted in the biliary tree, obstructive jaundice (common bile duct) or acute pancreatitis (ampulla of Vater) may occur. The symptoms of cholelithiasis may cease spontaneously once the stone is passed through the biliary tract or may persist, requiring surgical removal.

Laboratory diagnosis of gallstones in pregnancy is the same as in nonpregnant patients. The leukocyte count and differential may be normal or slightly elevated, depending on the degree of cholangitis. Hyperbilirubinemia and elevation in levels of aminotransferases [aspartate aminotransferase, AST (formerly called SGOT) and alanine aminotransferase, ALT (formerly called SGPT)] may be present. The serum alkaline phosphatase level is elevated by biliary obstruction. This is not helpful during pregnancy because elevated serum alkaline phosphatase is normal in the pregnant patient as a result of placental production. The presence of acute pancreatitis as a result of common duct stones may cause pancreatitis and elevated serum amylase and lipase levels.³⁴

Real-time ultrasound has revolutionized the diagnosis of biliary tract disease during pregnancy. In a review, the maternal gallbladder was visualized in 97.4% of women who underwent gallbladder ultrasound as part of routine obstetric ultrasound screening.⁷⁶ An adequate view of the gallbladder could be visualized in 96% of patients within 2 min, suggesting that the gallbladder can be readily, quickly, and adequately visualized during pregnancy. While routine gallbladder sonography is not necessary, any symptomatic patients should be evaluated for gallbladder disease during pregnancy. Several other studies have also shown ultrasound to be 95–98% sensitive in diagnosing both solitary and multiple gallstones in the gallbladder or biliary tract.⁷⁷ The technique used in the pregnant and nonpregnant patient is the same and has been well described.⁷⁷ Ultrasonography, which has been used in all trimesters to identify gallstones, is completely safe during

pregnancy and should be part of the evaluation of any pregnant woman with right upper quadrant pain.⁷⁷

The treatment of cholelithiasis during pregnancy is the same as in the nonpregnant patient. Accurate diagnosis should be made as described previously. Therapy should be tailored to the patient's symptoms, physical examination, gestational age, duration of illness, and clinical condition. Asymptomatic gallstones do not require any therapy. Most patients who have silent gallstones never develop symptoms. Cholecystectomy is recommended for the patient with gallstones who has recurrent episodes of biliary colic, common bile duct gallstones, and gallstone pancreatitis.³⁹ Cholecystectomy is the second most frequent nonobstetric abdominal surgical procedure performed in pregnancy. Nonoperative therapy consisting of hospitalization, antibiotics, analgesia, nil by mouth, and nasogastric suction may be all that is necessary in patients who have mild illness. Patients with symptoms that do not improve with observation and medical therapy require prompt cholecystectomy. Many authors have demonstrated that a delay in surgery for biliary tract disease complications results in increased maternal and fetal morbidity and mortality.³⁹ Gallbladder rupture, an unusual complication, has also occurred during pregnancy.⁷⁸ In their review, Davis et al.⁷⁹ reported that only 40% of patients with symptomatic cholelithiasis responded to conservative medical management. Nineteen percent of their patients required readmission, and 45% who failed conservative management required surgery. Cholecystectomy, when indicated, can be performed by either the laparotomy or the more popular laparoscopic approach.³⁹ During pregnancy, it should be performed during the second trimester if possible when pregnancy outcome is best. Several additional recommendations should be kept in mind when a patient requires cholecystectomy in the second half of pregnancy:

- Tocolytic therapy may be necessary and should be instituted if preterm labor occurs.
- There are no data to support or condemn the use of prophylactic tocolysis around the time of surgery.
- Surgery should be delayed until after delivery if possible when symptoms arise in the third trimester, although laparoscopic cholecystectomy has been performed safely even at that time.⁸⁰

The safety of laparoscopic cholecystectomy during pregnancy has been reviewed by several authors, and it is a safe procedure during pregnancy. The procedure has become the standard of care for treatment.³⁹

Endoscopic management of biliary disease during pregnancy has been proposed.⁸¹ Endoscopic retrograde cholangiopancreatography (ERCP) has been shown to decrease morbidity, mortality, and costs as a definitive treatment alternative for pancreaticobiliary disease in pregnancy. However, further clinical evaluation of this aggressive endoscopic intervention during pregnancy is necessary.³⁹

Intraoperative cholangiography is a controversial method of treating biliary disease during pregnancy. Several authors

propose that intraoperative cholangiography is probably safe in the second and third trimesters because of the small amount of radiation used during a period when organogenesis is complete.⁷⁷ Liberman and colleagues⁸² advocate routine intraoperative cholangiography in all pregnant patients undergoing laparoscopic cholecystectomy because of the increased incidence of common bile duct stones. Some argue that intraoperative cholangiography should be used only when there is a question of choledocholithiasis on the basis of clinical, biochemical, or ultrasonic evidence.⁷⁷ Alternative methods of investigating the common bile duct during surgery without X-ray exposure include intraoperative ultrasonography, transcystic duct choledochoscopy, and endoscopic papillotomy performed under ultrasonographic guidance.⁷⁷ If there is high clinical suspicion for choledocholithiasis or cholangitis, preoperative ERCP should be attempted and has a high degree of success.

Acute cholecystitis

Acute cholecystitis is a rare gastrointestinal disorder during pregnancy. The incidence is not well known. Landers et al.,⁸³ investigating patients at two hospitals in San Francisco, reported an incidence of 1 per 1000 births. The rate of acute cholecystitis in pregnancy in their report is higher than the 6–20 per 100 000 expected from other series. Fewer pregnant women develop acute cholecystitis than appendicitis during pregnancy.

Acute cholecystitis and appendicitis must be included frequently in the differential diagnosis of the pregnant patient presenting with right upper quadrant pain. Acute pancreatitis must also be considered in the differential diagnosis and may coexist with acute cholecystitis. The incidence of acute cholecystitis does not change through all three trimesters.

The clinical manifestations of acute cholecystitis during pregnancy are the same as in the nonpregnant patient. An attack usually begins with abdominal pain, which may increase in severity. The pain is in the right upper quadrant or epigastrium, and a positive Murphy's sign (right upper quadrant tenderness that is increased with while taking a deep breath) is elicited. Between 70% and 80% of patients have had a previous episode of biliary colic, and a history of previous fatty food intolerance can usually be obtained. The pain may radiate to the back and be associated with low-grade fever, chills, nausea, vomiting, and anorexia. As with other intra-abdominal inflammation, peritoneal signs may be absent. The leukocyte count may be normal or mildly elevated. If gallstone pancreatitis is present, there is an elevation in the serum amylase. When common bile duct obstruction occurs, there will be hyperbilirubinemia and liver enzyme elevation. The evaluation of laboratory data is rarely diagnostic, but the use of ultrasound can be.

There is no evidence that the ultrasonographic appearance of the gallbladder changes during pregnancy. Gallstones within the gallbladder or biliary tract are easily seen with

sonography and appear as an echodense area within the gallbladder or biliary tract. They usually cast a shadow and move with a change in position of the patient. The gallbladder wall may be thickened due to chronic cholecystitis, and the biliary ducts dilated due to an impacted stone. Conservative medical management is the mainstay of the treatment of the pregnant patient with acute cholecystitis. This consists of nasogastric suction when necessary, analgesia, intravenous hydration, and antibiotics. Most patients will respond to this medical management. Cholecystectomy should be reserved for those patients who have gallstone pancreatitis, jaundice, repeated attacks, or who fail medical management. When necessary, it should be performed during the second trimester. In the series by Landers et al.,⁸³ 84% of the patients were successfully treated conservatively. Favorable pregnancy outcomes occurred when those patients who failed conservative management had their cholecystectomy, preferably during the second trimester. Because conservative management of acute cholecystitis or cholelithiasis is not always successful during pregnancy, surgical therapy should be considered.³⁹ Surgery during the first trimester can result in spontaneous abortion.^{39,83} As discussed in the previous section, laparoscopic cholecystectomy can be performed safely and effectively during pregnancy.⁸⁴ While the optimal time for laparoscopic surgery remains the second trimester of pregnancy, no increase in fetal loss has been shown when the procedure is performed in the first trimester.⁸⁴ Preterm labor remains a concern of laparoscopic cholecystectomy performed in the third trimester, but the incidence may be lower than with a laparotomy surgical approach.^{79,84}

In a study performed by Affleck et al.,⁸⁵ 47 patients underwent laparoscopic cholecystectomy during pregnancy. The incidence of preterm delivery among these patients was 11.9%. Younger patient age was found to correlate with preterm delivery. In the same study, 15 laparoscopic cholecystectomies were performed during the third trimester, each without any adverse maternal or fetal outcomes. These outcomes suggest that laparoscopic cholecystectomy may be performed safely in all trimesters.

If preterm labor occurs as a result of performing a cholecystectomy, it should be treated with aggressive tocolysis. Maternal morbidity is not increased when cholecystectomy is performed during pregnancy. Fetal loss after cholecystectomy during pregnancy has been reported to occur most frequently during the first trimester.⁸⁶ When necessary (gallstone pancreatitis, worsened maternal condition with medical therapy, or complications), cholecystectomy should not be delayed because of pregnancy. Patients should be educated on the potential risks associated with laparoscopic surgery, including trocar injury to the uterus and fetus, effect of pneumoperitoneum on both mother and fetus, induction of preterm labor, decreased uterine blood flow, and increased fetal acidosis. The Society of American Gastrointestinal Endoscopic Surgeons (SAGES)⁸⁶ has adopted some guidelines to enhance operative safety in the pregnant patient including:

- 1 When possible, operative intervention should be deferred until the second trimester, when fetal risk is low.
- 2 Because pneumoperitoneum enhances lower extremity venous stasis already present in a gravid patient, and because pregnancy is a hypercoagulable state, pneumatic compression devices must be used.
- 3 Fetal and uterine status, as well as maternal endtidal carbon dioxide and arterial blood gases, should be monitored.
- 4 The uterus should be protected with a lead shield if intraoperative cholangiography is a possibility. Fluoroscopy should be used selectively.
- 5 Given the enlarged gravid uterus, abdominal access should be attained using an open technique.
- 6 Dependent positioning should be used to shift the uterus off the inferior vena cava.
- 7 Pneumoperitoneum pressures should be minimized (8–12 mmHg) and not allowed to exceed 15 mmHg.
- 8 Obstetric consultation should be obtained preoperatively.

Pancreatitis

The exact incidence of acute pancreatitis during pregnancy has been difficult to determine. It is not common and has been reported to occur in 1 per 1000 to 1 per 12 000 pregnancies in an extensive review by Wilkinson.⁸⁷ Although acute pancreatitis may occur at any stage of gestation, it is a disease of late pregnancy, particularly the third trimester, or the early postpartum period.^{88,89} Relapses of pancreatitis occur, with an average of two readmissions during the affected pregnancy. It is important to counsel pregnant patients about the relapsing nature of pancreatitis, occurring during the first trimester; however, a favorable prognosis for the pregnancy should be expected.⁹⁰ Pancreatitis can reoccur during the same, a subsequent pregnancy, or the puerperium.⁹¹ When pancreatitis develops in women of less than 30 years of age, half of them are pregnant.⁸⁹

Pregnancy probably predisposes a woman to the development not of pancreatitis but of cholelithiasis,⁹² which is the most common cause of acute pancreatitis in the pregnant patient. Other factors that predispose to the development of acute pancreatitis during pregnancy include alcoholism, acute infections, abdominal surgery, abdominal trauma, pyelonephritis, tetracycline or thiazide use during pregnancy, and, rarely, pregnancy-induced hypertension.³¹ Hyperlipidemia may be the second most common cause of pancreatitis during pregnancy after cholelithiasis.⁹³ Gestational diabetes in the presence of severe hyperlipidemia has also been reported as a cause of acute pancreatitis. However, biliary disease is at least present in, if not responsible for, 90% of pancreatitis in pregnancy.^{88,89} The gallstone can block the ampulla of Vater, causing active pancreatic proteolytic enzymes to cause autodigestion. The most common predisposing factor in the non-pregnant patient is alcoholism.³⁴

The clinical picture of acute pancreatitis is characteristic. The symptoms and signs include a rapid onset of constant,

central mid-epigastric pain that may radiate to the chest and back and can be quite severe. In mild cases of pancreatitis, pain may be the only symptom that the patient experiences. Not infrequently, however, nausea and severe vomiting may occur alone or with pain. Low-grade fever and absent or decreased bowel sounds also aid in the diagnosis. The classic clinical presentation of a patient with pancreatitis is an individual rocking in the bed with her knees drawn up and trunk flexed in agony.⁴⁴ The pain may also radiate to the flanks or shoulders due to the development of peritoneal irritation. Other symptoms include tachycardia in response to the pain, hypotension, ascites, pleural effusion, hypotonic bowel sounds or ileus, tenderness over the epigastrium, and generalized peritonitis. An adynamic ileus may be demonstrated on radiographic examination. The severity of the clinical features depends on the severity of the pancreatitis and whether or not complications occur, such as pseudocyst or abscess formation.^{34,94} Rarely is the white blood cell count above 30 000 cells per mL. It may even be within the range for normal pregnancy, 10 000–20 000 cells/mL. The serum amylase is the specific test used to diagnose pancreatitis and is usually elevated to more than 200 IU/mL. However, it is elevated in other conditions causing an acute abdomen, such as perforation of a peptic ulcer, cholecystitis, intestinal bowel obstruction, hepatic trauma, and ruptured ectopic pregnancy.⁴² The increase occurs rather quickly after the onset of the illness, usually within 12–24 h, but values do not correlate with the severity of the disease. A serum amylase above 1000 IU/mL is almost always indicative of pancreatitis or an obstruction of the pancreatic duct.⁹¹ Serum amylase has been reported to be both increased and unchanged in the normal pregnancy.^{95,96} These mild changes result in fluctuations in the serum amylase, but not to the degree that would cause confusion in the diagnosis of acute pancreatitis.

Other abnormal laboratory data seen in acute pancreatitis include slight elevation of liver function test results, elevated serum lipase, hemoconcentration, hyperglycemia, hypocalcemia, and acidemia due to abnormal pancreatic function. Diagnostic ultrasound can be used to visualize the pancreas for the presence of pseudocyst or abscess.³⁴ At the same time, the gallbladder and biliary ducts can be visualized to rule out the presence of gallstones. The pancreas can also be evaluated during pregnancy by a CT scan. This procedure is safe to perform during pregnancy, because the dose of radiation given to the fetus is low.^{32,58} As both ultrasound and CT demonstrate pancreatitis, failure to demonstrate enlargement of the pancreas in a case of suspected acute pancreatitis should institute a search for other causes of hyperamylasemia.

Treatment for acute pancreatitis is primarily nonoperative.^{34,44} Management includes intravenous fluid hydration to correct hypovolemia and electrolyte imbalance, correction of hyperglycemia, enteric rest with nasogastric suction, broad-spectrum antibiotics, and adequate analgesia. Insulin may be necessary to reduce the blood sugar. Acute pancreatitis, when managed appropriately, usually subsides in 2–3 days. Chole-

cystectomy is reserved for the patient with recurrent attacks of pancreatitis due to gallstones.⁴² Cholecystectomy in the midtrimester has been recommended because of the relapsing nature of gallstone pancreatitis. The risks of anesthesia and preterm labor are also lowest at that time. If pancreatitis during pregnancy is due to hyperlipidemia, hemodialysis, plasma exchange, immunospecific apheresis, and a combination of these have been used for the treatment.⁹⁷ Several reports suggest a maternal mortality rate as high as 20% in cases of acute pancreatitis secondary to hyperlipidemia during pregnancy. Because of peritoneal irritation, if the patient is in the second half of pregnancy, an attempt should be made to detect preterm labor early and to treat it once diagnosed. Magnesium sulfate would be the tocolytic drug of choice, because hyperglycemia could be worsened if the betamimetic drugs were used.⁹⁸ Theoretically, the prostaglandin antagonists may be effective, because animal experiments have shown an elevation of prostaglandin-like activity in the pancreatic venous drainage and peritoneal exudates with induced pancreatitis.⁹⁹ The clinician should be concerned about maintaining adequate volume replacement and electrolyte balance and should be vigilant for the appearance of complications in the patient who does not improve rapidly.

The most feared complications are hypocalcemia, pancreatic abscess, and pseudocyst formation, but they occur rarely during pregnancy or postpartum. Patients with necrotizing pancreatitis require hospitalization in an intensive care unit. They should receive treatment with intravenous fluids, antibiotics and, if necessary, surgical debridement.¹⁰⁰ Total parenteral nutrition can be used safely and effectively in the management of pancreatitis during pregnancy, when there is concern for the nutritional status of the mother or the development of intrauterine growth restriction.⁸⁸ Maternal mortality is low when diagnosis is made promptly and appropriate management is instituted. Pancreatitis is now a rare cause of maternal death unless the diagnosis is either delayed or missed entirely. The prognosis for the fetus is also good unless severe peritonitis occurs, which predisposes the patient to spontaneous abortion or preterm birth. Preterm labor occurs in 60% of patients when pancreatitis develops late in pregnancy. The mode of delivery is not affected by pancreatitis and, unless contraindicated for obstetric reasons, vaginal delivery is recommended.^{88,91}

Effects on the fetus of drugs used in treating gastrointestinal diseases

Throughout this chapter, statements have been made about the teratogenic effect of drugs used in managing these conditions on the fetus. In 1979, the US FDA established a system of five categories to indicate the potential of systemically absorbed drugs to be teratogenic. These risk categories were defined as A, B, C, D, and X and are used by manufacturers to rate their

Table 43.1 Food and Drug Administration risk categories.

Category A	Controlled studies in women fail to demonstrate a risk to the fetus in the first trimester (and there is no evidence of a risk in later trimesters), and the possibility of fetal harm appears remote.
Category B	Either animal reproduction studies have not demonstrated a fetal risk but there are no controlled studies in pregnant women or animal reproduction studies have shown an adverse effect (other than a decrease in fertility) that was not confirmed in controlled studies in women in the first trimester (and there is no evidence of a risk in later trimesters).
Category C	Either studies in animals have revealed adverse effects on the fetus (teratogenic, embryocidal, or other) and there are no controlled studies in women or studies in women and animals are not available. Drugs should be given only if the potential benefit justifies the potential risk to the fetus.
Category D	There is positive evidence of human fetal risk, but the benefits from use in pregnant women may be acceptable despite the risk (e.g., if the drug is needed in a life-threatening situation or for a serious disease for which safer drugs cannot be used or are ineffective).
Category X	Studies in animals or human beings have demonstrated fetal abnormalities, or there is evidence of fetal risk based on human experience, or both, and the risk of the use of the drug in pregnant women clearly outweighs any possible benefit. The drug is contraindicated in women who are or may become pregnant.

products for use during pregnancy (Table 43.1).¹⁰¹ This classification is currently under revision by the FDA. A review of data on teratology by the American College of Obstetricians and Gynecologists found none of the commonly used drugs in the treatment of gastrointestinal disease during pregnancy to be teratogenic.¹⁰² Table 43.2 lists drugs frequently used in the treatment of gastrointestinal diseases during pregnancy with their FDA risk category.^{58,59} The maternal condition, gestational age, treatment need, and benefit to the mother and risk to the fetus, especially of category C or X drugs, must be considered when these drugs are used during pregnancy.^{58,59}

Total parenteral nutrition in pregnancy

Pregnant patients unable to consume sufficient nutrients orally require an effective method of feeding. Alternative forms of nutrition are being used more frequently in obstetrics.¹⁰³ This may be particularly necessary to maintain maternal nutrition when a gastrointestinal disease complicates pregnancy, and can be given as enteral nutrition (tube feeding) or as total parenteral nutrition. Total parenteral nutrition, parenteral nutrition, hyperalimentation, intravenous hyperalimentation, and intravenous feedings are used synonymously and interchangeably to describe the various methods of providing all required nutrients intravenously.¹⁰⁴ Total parenteral nutrition, in order to meet basal, maintenance level of required nutrients, as well as the additional demands of growth and development of the patient and fetus, is hyperosmolar and requires jugular or subclavian venous catheterization.^{105,106} Subclavian venous catheterization is now the preferred technique for long-term inpatient total parenteral nutrition.

Numerous authors have reported long-term total parenteral nutrition with good results in a variety of hospitalized or outpatient pregnant patients at significant risk for malnutrition and poor fetal outcome.^{14,105–107} Patients at high risk for malnutrition during pregnancy may also benefit from total parenteral nutrition. Silberman and Eisenberg¹⁰⁴ discuss in detail,

Table 43.2 Gastrointestinal drugs frequently used in the treatment of gastrointestinal disorders during pregnancy.

Drugs	FDA risk category (see Table 43.1)
Azathioprine	D
Cimetidine	B
Diazepam	D
Diphenoxylate	C
Doxylamine	B
Droperidol	C
Esomeprazole	B
Famotidine	B
Lansoprazole	B
Lidocaine	C
Loperamide	B
Meperidine	B
Mesalamine	B
Metoclopramide	B
Misoprostol	X
Nizatidine	C
Olsalazine	C
Omeprazole	C
Pantoprazole	B
Prednisone	B
Prochlorperazine	C
Promethazine	C
Rabeprazole	B
Ranitidine	B
Sulcralfate	B
Tetracycline	D
Trimethobenzamide	C

but succinctly, therapeutic nutrition in the hospitalized patient and principles applicable to the outpatient and pregnant patient.

Total parenteral nutrition can be complicated by death of the nonpregnant patient or by maternal and/or fetal death in

the pregnant patient. Other complications include accidental pneumothorax or hemothorax, catheter infection, various metabolic disorders, glycosuria, hypoglycemia and, rarely, clinical sepsis.^{104,108} New findings and diagnostic advances warrant revisiting key features of acute nonobstetric abdominal pain in pregnancy.¹ Wernicke–Korsakoff syndrome, with irreversible neurologic abnormalities, has occurred after institution of total parenteral nutrition and has been reported by various authors.^{103,106}

There is general agreement that total parenteral nutrition does not cause preterm labor, small for gestational age infants,

or fetal death. However, the disease process for which parenteral nutrition is being given may be the cause of this adverse perinatal outcome.¹⁰⁹ It has been demonstrated that enteral or total parenteral nutrition can be safely and effectively administered during pregnancy. A team of qualified, knowledgeable individuals who are familiar with the technique being used should explain it to the patient, obtain written consent, and manage the administration of the parenteral nutrition. Total parenteral nutrition should be administered in hospitals with an intensive care nursery, because many of the infants of the mothers who are receiving this therapy deliver preterm.^{110–112}

Key points

- 1 Nausea with or without vomiting is an especially common symptom during early pregnancy and the most common gastrointestinal complaint. It usually occurs during the first trimester of pregnancy and, by mid-second trimester, most women no longer complain of these symptoms.
- 2 Hyperemesis gravidarum is the abnormal condition of pregnancy associated with pernicious nausea and vomiting. Hyperemesis is both infrequent and uncommon.
- 3 Refractory hyperemesis gravidarum has been successfully treated with corticosteroid therapy, which is effective in suppressing symptoms of intractable hyperemesis, decreasing the length of hospitalization, and allowing normal maternal nutrition.
- 4 The role of psychosocial stressors, such as undesired pregnancy, in the etiology of nausea, vomiting, and hyperemesis gravidarum has been only partially studied. It is believed that psychological factors contribute to excessive nausea and vomiting during pregnancy.
- 5 A few patients with hyperemesis gravidarum have transient hyperthyroidism, which in these patients is common, self-limited, and requires no therapy.
- 6 Many pregnant women enter pregnancy with poor dental care. Their teeth are in poor condition, and numerous cavities and gingivitis are present owing to poor dental hygiene.
- 7 Radiographs, which are often necessary to establish a proper dental diagnosis, may be safely taken during any stage of pregnancy. The maternal abdomen should be shielded with a lead apron.
- 8 Heartburn is really a symptom of reflux esophagitis that is a common, bothersome complaint during pregnancy and occurs in as many as 70% of pregnant patients.
- 9 Treatment of reflux esophagitis during pregnancy consists primarily of neutralizing the acid material that is being refluxed into the esophagus, thereby decreasing gastroesophageal reflux.
- 10 The development of peptic ulcer disease during pregnancy is uncommon and rare. Patients who have peptic ulcers before pregnancy frequently experience fewer symptoms during pregnancy and may even become totally asymptomatic.
- 11 Patients with peptic ulcer disease should avoid a diet of foods that cause discomfort. The H₂ receptor antagonists and the proton pump inhibitors appear to be safe to use during pregnancy.
- 12 The most common cause of intestinal obstruction in the pregnant woman is adhesions.
- 13 The term inflammatory bowel disease refers to a group of idiopathic chronic inflammatory diseases of the intestinal tract. The two most commonly seen during pregnancy are ulcerative colitis and Crohn's disease.
- 14 There is little evidence to suggest that pregnancy has an effect on inflammatory bowel disease. Pregnancy has little or no effect on Crohn's disease and the overall maternal prognosis is good.
- 15 Appendicitis is the most common cause of an acute abdomen during pregnancy. The most frequent condition misdiagnosed as appendicitis is pyelonephritis.
- 16 Pregnant women have a higher mortality rate when they develop appendicitis. This is primarily due to procrastination in diagnosis and treatment, with resultant perforation of the appendix, peritonitis, and preterm labor.
- 17 Both computed axial tomography and magnetic resonance imaging are helpful and safe during pregnancy in the diagnosis of acute appendicitis and other gastrointestinal diseases of pregnancy. The emergency room physician, other clinicians, or radiologists should not hesitate to use them when they are indicated.
- 18 Gastric restrictive operations have now developed as the operation of choice for the patient who is morbidly obese. It has been recommended that a woman undergoing one of these procedures should not become pregnant for at least 1 year because, during that year,

- significant postoperative metabolic changes occur in the patient.
- 19 The prevention and treatment of constipation during pregnancy should consist mainly of nutrition counseling, increasing fluid intake, daily exercise, and dietary modification to increase the fiber content.
 - 20 Most diarrhea that occurs during pregnancy is nonspecific and can be managed with a variety of nonsystemic and systemic medications.
 - 21 Pregnancy predisposes a woman to developing gallstones by decreasing gallbladder contractility and mobility. About 2–5.3% of asymptomatic women undergoing routine obstetrical ultrasound examinations have cholelithiasis for which no immediate treatment is required.
 - 22 The gallbladder can be readily, quickly, and adequately visualized by ultrasound during pregnancy. Ultrasound has been shown to be 95–98% sensitive in diagnosing both solitary and multiple gallstones in the gallbladder or biliary tree.
 - 23 Biliary colic occurs when gallstones become impacted or pass through the biliary tree, and it is the most common symptom that gallstones produce during pregnancy. Biliary colic typically presents with right upper quadrant pain that is epigastric, colicky, or steady in intensity accompanied by nausea, vomiting and, if cholangitis is present, fever.
 - 24 Obstructive jaundice can occur when the gallstone becomes impacted in the common bile duct or ampulla of Vater causing acute pancreatitis.
 - 25 Cholecystectomy should be reserved for the patient with gallstones who has recurrent episodes of biliary colic, common bile duct gallstones, and gallstone pancreatitis. Nonoperative therapy for a patient with gallstones includes hospitalization, analgesia, nil by mouth, and nasogastric suction.
 - 26 When performed during the second trimester, cholecystectomy carries the most favorable pregnancy outcome.
 - 27 The clinical manifestations of acute cholecystitis during pregnancy are right upper quadrant or epigastric pain that radiates to the back and can be associated with low-grade fever and chills. Nausea, vomiting, anorexia, and fatty food intolerance may accompany the pain.
 - 28 Conservative medical management is the mainstay of treatment of acute cholecystitis during pregnancy.
 - 29 Pancreatitis is uncommon during pregnancy and most typically develops in the third trimester. Treatment for acute pancreatitis is primarily nonoperative.
 - 30 Factors that predispose to the development of acute pancreatitis during pregnancy include alcoholism, acute infections, abdominal surgery, abdominal trauma, pyelonephritis, tetracycline or thiazide use during pregnancy, pregnancy-induced hypertension, eclamptic seizures, hyperlipidemia, gestational diabetes, and hyperparathyroidism.
 - 31 Cholelithiasis is the most common cause of acute pancreatitis during pregnancy. The symptoms and signs of acute pancreatitis during pregnancy include a rapid onset of constant, central mid-epigastric pain that may radiate to the chest and back and can be quite severe. A low-grade fever and absent or decreased bowel sounds may also be present.
 - 32 Serum amylase level is usually elevated to more than 200 IU/mL in acute pancreatitis. A serum amylase level above 1000 IU/mL is almost always indicative of pancreatitis or an obstruction of the pancreatic duct.
 - 33 Careful consideration should be made when prescribing drugs that fall under categories C, D, and X of the Food and Drug Administration's risk category classification, which is being revised.
 - 34 Pregnant patients at high risk of malnutrition during pregnancy may benefit from total parenteral nutrition, which can be used safely during pregnancy.

Pregnancy is an altered but normal physiological state. Pregnancy causes alterations in the normal physiology of many organs, but its effect on the liver is minimal. Liver disease is uncommon in pregnancy, but its effect on the patient and the fetus can be severe, thus making it more challenging to manage. While any disease of the liver can affect the pregnant woman, there are some diseases that are unique to pregnancy, such as hemolysis, elevated liver function, and low platelets (HELLP) syndrome, acute fatty liver of pregnancy, etc. Some other diseases such as hepatitis E may take a more serious course in pregnant women compared with the general population. Because of the altered physiological state, some disorders are more likely to occur in pregnancy, e.g., Budd–Chiari syndrome, due to the hypercoagulable state (Table 44.1).

Normal pregnancy and liver

Pregnancy alters the normal hemodynamics of the body and causes certain biochemical and physical changes, which should be kept in mind when assessing clinical and biochemical parameters, as some of these can be similar to changes associated with liver disease.¹ Spider angiomas and palmar erythema are seen in pregnancy, as well as in liver disease patients. However, these changes are normal in pregnancy, can be seen in more than 50% of pregnant women, and disappear after delivery. There is no hepatosplenomegaly in pregnancy. Liver histology remains unchanged. Jaundice is not a normal physiological finding in pregnancy, and should prompt further investigation. Hemodynamic and biochemical changes in normal pregnancy are outlined in Table 44.2. Most biochemical tests used to assess liver injury or liver function are not altered in pregnancy. Therefore, increase in levels of aspartate aminotransferase (AST), alanine aminotransferase (ALT), serum bilirubin, and fasting serum bile acid concentration indicate liver disease, should be considered abnormal, just as in a non-pregnant woman, and should be investigated further.^{2–4}

Liver diseases unique to pregnancy

Liver diseases unique to pregnancy include hyperemesis gravidarum, intrahepatic cholestasis of pregnancy (ICP), preeclampsia- and eclampsia-related liver diseases including HELLP syndrome, and acute fatty liver of pregnancy (AFLP). These present at different gestational periods, and this knowledge can be very helpful in suspecting and diagnosing these diseases (Table 44.3). Diseases that are not unique to pregnancy, such as viral hepatitis, drug hepatotoxicity, etc., can also occur in a pregnant woman and should be considered in the differential diagnosis of liver disease in a pregnant woman. Salient features of liver diseases unique to pregnancy are summarized later in the text (see Table 44.6).

Hyperemesis gravidarum

Hyperemesis gravidarum is characterized by severe nausea and vomiting during pregnancy. It can lead to dehydration and ketosis. It is more severe than the common morning sickness. While nausea and vomiting can be seen in up to 50% of pregnancies, hyperemesis gravidarum is seen in only 1–1.5% of all pregnancies.^{5,6} It generally occurs in the first trimester of pregnancy, but can occur as late as the 20th week. Abnormal liver enzymes and mild hyperbilirubinemia can be seen in more than 50% of cases.^{7,8}

Pathophysiology and pathology

The pathogenesis of hyperemesis gravidarum remains unclear. Liver involvement is secondary to the disorder itself and not the cause of the disorder. Gestational hormones that peak in early pregnancy may affect both liver and thyroid. Liver biopsy is not needed in most situations but, if performed, it is usually normal or may show centrilobular vacuolation, cell dropout, and rare bile plugs. There is usually no inflammation, and either no or minimal fat.^{7,9}

Table 44.1 Liver diseases in pregnancy.

<i>Liver diseases unique to pregnancy</i>	
Hyperemesis gravidarum	
Intrahepatic cholestasis of pregnancy	
Preeclampsia and liver disease including HELLP syndrome, hepatic infarction, hepatic hematoma, and rupture	
Acute fatty liver of pregnancy	
<i>Common liver diseases occurring concurrently with pregnancy or exacerbated by pregnancy</i>	
Acute viral hepatitis: A, B, C, E, Herpes simplex	
Drug hepatotoxicity	
Biliary and pancreatic diseases	
Budd–Chiari syndrome	
Other diseases	
<i>Pregnancy in the presence of chronic liver disease</i>	
Cirrhosis and portal hypertension	
Chronic hepatitis B	
Chronic hepatitis C	
Autoimmune hepatitis	
Primary biliary cirrhosis	
Focal nodular hyperplasia and hepatic adenoma	
Liver transplantation	

Table 44.2 Hemodynamic and biochemical changes in normal pregnancy.

<i>Hemodynamic changes</i>	
Plasma volume	↑ Between weeks 6 and 36 by 50%. ↓ After delivery
Red cell volume	↑ By about 20%. ↓ After delivery
Cardiac output	↑ Until second trimester. Normalizes by term
Systemic vascular resistance	↓ Due to systemic vasodilation and placental circulation
Absolute hepatic blood flow	Unchanged
<i>Biochemical changes</i>	
Serum albumin	↓ As pregnancy advances, due to hemodilution
ALP	↑ Mainly placental ALP
ALT	No change
AST	No change
Serum bilirubin	No change or mild ↓
Direct bilirubin	No change
Fasting total bile acid	No change
GGT	Mild ↓
Serum fibrinogen	↑
Prothrombin time/INR	No change

ALP, alkaline phosphatase; ALT, alanine aminotransferase; AST, aspartate aminotransferase; GGT, gamma-glutamyltransferase; INR, international normalized ratio.

Table 44.3 Onset of liver diseases unique to pregnancy by trimester.

Hyperemesis gravidarum	Early first trimester
Intrahepatic cholestasis of pregnancy	Anytime. Usually late second or third trimester
Preeclampsia	Late second or third trimester
HELLP syndrome	Third trimester. Sometimes postpartum
Acute fatty liver of pregnancy	Third trimester. Sometimes postpartum

Clinical and biochemical features

Patients usually present with intractable severe nausea and vomiting in the 4th to 10th week of gestation, but can present as late as the 20th week. Vomiting can be severe and lead to dehydration, malnutrition, and ketosis. It is more common in primiparous than in multiparous women. Usually, the patient has no other complaint such as abdominal pain or fever. When the liver is involved, there can be significant elevations of AST and ALT ranging from mild elevation to 500–1000 IU/L. Bilirubin elevation is usually mild and so is alkaline phosphatase (ALP; up to twice normal levels).^{9,10}

Management, maternal and fetal outcome

Most patients respond to intravenous rehydration and bowel rest for a few days, followed by a high-carbohydrate, low-fat diet. The symptoms, as well as liver test abnormalities, usually resolve quickly with this treatment. Antiemetics such as ondansetron, phenargan, and droperidol are frequently needed for symptom control.^{11,12} Corticosteroids may be useful in refractory cases.¹³ Enteral nutrition via a gastric or duodenal feeding tube can be useful¹⁴ and, rarely, parenteral nutrition may be needed. Symptoms usually resolve by late first or early second trimester. There is usually no impact on the child. Infants born to affected patients do not differ from those of normal patients in terms of birthweight, maturity at birth, or birth defects.^{5,6} However, in patients with severe hyperemesis, the infant birthweight may be lower than normal.¹⁵

Intrahepatic cholestasis of pregnancy (ICP)

ICP is a benign cholestatic disorder that usually occurs during the second or third trimester of pregnancy and disappears shortly after delivery. It is characterized by pruritis, cholestatic liver test abnormalities, and occasionally jaundice. It is not a life-threatening disease, but can cause significant discomfort and affect maternal well-being.¹⁶ It can sometimes be associated with an increased incidence of postpartum hemorrhage, probably as a result of vitamin K malabsorption. There is wide variation in its prevalence across the world, with low rates of 1–2

per 10 000 pregnancies in the United States, Asia, and Australia, and high rates up to 10–200 per 10 000 pregnancies in Europe.^{17,18} Prevalence of 15.6% was reported from Chile,¹⁹ although lower rates of 4–6.5% have been reported in more recent studies.^{20,21} The reason for this is unclear. ICP can occur in primiparous or multiparous women, can recur in subsequent pregnancies, and is more common in multiple gestations.^{18,22}

Pathophysiology and pathology

The exact cause of ICP is unknown. Genetic factors, hormonal exposure, and exogenous factors may all play a role in its pathogenesis.²³ Genetic factors may explain the wide geographical variation and high incidence in some ethnic groups such as Native Americans in Chile.¹⁹ Premature truncation or missense mutation of the *MDR3* gene has been reported.²⁴ A role for estrogens has been strongly suggested. ICP occurs in the third trimester, when estrogen levels peak,^{18,21,25} and occurs five times more commonly in multiple gestations, where estrogen levels are high.²⁶ Experimental cholestasis can be induced in nonpregnant women with a previous history of ICP by the administration of ethinylestradiol.^{27,28} Abnormal progesterone metabolism may also be involved in the pathogenesis of ICP. In ICP patients, the levels of sulfated metabolites of progesterone are increased.²⁸ Oral administration of progesterone in the third trimester of pregnancy has been shown to increase serum bile acid concentration and serum ALT levels.²⁹ Progesterone should not be prescribed in pregnant women with a history of ICP, or in late pregnancy, and should be withdrawn if cholestasis occurs during pregnancy.^{1,16} Exogenous factors may also be important in the pathogenesis of ICP, as suggested by a recurrence rate of 45–70%^{30,31} in subsequent pregnancies, seasonal variation in incidence in many countries, and decreasing incidence in some high-prevalence countries such as Sweden³² and Chile.³⁰ Liver biopsy is rarely necessary for diagnosis. Histopathology shows cholestasis, with bile plugs in hepatocytes and canaliculi, predominantly in the centrilobular region. There is no inflammation or necrosis, and portal tracts are unaffected (Fig. 44.1).³³

Clinical and biochemical features

The main symptom of ICP is pruritis, which can be very severe, uncomfortable, and difficult to tolerate. It can involve any part of the body, but usually involves the hands and feet, especially the palms and soles. It is often generalized and is usually worse at night, resulting in sleep deprivation and psychological distress.^{26,34–36} Pruritis generally develops in the third trimester, but can occur as early as the sixth week.^{31,37} Jaundice develops in only 10–15% of cases, is usually mild, with serum bilirubin less than six times the upper limit of normal, and resolves rapidly after delivery, within 1–40 days. Jaundice in the absence of pruritis is rare.^{26,31,38} ALT and AST are elevated 2- to 10-fold above the upper limit of normal. ALT elevation is a sensitive test for ICP.³⁹ Viral hepatitis should be ruled out in all cases with elevated ALT and AST. Liver histology does not show any hepatocyte injury, and the

Figure 44.1 Liver biopsy showing cholestasis of pregnancy. Arrows point to bile plugs within canaliculi (bilirubinostasis). Note minimal accompanying inflammation (reprinted from Burt et al., with permission from Elsevier).

cause of elevated liver transaminases is thought to be an increase in membrane permeability. Serum gamma-glutamyl-transferase (GGT) is usually normal or mildly increased. Serum total bile acid (TBA) concentrations are increased. Increased serum cholic acid levels, or a ratio of cholic to chenodeoxycholic acid level of > 1 may be the earliest and most sensitive predictor of ICP, even before the onset of symptoms.³³ Measurement of serum TBA concentration is a useful diagnostic test for ICP, especially when the patient has pruritis but normal ALT and AST levels.³⁰ The serum bile acid and aminotransferase levels decrease rapidly after delivery and, as a rule, normalize in a few weeks. Prothrombin time is usually normal. It can sometimes be abnormal because of vitamin K deficiency, and should be checked before delivery and corrected with vitamin K, to avoid bleeding complications.

Maternal and fetal outcome

Severe pruritis can lead to fatigue and psychological distress for the mother. However, the overall maternal prognosis is good. There is a slight increase in the risk of postpartum hemorrhage due to vitamin K malabsorption, but this is easily corrected by administration of vitamin K prior to delivery. ICP does increase the risk for the fetus, with an increase in risk of prematurity, stillbirth, meconium-stained amniotic fluid, and abnormal fetal heart rate patterns.^{21,40–43} The higher rate of multiple pregnancies in ICP may also contribute to high rates of prematurity.³¹ Antenatal testing, amniocentesis, and early induction of labor, once fetal lung maturity is achieved, decrease fetal mortality rates.^{22,44}

Medical and obstetric management

The aim of management is treatment of maternal symptoms and improvement of fetal outcome. Hydroxyzine, other anti-

histaminics, benzodiazepines, and tranquilizers are used to treat symptoms, but have limited success and do not improve biochemical parameters or fetal outcome. Low-dose phenobarbital (2–5 mg/kg) has been found to be effective in controlling pruritis in about 50% of patients in one study,¹⁸ but not in others.²¹ Cholestyramine (8–16 g/day) decreases ileal absorption and increases fecal excretion of bile acids by binding bile acids in the small bowel. It improves maternal symptoms to some extent, but does not improve biochemical parameters or fetal outcome.^{21,45} In many studies, ursodeoxycholic acid (UDCA) has been effective. It is a naturally occurring bile acid, which modifies the bile acid pool composition by replacing lithocholic acid, which is mildly cytotoxic to hepatocyte membranes, and by decreasing the absorption of cholic and chenodeoxycholic acid. It relieved pruritis, improved liver blood test values, and prevented prematurity in most patients. No major side-effects have been reported in mother or baby, and it was not found to be teratogenic.^{28,46–49} Fetal outcome improves if the condition is diagnosed early and managed actively, including fetal surveillance. It is difficult to decide the best time for delivery. Risk of prematurity and the risk of intrauterine death of the fetus have to be taken into account when deciding the best time to deliver. In patients with severe cholestasis, delivery should be considered after 36 weeks' gestation if the fetal lungs have matured, or as soon as possible thereafter.²¹

Preeclampsia and liver disease

Preeclampsia is a multisystem disorder of unknown etiology that presents in the late second or third trimester of pregnancy and is characterized by a triad of hypertension, proteinuria, and edema.³ It complicates 3–5% of all pregnancies and is a major cause of maternal and fetal morbidity and mortality. The etiology and pathogenesis of preeclampsia are poorly understood. Genetic and immunological factors have been implicated,^{50–52} as well as paternal or fetal factors.⁵³ The drop

in systemic vascular resistance typically seen in normal pregnancy fails to occur, and the sensitivity of the vascular system to vasospasm is enhanced, resulting in poor perfusion of a variety of organs including the liver, causing ischemic injury. The spectrum of liver disease in preeclampsia ranges from subclinical involvement at one end of the spectrum to HELLP syndrome, hepatic infarction, and rupture of liver at the other end of the spectrum. Acute fatty liver of pregnancy is also associated with preeclampsia in about half the cases, but is a distinct syndrome. The commonest liver disorder seen in the presence of preeclampsia is HELLP syndrome. The exact mechanism for this is unknown.

HELLP syndrome

HELLP syndrome is defined as hemolysis, elevated liver test values and low platelets in a patient with preeclampsia. It affects approximately 0.1–0.6% of pregnancies, and 4–12% of patients with severe preeclampsia. The majority of cases (about 70%) occur in the third trimester, and the rest occur postpartum.¹

Pathophysiology and pathology

The peripheral smear characteristically shows features of microangiopathic hemolytic anemia, with characteristic schistocytes and burr cells. Liver biopsy is not necessary for diagnosis and can be high risk given the possibility of hematoma and liver rupture seen in HELLP syndrome. Liver histology is characterized by periportal hemorrhage, and periportal and focal parenchymal necrosis, with hyaline deposits^{54,55} (Fig. 44.2). There is fibrin deposition and microthrombi in sinusoids. Steatosis can be seen in some patients, but it is usually macrovesicular fat distribution throughout the liver lobule that distinguishes it from the microvesicular centrilobular fat distribution typical of acute fatty liver of pregnancy.⁵⁶ Rarely, hepatic infarction and rupture of the liver capsule from underlying bleeding can occur.

Figure 44.2 Liver in toxemia of pregnancy. (A) Area of periportal necrosis (arrow) with intrasinusoidal fibrin deposition. (B) Hepatic arterioles showing vacuolosis and intrasinusoidal fibrin deposition. Masson's trichrome stain (reprinted from Burt et al., with permission from Elsevier).

Clinical and biochemical features:

There is wide variation in the clinical presentation, varying from no symptoms other than mild abdominal pain to severe life-threatening illness. The typical presenting symptoms are right upper quadrant or epigastric pain (65–90% of patients), malaise (90%), nausea and vomiting (36–50%), and headache (31%). Although liver enzyme elevation is common, jaundice is seen in only 5% of patients.^{57,58} Hypertension and proteinuria typical of preeclampsia are seen in the majority of patients. Hypertension can be absent in 15–20% of patients.^{58,59} Physical examination reveals right upper quadrant tenderness (80%) and weight gain with edema (60%).⁵⁸ On laboratory testing, there is evidence of hemolytic anemia with a drop in hemoglobin, abnormal peripheral smear showing schistocytes and burr cells, and elevated serum lactate dehydrogenase (LDH). Liver enzymes are elevated modestly, but may sometimes be above 1000 IU/L. Usually, AST levels are higher than ALT levels. Platelet count is decreased below 100 000 cells/mm³.¹⁶ Coagulation studies including prothrombin time and fibrinogen levels are usually normal (Table 44.4).

Maternal and fetal outcome

The mortality rate for women with HELLP syndrome is 1–3%, although rates as high as 25% have been reported.^{3,57} The most important causes of maternal morbidity and mortality are stroke, disseminated intravascular coagulation (DIC; 20% of patients), and spontaneous or postpartum hemorrhage. Other causes of morbidity and mortality include hypertension, eclampsia, pulmonary edema (6%), acute renal failure (7%), abruptio placentae (16%) and, rarely, hepatic rupture.⁵⁷ Perinatal mortality of infants is about 35% (range 10–60% in different series). Besides prematurity, infants born to mothers with HELLP are at increased risk of thrombocytopenia.^{60,61}

Table 44.4 Diagnostic laboratory and pathological features of HELLP syndrome.

Hemolytic anemia

Decrease in Hb
Peripheral smear: schistocytes and burr cells
Total bilirubin > 1.2 mg/dL, mainly unconjugated
Lactate dehydrogenase > 600 U/L

Elevated liver enzymes

Serum AST > 70 U/L or > twice normal
AST > ALT
AST and ALT up to 1000 IU/L

Thrombocytopenia

Platelet count < 100 000/mL

Liver biopsy

Periportal hemorrhage and periportal or focal parenchymal necrosis with hyaline deposits. Fibrin microthrombi and fibrinogen deposits in sinusoids

ALT, alanine aminotransferase; AST, aspartate aminotransferase; Hb, hemoglobin.

The risk of recurrent HELLP in subsequent pregnancies is 3–27% according to different studies.^{62,63}

Management

Management of HELLP and preeclampsia is supportive and may require intensive care unit (ICU) care. Delivery is the definitive treatment for HELLP, preeclampsia, and eclampsia.³ The best timing for delivery is determined by the balance between fetal gestational age and lung maturity and the severity of HELLP and preeclampsia. If preeclampsia is severe or develops after the 36th week of gestation and the fetal lungs are likely to be mature, the baby should be delivered. If preeclampsia is seen in the early third trimester and is mild, then expectant management can be followed with close monitoring.⁶⁴ Corticosteroids have been shown to improve maternal platelet count and liver enzymes, and to promote fetal lung maturity, along with a trend toward improving fetal outcome.^{61,65,66}

Hepatic infarction

Hepatic infarction is a severe but rare complication of preeclampsia, and may be considered an extension of HELLP syndrome.⁶⁷ Patients present with severe abdominal or chest pain and fever without an obvious source. White blood cell (WBC) count is elevated and aminotransferases may be very high, sometimes > 5000 U. In severe cases, patient may have acute liver failure due to massive liver damage, with encephalopathy, coagulopathy, and jaundice.⁶⁸ Abdominal computerized tomography (CT) scan or magnetic resonance imaging (MRI) are the imaging modalities of choice for seeing liver infarcts.⁶⁹ Management is mainly supportive. Fortunately, most patients recover completely, with no long-term sequelae.

Subcapsular hematoma and rupture of liver

These are rare but the most severe complications of preeclamptic liver involvement. When the rupture is contained within the capsule of the liver, the patient presents with severe right upper quadrant abdominal pain, but is hemodynamically stable.⁷⁰ Abdominal CT helps to make a definitive diagnosis. Management is supportive. Patients with hepatic rupture present with severe abdominal pain, shock, and hemoperitoneum. Mortality is very high. Most patients undergo emergency laparotomy with liver resection and packing.⁷¹ Arterial embolization to control hemorrhage has also been suggested.⁷² Liver transplant has been done in some cases.^{73,74} Early diagnosis and prompt delivery are essential.^{74,75}

Acute fatty liver of pregnancy (AFLP)

AFLP was first described by Sheehan in 1940.⁷⁶ It is a rare disease, occurring in the third trimester, and has a high mortality risk. It occurs in 1 in every 7000–14 000 deliveries and

has a worldwide prevalence.^{77,78} Women in their first pregnancy or women carrying more than one fetus are most often affected.^{79,80} It occurs in the third trimester, although in some cases it may be diagnosed postpartum, even though the disease starts before delivery in all cases. Rare cases have been described occurring between 22 and 26 weeks.^{81–83} Before 1980, both maternal and fetal mortality rates of 70–90% were reported,^{77,84–87} but recent data show mortality rates of less than 20%,^{88–90} mostly because of greater disease awareness, earlier diagnosis, and improved ICU care. Patients who survive have no long-term sequelae, and liver histology completely returns to normal.^{78,85} Recurrence in subsequent pregnancies is rare.³

Pathophysiology and pathology

The etiology of AFLP is not known. It belongs to a group of liver diseases characterized by microvesicular steatosis and mitochondrial dysfunction. Other disorders in this group include Reye syndrome, drug hepatotoxicity with sodium valproate and tetracycline, and Jamaican vomiting sickness.¹ A genetic factor has been suggested, but no familial cases have

been reported. Recently, a mutation (Glu474Gln mutation) in the long-chain 3-hydroxyacyl-coenzyme A dehydrogenase (LCHAD), a fatty acid β -oxidation enzyme, has been suggested.^{86,87,91} Women with LCHAD deficiency do not always have liver disease. Liver disease occurs most often when severe fetal deficiency of the enzyme activity results in accumulation of metabolites in the fetus and fetal–maternal transfer.⁹² Liver biopsy is the most definitive way to confirm diagnosis but, as it is invasive, the benefit and risk have to be assessed. It is definitely indicated after common illnesses such as viral hepatitis have been excluded, and there is doubt about the diagnosis of AFLP. The overall liver architecture is intact. There is microvesicular fatty infiltration of hepatocytes, which are swollen. Minute fatty droplets surround the central nucleus, giving a foamy appearance to the cytoplasm. The changes are most prominent in the pericentral zone and midzone (zones 2 and 3), and spare the periportal hepatocytes. Subtle inflammation and necrosis of hepatocytes may be present⁹³ (Fig. 44.3). Electron microscopy can confirm fat droplets in the cytoplasm and changes in mitochondrial morphology.⁸¹

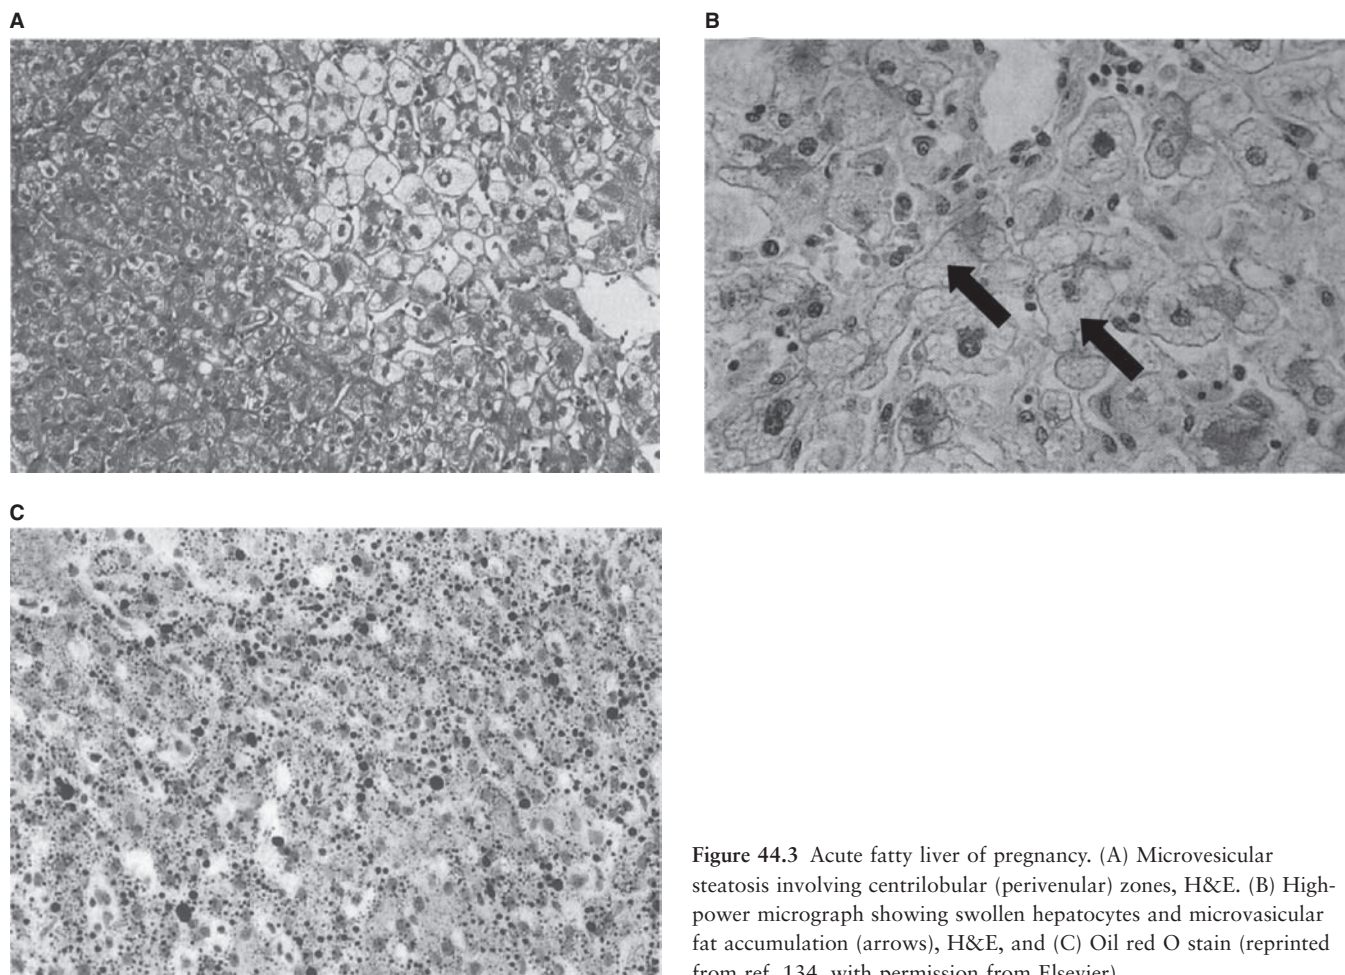

Figure 44.3 Acute fatty liver of pregnancy. (A) Microvesicular steatosis involving centrilobular (perivenular) zones, H&E. (B) High-power micrograph showing swollen hepatocytes and microvascular fat accumulation (arrows), H&E, and (C) Oil red O stain (reprinted from ref. 134, with permission from Elsevier).

Table 44.5 Diagnostic clinical, laboratory, and pathological features of acute fatty liver of pregnancy.*Clinical*

Acute-onset nausea, vomiting
 Right upper quadrant or epigastric pain
 Flu-like symptoms: malaise, anorexia, headache
 Jaundice
 Encephalopathy: somnolence, irritability, sleep alterations, asterixis, progressing to seizures and coma

Laboratory tests

Leukocytosis
 Coagulation disorders: increased prothrombin time, decreased fibrinogen and clotting factors, thrombocytopenia, DIC
 Elevated liver enzymes: AST, ALT (up to 1000 IU/L), bilirubin (up to 5–15 mg/dL), ALP
 Hypoglycemia
 Renal failure: elevated BUN and creatinine

Liver biopsy

Microvesicular steatosis with foamy appearance of cytoplasm. Mild inflammation and hepatocyte necrosis

ALP, alkaline phosphatase; ALT, alanine aminotransferase; AST, aspartate aminotransferase; BUN, blood urea nitrogen; DIC, disseminated intravascular coagulation.

Clinical and biochemical features (Table 44.5)

AFLP generally presents with acute onset of nausea and vomiting (70% of cases), right upper quadrant or epigastric abdominal pain (50–80%), or flu-like symptoms of malaise, headache, and anorexia.^{78,81,90} Jaundice usually occurs 1–2 weeks after the onset of these systemic symptoms. Pruritis is rare.^{81,89} About half the patients have preeclampsia. Physical examination is usually unremarkable except for jaundice. The liver edge may be palpable.

Leukocytosis is common. Coagulation disorders, including thrombocytopenia, decreased clotting factors, and DIC, are frequently seen. Liver enzymes are elevated with moderate increases in ALT and AST (usually < 1000 IU/L), increased ALP, and increased hyperbilirubinemia (usually between 5 and 15 mg/dL and mostly conjugated). Hypoglycemia and renal dysfunction can develop.^{16,81,89} Radiological imaging studies (ultrasound, CT, MRI) can show fatty liver, but do not have any specific pattern on which to base a radiological diagnosis.⁹⁴

Maternal and fetal outcome

Most patients improve 1–4 weeks postpartum, following spontaneous or induced delivery or Cesarean section. Rarely, the disease may worsen postpartum.^{84,86,95,96} If untreated, AFLP typically progresses to fulminant hepatic failure with encephalopathy, coagulopathy, DIC, cerebral edema, renal failure, pancreatitis, gastrointestinal or uterine bleeding, seizures, coma, and death. Infection is a common complication.^{81,89} As pointed out earlier, with better management,

maternal and fetal mortality has decreased from 85% before 1980 to less than 20% in 2000.

Management

Timely diagnosis, intensive monitoring and management, and early delivery are the key to a successful outcome. There is no specific therapy. Prompt delivery is recommended to improve maternal and fetal outcomes. Severely affected patients (encephalopathy, coagulopathy, severe jaundice, etc.) should be monitored in the ICU.^{84,86,95,97,98} Liver transplantation is a possible therapeutic option in postpartum patients who do not improve rapidly after delivery.^{88,99}

Liver diseases occurring concurrently with pregnancy or exacerbated by pregnancy**Viral hepatitis in pregnancy**

All the hepatotropic viruses can affect a pregnant woman. A detailed discussion of viral hepatitis is beyond the scope of this book. A brief discussion of hepatitis A, B, C, E, and herpes simplex viral hepatitis, pertinent to pregnancy, follows. For detailed discussion, the reader is referred to a liver textbook.^{1,100} Acute viral hepatitis is a systemic illness with fever, malaise, nausea, vomiting, anorexia, and fatigue at presentation, followed by jaundice. Aminotransferase concentrations are markedly elevated (> 500 IU/L and usually > 1000 IU/L).

Hepatitis A has the same course in pregnant women as in nonpregnant women.¹⁰¹ Although intrauterine transmission to the fetus has been reported, it is rare. Maternal or fetal outcomes are not affected by hepatitis A. In cases of possible exposure, pooled serum immunoglobulin administration 3–6 months before to 2 weeks after exposure can attenuate or prevent the clinical symptoms. Hepatitis vaccine can be safely and successfully administered to a pregnant woman at high risk of exposure, such as when traveling to an endemic area or a healthcare worker at high risk.¹⁰²

Hepatitis B is usually acquired by the parenteral route as in blood transfusion, intravenous drug use, or exposure to blood or sexual secretions from an infected patient. Its main relevance in pregnancy is the risk of vertical transmission to the child, who can then develop chronic hepatitis B. More than 95% of perinatal transmission occurs intrapartum. Risk of maternal–fetal transmission is 90% in hepatitis Be antigen (HBeAg)-positive mothers and 10–40% in HBeAg-negative mothers.^{103,104} Therefore, antepartum hepatitis B surface antigen (HBsAg) testing is essential in pregnant women. Seronegative mothers can safely receive hepatitis B virus (HBV) vaccine. Infants born to HBsAg-positive mothers should receive human hepatitis B immune globulin (HBIG) at delivery, followed by HBV vaccine.¹⁰² Active and passive immunization of the infant also decreases the risk of HBV transmitted by maternal milk in breastfed infants.¹⁰⁵ Lamivudine, a nucleoside analog therapy for hepatitis B, has also been

used safely in the last 4 weeks of pregnancy to decrease the risk of vertical transmission.¹⁰⁶ Infants who acquire infection at birth have a high risk of developing chronic hepatitis B, as their immune system is immature. The infected infants may remain completely asymptomatic and have normal liver enzymes, despite active replication of hepatitis B.

Hepatitis C virus (HCV) infection during pregnancy does not interfere with normal pregnancy unless the patient has cirrhosis. Pregnancy does not alter the natural course of infection either.¹⁶ The risk of vertical transmission of HCV from mother to fetus is up to 10% in women who are antibody positive but negative on polymerase chain reaction (PCR) analysis, and up to 33% in women who are positive for HCV RNA on PCR.¹⁰⁷ Risk of transmission is higher if the patient has a HCV viral load of more than 1 million copies/mL or is co-infected with human immunodeficiency virus (HIV).^{108,109} Breastfeeding does not increase transmission risk.¹¹⁰ Unlike hepatitis B, as yet, there is no vaccine and no known method for interrupting the transmission of the hepatitis C virus.

Hepatitis E virus (HEV) is notorious for its severe course and bad outcome in pregnant women. It occurs mainly in developing countries and is rare in the United States. HEV is a feco-orally transmitted infection, which is usually a mild and self-limited illness in nonpregnant patients, but commonly causes fulminant hepatic failure during pregnancy (up to 58%).¹¹¹ Mortality is 1.5% in the first trimester, 8.5% in the second, and 21% during the third trimester.¹¹² HEV infection in the third trimester is associated with higher fetal mortality.¹¹² Treatment is supportive.

Herpes simplex hepatitis

Similar to hepatitis E, herpes simplex follows a more severe course in pregnant women and can cause fulminant hepatitis in these women.^{113,114} Patients usually present with a nonspecific viral syndrome including fever and upper respiratory symptoms. On laboratory tests, they are found to have markedly elevated transaminases and only mild elevation of bilirubin. Accompanying genital vesicular eruptions are common, and culture of these lesions can establish the diagnosis. In other cases, liver biopsy may be needed for diagnosis. It demonstrates classical intranuclear inclusions (Fig. 44.4). Immunocytochemistry may be needed to confirm the diagnosis. Patients can be treated successfully with acyclovir, and early delivery is not necessary.

Hepatic vein thrombosis (Budd–Chiari syndrome)

Budd–Chiari syndrome is caused by hepatic vein thrombosis involving a large hepatic vein. It occurs most commonly in the setting of a hypercoagulable state. Both pregnancy and oral contraceptive therapy are associated with a hypercoagulable state,¹¹⁵ and are associated with an increased incidence of Budd–Chiari syndrome. Reports from India suggest that it is more common in pregnant women, usually occurring after delivery.^{1,116,117} In the Western literature, many reports have

Figure 44.4 Herpes simplex hepatitis. High-power view showing zones of necrotic hepatocytes with intranuclear inclusions typical of Herpes simplex infection (arrows) (courtesy of Laura W. Lamps, Department of Pathology, University of Arkansas for Medical Sciences, Little Rock, AR, USA).

linked Budd–Chiari syndrome with underlying procoagulant disorders such as anticardiolipin antibody,^{118,119} factor V Leiden mutation,¹²⁰ thrombotic thrombocytopenic purpura,¹²¹ or myeloproliferative disorders such as polycythemia rubra vera.¹²² Patients usually present soon after delivery with abdominal pain, rapid accumulation of ascites, and hepatomegaly. Liver function deteriorates rapidly. Prognosis is poor. Liver transplantation may be needed to save the patient,^{120,123} but many patients can be managed successfully with supportive care, prompt delivery, and anticoagulation.¹

Cholelithiasis

Gallbladder motility decreases during pregnancy, and the lithogenicity of bile increases, resulting in an increased incidence of gallstones.¹²⁴ About 2% of women develop gallstones during pregnancy, with multigravida at higher risk.¹²⁵ Most of the women remain asymptomatic. Sometimes, the patient presents with one of the complications of cholelithiasis such as biliary colic, acute cholecystitis, or acute gallstone pancreatitis. Most of these patients respond very well to conservative management but, if they remain symptomatic, then cholecystectomy may be necessary^{126,127} and can be performed either laparoscopically or by the open route. Common bile duct stones can be managed with endoscopic retrograde cholangiopancreatography (ERCP) and sphincterotomy.¹²⁸

Cirrhosis and portal hypertension

Chronic liver disease is associated with a decrease in fertility, with anovulation, amenorrhea, and premature menopause being more common in these patients. If a woman has cirrhosis and does get pregnant, she can usually sustain the preg-

nancy without major worsening of liver function.¹²⁹ However, progressive liver failure, ascites, and hepatic coma have been reported in a few patients who have cirrhosis and become pregnant.^{129,130} There is an increased incidence of stillbirths and premature delivery.^{129,131,132} On the other hand, in patients with noncirrhotic portal hypertension, fertility is not

decreased.¹³³ However, worsening of portal hypertension with increased risk of variceal bleeding occurs, due to a marked increase in blood volume and azygous flow during pregnancy.^{131–133}

For a summary of liver diseases in pregnancy, see Table 44.6.

Table 44.6 Salient features of liver diseases in pregnancy by trimester.

Trimester of onset	Liver condition	Main symptoms	Laboratory tests	Histology	Management
First	Hyperemesis gravidarum	Nausea, vomiting	↑ AST, ALT, ketosis	Central vacuolization	Intravenous hydration, bowel rest, antiemetics. TPN in severe cases
Second	Cholestasis of pregnancy	Pruritis, jaundice ±	↑ AST, ALT, total bile acids. Mild ↓ bilirubin	Cholestasis. No inflammation	Antihistaminics, phenobarbital, ursodeoxycholic acid. Early delivery ±
Third	HELLP syndrome	Abdominal pain, malaise, nausea, vomiting	Low platelets. ↑ AST, ALT, LDH. Hemolysis	Periportal hemorrhage, focal parenchymal necrosis	Supportive. Early delivery when possible
	Hepatic infarction	Severe abdominal or chest pain. Acute liver failure	↑ WBC, ↑↑ AST, ALT, ↑ bilirubin, coagulopathy. CT/MRI diagnostic	–	Supportive. May need ICU
	Hepatic rupture	Severe abdominal pain. Shock	Abdominal CT	–	Laparotomy. Prompt delivery
	Acute fatty liver of pregnancy	Nausea, vomiting, abdominal pain	↑ Prothrombin time, DIC. ↑ AST, ALT, bilirubin, ALP	Microvesicular fat in hepatocytes	Supportive care. Prompt delivery
Any	Viral hepatitis	Nausea, vomiting, jaundice	↑ AST, ALT, bilirubin. Hepatitis serology	Inflammation and hepatocyte necrosis	Supportive

ALP, alkaline phosphatase; ALT, alanine aminotransferase; AST, aspartate aminotransferase; CT, computerized tomography; DIC, disseminated intravascular coagulation; HELLP, hemolysis, elevated liver function, and low platelets; ICU, intensive care unit; LDH, lactate dehydrogenase; MRI, magnetic resonance imaging; TPN, total parenteral nutrition; WBC, white blood cells.

Key points

- Most liver blood tests are not altered in pregnancy. Therefore, elevation of bilirubin, AST, ALT, or TBA concentration indicates liver disease and should be investigated.
- Elevation of alkaline phosphatase in pregnancy is usually of placental origin and should not be considered abnormal unless associated with other liver test abnormalities or clinical features of liver disease.
- Some liver diseases are seen only in pregnancy, e.g., intrahepatic cholestasis of pregnancy (ICP), hyperemesis gravidarum, HELLP syndrome, and acute fatty liver of pregnancy (AFLP). Gestational age can help significantly in differential diagnosis. For example: first trimester – hyperemesis gravidarum; second or third trimester – ICP; third trimester – HELLP syndrome or AFLP.
- Common liver diseases such as viral hepatitis, drug hepatotoxicity, etc. can occur during pregnancy and should always be considered in the differential diagnosis.
- Pregnancy in patients with advanced chronic liver disease is rare. Some patients with conditions such as autoimmune hepatitis, Wilson's disease, etc. may regain fertility after successful treatment and should continue their treatment during pregnancy. In patients with mild chronic liver disease such as hepatitis B or C, pregnancy is common.

- 6 Acute viral hepatitis E and Herpes simplex hepatitis can take a more severe course in pregnant patients, with higher mortality rates than in nonpregnant patients.
- 7 The incidence of some diseases such as cholelithiasis and Budd–Chiari syndrome is increased during pregnancy because of alterations in biliary physiology and the hypercoagulable state associated with pregnancy respectively.
- 8 Patients with hyperemesis gravidarum present with severe nausea and vomiting between the 4th and 10th weeks of gestation, far worse and more prolonged than common morning sickness, which can lead to dehydration and ketosis. AST and ALT can be mildly or significantly elevated (up to 500–1000 IU/L), but bilirubin elevation is mild. All symptoms and laboratory abnormalities usually resolve with conservative supportive management by the second trimester.
- 9 ICP is a benign cholestatic disorder that occurs during the second or third trimester, and resolves after delivery. It is characterized by pruritis, elevated serum TBA concentration, mild to moderate AST and ALT elevation and, in 10–15% of cases, mild elevation of bilirubin. It may have an adverse effect on the fetus, and early delivery after 36 weeks of gestation may have to be considered.
- 10 Preeclampsia is a multisystem disorder that occurs in 3–5% of pregnancies in the second or third trimester, and is characterized by hypertension, edema, and proteinuria. It can be associated with many liver disorders including HELLP syndrome, hepatic infarction, subcapsular hematoma, and hepatic rupture. The commonest of these is HELLP syndrome.
- 11 HELLP syndrome is characterized by hemolysis (drop in Hb, schistocytes and burr cells on peripheral smear, high LDH), elevated liver enzymes (elevated AST and ALT), and low platelets ($< 100\,000$ cells/mm³). Clinical symptoms can vary in severity and include abdominal pain, malaise, nausea, and vomiting. It can be associated with increased maternal and fetal mortality. Management is supportive. Delivery is the definitive treatment for HELLP and preeclampsia.
- 12 Hepatic infarction should be considered in a patient with preeclampsia presenting with severe abdominal pain and fever without an obvious source. WBC count is elevated, and liver enzymes can be very high (ALT, AST > 1000 IU/L). CT and MRI can establish the diagnosis. Management is supportive and most patients recover.
- 13 Hepatic rupture is a rare complication of preeclampsia, but should be considered in a patient presenting with severe right upper quadrant abdominal pain, shock, and hemoperitoneum. Emergency CT to confirm diagnosis, followed by urgent laparotomy with liver resection and packing should be done. Mortality is very high. Arterial embolization has been tried in some cases.
- 14 AFLP is a rare disorder, but has a very high mortality rate (20%, despite high-quality care). It occurs in the third trimester, and rarely postpartum. The histological hallmark is microvesicular steatosis with fatty droplets in hepatocyte cytoplasm, giving a foamy appearance.
- 15 Clinical symptoms of AFLP are nonspecific, including nausea, vomiting, abdominal pain, and malaise. AST and ALT are elevated (usually < 1000 IU/L), and bilirubin is elevated to 5–15 mg/dL. The patient can progress rapidly to fulminant liver failure with encephalopathy, coagulopathy, DIC, and cerebral edema. Other complications include hypoglycemia, renal failure, pancreatitis, gastrointestinal and uterine bleeding, and seizures. The patient can die of bleeding complications, hepatic coma, infection, or multisystem failure. Timely diagnosis, intensive monitoring, ICU care, and prompt delivery are key to a successful outcome. Most patients improve 1–4 weeks postpartum, with complete recovery of liver function and no long-term sequelae.
- 16 Hepatitis B is acquired by the parenteral route or via sexual secretions. It causes acute hepatitis with elevated liver enzymes, jaundice, and hyperbilirubinemia, severe malaise, anorexia and, infrequently, fulminant liver failure. If acquired in adulthood, about 90–95% of patients clear the infection spontaneously, 2–5% develop chronic active hepatitis B, and 2–5% become carriers. Persistence of HBsAg 6 months after exposure indicates chronicity. Anyone with HBsAg in the blood can be infectious, and the risk of transmission is much higher if there is active replication, indicated by the presence of HBeAg in the blood. If the infection is acquired in infancy, the risk of chronicity is about 90%, and the patient may have no symptoms and normal liver enzymes. This is thought to be due to the immature immune system of infants.
- 17 If the mother has hepatitis B, there is a high risk of vertical maternal–fetal transmission (90% in HBeAg-positive mothers and 10–40% in HBeAg-negative, HBsAg-positive mothers). Ninety-five percent of perinatal transmission occurs in the intrapartum period, and less than 5% is transplacental. Infants born to HBsAg-positive mothers should receive human hepatitis B immune globulin (HBIG) at delivery, followed by HBV vaccine, to decrease the risk of the child developing hepatitis B. All pregnant women should be tested for hepatitis B.
- 18 Hepatitis C is parenterally acquired (blood products, intravenous drug use, multiple sexual partners, etc.) and causes chronic hepatitis in 85% of those infected. Unlike hepatitis B, the spontaneous clearance rate for hepatitis C is only 15%. It progresses to cirrhosis in 20% of cases over a 20-year period. It does not interfere with normal pregnancy. The risk of transmission to the fetus is 10% in HCV antibody-positive but PCR-negative patients, and 33% in PCR-positive patients. As yet, there is no vaccine for

hepatitis C and no known method of interrupting transmission to the fetus.

- 19 Hepatitis E occurs mainly in developing countries and is rare in the United States. It is transmitted feco-orally and usually causes a self-limiting hepatitis but, in the setting of pregnancy, it takes a more severe course and causes fulminant hepatic failure, with high mortality.
- 20 Pregnancy causes a decrease in gallbladder motility and increased lithogenicity of bile, resulting in increased incidence of gallstones and a risk of complications of cholelithiasis, such as acute cholecystitis, gallstone colic, gallstone pancreatitis, etc.
- 21 Budd–Chiari syndrome is caused by hepatic vein thrombosis, and its incidence is increased in pregnancy owing to a physiological hypercoagulable state. Patients present with abdominal pain, rapid accumulation of ascites, and hepatomegaly. Prognosis is poor, with progression to liver failure. Management includes supportive care, prompt delivery, and anticoagulation.

Pregnancy complicated by renal disorders

Michelle W. Krause and Sudhir V. Shah

Recent epidemiological studies indicate that chronic kidney disease (CKD) is common and affects 20 million Americans.¹ This, coupled with the evidence that the incidence of pregnancy in women with CKD is rising, makes it important to understand how pregnancy affects the kidney as well as how kidney disease affects both the mother and the fetus. In addition, women are susceptible to acute renal failure (ARF) with causes unique to pregnancy. Despite the advancement of medical technology in both obstetrics and neonatology, kidney disease in pregnancy is associated with significant maternal and fetal morbidity and mortality. In this chapter, we focus on the impact of the physiological changes of pregnancy in normal and in diseased kidneys as well as the importance of renal function on maternal and fetal outcomes.

Renal physiology and pregnancy

The marked decrease in the peripheral vascular resistance during pregnancy results in a reduction in blood pressure and significant changes in systemic and renal hemodynamics, including net retention of sodium and water, an increase in cardiac output, and an increase in the glomerular filtration rate (GFR) (Table 45.1).^{2,3} These changes occur early in conception and are generally maintained throughout pregnancy. The increase in the GFR results in lower values for blood urea nitrogen (BUN) and creatinine. Thus, serum markers of renal function that are considered normal for non-pregnant women may signify underlying renal impairment in pregnancy.

Acute renal failure in pregnancy

Advancements in sterile technique and obstetric delivery have led to a dramatic decrease in ARF during pregnancy, now accounting for only 15% of ARF compared with 50% previously.^{4,5} Traditionally, ARF is categorized into three distinct entities: prerenal ARF, intrinsic renal ARF, and postrenal ARF,

based on the type of injury causing changes in renal function. Pregnant women are at risk for the same causes of ARF as in the general population; however, etiologies specific for pregnancy-related ARF are depicted in Figure 45.1. Prerenal ARF refers to conditions in which the kidney itself is normal, but in which there is a decrease in renal perfusion. In certain pregnancy states, such as hyperemesis gravidarum, severe vomiting with volume depletion may be a contributing cause of prerenal ARF. Additionally, septic abortions in the first trimester with alterations in renal perfusion have been associated with prerenal ARF. Causes of intrinsic renal ARF in pregnancy are generally more serious than the prerenal or postrenal disorders. Intrinsic renal ARF is characterized by tissue damage with loss of renal tubular function. The most common etiologies of intrinsic renal ARF are the hemolysis, elevated liver function, and low platelets (HELLP) syndrome, postpartum hemorrhage, and the preeclampsia/eclampsia syndrome. Uncommon conditions of intrinsic renal ARF in pregnancy are glomerulonephritis, abruptio placentae, cortical necrosis, and acute fatty liver of pregnancy.^{5,6} Lastly, postrenal causes of ARF result from a blockage of urine flow beyond the kidney itself. In pregnancy, the gravid uterus may exert pressure on the ureters, resulting in mild to moderate hydronephrosis, but not typically renal failure.⁷ In conditions of polyhydramnios in the third trimester, the enlarged uterus may compress the ureters causing obstructive ARF.⁸ Nephrolithiasis may also result in postrenal ARF in pregnancy. Pregnancy alone does not cause an increased risk for the development of renal calculi compared with the general population, but they may be difficult to diagnose as the presentation of back pain and urinary symptoms may be identical to urinary infections or premature labor.

The evaluation of ARF in pregnancy consists of a detailed history and physical examination as well as evaluation of the urine, laboratory studies, and radiographic imaging of the kidneys and the collecting system to distinguish between prerenal ARF and intrinsic or postrenal ARF (Table 45.2). The majority of causes of ARF are prerenal, and the diagnosis is supported by a bland urine sediment, a low fractional excre-

tion of sodium (FeNa), and a BUN to creatinine ratio $> 20:1$. Distinguishing between intrinsic ARF disorders such as preeclampsia or glomerulonephritis may be challenging in the pregnant patient, as both may present with hypertension, proteinuria, edema, and renal failure. The clinical history may support glomerulonephritis with symptoms and signs of systemic diseases such as arthritis and skin rashes in autoimmune disorders that are not common in preeclampsia. Additionally, there may be laboratory abnormalities such as a positive antinuclear antibody (ANA) test and hypocomplementemia in lupus nephritis or coexisting hepatitis C infection in membranoproliferative glomerulonephritis and cryoglobulinemia,

whereas in preeclampsia, there are no associated serological abnormalities. Moreover, the urine sediment may have hematuria, pyuria, or casts in nonpreeclamptic intrinsic renal disorders. In rare instances, a renal biopsy may be performed to determine the underlying renal pathology if the clinical and laboratory evaluation is unable to distinguish between preeclampsia and intrinsic renal disease. On renal histology, there is swelling of glomerular cells in preeclampsia termed “endotheliosis” (Fig. 45.2), and there is no appreciable glomerular proliferation or immune complex deposition that is seen in some types of glomerulonephritis. Lastly, the diagnosis of postrenal ARF largely relies on radiographic imaging with ultrasonography of the kidneys and collecting system to assess for hydronephrosis, renal calculi, masses, or increased postvoid urinary residuals in the bladder.

The treatment of ARF is based on correcting the underlying etiology. An intravenous fluid challenge to correct volume depletion and impaired renal perfusion is warranted in a hospitalized setting with careful monitoring for signs of volume overload to distinguish between prerenal ARF and intrinsic renal ARF. The treatment of preeclampsia with renal dysfunction is delivery of the fetus, whereas some of the glomerular disorders can be managed with immunosuppressive therapy to prolong pregnancy for fetal viability. Failure of proteinuria and renal function to return to normal within 12 weeks postpartum suggests underlying glomerular pathology, and a referral to a nephrologist for evaluation and treatment is indicated. For postrenal ARF, polyhydramnios can be corrected by fluid aspiration with amniocentesis or, more

Table 45.1 Systemic and renal physiologic changes in pregnancy.

	Normal	Pregnancy
Blood pressure	120/80 mmHg	110/60 mmHg
Cardiac output	4–5 L/min	6–7 L/min
Plasma volume	2.5–3.0 L	3.75–4.5 L
Renal plasma flow	650 mL/min	975–1000 mL/min
Glomerular filtration rate	100 mL/min/1.73 m ²	140 mL/min/1.73 m ²
Blood urea nitrogen	8–10 mg/dL	5–8 mg/dL
Creatinine	1.0–1.2 mg/dL	0.4–0.8 mg/dL
Sodium	135–145 mEq/L	130–135 mEq/L
Hematocrit	36–46%	30–36%
Serum bicarbonate	22–30 mEq/L	18–22 mEq/L

Table 45.2 Evaluation of acute renal failure in pregnancy.

	Prerenal ARF	Intrinsic renal ARF	Postrenal ARF
BUN : Cr ratio	20 : 1	10–15 : 1	10–15 : 1
Urinalysis			
Urine sodium	< 20 mEq/L	> 40 mEq/L	> 40 mEq/L
Hematuria	–	±	±
Proteinuria	–	±	±
Volume	Low	Low or normal	Low
Osmolality	High	Low	Low/normal
FeNa	< 1%	> 1%	> 1%
Volume status	Low	Normal/high	Normal/high
Renal ultrasonography	Normal	Normal	Abnormal

Cr, creatinine.

Figure 45.1 Etiologies of acute renal failure in pregnancy. TTP, thrombotic thrombocytopenic purpura.

Figure 45.2 Renal pathological changes in preeclampsia. Light micrograph of a renal glomerulus in preeclampsia. “Endotheliosis” refers to swelling of the mesangial and endothelial cells with loss of the capillary lumen and absence of cellular proliferation.

Table 45.3 Maternal and fetal outcomes in women with normal pregnancy compared with those with pre-existing renal disease.

	Normal	Increased creatinine	Proteinuria < 500 mg/day	Proteinuria > 500 mg/day
Maternal outcomes				
Preeclampsia/eclampsia	5–8%	25%	42%	29–64%
Progressive renal failure	< 1%	15–30%	–	–
Endstage renal disease (1 year)	< 1%	6–45%	–	–
Fetal outcomes				
Intrauterine growth restriction	5%	33%	4%	23–45%
Prematurity	10%	33%	62%	45–91%

Data derived from refs 10–19 and 21.

rarely, placement of percutaneous nephrostomy tubes.⁸ The treatment of nephrolithiasis is largely supportive as > 70% of stones will pass spontaneously. For those stones that do not pass, ureteral stents, percutaneous nephrostomy tubes, and ureteroscopy with stone removal are all safe methods that may be utilized during pregnancy.⁹

Renal replacement therapy in the form of dialysis is required in < 1% of all cases of ARF. Dialysis is indicated in pregnancy for hyperkalemia and metabolic acidosis that is not responding to medical therapy, volume overload, uremia, or the inability to maintain adequate nutrition.

Pregnancy and pre-existing renal disease

In contrast to ARF, which is characterized as a sudden change in renal function, chronic kidney disease (CKD) is defined as kidney damage for ≥ 3 months with structural or functional

abnormalities of the kidney. Renal disease in pregnancy can be classified into those with CKD diagnosed prior to conception, CKD unknown prior to conception but discovered during the pregnancy and, thirdly, renal disease that develops during pregnancy. Regardless of the etiology of CKD, with the exception of lupus nephritis, the degree of renal impairment at the time of conception largely defines the risk and outcome for both the mother and the fetus (Table 45.3). In general, women with CKD have a fourfold increased risk of adverse maternal outcomes including preeclampsia, eclampsia, and abruptio placentae compared with women without renal disease. Similarly, there is a twofold increased risk of adverse fetal events including intrauterine growth restriction, low birthweight, prematurity, and neonatal death in women with renal disease compared with women without renal disease.¹⁰

Vesicoureteral reflux (VUR) is one of the most common causes of CKD in women during pregnancy. VUR results from urine flowing back from the bladder into the ureters causing chronic infections and scarring of the kidney with loss of renal

function. The diagnosis may be missed prior to conception, as recurrent urinary tract infections may have been underappreciated, and no laboratory or urinary studies may have been performed before the first prenatal visit. As with other disorders of CKD, VUR has adverse maternal and fetal effects, especially when there is pre-existing chronic hypertension. It is estimated that 25% of women will have preeclampsia, 33% premature births, and 20% will have deterioration of renal function during pregnancy. Interestingly, there appears to be a genetic predisposition to VUR as almost half of infants born to mothers with urinary reflux will have abnormal micturating cystourethrography consistent with VUR.¹¹ Urinary tract infection is a common sequela in pregnant women with VUR, so surveillance and treatment for asymptomatic bacteriuria are recommended.¹²

Another common cause of CKD in pregnancy is diabetes mellitus. Individuals with diabetes mellitus may have normal proteinuria (< 30mg/24h), microalbuminuria (30–300mg/24 h), or increased macroalbuminuria (> 300mg/24h) in addition to abnormal renal function defined by a GFR < 90 mL/min/1.73 m². Even with normal renal function and a lack of proteinuria, women with diabetes mellitus suffer from a higher risk of premature births and preeclampsia than the general population. Superimposed microalbuminuria and proteinuria have an additive risk. Some 62% of women with microalbuminuria experience preterm births, and 42% are diagnosed with preeclampsia, whereas the risks for preterm births and preeclampsia are 91% and 64%, respectively, in women with overt proteinuria.¹³

Nephrotic syndrome and glomerular disorders such as membranous glomerulonephritis, focal segmental glomerulosclerosis (FSGS), and immunoglobulin (Ig) A nephropathy are typically detected prior to conception, but may be diagnosed or develop *de novo* during pregnancy. As these disorders are relatively uncommon in the pregnant population, there is a paucity of data as to how best to manage these patients. Women with chronic proteinuria have successful pregnancies with > 90% resulting in live births; there is a worse outcome for those with > 500mg of proteinuria in 24h at the time of conception. These women have a high incidence of hypertension, and more than half will have increases in proteinuria throughout the duration of the pregnancy. There is also an associated 45% risk of premature births, a 25% risk of intrauterine growth restriction, and a 30% risk of preeclampsia. Interestingly, even with normal renal function at the start of pregnancy, a small proportion of women with chronic proteinuria will progress to endstage renal disease (ESRD) within 1 year of delivery.¹⁴

Women with CKD are at risk for progressive loss of renal function throughout gestation. In those women with a creatinine of < 1.5 mg/dL at the time of conception, there is an associated 15% decline in renal function during pregnancy, and an estimated 6% will progress to ESRD within 1 year. For those women with a creatinine of 1.5–2.9 mg/dL at the time of conception, there is an associated 30% decline in renal

function during pregnancy, and an estimated 20% will progress to ESRD in 1 year. For those women with a creatinine of > 3.0mg/dL at the time of conception, 45% will progress to ESRD in 1 year.^{15,16} It is thought that the increased stress imposed on the kidney with pregnancy, uncontrolled hypertension, and urinary tract infections contribute to loss of renal function during pregnancy.

Systemic lupus erythematosus (SLE) deserves special mention, as pregnancy may be associated with worsening disease activity and a high rate of fetal loss. Disease flares are estimated to occur in about one-third of pregnancies in women with underlying SLE. Approximately 50% of these flares occur in the postpartum period, and one quarter will occur in the second trimester. Lupus flares have been linked to stopping immunosuppressive therapy, a history of active disease as defined by more than three flares prior to conception, as well as active disease at the time of conception.¹⁷ Adverse fetal outcomes such as death, prematurity, and intrauterine growth restriction are higher in women with lupus and concomitant antiphospholipid antibody syndrome, hypocomplementemia, and hypertension.¹⁸ The antiphospholipid antibody syndrome is of particular concern in pregnancy because of risks of recurrent miscarriage, intrauterine growth restriction, preeclampsia, preterm labor, and fetal death. Renal involvement of the antiphospholipid antibody syndrome has been described historically with thrombotic vascular events and cortical necrosis resulting in permanent renal failure. Recently, there have been cases of the antiphospholipid antibody syndrome associated with glomerular disorders such as membranous glomerulopathy, minimal change disease, and even pauci-immune glomerulonephritis.¹⁹

The treatment of CKD in pregnant women is primarily directed at control of blood pressure with antihypertensive agents that are considered safe in pregnancy (Table 45.4) and monitoring and treatment of asymptomatic bacteriuria and urinary tract infections angiotensin-converting enzyme (ACE).

Table 45.4 Antihypertensive agents in pregnancy.

Central-acting adrenergic agents
Methyldopa 0.25–3.0 g/day
Clonidine 0.1–1.2 mg/day
Beta-adrenergic blocking agents
Atenolol 25–100 mg/day
Metoprolol 25–400 mg/day
Labetalol 200–2400 mg/day
Propranolol 40–240 mg/day
Calcium-channel blocking agents
Nifedipine 30–120 mg/day
Diltiazem 60–360 mg/day
Verapamil 80–480 mg/day
Vasodilators
Hydralazine 50–300 mg/day

Women taking angiotensin-converting enzyme (ACE) inhibitors in the first trimester of pregnancy have a nearly threefold risk of congenital fetal malformations than women not taking these agents and thus women should be counseled to discontinue these agents if trying to conceive or stop as soon as a pregnancy is recognized.¹⁸ For women with diabetes, the goal hemoglobin A1c (HbA1c) should be less than 7%, and close involvement with a dietitian is necessary to avoid hyperglycemia that may contribute to macrosomia and polyhydramnios. For those women with underlying glomerular disorders, immunosuppressive agents such as cyclosporine and prednisone are safe in pregnancy and are useful in keeping renal disease in remission and treating disease flares activated by pregnancy. For those with the antiphospholipid antibody syndrome and renal failure, plasma exchange has been associated with improvement in renal function.²¹ Lastly, delivery is recommended for women if there is rapid deterioration of renal function or if there is concern for superimposed preeclampsia or eclampsia.

Pregnancy in endstage renal disease

Pregnancy is a relatively uncommon phenomenon in women with ESRD on renal replacement therapy. In the mid-1990s, the conception rate for women of childbearing age on dialysis was 2.2%.²² Other reports similarly estimate the conception rate at 0.3–1.5% each year.²³ There is no difference in maternal or fetal outcomes based on dialysis modality. Rather, because of the enlarging gravid uterus, most pregnant women with ESRD on peritoneal dialysis therapy will temporarily transfer to hemodialysis therapy for comfort in the second and third trimesters.²⁴ In recent years, with aggressive dialysis therapy and management of hypertension, approximately 50% of pregnancies in women with ESRD result in live births.²⁵ Most pregnancies will be complicated by intrauterine growth restriction, preeclampsia, and prematurity. In one study of pregnancies in women on renal replacement therapy, the average time to delivery was 30.5 weeks.²⁶

The care of a pregnant dialysis patient is complex and begins with a dialysis prescription aimed at reducing the BUN to less than 45–50 mg/dL.²⁷ This translates into > 20 hours/week on hemodialysis, often over five or six treatments. The metabolic disturbances are also challenging for the pregnant dialysis patient. The target hemoglobin and hematocrit is 11–12 g/dL and 33–36%, respectively, with the use of erythropoietin. There needs to be judicious monitoring of calcium, phosphorous, and potassium as levels may decrease with the increase in weekly dialysis. In addition, the target bicarbonate level should also be maintained at 18–20 mEq/L to avoid ill-effects from metabolic acidosis. Hypertensive therapy should be continued using medications with a favorable safety profile in pregnancy (Table 45.4). Lastly, the dry weight of the patient needs to be watched carefully and on average increase by 0.5 kg/week after the first trimester to take into account the weight gain required for fetal growth.^{24,28}

Pregnancies in renal transplant recipients are more successful than those in women with ESRD on renal replacement therapy. Generally, ovarian function and resumption of menstruation will occur within the first year after transplantation. For those women who wish to conceive, > 90% of pregnancies will result in live births after the first trimester.^{29,30} Despite this, women with a renal transplant should still be considered at high risk with an increased incidence of prematurity in 45–60% of cases, intrauterine growth restriction in 20–30%, and 30% superimposed preeclampsia.^{29,31} Although most nephrologists agree that pregnancy itself does not permanently alter renal allograft function or predispose to acute rejection of the renal transplant, one small study reported an increase in the serum creatinine of 0.5–0.7 mg/dL within 1 year of pregnancy in transplant patients compared with nonpregnant control subjects.³² Ideally, it is recommended that women should wait until a year after their renal transplant to conceive when they are on a stable maintenance immunosuppressive regimen. Several immunosuppressive transplant medications have a documented safety profile in pregnancy, and these include prednisone, cyclosporine, and azathioprine.^{33,34} Other immunosuppressive transplant medications such as mycophenolate mofetil and sirolimus are contraindicated in pregnancy because of an association with fetal malformations and should be stopped several weeks prior to conception.³⁵ There are limited data on the use of tacrolimus in pregnant transplant recipients, so most nephrologists favor a regimen utilizing prednisone, cyclosporine, and/or azathioprine. There is no contraindication for vaginal deliveries in renal transplant recipients. If Cesarean delivery is required, the obstetrician should have access to the operative history of the patient to avoid complications arising from the change in anatomy associated with the transplanted kidney and ureter in the pelvis.

Conclusions

Women with renal disease who plan to become pregnant need to make their wishes clear and have an open dialogue with their physicians as many medications such as ACE inhibitors, angiotensin receptor blocking medications, and certain immunosuppressive medications need to be discontinued prior to conception. Additionally, women with renal disease need to be informed of the increased risk for themselves as well as for the fetus of adverse outcomes. In the ESRD population, aggressive dialysis needs to be instituted early in pregnancy, as the risk of miscarriage is high in the first trimester. Special attention and interactions with nurses and dietitians may also be helpful in monitoring adequate nutritional intake, fetal development, blood pressure monitoring, and weight gain. Although this unique group of women with renal disease and pregnancy is challenging to manage from a medical perspective, successful outcomes can be achieved with careful monitoring of both the fetus and the mother.

Key points

- 1 Chronic kidney disease is common, and there is a high likelihood that obstetricians will manage women with chronic kidney disease during pregnancy.
- 2 Changes in peripheral vascular resistance and reductions in blood pressure during pregnancy result in significant alterations in renal and systemic hemodynamics.
- 3 Serum markers of renal function are lower in pregnancy and may confound the ability to diagnose pre-existing renal disease.
- 4 There are unique causes of acute renal failure that occur in pregnancy.
- 5 Certain types of renal disease can present with the same signs and symptoms as preeclampsia/eclampsia and may be difficult to distinguish clinically.
- 6 Dialysis is safe in pregnancy for acute renal failure when the kidney is unable to maintain fluid and metabolic homeostasis.
- 7 The degree of renal impairment in chronic kidney disease largely determines the outcome for both the mother and the fetus.
- 8 Women with pre-existing renal disease have an increased risk of preeclampsia/eclampsia, progressive renal failure, and abruptio placentae.
- 9 Infants born to women with pre-existing renal failure have an increased risk of intrauterine growth restriction, prematurity, and fetal death.
- 10 Women with renal disease and significant proteinuria have worse outcomes than those with microalbuminuria or without proteinuria.
- 11 Pregnancy in women with systemic lupus erythematosus can be associated with increased disease activity and fetal loss.
- 12 The antiphospholipid antibody syndrome is associated with thrombotic events and renal failure.
- 13 Blood pressure control with antihypertensive medications that are safe in pregnancy is required for the majority of women with chronic kidney disease.
- 14 Immunosuppressive medications can be maintained in pregnancy to keep underlying renal glomerular disorders in remission.
- 15 Pregnancy is uncommon in women with endstage renal disease.
- 16 An increase in the amount of dialysis and careful monitoring of blood pressure and volume status are needed for pregnant women on dialysis.
- 17 Pregnancy is safe in women with kidney transplants without an increased risk of rejection or loss of the graft.
- 18 Immunosuppression may need to be adjusted during pregnancy in women with kidney transplants.
- 19 Collaboration with nephrologists and obstetricians is necessary to manage pregnancy in women with kidney disease.
- 20 Referral for dietary counseling and serial monitoring of fetal development is warranted in women with kidney disease because of the unique requirements in this population.

Neurological disorders in pregnancy

R. Lee Archer, Stacy A. Rudnicki, and Bashir S. Shihabuddin

Pregnancy predisposes to some serious neurological problems, such as eclampsia, cerebrovascular disorders, and benign intracranial hypertension, and to a number of disorders that are relatively benign, including carpal tunnel syndrome, meralgia paresthetica, and Bell's palsy. In addition, women of childbearing age can have other neurological problems that are not uncommon and often require special attention during pregnancy. These include epilepsy, migraine headaches, and autoimmune diseases such as multiple sclerosis, myasthenia gravis, and Guillain-Barré syndrome.

Headaches

Headaches are among the most common of human ills and can be a sign of many different neurological problems.¹⁻⁴ A flow diagram to guide management is presented in Fig. 46.1. If headaches during pregnancy have been present for years, are unchanged in character, and the neurological examination is normal, then further attention is rarely warranted,¹ except perhaps to modify medications to protect the fetus.³

Most tension headaches are manageable without daily medication but, in severe cases, preventative treatment with low doses of tricyclic antidepressants (e.g., imipramine 10–50 mg at bedtime) may be justified.¹ Migraine headaches are often improved during pregnancy, but still constitute a large share of the headaches seen. They are most often unilateral with a throbbing quality and may be accompanied by nausea, photophobia, and phonophobia.⁷ When necessary, migraine preventative medications may be used, such as beta-blockers³ (e.g., atenolol 50–100 mg daily) or tricyclic antidepressants but, in general, migraineurs are managed best with limited doses (10–20 per month) of analgesics. Combinations of caffeine, butalbital, and acetaminophen (with codeine when necessary) are particularly effective and safe. Patients who use analgesics on more than 3 days/week are predisposed to analgesic rebound headaches,⁷ and the frequent use of opioid analgesics runs the risk of withdrawal problems in the newborn.

The new onset of headaches or a significant change in the

character or frequency of headaches during pregnancy should always cause concern. Preeclampsia is frequently accompanied by headache,¹⁶ and all gravidas with new-onset headache deserve careful observation for this disorder. Benign intracranial hypertension is more likely to occur during pregnancy and usually presents with a constant holocephalic headache and papilledema.¹ Blindness may result without treatment. Treatments include serial lumbar punctures (the mainstay), cautious control of weight gain, occasionally acetazolamide (a class C drug), and, very rarely, surgical procedures such as lumboperitoneal shunting or optic nerve sheath fenestration.¹ Regular ophthalmological follow-up with visual field determination is imperative to confirm stability, as the visual loss tends to occur peripherally and may not be noticed by the patient until it is advanced.

The presence of new problems with focal neurological signs, such as hemianesthesia or hemiparesis, with a headache should prompt further investigation as a rule. Confidence that the symptoms represent a migraine aura would be a notable exception. Magnetic resonance imaging (MRI) has never been known to cause fetal harm and is considered the imaging procedure of choice in neurological evaluations during pregnancy.^{3,5,6} When a cerebrovascular insult is in the differential, consideration should be given to doing diffusion-weighted imaging, as well as magnetic resonance angiography and venography at the same sitting, as these will usually clarify the pathology and guide management.

The very sudden onset of a severe or even moderately severe headache should raise concern for the possibility of a subarachnoid hemorrhage (SAH). A computerized tomographic (CT) scan will discern the presence of blood more often than MRI, but even a normal CT scan will miss a SAH 5% of the time; a lumbar puncture is mandatory when this diagnosis is suspected (preferably after urgent imaging).¹ The risk of SAH increases around the time of delivery.⁹ Causes include berry aneurysms and arteriovenous malformations. Immediate workup and treatment are mandatory with neurosurgical consultation to help determine the timing of arteriography, as the risk of a fatal subsequent bleed is high, and arteriography may cause a stroke by inducing vasospasm.⁸

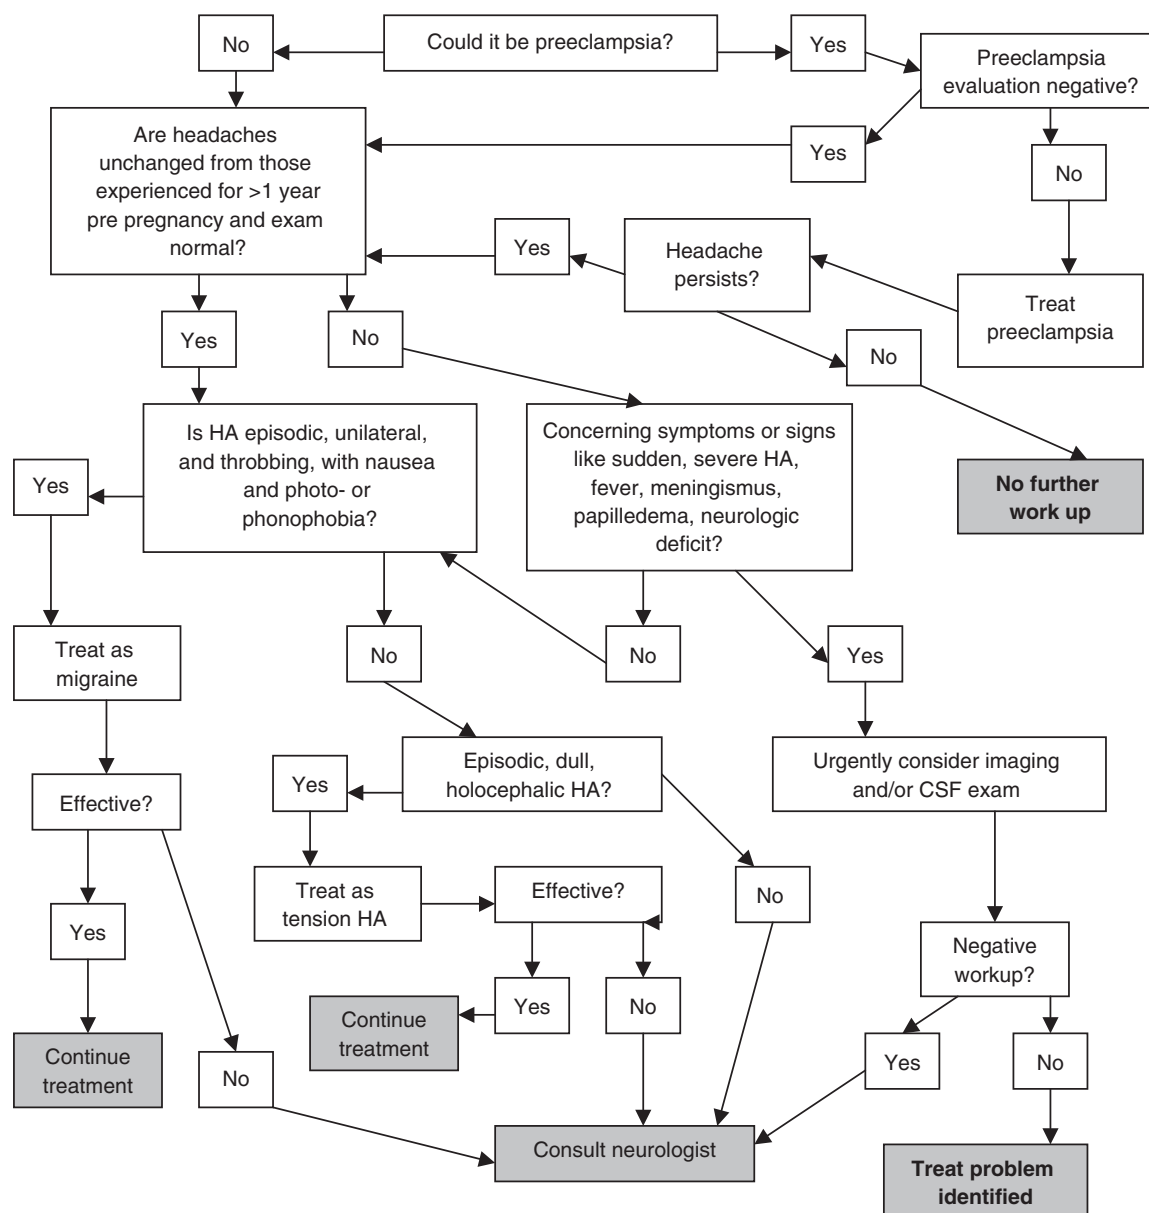

Figure 46.1 Flow diagram for headaches in pregnancy. CSF, cerebrospinal fluid; HA, headache.

Strokes

Strokes occur in 5–15 out of 100 000 pregnancies.⁸ Urgent evaluation is indicated for the pregnant patient with stroke, just as in the general population.¹⁰ Intracerebral hemorrhages generally present with profound hemiparesis and headache, sometimes progressing quickly to coma.⁸ Treatment is primarily supportive, unless the size of the hemorrhage or bleeding into the ven-

tricular system necessitates surgical intervention to relieve pressure on other parts of the brain.⁸ Nonhemorrhagic strokes are either thrombotic or embolic. Thrombotic strokes may be arterial or venous. Venous sinus thrombosis is more common in the puerperium, and the new onset of headaches with any neurological symptoms or signs (such as headache with papilledema) during this period should cause concern for this possibility. Other cerebrovascular disorders associated with or more common during pregnancy include air or amniotic fluid

embolism, embolic strokes caused by right-to-left shunts through a patent foramen ovale, hypercoagulable states (such as antiphospholipid syndrome), and metastatic choriocarcinoma.

Appropriate testing and treatment is evolving rapidly in this field, with clot retrieval devices recently becoming available and intra-arterial thrombolysis an option at many institutions, so management should involve neurological consultation. Anticoagulation with warfarin or heparin has been proven to be of benefit in atrial fibrillation and, in addition, many authorities recommend it with venous sinus thrombosis, hypercoagulable states, acute arterial dissection, and in the case of many other types of cardiac embolic strokes. Heparin (particularly low-molecular-weight heparin) is considered by most the anticoagulant of choice in pregnancy, because it does not cross the placenta and because warfarin is teratogenic in the first trimester.⁸

Multiple sclerosis

A diagnosis of multiple sclerosis does not contraindicate pregnancy, but the postpartum period is associated with an increased incidence of exacerbations,^{11,14} and any neurological disability present (such as paraplegia) can certainly complicate management. None of the available treatments is approved for use during pregnancy, but anecdotal reports suggest that glatiramer acetate may be safe.^{12,13} There are no known anesthetic contraindications.^{12,15}

Focal neuropathies during pregnancy

Up to 62% of pregnant women have symptoms of carpal tunnel syndrome (which includes numbness and tingling in all fingers except the little one).¹⁷ Wrist splints at night are beneficial, and steroid injections may be used when symptoms are severe. Spontaneous resolution following delivery is common.^{18–20} Bell's palsy is three times more likely to occur in pregnancy. Onset is typically during the third trimester or puerperium.²¹ It is associated with an increased risk of preeclampsia and hypertension.²³ Prognosis for recovery from an incomplete Bell's palsy is excellent but, for those with complete facial paralysis, pregnancy is associated with a worse prognosis.²⁴ Meralgia paresthetica (a neuropathy of the lateral femoral cutaneous nerve) causes numbness or burning pain in the lateral thigh. Symptoms generally resolve within a few months after delivery as weight is lost.²⁵ For patients who have significant pain, topical capsaicin may be beneficial.²⁶ Approximately 1% of postpartum women have leg numbness or weakness confirmed by neurological examination. The femoral and lateral femoral cutaneous nerves are commonly involved. The common fibular, sciatic, and obturator nerves, lumbosacral plexus, and lumbosacral roots are occasionally involved.²⁷ Injuries may be more common in small and/or nulliparous women, in those with a prolonged second stage of

labor, when the fetus is large, or with midforceps rotation.^{27–29} Recovery may take anywhere from a week to 18 months, with some patients having persistent problems.²⁷

Peripheral neuropathy

Thiamine deficiency may occur with hyperemesis gravidarum, resulting in either a peripheral neuropathy or Wernicke's encephalopathy. Intravenous thiamine may reverse the encephalopathy, but the neuropathy, which may be severe, improves slowly and recovery may be incomplete.^{30,31} Guillain-Barré syndrome may occur during pregnancy, but pregnant women do not appear to be at increased risk. Plasmapheresis for Guillain-Barré syndrome appears to be safe.³²

Neuromuscular junction and muscle disorders

Women with myasthenia gravis (MG) may occasionally have their first symptoms during pregnancy. Exacerbations occur during pregnancy in 15–41% of myasthenics, and in an additional 16–30% during the puerperium. The latter is not influenced by mode of delivery.^{35–37}

Because magnesium impairs neuromuscular transmission, it should be used very cautiously in treating preeclampsia and eclampsia in myasthenics.³⁸ Similarly, neuromuscular blocking agents should be avoided.³⁹ MG may cause fatigue during the second phase of labor, but the first stage is not affected as MG does not affect smooth muscle.

As weight gain increases during pregnancy, there may be increased ambulation difficulties in patients with muscular dystrophies and congenital myopathies.⁴⁰ Both increased incidences of preterm labor and a higher rate of Cesarean sections occur in women with myotonic dystrophy (the most common muscular dystrophy of adulthood).⁴¹ Rarely, women with myotonic dystrophy may develop a cardiomyopathy with congestive heart failure during pregnancy.^{42,43} Inflammatory myopathies (dermatomyositis and polymyositis) have rarely been reported during pregnancy, but there is a sense that increased fetal loss and premature labor are common, particularly when the diseases are active.^{45,46}

Treatment of any of the autoimmune neurologic diseases should be done in conjunction with a neurologist, as the risks of immunosuppression in a pregnant patient must be carefully weighed against the risks of untreated disease. Prednisone is considered safe during pregnancy when needed for autoimmune diseases. Azathioprine, a class D drug, may be the safest of the other immune suppressants.

Epilepsy

Although women with epilepsy have an increased risk of obstetric complications, worsening seizure control, and

adverse neonatal outcomes, around 95% have an uncomplicated pregnancy course and give birth to normal offspring. These women, however, do have a higher rate of spontaneous and elective abortion than the general population and are more likely to undergo labor induction and Cesarean section procedures.^{47–49}

Factors leading to increased seizure frequency during pregnancy include declining antiepileptic drug (AED) concentrations, noncompliance, stress, and sleep deprivation.^{51,54,55} Serum AED concentrations start declining in the first trimester, reach a nadir near term, then return to preconception levels within 4–12 weeks postpartum if the dose is not altered.⁵⁶ Anticonvulsant levels should be checked every 1–3 months, and the goal should be to maintain prepregnancy levels. Anticonvulsant changes should be considered prior to pregnancy to optimize safety to the fetus and, in general, should not be done during pregnancy. Infants born to women with epilepsy are at increased risk of congenital malformations, cognitive impairment, and developmental delays. Contributing factors to these adverse outcomes are intrauterine AED exposure, folic acid deficiency, seizure control, seizure type, genetics, maternal health, smoking, and lower socioeconomic class.⁵⁷ The incidence of major congenital malformations in infants born to women with epilepsy is 4–8%, which represents a twofold increase over the incidence in the general population.⁵⁸ Phenytoin, carbamazepine, phenobarbital, primidone,

and valproic acid (VPA) are associated with an increased risk of major malformations, especially for women on polytherapy and women exposed to high serum AED concentrations during the first trimester. This has been demonstrated most consistently with the use of VPA.^{59,60} Therefore polytherapy and VPA should be avoided whenever possible. Adequate information regarding the safety of other, newer AEDs during pregnancy is not available yet, although lamotrigine looks promising. Kaplan⁶¹ and Tomson and Battino⁶² have provided excellent reviews of AEDs and teratogenicity.

Folic acid deficiency is associated with the development of congenital malformations, mainly neural tube defects (NTDs). Folic acid levels decline during pregnancy, and the antifolate effect of some AEDs predisposes women with epilepsy to folic acid deficiency.⁶⁵ Folic acid supplementation of 0.4–4 mg daily, beginning 1 month before conception and continuing through pregnancy, reduces the incidence of NTDs by 50–70%. The higher dose of 4 mg daily is used in women who have a prior history of offspring with NTDs.⁶⁶ Infants born to women taking enzyme-inducing AEDs are also at greater risk of hemorrhagic complications because of the reduced activity of vitamin K-dependent clotting factors.⁶⁷ For this reason, women taking enzyme-inducing AEDs should be treated with oral vitamin K 10–20 mg daily during the last month of pregnancy. Infants should receive vitamin K 1 mg intramuscularly at birth and, if needed, fresh frozen plasma.

Key points

- 1 Azathioprine is possibly safe (FDA pregnancy class D).
- 2 Magnesium should be used judiciously in myasthenics, and neuromuscular blocking agents should be avoided as they can exacerbate MG symptoms.
- 3 Multiple sclerosis does not contraindicate pregnancy, but exacerbations are more frequent in the postpartum period.
- 4 Anticonvulsant level checks and necessary medication changes should be made at 1- to 3-month intervals during pregnancy in all women with epilepsy.
- 5 Oral vitamin K 20 mg supplementation should be given daily for women on enzyme-inducing anticonvulsants (e.g., phenytoin and carbamazepine) during the last month of pregnancy; newborns should be given vitamin K 1 mg intramuscularly and fresh frozen plasma if necessary.
- 6 Medication compliance, adequate rest, and stress reduction should be encouraged in all women with epilepsy.
- 7 The incidence of major congenital malformations is 4–8% for all women with epilepsy.
- 8 Strokes are more common during pregnancy.
- 9 Strokes should be treated urgently, as with any nonpregnant patient.
- 10 Unusual causes of stroke that are more common in pregnancy include: right-to-left shunt through a patent septal defect; air embolism; amniotic fluid embolism; venous sinus thromboses in the puerperium; choriocarcinoma; hypercoagulable states (e.g., antiphospholipid antibody syndrome)
- 11 MRI is the imaging method of choice (except when hemorrhage is suspected).

- 12 CT scans have a 5% chance of missing a SAH.
- 13 Sudden, severe headaches may herald the onset of a SAH (which occur more commonly during the third trimester).
- 14 A change in headache pattern during pregnancy should prompt concern as to the cause because many serious disorders, including preeclampsia, benign intracranial hypertension, cerebral venous sinus thrombosis, and subarachnoid hemorrhage, can present with a headache.
- 15 Concerning symptoms and signs that may accompany headache include: sudden onset of a severe headache, papilledema, fever, and focal neurological signs (such as hemiparesis and hemianesthesia).
- 16 Headaches that have been present for over a year before pregnancy and that have not changed in frequency or type, in someone with a normal neurological examination, do not require additional workup as a rule.
- 17 Benign intracranial hypertension presents with a constant holocephalic headache and papilledema; it may cause blindness if untreated.
- 18 Cerebral venous sinus thrombosis is more common in the puerperium.
- 19 Heparin is generally considered to be the anticoagulant of choice during pregnancy as warfarin is teratogenic in the first trimester and heparin does not cross the placenta.
- 20 Carpal tunnel syndrome symptoms occur in 62% of pregnant women, and wrist splints at night generally help. Spontaneous resolution after delivery is common.
- 21 Meralgia paresthetica causes a burning pain on the side of the thigh and typically improves spontaneously after pregnancy. It may improve with topical capsaicin.
- 22 Approximately 1% of women have postpartum leg weakness or numbness attributed to a focal neuropathy, the most common of which are the femoral and lateral femoral cutaneous nerves.
- 23 A thiamine deficiency neuropathy may be caused by hyperemesis gravidarum.
- 24 Treatment of any autoimmune neurological disease in pregnancy should involve a neurologist to assist in weighing the pros and cons of immune suppression.
- 25 Guillain-Barré syndrome can be safely treated with plasmapheresis during pregnancy.
- 26 Women with epilepsy on anticonvulsants should be on 0.4–4 mg of folic acid daily, the higher dose being used for women with previous infants affected by neural tube defects.
- 27 Polytherapy and valproic acid should be avoided in epileptic women during pregnancy, if feasible, as both increase the chances of birth defects.
- 28 Consideration for changing AEDs to benefit the fetus should be done before and generally not during the pregnancy course.
- 29 Prednisone is generally safe to use when necessary for autoimmune diseases during pregnancy.
- 30 The AED serum levels during pregnancy should be maintained at prepregnancy levels.

Thromboembolic disorders of pregnancy

Michael J. Paidas, Christian M. Pettker, and Charles J. Lockwood

Venous thromboembolism (VTE) poses significant maternal and fetal risks in pregnancy. It is estimated that VTE complicates 1 in 1000 pregnancies, but the precise frequency of thromboembolism is probably underestimated, given the reluctance to perform diagnostic tests in pregnancy secondary to fears of radiation exposure to the fetus. Pregnancy has been associated with a sixfold higher incidence of VTE compared with age-matched nonpregnant women, and pulmonary embolism remains a leading cause of maternal mortality.^{1,2} In the USA, death from pulmonary embolism occurs in 2 in 100 000 deliveries and represents 11% of maternal deaths.³ Postpartum deep venous thrombosis (DVT) is more common than antepartum DVT, with reported rates of 0.61 in 1000 and 0.13 in 1000 pregnancies respectively.⁴ Timely diagnosis and treatment of DVT are essential as a quarter of patients with DVT develop pulmonary embolism, with a 15% mortality rate,⁵ and two-thirds of these deaths occur within 30 min of the pulmonary embolism.⁶ Institution of anticoagulation once the diagnosis of DVT has been made significantly reduces both the risk of pulmonary embolism (5%) and the mortality rate (< 1%).⁷

Pregnancy and the hemostatic system: clot formation, thrombin regulation, and fibrinolysis

Platelet plug formation: adhesion, activation, and aggregation

Following vascular disruption, platelets adhere to subendothelial collagen, mediated by von Willebrand factor “bridges” anchored at one end to subendothelial collagen and at the other to the platelet GPIb/IX/V receptor.⁸ Platelets also adhere to other subendothelial extracellular matrix proteins. Adherent platelets are then activated, and increases in phospholipase C activity promote the synthesis of thromboxane and the phosphorylation of key platelet proteins that promote granule release, including α -granules containing von Willebrand factor, thrombospondin, platelet factor 4, fibrinogen,

beta-thromboglobulin, and platelet-derived growth factor, as well as dense granules containing adenosine diphosphate and serotonin. Adenosine diphosphate induces a conformational change in the GPIIb/IIIa receptor on the platelet membrane, resulting in platelet aggregation via high-affinity fibrinogen formation and other proteins.⁹

Alpha-granule release also promotes exteriorization of platelet factor 4, a chemokine with potent heparin-neutralizing activity, as well as other procoagulant factors, leading to thrombin generation. Thrombin binds to type 1 and type 4 protease-activated receptors (PAR-1, -4) on the platelet membrane, serving as stimuli for platelet activation. Other factors, such as epinephrine and platelet activation factor, contribute to platelet activation. Platelet activation is limited by blood flow and agents elaborated by an intact endothelium, including prostacyclin, nitric oxide, and adenosine diphosphatase (ADPase) (Fig. 47.1).

Fibrin plug formation: the coagulation cascade

Tissue factor (TF), a cell membrane-bound glycoprotein, is ultimately responsible for the initiation of adequate hemostasis, as platelet activation alone cannot generate an effective hemostatic plug.¹⁰ Intrauterine survival is not possible in the absence of TF, unlike the absence of either platelets or fibrinogen.¹¹ Tissue factor is expressed on the cell membranes of perivascular smooth muscle cells, fibroblasts, and tissue parenchymal cells; TF also circulates in the blood in very low concentrations as part of cell-derived microparticles or in a truncated soluble form.^{11,12} These TF-bearing microparticles contribute to clotting by binding to platelets at sites of vascular injury through the interaction of P-selectin glycoprotein ligand-1 on microparticles with surface P-selectin on activated platelets.¹³ In the presence of ionized calcium, perivascular cell- or platelet-bound TF comes into contact with plasma factor VII on negatively charged (anionic) cell membrane phospholipids (Fig. 47.1).

Factor VII has low intrinsic clotting activity, autoactivates after binding to TF, and/or can be activated by thrombin, as

Figure 47.1 Activation of the clotting cascade leading to formation of a fibrin plug. Tissue factor initiates the extrinsic clotting cascade. Factor Xa complexes with its cofactor, factor Va, to convert prothrombin to thrombin. Thrombin cleaves fibrinogen to produce fibrin. A second pathway of thrombin generation is also available. See text for details.

well as factors IXa, Xa, or XIIIa.^{10,14} The complex of TF/factor VII(a) can either directly activate factor X (formerly known as the extrinsic pathway) or generate factor Xa by initially activating factor IX. Factor IX complexes with its cofactor, factor VIIIa, to activate factor X (formerly known as the intrinsic pathway). Once activated, factor Xa complexes with its cofactor, factor Va, to convert factor II (prothrombin) to factor IIa (thrombin). The cofactors, factors V and VIII, can each be activated by either thrombin or factor Xa (Fig. 47.1).

A second pathway of thrombin generation is available, which results from activation of factor XI by thrombin-activated factor XIIa, typically on the surface of activated platelets. Factor XII can be activated by the action of kallikrein and its cofactor, high-molecular-weight kininogen, and by plasmin. Factor IX activation can also occur via factor XIa.

Fibrinogen is cleaved by thrombin to produce fibrin. A stable hemostatic plug is created as fibrin monomers self-polymerize and are cross-linked by thrombin-activated factor XIIIa (Fig. 47.1). Thus, thrombin is the ultimate arbiter of clotting as it not only activates platelets and generates fibrin but, along

with factor Xa, activates the crucial clotting cofactors, factors V and VIII, and mediates the aforementioned activation of factors VII, XII, and XIII (Fig. 47.1).

The anticoagulant system

The anticoagulant system provides balance in the hemostatic system to prevent excessive or inappropriate thrombin generation. The anticoagulant system consists of effector and inhibitor molecules (Fig. 47.2). The first inhibitory molecule is tissue factor pathway inhibitor (TFPI), which forms a complex with TF , factor VIIa, and factor Xa (the prothrombinase complex).¹⁵ This block can be bypassed by the generation of factor XIa. Additionally, during the time period (10–15 s) before TFPI-mediated prothrombinase inhibition, a sufficient amount of factors Va, VIIIa, IXa, Xa, and thrombin can be generated to sustain clotting.

The protein C system plays a central role in regulating thrombin. Once thrombin is formed, it binds to thrombomodulin on the endothelial cell surface. A resultant conformational change permits thrombin to activate protein C when

Figure 47.2 The anticoagulant and fibrinolytic systems. Key components of the anticoagulant system, which prevents excessive or inappropriate thrombin generation, consists of tissue factor pathway inhibitor, the protein C system, and antithrombin. The fibrinolytic system is critical for the prevention of thrombosis. Plasmin degrades fibrin, leading to the formation of fibrin degradation products. Plasmin is created by the proteolysis of plasminogen under proteolysis by urokinase-type plasminogen activator (uPA) or tissue-type plasminogen activator (tPA). Inhibitors of fibrinolysis include plasminogen activator inhibitor-1 (PAI-1), plasminogen activator inhibitor-2 (PAI-2), and thrombin-activatable fibrinolysis inhibitor (TAFI). See text for details.

bound to damaged endothelium or to the endothelial protein C receptor (EPCR). Activated protein C (APC) then binds to its cofactor, protein S (PS), to inactivate factors Va and VIIIa.¹⁶ Factor Va acts as a second cofactor in APC-mediated factor VIIIa inactivation.

Protein Z (PZ) is a 62-kDa, vitamin K-dependent plasma protein that serves as a cofactor for a PZ-dependent protease inhibitor (ZPI) of factor Xa.^{17,18} When ZPI is complexed to PZ, its inhibitory activity is enhanced 1000-fold.¹⁹ The ZPI molecule also inhibits factor XIa in a PZ-independent process. PZ is critical for regulation of factor Xa activity along with TFPI.^{19–21} PZ increases rapidly during the first months of life, followed by slow increases in childhood, with adult levels reached during puberty.^{22,23} PZ deficiency influences the prothrombotic phenotype in factor V Leiden patients,²⁴ and low plasma PZ levels have been reported in patients with antiphospholipid antibodies.^{25,26} There is also some evidence suggesting a role for PZ deficiency in a bleeding tendency.²⁷

The most active inhibitor of both factor Xa and thrombin is antithrombin. Antithrombin binds either thrombin or factor

Xa and vitronectin. A conformational change facilitates binding to heparin, which augments antithrombin's rate of thrombin inactivation 1000-fold.²⁸ A similar inhibitory mechanism is initiated by heparin cofactor II and α -2 macroglobulin.

Fibrinolysis

Fibrinolysis is also crucial to the prevention of thrombosis (Fig. 47.2). Plasmin degrades fibrin, leading to fibrin degradation products. Plasmin is created by the proteolysis of plasminogen via tissue-type plasminogen activator (tPA) embedded in fibrin. Endothelial cells produce a second plasminogen activator, urokinase-type plasminogen activator (uPA). There is also a series of inhibitors of fibrinolysis (Fig. 47.2). Plasmin is directly inhibited by α 2-plasmin inhibitor, which can be bound to the fibrin clot to prevent premature fibrinolysis. Platelets and endothelial cells release type 1 plasminogen activator inhibitor (PAI-1) in response to thrombin binding to its PARs. The decidua is also a very rich source of

PAI-1, while the placenta is the chief source of PAI-2.²⁹ Thrombin-activatable fibrinolysis inhibitor (TAFI), activated by the thrombin–thrombomodulin complex, is a fourth fibrinolysis inhibitor.³⁰ The fibrinolytic system exerts anticoagulant effects. For example, fibrin degradation products inhibit thrombin action, a major source of hemorrhage in disseminated intravascular coagulation (DIC). In addition, PAI-1 bound to vitronectin and heparin directly inhibits thrombin and factor Xa activity.³¹

Risk factors for VTE

Clinical risk factors for VTE in pregnancy

Vascular stasis, hypercoagulability, and vascular trauma (Virchow's triad) remain the three prime antecedents to thrombosis. Clinical risk factors for VTE include pregnancy, obesity, surgery, infection, trauma, cancer, nephrotic syndrome, hyperviscosity syndromes, immobilization, congestive heart failure, estrogen-containing contraceptives and postmenopausal hormone therapy, prior VTE, and the presence of acquired and inherited thrombophilias. These conditions increase clotting potential through a variety of mechanisms including: increases in TF, clotting factors, and PAI-1; decreases in PS levels; increasing stasis; vascular injury. In women, pregnancy in thrombophilic patients and pregnancy in patients with a prior history of thromboembolism confer the highest risks of thromboembolism (Table 47.1).³² Specific pregnancy-associated clinical risk factors can be stratified and are detailed in Table 47.2.^{33–35}

Hemostatic changes in pregnancy

Substantial changes must occur in local decidual and systemic coagulation, anticoagulant, and fibrinolytic systems to meet

the hemostatic challenges of pregnancy, including avoidance of hemorrhage at implantation, placental, and the third stage of labor. Progesterone augments perivascular decidual cell TF and PAI-1 expression.^{29,36} Transgenic TF knockout mice rescued by the expression of low levels of human TF have been found to have a 14% incidence of fatal postpartum hemorrhage, underscoring the importance of decidual TF.³⁷ Obstetric conditions associated with impaired decidualization (e.g., ectopic and Cesarean scar pregnancy, placenta previa and accreta) are associated with potential lethal hemorrhage in humans.

Pregnancy is associated with significant elevations of a number of clotting factors. Fibrinogen concentration is doubled, and 20–1000% increases in factors VII, VIII, IX, X, XII, and von Willebrand factor have been observed, with maximum levels reached at term.³⁸ Prothrombin and factor V levels remain unchanged, while levels of factors XIII and XI decline modestly. The net effect of these changes is to increase thrombin-generating potential. Coagulation activation markers in normal pregnancy are elevated, as evidenced by

Table 47.1 Risk of venous thromboembolic disease in women: a qualitative systematic review.³²

Risk factor	Risk per 1000 women–years
Pregnancy	1.23

†First trimester, 0–14 weeks; second trimester, 14–27 weeks; third trimester, \geq 27 weeks.

increased thrombin activity, increased soluble fibrin levels (9.2–13.4 nmol/L), increased thrombin–antithrombin (TAT) complexes (3.1–7.1 $\mu g/L$), and increased levels of fibrin D-dimer (91–198 $\mu g/L$).³⁹ Fifty percent of women had elevated TAT levels (11/22), and 36% of women had elevated levels of D-dimers (9/25) in the first trimester.

Significant changes in the natural anticoagulant and fibrinolytic systems occur in normal pregnancy. Protein S levels decrease significantly in normal pregnancy. Mean PS free antigen levels have been reported to be 38.9 \pm 10.3% and 31.2 \pm 7.4% in the second and third trimesters respectively.⁴⁰ In a follow-up study, free PS antigen levels in the first trimester were found to be 39% (SD 10.5), compared with the reference range in nonpregnancy of 88% (SD 19), $P < 0.05$.⁴¹ The PS carrier molecule, complement 4B-binding protein, is increased in pregnancy, and is one explanation for the diminished PS levels in pregnancy. Studies on PZ levels in pregnancy are conflicting, with one group of investigators demonstrating lower levels as pregnancy progresses in a cross-sectional study,⁴⁰ while another group of investigators have demonstrated that PZ levels are increased by 20% ($P = 0.006$) from first trimester to delivery, followed by a 30% decrease ($P < 0.0001$) 6–12 weeks after delivery.⁴² Levels of PAI-1 increase three- to fourfold during pregnancy; plasma PAI-2 values are low prior to pregnancy and reach concentrations of 160 $\mu g/L$ at term. Table 47.3 summarizes the relevant pregnancy-associated changes in the hemostatic system.⁴³ The prothrombotic hemostatic changes are exacerbated by pregnancy-associated venous stasis in the lower extremities because of compression of the inferior vena cava and pelvic veins by the enlarging uterus, as well as a hormone-mediated increase in deep vein capacitance secondary to increased cir-

Inherited thrombophilias

Inherited thrombophilias are a heterogeneous group of disorders associated with varying degrees of increased thrombotic risk. Until recently, these disorders consisted of deficiencies in PS, PC, and antithrombin. An association between a mutation in the factor V gene and increased thrombotic risk was first reported in 1994, termed the factor V Leiden mutation.⁴⁴ This relatively common mutation is present in 5% of American Caucasians, 1% of African-Americans, and 5–9% of Europeans, but is rare in Asian and African populations.^{45,46} The factor V mutation is associated with resistance to APC and is

inherited primarily in an autosomal-dominant fashion.^{46,47} Heterozygosity is found in 20–40% of nonpregnant patients with thromboembolic disease, whereas homozygosity confers a > 100-fold risk of thromboembolic disease.⁴⁶ More recently, the prothrombin gene mutation (prothrombin G20210A) has been found to increase circulating prothrombin levels and, hence, the risk of both thrombosis and pregnancy complications.^{46,48} In women with a history of VTE during pregnancy, prothrombin G20210A was found in 17% of patients compared with 1% of age-matched controls, and the factor V Leiden mutation was found in nearly 45% of patients.⁴⁹ However, a prospective study involving over 5000 patients designed to determine whether patients carrying the factor V Leiden mutation were at increased risk for venous thromboembolism compared with patients who were factor V Leiden negative did not find that factor V Leiden conferred an increased risk of thromboembolism.⁵⁰ Homozygosity for prothrombin G20210A confers an equivalent risk of VTE to that of factor V Leiden homozygosity.⁴⁶

Other inherited thrombophilic mutations, including methylene tetrahydrofolate reductase (MTHFR) C667T and A1298C (often associated with hyperhomocysteinemia) and PAI gene mutations 4G/4G, 4G/5G, and 5G/5G, have been weakly associated, if at all, with thrombotic risk and pregnancy complications.^{51–53} Table 47.5 summarizes the thromboembolic risks associated with the significant known thrombophilic mutations.^{54–61} Heterozygous factor V Leiden is associated with a 0.2% risk of thromboembolism associated with pregnancy, while heterozygous prothrombin gene mutation is associated with a 0.5% risk. Compound heterozygous factor V Leiden and prothrombin gene mutations are associated with a 4.6% risk of thromboembolism.

Acquired thrombophilia

The well-characterized antiphospholipid antibody syndrome (APS) is defined by the combination of VTE, obstetric complications, and antiphospholipid antibodies (APA).⁶² By definition APA-related thrombosis can occur in any tissue or organ except superficial veins, while accepted associated obstetric complications include at least one fetal death at or beyond the 10th week of gestation, or at least one premature birth at or before the 34th week, or at least three consecutive spontaneous abortions before the 10th week. All other causes of pregnancy morbidity must be excluded. APAs must be present on two or more occasions at least 6 weeks apart, and are immunoglobulins directed against proteins bound to negatively charged surfaces, usually anionic phospholipids.⁶³ Thus, APAs can be detected by screening for antibodies that:

- directly bind these protein epitopes (e.g., anti-β2-glycoprotein-1, prothrombin, annexin V, APC, PS, PZ, ZPI, high- and low-molecular-weight kininogens, tPA, factors VIIa and XII, the complement cascade constituents, C4 and CH, and oxidized low-density lipoprotein antibodies); or
- are bound to proteins present in an anionic phospholipid matrix (e.g., anticardiolipin and phosphatidylserine antibodies); or
- exert downstream effects on prothrombin activation in a phospholipid milieu (i.e., lupus anticoagulants).⁶⁴

Venous thrombotic events associated with APA include DVT with or without acute pulmonary embolus, while the most common arterial events include cerebral vascular accidents and transient ischemic attacks. At least half of patients with APA have systemic lupus erythematosus. Anticardiolipin

antibodies were associated with an odds ratio (OR) of 2.17 (1.51–3.11; 14 studies) for any thrombosis, 2.50 (1.51–4.14) for DVT and APE, and 3.91 (1.14–13.38) for recurrent VTE.⁶⁵ Patients with systemic lupus erythematosus and lupus anticoagulants were at a sixfold greater risk of VTE compared with systemic lupus erythematosus patients without lupus anticoagulants, while systemic lupus erythematosus patients with anticardiolipin antibodies had a twofold greater risk of VTE compared with systemic lupus erythematosus patients without these antibodies. The lifetime prevalence of arterial or venous thrombosis in affected patients with antiphospholipid antibodies is about 30%, with an event rate of 1% per year.⁶⁴ These antibodies are present in up to 20% of individuals with VTE.⁶⁶ A review of 25 prospective, cohort and case–control studies involving more than 7000 patients observed an OR range for arterial and venous thromboses in patients with lupus anticoagulants of 8.65–10.84 and 4.09–16.2, respectively, and 1.0–18.0 and 1.0–2.51 for anticardiolipin antibodies.⁶⁴

There is a 5% risk of VTE during pregnancy and the puerperium among patients with APA despite treatment.⁶⁷ Recurrence risks of up to 30% have been reported in APA-positive patients with a prior VTE; thus, long-term prophylaxis is required in these patients. A severe form of APS is termed catastrophic APS, or CAPS, which is defined as a potentially life-threatening variant with multiple vessel thromboses leading to multiorgan failure.⁶⁸ In the Euro-Phospholipid Project Group (13 countries included), DVT, thrombocytopenia, stroke, pulmonary embolism, and transient ischemic attacks were found in 31.7%, 21.9%, 13.1%, 9.0%, and 7.0% of cases respectively.

APA are associated with obstetric complications in about 15–20% of cases including fetal loss after 9 weeks' gestation, abruptio placentae, severe preeclampsia, and intrauterine growth restriction (IUGR). Reported ORs for lupus anticoagulant-associated fetal loss range from 3.0 to 4.8, while anticardiolipin antibodies display a wider range of reported ORs of 0.86–20.0.⁶³ It is unclear whether APA are also associated with recurrent (> 3) early spontaneous abortion in the absence of stillbirth. Fifty percent or more of pregnancy losses in APA patients occur after the 10th week.⁶⁹ Patients

with APA more often display initial fetal cardiac activity compared with patients with unexplained first trimester spontaneous abortions without APA (86% vs 43%; $P < 0.01$).⁷⁰ APA have been commonly found in the general obstetric population, with one survey demonstrating that 2.2% of such patients have either IgM or IgG anticardiolipin antibodies, with most such women having relatively uncomplicated pregnancies.⁷¹ Other factors may play a role in the pathogenesis of APA. Potential mechanism(s) by which APA induce arterial and venous thrombosis as well as adverse pregnancy outcomes include: APA-mediated impairment of endothelial thrombomodulin and APC-mediated anticoagulation; induction of endothelial TF expression; impairment of fibrinolysis and antithrombin activity; augmented platelet activation and/or adhesion; impairment of the anticoagulant effects of the anionic phospholipid binding proteins β 2-glycoprotein-1 and annexin V.^{72,73} APA induction of complement activation has been suggested to play a role in fetal loss, with heparin preventing such aberrant activation.⁷⁴

Adverse pregnancy outcome and inherited thrombophilias

Inherited thrombophilic conditions have been implicated in a variety of obstetrical complications, including severe preeclampsia and related conditions, late fetal loss (≥ 20 weeks), severe IUGR (< 5th percentile), and abruptio placentae. The frequency, recurrence risks, and impact in subsequent pregnancies for the general population without regard to thrombophilia are listed in Table 47.6.

Severe preeclampsia/syndrome of hemolysis, elevated liver enzymes, and low platelets (HELLP)

Several studies (mostly case–controlled) have evaluated the relationship between heterozygous factor V Leiden and severe preeclampsia. Factor V Leiden was identified in 4.5–26% of patients with severe preeclampsia, eclampsia, or HELLP syndrome (Table 47.7).^{75–90} Kupferminc et al.⁷⁹ found that a thrombophilic mutation was present in 67% of patients who had previous adverse pregnancy outcome (APO). The system-

FVL, factor V Leiden; PG, prothrombin gene; SPE, severe preeclampsia.

atic review by Alfirevic⁹¹ suggested a positive association between factor V Leiden and preeclampsia/eclampsia [OR 1.6, 95% confidence interval (CI) 1.2–2.1]. Factor V Leiden occurred in 11.4% (95/830) of patients with severe preeclampsia, with an OR of 2.84 (95% CI 1.95–4.14) in the study by Morrison.⁹² The prothrombin gene mutation was identified in up to 9.1% of cases, whereas PS deficiency was reported in 5–25% of cases (Table 47.7). Paidas et al.⁴⁰ found that there was a significant decrease in PZ levels in patients ($n = 51$) with a variety of APO, including IUGR, preeclampsia, preterm delivery, and bleeding in pregnancy compared with women ($n = 51$) with normal pregnancy outcomes (NPO) (second trimester 1.5 ± 0.4 vs $2.0 \pm 0.5 \mu\text{g/mL}$, $P < 0.0001$; and third trimester 1.6 ± 0.5 vs $1.9 \pm 0.5 \mu\text{g/mL}$, $P < 0.0002$). PZ levels at the 20th percentile ($1.30 \mu\text{g/mL}$) were associated with an increased risk of APO (OR 4.25, 95% CI 1.536–11.759, with a sensitivity of 93%, specificity 32%). In the same group of patients, PS levels were significantly lower in the second and third trimesters among patients with APO compared with patients with NPO (second trimester $34.4 \pm 11.8\%$ vs $38.9 \pm 10.3\%$, $P < 0.05$ respectively; and third trimester 27.5 ± 8.4 vs 31.2 ± 7.4 , $P < 0.025$ respectively). The authors speculate that decreased PZ and PS levels are additional risk factors for APO. These authors also compared first trimester (first trimester) PZ levels in 103 women with subsequent NPO, 106 women with APO, and 20 women known to be thrombophilic, with 6/20 of these women having had APO. The mean first trimester PZ level was significantly lower among patients with APO compared with pregnant control subjects (1.81 ± 0.7 vs $2.21 \pm 0.8 \mu\text{g/mL}$, respectively, $P < 0.001$). Of patients with known thrombophilia, those with APO had a tendency for lower mean PZ levels compared with those

thrombophilic women with NPO (1.5 ± 0.6 vs $2.3 \pm 0.9 \mu\text{g/mL}$, respectively, $P < 0.0631$). Thus, there is compelling evidence that PZ is another thrombophilic condition associated with pregnancy complications. Further studies are needed to confirm the findings of Paidas et al. who have demonstrated that lower than normal pregnancy-associated PS levels are associated with a variety of adverse pregnancy outcomes.

Abruptio placentae and thrombophilia

The determination of the relationship between thrombophilias and abruptio placentae (decidual hemorrhage) is difficult secondary to the limited number of studies and the confounding variables, including chronic hypertension, and cigarette and cocaine use.^{93,94,113,114} de Vries⁹⁵ found that 9/31 (29%) patients with abruptio placentae had a PS deficiency, compared with their general population prevalence of 0.2–2%. The prevalence of factor V Leiden, prothrombin gene mutation, and PS deficiency was 22–30%, 18–20%, and 0–29%, respectively (Table 47.8).^{79,85,95–97}

IUGR

Infante-Rivard et al.⁵¹ found rates of 4.5% and 2.5% for factor V Leiden and prothrombin gene mutation, respectively, when IUGR was defined as < 10 th percentile. In a recent systematic review, factor V Leiden and prothrombin gene mutation were associated with an increased risk of IUGR: OR 2.7 (1.3–5.5), and OR 2.5 (1.3–5.0), respectively, in 10 case–control studies.⁹⁸ However, in five cohort studies (three prospective, two retrospective), the relative risk was 0.99 (0.5–1.9). The authors concluded that both factor V Leiden and prothrombin gene

mutation confer an increased risk of giving birth to an IUGR infant, although this may be driven by small, poor-quality studies that demonstrated extreme associations.

Fetal loss

In a meta-analysis of 31 studies, Rey et al.⁹⁹ found that factor V Leiden was associated with an increased risk of late fetal loss (OR 3.26, 95% CI 1.82–5.83). Gris¹⁰⁰ found a positive correlation between the number of stillbirths and the prevalence of thrombophilias among 232 women with previous late fetal loss (22 weeks) and 464 control subjects. PS deficiency was found in 9 out of 84 (10.7%) with at least two stillbirths, and the presence of factor V Leiden was associated with a high risk of fetal loss at > 22 weeks (OR 7.83, 95% CI 2.83–21.67). Martinelli¹⁰¹ found that the risk of late fetal death (> 20 weeks) was threefold higher if the patient was a carrier of either factor V Leiden or prothrombin gene mutation. The relative risk of carriers (factor V Leiden, prothrombin gene mutation) for late fetal loss was 3.2 (1.0–10.9) and 3.3 (1.1–10.3) respectively. Martinelli¹⁰² evaluated recurrent late loss and found that factor V Leiden was present in 28.6% of patients with recurrent late loss.

Rey et al.⁹⁹ pooled data from nine studies ($n = 2087$) and found a significant association between fetal loss and the prothrombin gene mutation. Prothrombin gene mutation was associated with recurrent fetal loss before 25 weeks ($n = 690$ women, OR 2.56, 95% CI 1.04–6.29) and with nonrecurrent fetal loss after 20 weeks (five studies, $n = 1299$, OR 2.3, 95% CI 1.09–4.87). The prevalence of prothrombin gene mutation ranges from 0 to 33%, and of PS deficiency from 29% to 92% (Table 47.9).^{79,85,91,99,100,103–111} On the other hand, Hefler et al.¹¹⁰ did not find any significant association between factor V Leiden, prothrombin gene mutation, or PS deficiency and fetal death (median gestational age 34 weeks, with range 20–42 weeks). Two other studies that examined recurrent fetal loss and PS deficiency found a significant association (OR 14.7, 95% CI 0.99–218).^{100,108} Rey et al.⁹⁹ found that PS deficiency was associated with nonrecurrent loss after 22 weeks in three studies ($n = 565$, OR 7.39, 95% CI 1.28–42.83).

Early pregnancy loss and thrombophilia

The association between early pregnancy loss and thrombophilia has also yielded conflicting results. In three recent systematic reviews, the diversity among the included studies

Review: Thrombophilia and early pregnancy loss
 Comparison: 01 Factor V Leiden and recurrent fetal loss before 13 weeks
 Outcome: 02 Recurrent fetal loss before 13 weeks

Figure 47.3 Recurrent first trimester loss and factor V Leiden (from ref. 114). A recent meta-analysis suggests that the factor V Leiden is associated with an increased risk of recurrent first trimester loss (odds ratio 1.67, 95% CI 1.16–2.40).

Review: Thrombophilia and early pregnancy loss
 Comparison: 02 Prothrombin mutation and recurrent fetal loss before 13 weeks
 Outcome: 01 Recurrent fetal loss before 13 weeks

Figure 47.4 Recurrent first trimester loss and prothrombin gene mutation G20210A (from ref. 114). A recent meta-analysis suggests that the prothrombin gene mutation G2021A is associated with an increased risk of recurrent first trimester loss (odds ratio 2.25, 95% CI 1.20–4.21).

implies that these meta-analyses included heterogeneous studies.^{99,112–114} Factors influencing results include inclusion of isolated or recurrent fetal loss, presence or absence of successful live birth in obstetrical history, gestational age cutoff for evaluation, and inclusion of proper control groups. Figures 47.3 and 47.4 demonstrate the latest compilation of data concerning pregnancy loss and factor V Leiden and prothrombin gene mutation respectively.¹¹⁴ The typical OR for factor V Leiden is 1.67 (1.16–2.40) and, for prothrombin gene mutation, the typical OR is 2.25 (1.20–4.21). There was no increased risk of loss for the MTHFR C677T mutation.¹⁰⁵ Roque et al.¹¹⁵ reported that the odds of having thrombophilia were actually significantly lower in women with recurrent embryonic losses. In this retrospective cohort study, patients with recurrent early pregnancy loss (two or more) were stratified by gestational age into losses before 9 weeks and 6 days and losses from 10 weeks to 14 weeks and 0 days. Simple correlations between individual factors of thrombophilia and

early first trimester loss (below 10 weeks) were mostly non-significant and negative for all parameters, when compared with those in late first trimester losses. These authors investigated the association of thrombophilia (anticardiolipin antibodies, lupus anticoagulant, factor V Leiden, prothrombin gene mutation G20210A, homocysteine, deficiencies in PC, PS, or antithrombin, and one measure of thrombophilia or more) and adverse pregnancy outcome in 491 patients with a history of preeclampsia, IUGR < 10th percentile, fetal loss at > 14 weeks, recurrent abortion prior to 14 weeks, abruptio placentae, preterm delivery, and history of thromboembolism. Thrombophilia was associated with an increased risk of fetal loss at > 14 weeks, IUGR, abruptio placentae, and preeclampsia. There was a “dose-dependent” increase in abruptio risk (OR 3.6, 95% CI 1.20–8.6). In those with thrombophilia, preeclampsia was noted in 9%, abruptio in 5.5%, IUGR < 10th percentile in 37%, fetal loss at > 14 weeks in 16.5%, and preterm delivery in 33%. Biological considerations might

explain a reduced influence of thrombophilic factors in very early pregnancy losses (< 10 weeks). The blood flow pattern and oxygenation at the placental site change at about 10 weeks of gestation.

Anticoagulation to prevent recurrent adverse pregnancy outcomes in women with thrombophilia

Heparin and aspirin administration is the best strategy for the treatment of recurrent pregnancy loss associated with APS, according to the Cochrane review in 2002.¹¹⁶ This approach has been associated with a 54% reduction in pregnancy loss and is better than aspirin alone. Steroid administration is associated with an excessive risk of prematurity, and therefore is not recommended as a first-line prevention strategy.

Given that uteroplacental thrombosis is a feature of pregnancies complicated by IUGR, severe preeclampsia and abruptio placentae, and fetal loss in women with thrombophilia, prophylaxis with heparin has been offered to prevent recur-

rent pregnancy complications in the setting of inherited thrombophilias. The rationale for this approach is that maternal heparin administration will decrease vascular injury and thrombin generation, thereby reducing thrombosis in the uteroplacental circulation.

There are few published studies describing the use of low-molecular-weight heparin (LMWH) with previous adverse pregnancy outcomes (Table 47.10).^{117–124} Kupferminc et al.¹²⁰ treated 33 women with a history of severe preeclampsia, abruptio placenta, IUGR, or fetal demise and a known thrombophilia with LMWH and low-dose aspirin (LDA). Treated patients had a higher infant birthweight and a higher gestational age at delivery than in the previous pregnancy. Treated pregnancies were not associated with fetal losses or severe preeclampsia. Riyazi et al.¹¹⁷ found that treatment with LMWH and LDA in patients with previous early-onset preeclampsia and/or severe IUGR and a thrombophilic disorder resulted in a higher infant birthweight than in patients with a comparable history but not receiving this intervention.

Paidas et al.¹²² evaluated a cohort of patients carrying either factor V Leiden or prothrombin gene mutation who experi-

Table 47.10 Heparin administration to prevent adverse pregnancy outcome.

Author (reference)	Year	No. of patients	Drug	Patients studied	Outcome
Riyazi et al. ¹¹⁷	1998	26	Nadroparin + ASA 80mg	Thrombophilia plus prior preeclampsia or IUGR	Treatment associated with lower rates of preeclampsia/IUGR compared with historical controls
Brenner ¹¹⁸	2000	50	Enoxaparin	Thrombophilia plus recurrent fetal loss	Treatment associated with higher live birth rates (75% vs 20%) compared with historical controls
Ogueh ¹¹⁹	2001	24	Unfractionated heparin	Thrombophilia plus IUGR or abruptio placentae	No improvement compared with historical control
Kupferminc et al. ¹²⁰	2001	33	Enoxaparin + ASA 100mg	Thrombophilia plus preeclampsia or IUGR	Higher birthweight and gestational age at delivery
Grandone ¹²¹	2002	25	Unfractionated heparin or enoxaparin	Thrombophilia + APO	Treatment was associated with lower rates of APO in treated (10%) vs untreated (93%)
Paidas et al. ¹²²	2004	41	Unfractionated or low-molecular-weight heparin	FVL or PGM plus history of fetal loss	Treatment was associated with an 80% reduction in fetal loss (OR 0.21, 95% CI 0.11–0.39)
Gris et al. ¹²³	2004	160	Enoxaparin or 100mg aspirin; folic acid 5mg	Thrombophilia plus fetal loss	Enoxaparin was superior to aspirin. 29% patients treated with LDA and 86% treated with enoxaparin had healthy live birth (OR 15.55, 95% CI 7–34)
Brenner et al. ¹²⁴	2004	183	Enoxaparin (40mg/day or 40mg b.i.d.)	Thrombophilia + ≥ three losses in the first trimester, or ≥ two losses in the second trimester, or ≥ one loss in the third trimester	Enoxaparin increased the rate of live births (81.4% vs 28.2%, $P < 0.01$ for 40mg, 76.5% vs 28.3%, $P < 0.01$ for 80mg), decreased the rate of preeclampsia (3.4% vs 7.1%, $P < 0.01$ for 40mg; 4.5% vs 15.7%, $P < 0.01$ for 80mg), and decreased the rate of abruptio placentae (4.4% vs 14.1%, $P < 0.01$ for 40mg; 3.4% vs 9.6%, $P < 0.1$ for 80mg)

enced at least one prior APO. A total of 41 patients (28 with factor V Leiden, 13 with prothrombin gene mutation) had 158 pregnancies. They compared the 41 heparin-treated pregnancy outcomes with the remaining 117 untreated pregnancies. Antenatal heparin administration consisted of enoxaparin, dalteparin, or unfractionated heparin. Antenatal heparin administration was associated with an 80% reduction in APO overall (OR 0.21, 95% CI 0.11–0.39, $P < 0.05$). This relationship persisted if first trimester losses were excluded ($n = 111$ total pregnancies, OR 0.46, 95% CI 0.23–0.94, $P < 0.05$).

Brenner et al.¹²⁴ reported on the LIVE-ENOX study, a multicenter prospective randomized trial to evaluate the efficacy and safety of two doses of enoxaparin (40 mg/day or 40 mg b.i.d.) in 183 women with recurrent pregnancy loss and thrombophilia. Inclusion criteria were \geq three losses in the first trimester, \geq two losses in the second trimester or \geq one loss in the third trimester. Compared with the patient's historical rates of live birth and pregnancy complications, enoxaparin increased the rate of live birth (81.4% vs 28.2%, $P < 0.01$ for 40 mg, 76.5% vs 28.3%, $P < 0.01$ for 80 mg), decreased the rate of preeclampsia (3.4% vs 7.1%, $P < 0.01$ for 40 mg; 4.5% vs 15.7%, $P < 0.01$ for 80 mg), and decreased the rate of abruptio placentae (4.4% vs 14.1%, $P < 0.01$ for 40 mg; 3.4% vs 9.6%, $P < 0.1$ for 80 mg). The lack of a placebo arm, use of historical control subjects, and the small number of patients are limitations of this study.

Gris et al.¹²³ compared the administration of LDA 100 mg daily with enoxaparin 40 mg daily from the 8th week of gestation in a cohort of patients with a prior loss after 10 weeks and the presence of heterozygous factor V Leiden, prothrombin gene mutation G20210A, or PS deficiency. The authors found that 23/80 patients treated with aspirin and 69/80 patients treated with enoxaparin had a successful pregnancy (OR 15.5, 95% CI 7–34, $P < 0.0001$). Birthweights were higher, and there were fewer small for gestational age infants in the enoxaparin group.

The small size and inadequate study designs of the published studies do not permit any firm recommendation regarding the antenatal administration of heparin for the sole indication of the prevention of adverse pregnancy outcome.¹²⁵ These authors strongly recommended a randomized trial to address the use of anticoagulation for prevention. According to a recent Cochrane review, based upon an extensive literature search from 1966 to 2004 of women with a history of \geq two spontaneous losses or one fetal demise without apparent cause other than inherited thrombophilia, only two trials were available for review.¹²⁶ The other study besides the Gris trial was the trial reported by Tulppala et al.,¹²⁷ which involved 82 patients and compared aspirin 50 mg versus placebo in women with three or more unexplained consecutive losses. No differences were noted between the aspirin compared with the placebo group (relative risk 1.00 (0.78–1.29).

Thrombophilia screening: testing and candidates

The selection of suitable patients for thrombophilia screening and the thrombophilia workup continue to evolve. At this time, suitable candidates for thrombophilia screening include those with a history of unexplained fetal loss at > 10 weeks; a history of severe preeclampsia/HELLP at < 36 weeks; a history of abruptio placentae; a history of IUGR \leq 5th percentile; a personal history of thrombosis; and a family history of thrombosis. Initial thrombophilia evaluation should include: protein C (functional level); PS (functional/free antigen level); antithrombin III (functional level); factor V Leiden [by polymerase chain reaction (PCR)]; prothrombin gene mutation 20210A (PCR); lupus anticoagulant; anticardiolipin antibody IgG, M, A; and platelet count. Other commonly ordered screens include MTHFR C677T mutation, fasting homocysteine level, and β 2-glycoprotein-1 IgG, M, A. Depending on the clinical scenario, thrombophilia evaluation can be extended to include other tests, such as PZ, other antiphospholipid antibodies, and the more uncommon factor V mutations, the angiotensin I-converting enzyme (ACE) gene polymorphism, components of the PC system, and PAI-I mutation. Large prospective studies are needed to address the role of the interaction of thrombophilic conditions in the causation of VTE and APO.

Pharmacology of anticoagulation in pregnancy

Thromboembolism and APO management continue to present clinical challenges. The available anticoagulant drugs for the prevention and treatment of VTE include warfarin, unfractionated heparin, LMWH, factor Xa inhibitors, and direct thrombin inhibitors. However, heparins are the mainstay of therapy in pregnancy. Unfractionated heparin enhances antithrombin activity, increases factor Xa inhibitor activity, and inhibits platelet aggregation.¹²⁸ LMWH is generated by chemical or enzymatic manipulation of unfractionated heparin from a molecular weight of 15 000 Da to 4000–6500 Da. The smaller size impedes its antithrombin but not antifactor Xa effects. Both LMWH and unfractionated heparin cross the placenta, are considered safe for pregnancy, and are compatible with breastfeeding. Complications associated with heparins include hemorrhage, osteoporosis, and thrombocytopenia. Heparin-induced thrombocytopenia (HIT) occurs in two forms. Type I HIT typically occurs within days of heparin exposure, is self-limited, and is not associated with significant risk of hemorrhage or thrombosis. Type II HIT is an immunoglobulin-mediated syndrome that occurs in the setting of venous or arterial thrombosis, usually 5–14 days following the initiation of heparin therapy. Fortunately, it is quite rare in pregnancy. Type II HIT can be confirmed by serotonin

release assays, heparin-induced platelet aggregation assays, flow cytometry, or solid phase immunoassay.¹²⁹

Unfractionated heparin has a short half-life and is administered subcutaneously or via continuous infusion. Usually, patients receiving unfractionated heparin require frequent laboratory monitoring and dosage adjustment. LMWH is administered subcutaneously either once or twice daily. It has advantages over unfractionated heparin including better bioavailability, longer plasma half-life, and more predictable pharmacokinetics and pharmacodynamics. LMWH is much more expensive than unfractionated heparin. A recent review has found that LMWH has a reassuring risk profile, including antenatal bleeding, 0.43 (0.22–0.75); postpartum hemorrhage more than 500 mL, 0.94 (0.61–1.37); wound hematoma, 0.61 (0.36–0.98); thrombocytopenia, 0.11 (0.02–0.32); HIT, 0.00 (0.00–0.11); and osteoporosis, 0.04 (< 0.01–0.20).¹³⁰

Coumarins are vitamin K antagonists that block the generation of vitamin KH₂. The latter serves as a cofactor for the post-translational carboxylation of glutamate residues to γ -carboxyglutamates on the N-terminal regions of prothrombin and factors VII, IX, and X as well as the anticlotting agents, PC and PS. The peak effect of warfarin, the most commonly used vitamin K antagonist, occurs 36–72 h after initiating therapy, and it has a half-life of 36–42 h. Aspirin and other nonsteroidal anti-inflammatory drugs, as well as high doses of penicillins and moxolactam, increase the risk of warfarin-associated bleeding by inhibiting platelet function. As PC has a relatively shorter half-life compared with most of the vitamin K-dependent clotting factors, warfarin may initially create a relatively prothrombotic state. Indeed, it may take 6 days to achieve full antithrombotic effects, especially in pregnancy, given the elevated levels of factor VIII and often occurring APC resistance. In pregnancy, it is critical to maintain these women on therapeutic doses of unfractionated heparin or LMWH for 5 days and until the international normalized ratio (INR) reaches the therapeutic range between 2.0 and 3.0 for two successive days.

Several other anticoagulants are now available that may have a role in limited circumstances in pregnancy.¹³¹ Danaparoid is another low-molecular-weight heparinoid that is especially useful in cases of HIT and in cases of heparin allergy. Fondaparinux is a synthetic heparin pentasaccharide that complexes with the antithrombin binding site for heparin to permit the selective inactivation of factor Xa but not thrombin. Given as a once-daily subcutaneous injection, fondaparinux is excreted in the kidney, has a half-life of 15 h, and does not appear to induce HIT. Direct thrombin inhibitors represent another class of anticoagulants.

Hirudin is a 65-amino-acid protein derived from the medicinal leech (*Hirudo medicinalis*). It can be used in patients with type II HIT and is readily available in a recombinant form, lepirudin. There is limited use of lepirudin in pregnancy. Argatroban is a synthetic direct thrombin inhibitor that

competitively binds to thrombin's active site, has a short half-life (45 min), and is cleared by the liver, making it the direct thrombin inhibitor of choice for patients with renal failure. Bivalirudin is a 20-amino-acid synthetic polypeptide analog of hirudin.

Management of venous thromboembolism in pregnancy: diagnosis of venous thromboembolism

Pregnant patients requiring therapeutic anticoagulation require meticulous care and a thorough understanding of the physiologic changes in pregnancy, underlying pathophysiology, and drug treatment effects. In pregnancy, the diagnosis of VTE is based on history, physical examination, and diagnostic studies. The typically cited signs and symptoms of DVT include erythema, warmth, pain, edema, tenderness, and a positive Homan's sign. However, among patients with these signs and symptoms, the diagnosis of DVT is confirmed in only one-third when reliable objective tests are performed.¹³² Venous ultrasound with or without color Doppler has become the primary diagnostic modality for evaluating patients at risk of DVT (Fig. 47.5). The most accurate ultrasonic criterion for diagnosing venous thrombosis is noncompressibility of the venous lumen in a transverse plane under gentle probe pressure using duplex and color flow Doppler.¹³² The sensitivity and specificity of venous ultrasound is generally reported to be 90–100% for proximal-vein thromboses, but is thought to be lower with calf-vein thrombosis.¹³³

Two other imaging modalities include magnetic resonance imaging (MRI) and impedance plethysmography. The published literature suggests that the range of sensitivity and specificity for MRI in the diagnosis of DVT is 80–100% and 90–100%, respectively, with median published rates of 100% for both.¹³⁴ Impedance plethysmography utilizes two sets of electrodes placed around the patient's calf and an oversized blood pressure cuff around the thigh. Published sensitivities and specificities for diagnosing proximal DVT range from 65% to 98% and 83% to 97% respectively.¹³³ It is expensive, and the test is insensitive (< 20%) for detecting calf-vein and small nonobstructing proximal-vein thromboses. Venography remains the “gold standard” for the diagnosis of DVT with a sensitivity and specificity of 100%, by definition. However, its radiation exposure is a significant disadvantage, and it is not typically used in pregnancy.

Acute pulmonary embolus (APE)

Tachypnea (> 20 breaths/min) and tachycardia (> 100 beats per minute; b.p.m.) are present in 90% of patients with APE, but are nonspecific indices of risk.¹³⁵ Symptoms such as dyspnea and pleuritic chest pain are present in up to 90% of

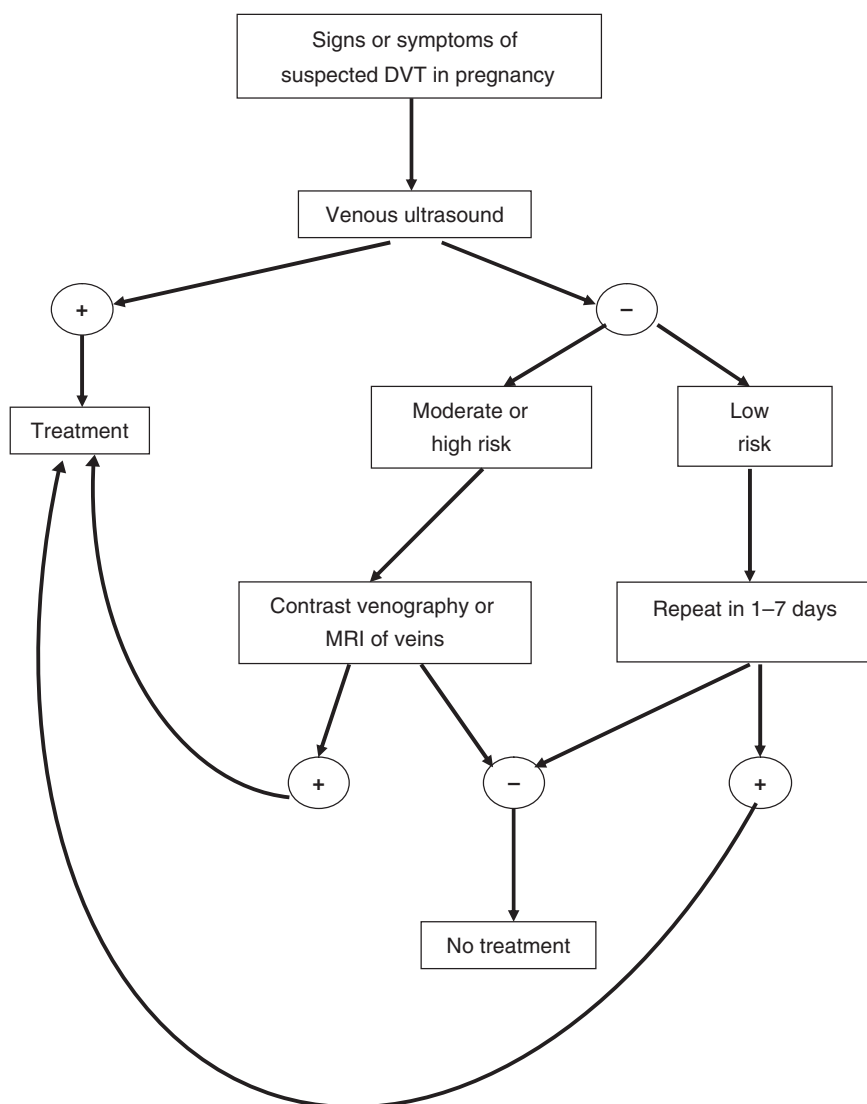

Figure 47.5 Management of suspected DVT in pregnancy. Once a DVT is suspected, a venous ultrasound should be performed to establish the diagnosis of DVT. If positive, anticoagulation should be instituted. If negative, additional testing or repeat venous ultrasound may be indicated, depending upon the level of suspicion for the presence of DVT.

patients with APE, while presyncope and syncope are rarer and indicative of massive emboli.¹³⁶

Electrocardiographic changes may be present in 87% of patients with proven APE who are without underlying cardiopulmonary disease; however, these findings are nonspecific. The Urokinase Pulmonary Embolism Trial found that 26–32% of those with massive APE had electrocardiogram (ECG) manifestations of acute cor pulmonale (S1 Q3 T3 pattern, right-bundle branch block, P-wave pulmonale, or right-axis deviation).¹³⁷ Assessments of arterial blood gases and oxygen saturation are also of limited value in APE; pO_2 values of > 80 mmHg are found in 29% of APE patients less than 40 years of age.¹³⁸ The alveolar–arterial oxygen tension difference appears to be a more useful indicator of disease with alveolar–arterial differences of > 20 mmHg present in 86% of patients with APE.¹³⁵ Chest radiographs may be abnormal in up to 84% of affected patients.¹³⁵ Common findings include pleural effusion, pulmonary infiltrates, atelectasis, and elevated

hemidiaphragm. A chest radiograph cannot be used to rule out a pulmonary embolism. More than 80% of patients with APE display sonographic imaging or Doppler abnormalities of right-ventricular size or function, including a dilated and hypokinetic right ventricle, tricuspid regurgitation, and absence of pre-existing pulmonary arterial or left-heart pathology.

To confidently diagnose pulmonary embolism, one or more specific diagnostic studies must be performed (Figs 47.6 and 47.7).

Ventilation–perfusion (V/Q) scanning has long been considered a mainstay of the diagnostic evaluation of patients with suspected APE. V/Q scanning is performed by imaging both the pulmonary vascular bed and the airspace. Perfusion scanning is accomplished by injecting isotopically labeled (e.g., technetium-99) human albumin macroaggregates into the bloodstream where they are deposited in the pulmonary capillary bed. Their topographic distribution is then assessed by a photoscanner. Ventilation scanning entails the inhalation of

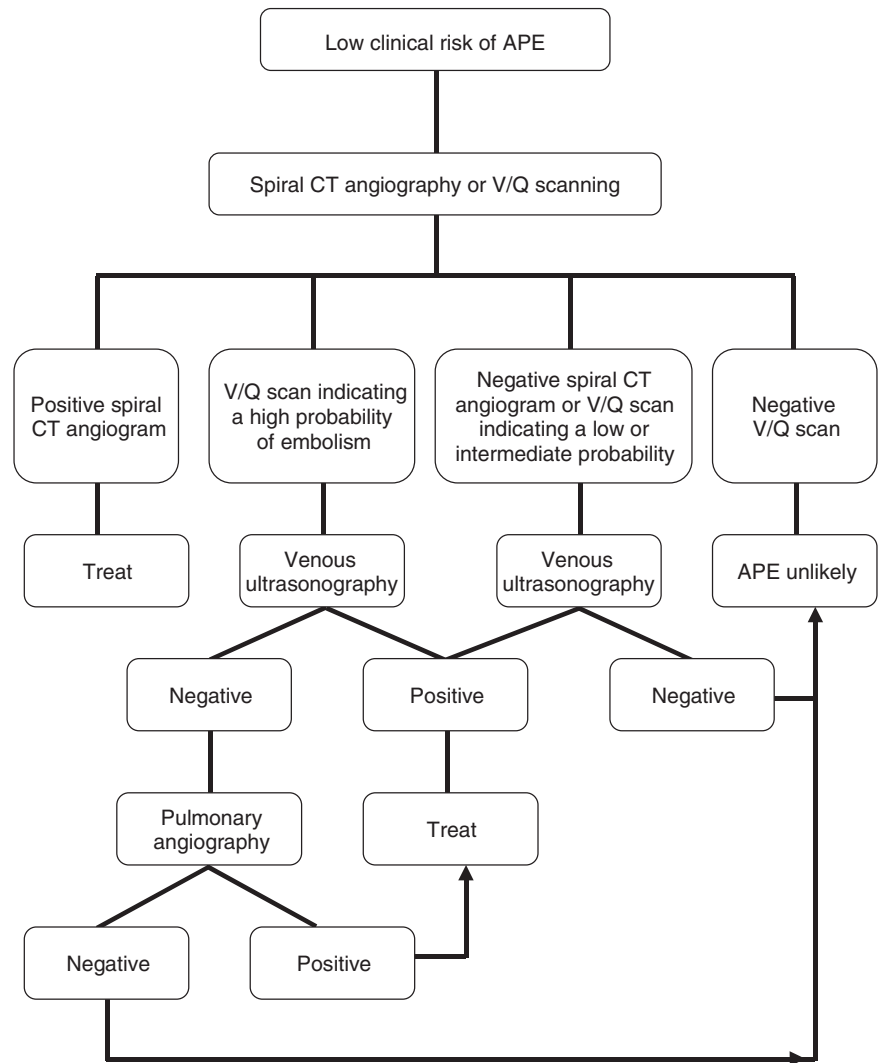

Figure 47.6 Management paradigm for patient at low clinical risk of acute pulmonary embolism. Spiral CT angiography or ventilation/perfusion scanning are indicated as first line imaging modalities. Anticoagulation is indicated in the setting of: a positive spiral CT angiography; a high probability V/Q scan along with a positive venous ultrasound; a positive pulmonary angiogram; negative spiral CT and positive venous ultrasound; low or intermediate V/Q scan and a positive venous ultrasound.

radiolabeled aerosols (e.g., xenon-133), whose distribution in alveolar spaces is assessed by a gamma camera. The combination of perfusion and ventilation scanning allows the discernment of characteristic patterns that can be used to assign diagnostic probabilities. Large mismatched defects (i.e., those associated with abnormal perfusion scans but normal ventilation scans) are associated with APE in 80–96% of high- and moderate-risk patients but in only 50% of low-risk patients.

The Prospective Investigation of Pulmonary Embolism Diagnosis (PIOPED) was a multicenter, collaborative effort designed to determine the sensitivity and specificity of V/Q scanning in patients with signs and symptoms of suspected APE.¹³⁹ Patients with high-probability scans had APE in 87.2% of cases, but only 41% of patients with APE had high-probability scans (sensitivity of 41% and specificity of 97%). Patients with intermediate-probability scans had APE in 33.3% of cases, while APE was present in 13.5% of patients with low-probability scans and 3.9% of patients with near-normal or normal scans.

An APE can be present in a substantial percentage of patients with nondiagnostic (low and intermediate probability) V/Q scans if there is a high clinical suspicion of APE. Conversely, 44% of low-risk patients with a high-probability V/Q scan will not ultimately be found to harbor an APE. Spiral (helical) computerized tomographic angiography (spiral CT) is a technique that requires the continuous movement of a patient through a CT scanner as a contrast bolus is administered.¹³⁴ It is of limited value with small subsegmental peripheral vessels and horizontally oriented vessels in the right middle lobe. Cross et al.¹⁴⁰ compared spiral CT with V/Q scans for the initial investigation of patients with suspected APE, and observed that a definitive diagnosis was more often possible following spiral CT than with V/Q scanning (90% vs 54%; $P < 0.001$). The principal difference between the two modalities was that spiral CT more often demonstrated non-embolic lesions responsible for the patients' symptoms. However, there was no difference in the prevalence or detection rate of APE in the two groups. The published sensitivity

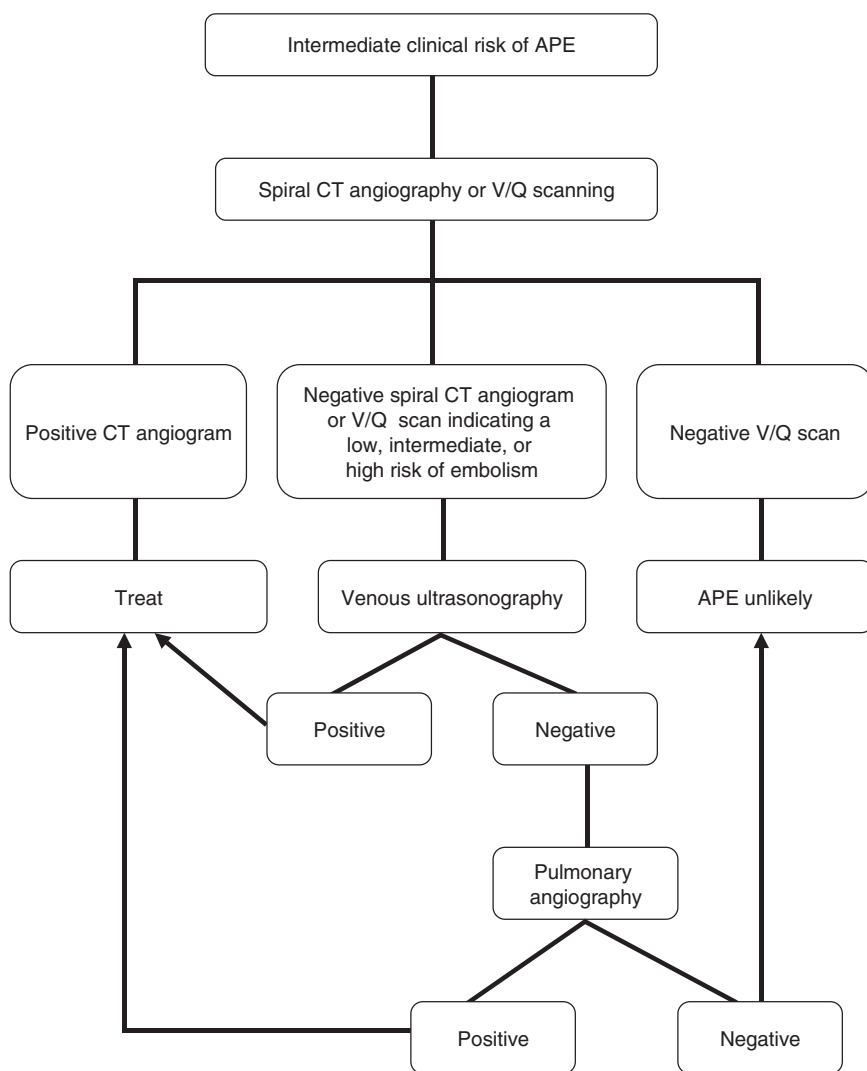

Figure 47.7 Management paradigm for patient at intermediate clinical risk of acute pulmonary embolism. Spiral CT angiography or ventilation/perfusion scanning are indicated as first line imaging modalities. Pulmonary angiography remains the gold standard for the diagnosis of APE. If there is a high clinical risk of acute pulmonary embolism, pulmonary angiography should be performed even if initial tests (spiral CT angiography or V/Q scanning) do not suggest APE.

ties and specificities of spiral CT for the diagnosis of APE range from 53% to 100% (median 87%) and from 78% to 97% (median 95%) respectively.¹³⁴

Conventional pulmonary arteriography

Pulmonary arteriography is considered the gold standard for the diagnosis of APE with sensitivities and specificities of 100% by definition.¹³⁴ An APE is diagnosed by the finding of an intraluminal filling defect on two views of a pulmonary artery. The procedure carries with it a 0.5% mortality rate and a complication rate of 3%. The majority (90%) of cases of APE arise from lower extremity DVTs; among patients with APE, 50% will be found to harbor a DVT, including up to 20% of patients without lower extremity signs or symptoms.¹³⁶ Finally, the routine use of D-dimer as a screen for thromboembolism is not helpful in pregnancy given the normal hematologic changes in pregnancy (Table 47.1).

Radiation exposure in pregnancy

Concern often arises about the level of radiation exposure to the fetus from the various diagnostic modalities employed in the evaluation of patients at risk for VTE. Limited contrast venography with an abdominal shield generates < 500 μ Gy (< 0.05 rad). Full venography without a shield exposes the fetus to 3.1 mGy (0.31 rad). Pulmonary arteriography from the brachial vein route generates less than 500 μ Gy (0.05 rad) but from the femoral vein route, it is 2.2–3.3 mGy (0.22–0.33 rad), making the former the preferable route in pregnancy. V/Q scans expose the fetus to less than 120 μ Gy (0.012 rad) from the technetium-99 perfusion scan and less than 190 μ Gy (0.019 rad) from the xenon-133 ventilation scan. Spiral CT angiography exposes the fetus to a maximum of 131 μ Gy (0.013 rad). Virtually all these exposures are substantially less than 5 rad and thus pose no known risk of spontaneous abortion, teratogenicity, or perinatal morbidity. Doses

above 1 rad may create a marginally increased risk of childhood leukemia (from 1:3000 baseline to 1:2000).^{141,142}

Neither mutagenic nor teratogenic effects have been described after the administration of gadolinium or iodinated contrast media.¹⁴³ Concerns about fetal goiter following maternal radiographic contrast exposure suggest that fetal heart rates should be assessed to rule out hypothyroidism, and neonatal thyroid function should be checked during the first week of life.¹⁴³

Treatment of venous thromboembolism

Before initiating anticoagulation therapy, a thrombophilia panel should be obtained as noted above. Functional clotting factor testing should be performed well after the cessation of anticoagulant therapy to diagnose a factor deficiency. Women with new-onset VTE during a current pregnancy should receive therapeutic anticoagulation for at least 20 weeks during the pregnancy followed by prophylactic therapy (Table 47.11). After delivery, patients require a minimum of 6 weeks of anticoagulation. During pregnancy, unfractionated heparin and LMWH are the anticoagulants of choice. Postpartum, oral anticoagulation with warfarin may be started and is considered to be safe in breastfeeding mothers. As osteoporosis is more common with doses of heparin greater than 15000 U/day employed for more than 6 months, all patients treated with heparin should receive 1500 mg of calcium supplementation per day. Postpartum bone densitometry may be appropriate in such patients.

In pregnancy, LMWH from multidose vials containing benzoyl alcohol, which is potentially toxic to the fetus and newborn, should be avoided. The goals of therapy for an acute VTE in pregnancy are to maintain the activated partial thromboplastin time (aPTT) between 1.5 and 2.5 times control when using unfractionated heparin. The dose required may vary greatly between women secondary to interpatient differences in heparin-binding proteins during pregnancy. The aPTT should be evaluated every 4–6 h during the initial phase of therapy and adjustments made in dosage as needed (see Tables 47.9 and 47.10). Intravenous therapeutic unfractionated heparin should be continued for at least 5–10 days or until clinical improvement is noted. Thereafter, therapeutic doses of unfractionated heparin may be administered subcutaneously every 8–12 h in order to maintain the aPTT at 1.5–2 times control levels 6 h after the injection. These should be continued for 20 weeks followed by prophylactic dosages. For example, prophylactic doses of unfractionated heparin can range from 5000 to 10000 U subcutaneously every 12 h titrated to maintain an antifactor Xa level of 0.1–0.2 IU/mL 6 h after the last injection. Patients with highly thrombogenic thrombophilias such as antithrombin deficiency or those homozygous for the factor V Leiden or prothrombin G20210A gene mutations or compound heterozygotes for

these mutations require therapeutic anticoagulation throughout pregnancy.

If vaginal or Cesarean delivery occurs more than 4 h after a prophylactic dose of unfractionated heparin, the patient is not at significant risk of hemorrhagic complications. Protamine sulfate may be administered to those patients with an elevated aPTT receiving prophylactic or therapeutic unfractionated heparin who are about to deliver vaginally or by Cesarean section.

Low-molecular-weight heparin

For therapeutic dosing, the antifactor Xa level should be maintained at 0.6–1.0 U/mL 4–6 h after injection (e.g., starting with enoxaparin 1 mg/kg subcutaneously every 12 h). Again, treatment should continue for 20 weeks and then prophylactic dosages should be given (e.g., enoxaparin 40 mg subcutaneously every 12 h, adjusted to maintain antifactor Xa levels at 0.1–0.2 U/mL 4 h after an injection). As noted, patients with highly thrombogenic thrombophilias require therapeutic anticoagulation throughout pregnancy. As regional anesthesia is contraindicated within 18–24 h of LMWH administration, we recommend switching to unfractionated heparin at 36 weeks or earlier if preterm delivery is expected.

If vaginal or Cesarean delivery occurs more than 12 h from prophylactic or 24 h from therapeutic doses of LMWH, the patient should not experience anticoagulation-related problems with delivery. Protamine may partially reverse the anticoagulant effects of LMWH (see previous section).

Postpartum

Either unfractionated heparin or LMWH can be restarted 3–6 h after vaginal delivery or 6–8 h after Cesarean delivery. Warfarin should be started on the first postdelivery day. Therapeutic doses of unfractionated heparin or LMWH are needed for 5 days and until the INR reaches the therapeutic range between 2.0 and 3.0 for 2 successive days.

Surgery and thrombolytic therapy

Pregnancy poses special concerns about such therapy given the risk of abruptio placentae and puerperal hemorrhage. Turrentine et al.,¹⁴⁴ reviewed outcomes among 172 pregnant patients treated with thrombolytic therapy and reported that the maternal mortality rate was 1.2%, the fetal loss rate was 6%, and that maternal complications from hemorrhage occurred in 8%. Recombinant tissue plasminogen activator (rtPA) has been successfully administered to treat a massive pulmonary embolism at a dose of 10 mg intravenous bolus, then 90 mg infusion/2 h, followed by unfractionated heparin for 48 h, then four times/day LMWH (antifactor Xa level 0.5–1.0 U/mL). This approach should be avoided peripartum

Table 47.11 Anticoagulation in pregnancy: indications and dosing.

Indication	Description	Antepartum		Postpartum	
		Therapeutic	Prophylactic	Therapeutic	Prophylactic
VTE current pregnancy		X		*	
High-risk thrombophilia	History of VTE or APO*	X			X
Factor V Leiden homozygous					
Prothrombin G20210A mutation homozygous	No history		X		X
Antithrombin III deficiency					
Intermediate-risk thrombophilia			X		X
Compound heterozygote (FVL/prothrombin G20210A)					
Low-risk thrombophilia	Prior VTE		X		X
Factor V Leiden heterozygous	History of APO† but not VTE		± X‡		X§
Prothrombin G20210A mutation heterozygous	No history of VTE or APO†				X§
Protein C deficiency					
Protein S deficiency					
Hyperhomocysteinemia (refractory to folate therapy)					
No thrombophilia	Prior VTE				X
Hyperhomocysteinemia	Prior VTE or		X		X§§

* VTE during current pregnancy should receive therapeutic anticoagulation for 20+ weeks during pregnancy, followed by prophylactic therapy for up to 6 weeks postpartum.

† Adverse pregnancy outcome (APO) includes early-onset severe preeclampsia, unexplained recurrent abruptio placentae, severe IUGR, intrauterine fetal demise (>10 weeks) with placental thrombosis or infarction.

‡ Patients with less thrombogenic thrombophilias and histories of APO should be treated prophylactically in the antepartum period if the clinical scenario suggests a high risk of recurrence or there are other thrombotic risk factors (obesity, immobilization, etc.).

§ If Cesarean delivery or first-degree relative with history of VTE.

§§ Cases of hyperhomocysteinemia unresponsive to folate, vitamin B6, and vitamin B12 therapy.

Notes

Unfractionated heparin (UFH)

- Initial dose of UFH for acute VTE to keep aPTT 1.5–2.5 times control. Thereafter, UFH may be given subcutaneously q 8–12 h to keep aPTT 1.5–2 times control (when tested 6 h after injection) for therapeutic levels.
- Prophylactic doses may range from 5000 to 10 000 units subcutaneously q 12 h and can be titrated to achieve heparin levels (by protamine titration assay) of 0.1–0.2 U/mL.

Low-molecular-weight heparin (LMWH)

- Therapeutic doses of Lovenox (enoxaparin) may start at 1 mg/kg subcutaneously q12 h. Therapeutic doses should be titrated to achieve antifactor Xa levels of 0.6–1.0 U/mL (when tested 4–6 h after injection).
- Prophylactic doses of Lovenox (enoxaparin) may start at 40 mg subcutaneously q12 h. Prophylactic doses should be titrated to achieve antifactor Xa levels of 0.1–0.2 U/mL 4 h after injection.
- Regional anesthesia is contraindicated within 18–24 h of LMWH and thus LMWH should be converted to UFH at 36 weeks or earlier if clinically indicated.

Postpartum

- Heparin anticoagulation (LMWH or UFH) may be restarted 3–6 h after vaginal delivery and 6–8 h after Cesarean.
- Warfarin anticoagulation may be started on postpartum day 1.
- Therapeutic doses of LMWH or UFH must be continued for 5 days and until the INR reaches the therapeutic range (2.0–3.0) for 2 successive days.

Maternal and fetal surveillance

- Fetal growth should be monitored every 4–6 weeks beginning at 20 weeks in all patients on anticoagulation.
- Nonstress tests (NSTs) and biophysical profiles (BPPs) may be appropriate at 36 weeks or earlier as clinically indicated.

because of the hemorrhagic risk from the placental site.¹⁴⁵ However, given the limited evidence of the benefit of such therapy, its use in pregnant patients should be limited.

Anticoagulation in pregnancy: special considerations

Recurrent VTE in women with prior VTE

Antepartum heparin is not necessary in patients without thrombophilia and whose prior VTE is associated with temporary risk factors, based upon the study by Brill-Edwards et al.¹⁴⁶ In a prospective evaluation of 125 women with a single previous episode of VTE, antepartum heparin was withheld. In the 95 patients who did not have a known thrombophilia and whose prior VTE was associated with a temporary risk factor, the recurrence of VTE was 0% (95% CI 0–8.0). In patients with thrombophilia and/or idiopathic prior VTE, the relative risk of recurrent antepartum VTE was 5.9 (1.2–16%). Antepartum prophylaxis is indicated in the latter group of patients. Postpartum anticoagulation is indicated in both groups.

Mechanical heart valves

There is no ideal anticoagulation strategy for this especially high-risk clinical dilemma. Some experts suggest using therapeutic LMWH in this setting, even though failures have occurred with this regimen.¹⁴⁷ One option is enoxaparin 1 mg/kg q 12h and warfarin discontinued either before or immediately after pregnancy is diagnosed. Trough levels of enoxaparin must be 0.5 IU/mL. Peak antifactor Xa levels should ideally be 0.8–1.0 IU/mL, but levels can safely be obtained with the upper range of the peak antifactor-Xa level being 1.5 IU/mL. Weekly peak and trough antifactor-Xa levels should be obtained.

Antithrombin deficiency

Patients with antithrombin deficiency represent the highest thrombogenic risk. Patients with antithrombin deficiency should receive antithrombin concentrate if they experience an acute arterial or venous thromboembolism. Human antithrombin III (ATIII) is available as Thrombate III® (Bayer Healthcare), a sterile, preservative-free, nonpyrogenic, biologically stable, lyophilized preparation of purified human ATIII. The baseline antithrombin level is expressed as the percentage of the normal level based on the functional ATIII assay. The goal is to increase the antithrombin levels to those found in normal human plasma (around 100%).

Summary

Thromboembolism continues to remain a leading cause of maternal mortality. Prompt diagnosis and initiation of therapy are essential to optimize maternal and perinatal outcome. Doppler ultrasound is a valuable test in the evaluation of patients suspected of having a deep venous thrombosis, while ventilation–perfusion scanning and spiral CT scanning are key diagnostic tests in the evaluation of patients suspected of having a pulmonary embolus. In select cases, pulmonary angiography is a necessary diagnostic test. Suitable candidates for thrombophilia screening include those with a history of unexplained fetal loss at > 10 weeks; a history of severe preeclampsia/HELLP at < 36 weeks; a history of abruptio placentae; a history of IUGR ≤ 5th percentile; a personal history of thrombosis; and a family history of thrombosis. Unfractionated heparin and LMWHs are the mainstay of treatment and prevention strategies to reduce the risk of thrombotic complications. Venous thromboembolism should be treated with therapeutic anticoagulation for a minimum of 20 weeks, with prophylactic dosing extended to a minimum of 6 weeks postpartum. Assessment of risk factors for thromboembolism will optimize treatment and prevention strategies and minimize hemorrhagic complications associated with anticoagulation.

Key points

- 1 Venous thromboembolism is a leading cause of death in women. It is estimated that VTE complicates 1 in 1000 pregnancies, but the precise frequency of thromboembolism is probably underestimated.
- 2 Pregnancy is associated with significant elevations in a number of clotting factors. Fibrinogen concentration is doubled, and 20–1000% increases in factors VII, VIII, IX, X, XII, and von Willebrand factor are observed, with maximum levels reached at term. Protein S decreases in pregnancy. Mean protein S free antigen levels have been reported to be $38.9 \pm 10.3\%$ and $31.2 \pm 7.4\%$ in the second and third trimesters respectively.
- 3 The high-risk thrombophilias include antithrombin III deficiency, factor V Leiden homozygosity, and prothrombin gene (G20210A) mutation. Heterozygous factor V Leiden is associated with a 0.2% risk of thromboembolism associated with pregnancy, while heterozygous prothrombin gene mutation is associated with a 0.5% risk. Compound heterozygous factor V Leiden and prothrombin gene mutation is associated with a 4.6% risk of thromboembolism.

- 4 Antiphospholipid antibody syndrome is defined by the combination of VTE, obstetric complications, and antiphospholipid antibodies (APA). Antiphospholipid antibodies must be present on two or more occasions at least 6 weeks apart, and are immunoglobulins directed against proteins bound to negatively charged surfaces, usually anionic phospholipids.
- 5 Antiphospholipid antibodies have commonly been found in the general obstetric population, with one survey demonstrating that 2.2% of such patients have either IgM or IgG anticardiolipin antibodies, with most such women having relatively uncomplicated pregnancies.
- 6 There is a 5% risk of VTE during pregnancy and the puerperium among patients with APA despite treatment.
- 7 Suitable candidates for thrombophilia screening include those with a history of unexplained fetal loss at > 10 weeks; a history of severe preeclampsia/HELLP at < 36 weeks; a history of abruptio placentae; a history of IUGR \leq 5th percentile; a personal history of thrombosis; and a family history of thrombosis.
- 8 Initial thrombophilia evaluation should include: protein C (functional level); PS (functional/free antigen level); ATIII (functional level); factor V Leiden (PCR); prothrombin gene mutation 20210A (PCR); lupus anticoagulant; anticardiolipin antibody IgG, M, A; and platelet count. Other commonly ordered screens include MTHFR C677T mutation, fasting homocysteine level, and β 2-glycoprotein-I IgG, M, A.
- 9 Heparin and aspirin administration is the best strategy for the treatment of recurrent pregnancy loss associated with antiphospholipid antibody syndrome.
- 10 Therapeutic anticoagulation during the antepartum period should be reserved for patients with mechanical heart valves, VTE in the current pregnancy, high-risk thrombophilias [antithrombin III deficiency, factor V Leiden homozygosity, or prothrombin gene (G20210A) mutation] with a history of VTE or adverse pregnancy outcome.
- 11 Venous thromboembolism should be treated with therapeutic anticoagulation for a minimum of 20 weeks, with prophylactic dosing extended to a minimum of 6 weeks postpartum.
- 12 Appropriate treatment of the antiphospholipid antibody syndrome includes prophylactic anticoagulation and aspirin in the antepartum period and prophylactic anticoagulation alone in the postpartum period.
- 13 Dosing of therapeutic anticoagulation should be titrated to keep the PTT between 1.5 and 2.5 times control for unfractionated heparin and antifactor Xa levels between 0.6 and 1.2 U/mL for LMWH.
- 14 Because of its long half-life and the difficulty in reversing its effects, LMWH should be switched to unfractionated heparin at 36 weeks or earlier (if early delivery is anticipated).
- 15 Heparin anticoagulation may be restarted 3–6 h after vaginal delivery and 6–8 h after Cesarean delivery. Warfarin may be started postpartum day 1.
- 16 Therapeutic doses of LMWH or unfractionated heparin must be continued for 5 days and until the INR reaches the therapeutic range (2.0–3.0) for 2 successive days.
- 17 Heparin anticoagulation has been associated with thrombocytopenia (3%) and osteoporosis and, thus, patients should be managed with periodic platelet counts and calcium supplementation.
- 18 Fetal surveillance of patients on anticoagulation during pregnancy should include fetal growth evaluation every 4–6 weeks beginning at 20 weeks and fetal testing with nonstress tests and/or biophysical profiles beginning at 36 weeks, or earlier if clinically indicated.
- 19 Antepartum heparin is not necessary in patients without thrombophilia and prior VTE associated with a temporary risk factor.
- 20 Two useful agents in pregnancy when heparin cannot be administered are: danaparoid, a low-molecular-weight heparinoid; and fondaparinux, a synthetic heparin pentasaccharide.

Coagulation and hematological disorders of pregnancy

Carl P. Weiner and Chien Oh

Red blood cell disorders/anemia

Normal physiological change

Functionally, anemia is defined as an inadequate red blood cell (RBC) mass to deliver the necessary oxygen to peripheral tissues. Clinically, anemia is defined as a hemoglobin (Hgb) or hematocrit below the lower limit of a given range, typically the 10th percentile. Age, gender, race, and pregnancy are all factors influencing the normal range.^{1,2} The “normal” hemoglobin value for an adult female is 12–15 g/dL. There is an increase in blood volume during pregnancy with a disproportionate rise in plasma volume, causing a net RBC dilution.³ The Centers for Disease Control (CDC) defines anemia during pregnancy as a hemoglobin level less than 11 g/dL in the first and third trimesters and less than 10.5 g/dL in the second trimester.⁴ This useful definition takes into account the increase in plasma volume, but it does not consider other changes that may increase the hemoglobin, such as smoking or hemoglobin variants.

The effect of anemia on pregnancy is dependent on the severity and the cause of the anemia. It is not cost-effective to test every woman with anemia, given that the vast majority have mild anemia secondary to iron deficiency. A trial of replacement therapy should be initiated if the woman is not already taking prenatal vitamins. At the very least, a follow-up complete blood count should be obtained to insure improvement. In cases of more severe anemia (Hgb < 9.0 g/dL), a careful evaluation may reveal a diagnosis with implications for the mother, fetus, and future children (e.g., a hereditary hemoglobinopathy or a hemolytic anemia).

Laboratory workup of anemia

Anemia may result from decreased RBC production, increased RBC destruction/loss, or dilution. The evaluation of anemia during pregnancy is the same as that in the nonpregnant subject (Fig. 48.1). A complete medical history and physical

examination may improve the efficiency of the evaluation. Questions about onset, duration, previous medical history, family history, diet, occupational exposures, and drug history are all potentially important. Physical signs such as fever, bruising, jaundice, hepatomegaly, and splenomegaly will direct the clinician to consider more serious causes of anemia.

The basic laboratory evaluation begins with a reticulocyte count. If the reticulocyte count is low or normal, the assumption is that the anemia is secondary to decreased RBC production. There are three morphological categories: microcytic [mean corpuscular volume (MCV) < 80], normocytic (MCV 80–100), and macrocytic (MCV > 100). Additional laboratory tests are selected based on the grouping. An elevated reticulocyte count suggests an increased RBC loss secondary to either blood loss (acute or chronic) or hemolysis.

The most common cause of microcytic anemia is iron deficiency. Potential iron studies of value may include serum ferritin, total iron-binding capacity (TIBC), and plasma iron levels. Ferritin and plasma iron values are all reduced in iron deficiency anemia, whereas the TIBC may be elevated. Ferritin correlates best with the marrow iron stores. Transferrin levels fluctuate daily and are rarely useful for the evaluation of iron deficiency.⁵ In practice, a serum ferritin is all that is necessary. Iron supplementation should be withheld for 24–48 h before testing. A hemoglobin electrophoresis in search of a hemoglobinopathy is the next step should the ferritin suggest adequate iron stores. In general, the MCV is lower in subjects with hemoglobinopathies than in those with iron deficiency anemia. Both the anemia of chronic disease and sideroblastic anemias are also part of the differential.

Macrocytic anemia usually results from nutritional deficiencies of either folate or vitamin B12. Additional causes of macrocytic anemia include specific drugs that interfere with DNA synthesis. The term megaloblastic anemia is not synonymous with macrocytic anemia. Megaloblastic anemia specifically describes the presence of megaloblasts, distinctive large cells with abnormal-appearing nuclear chromatin that reflects aberrant DNA synthesis. Pregnancy increases the demand upon the body's reserve, and a patient with marginal

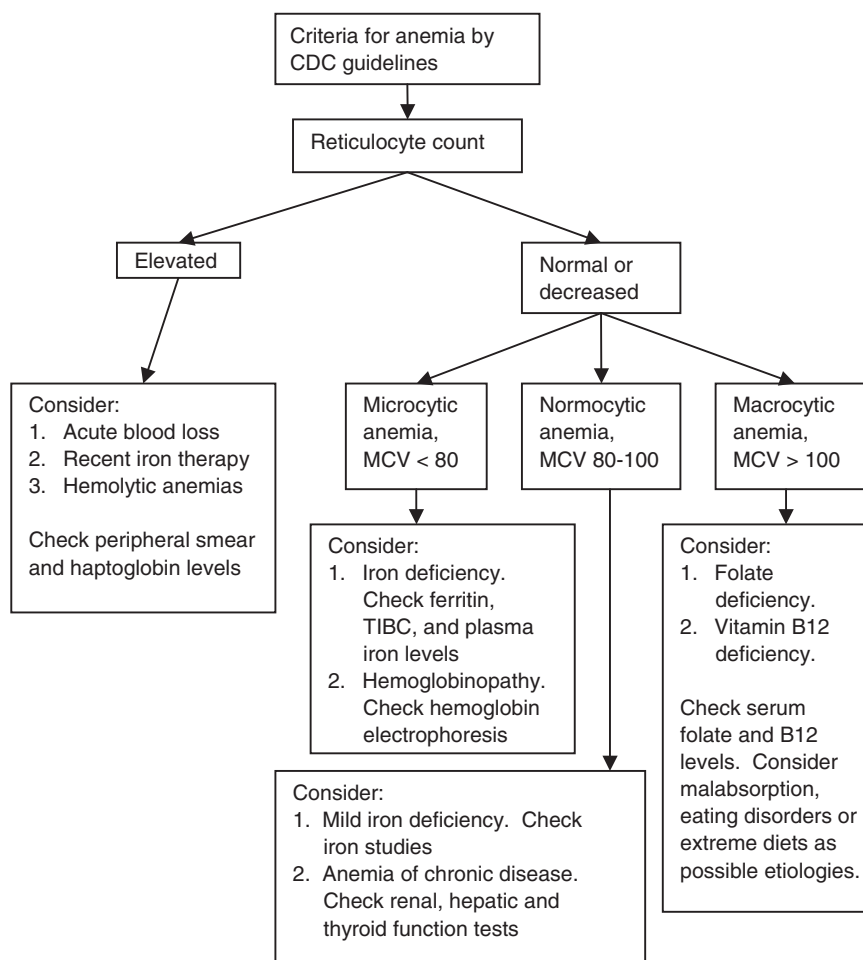

Figure 48.1 Workup algorithm for anemia.

stores may develop megaloblastic anemia. If macrocytic anemia is present, serum levels of B12 and folic acid need to be evaluated.

Normocytic anemia without reticulocytosis is perhaps the most difficult diagnosis because of the long differential. Etiologies include mild iron deficiency and anemia of chronic disease. In the absence of an identifiable, longstanding medical problem, thyroid, renal, and hepatic function tests should be considered.

If the reticulocyte count is elevated, recent blood loss (acute or chronic) or a hemolytic anemia must be considered in the differential diagnosis. Haptoglobin is a glycoprotein that binds free serum hemoglobin. Its level decreases as it binds hemoglobin and is subsequently cleared by the liver. A peripheral smear may also be useful, indicating hemolysis if schizo-

cytes or a hereditary hemolytic anemia (e.g., spherocytosis or sickle cell anemia) are seen. Thus, a low haptoglobin level and an abnormal peripheral smear may indicate hemolysis.

Nutritional anemias

Iron deficiency

The current CDC guidelines recommend 35 mg of elemental iron daily during pregnancy for patients who are not anemic. The effect of iron deficiency on pregnancy outcome is not entirely clear. The iron supplementation in patients who are deficient clearly raises hemoglobin and iron stores, but may not change perinatal outcome.⁶ Although several studies suggest an increase in low birthweight and preterm birth when

Table 48.1 Iron dextran protocol.

Indications: treatment of iron deficiency anemia in patients unable to absorb oral iron

Contraindications/precautions:

Hypersensitivity to iron dextran complex

Use caution in patients with asthma, hepatic impairment, and rheumatoid arthritis

Dosing recommendations:

Test dose:

Administer 0.5 mL i.v./i.m. prior to starting therapy

For the i.v. dose, dilute 25 mg/0.5 mL in 50 mL of NSS and infuse over 15 min

Have epinephrine at the bedside. Watch patient for 30 min after test dose for anaphylactic reactions

Dose (mL):

$0.0476 \times \text{weight (kg)} \times (14.8 - \text{observed Hgb}) + (1 \text{ mL}/5 \text{ kg to maximum of } 14 \text{ mL for iron stores})$

Maximum i.v. dose = 3000 mg (60 mL)

Dilute total dose in 250–1000 mL of NSS. Usual volume 500 mL

Maximum concentration = 50 mg/mL

Infuse over 1–6 h (no faster than 50 mg/min). Common infusion time over 2–3 h. Watch patient closely during first 25 mL for allergic reactions

Do not add iron dextran to TPN

Adverse effects:

CV flushing, hypotension, cardiovascular collapse (< 1%)

CNS dizziness, fever, headache (> 10%), chills (< 1%)

DERM urticaria, phlebitis (< 1%), staining of skin at i.m. site

GI nausea, vomiting, metallic taste, discoloration of urine (1–10%)

RESP diaphoresis (> 10%)

Note: diaphoresis, urticaria, fever, chills, and dizziness may be delayed 24–48 h after i.v. administration and 3–4 days after i.m. administration. Anaphylactic reactions occur generally in the first few minutes after administration

Pregnancy category: C

Monitoring: check blood pressure every 5 min during the test dose. Watch for allergic reactions and side-effects for 3–4 days. Monitor Hgb and reticulocyte count

CV, cardiovascular; CNS, central nervous system; DERM, dermatologic; GI, gastrointestinal; Hgb, hemoglobin; i.m., intramuscularly; i.v., intravenously; NSS, normal saline solution; RESP, respiratory; TPN, total parenteral nutrition.

the mother is iron deficient,^{7,8} it is not clear whether there is a cause and effect relationship. Fetal iron stores are not affected in most cases of iron deficiency anemia.^{9,10}

Iron deficiency is the most common cause of anemia in women of reproductive age, in part because of menstrual blood loss. The diagnosis is made when the ferritin level is low and the MCV is mildly decreased. Iron can be supplied as either ferrous sulfate (65 mg of elemental iron/325 mg) or ferrous gluconate (38 mg of elemental iron/325 mg) in a dose of 325 mg p.o. q.d. to t.i.d. Gastrointestinal transferrin becomes saturated after 7 days of twice-daily therapy. Supplemental vitamin C may increase iron absorption by enhancing the reduction of the ferrous to the ferric form, which increases intestinal absorption.

While elemental iron is best absorbed on an empty stomach, it may increase maternal nausea and vomiting. Many practitioners recommend taking the iron during or after meals, assuming that any decrease in absorption is offset by the excessive dose given. Constipation is common. There are many over-the-counter formulations that minimize constipation by including stool softeners.

Parenteral iron therapy may be of value when a patient fails to respond adequately to oral therapy. An example of an iron dextran protocol is listed in Table 48.1. A major risk of parenteral iron therapy is anaphylaxis, and anesthesia personnel should be readily available. Because of this risk, a firm diagnosis of severe iron deficiency should be made before administering parenteral iron.

Megaloblastic anemia

Megaloblastic anemia results from impaired DNA synthesis due to a deficiency of a required cofactor, usually either folic acid or vitamin B12. The diagnosis of megaloblastic anemia is suggested when the MCV is greater than 100 and there is hypersegmentation of the polymorphonuclear leukocytes. It is confirmed by serum testing. Folate supplementation with 2–4 mg daily should correct a folate deficiency. A B12 deficiency requires parenteral therapy with 1000 µg weekly for 6 weeks or until the deficiency has corrected. A prolonged vitamin B12 deficiency may lead to neuropathy and pernicious anemia. An isolated deficiency of either folic acid or B12 is

Table 48.2 Hemoglobin nomenclature.

Normal hemoglobins

Hgb A(A/A): normal adult hemoglobin. Composed of two α -chains and two β -chains

Hgb A2 (note: not the same as A/A): a less common, but normal form of adult hemoglobin. Composed of two α -chains and two δ -chains. Will be increased, typically $> 3.5\%$ in β -thalassemia

Hgb F: normal fetal hemoglobin. May be elevated in patients with β -thalassemias. Has a different oxygen dissociation curve than Hgb A

Hemoglobinopathies

Hgb SA: sickle cell trait. Defect in the β -chain. Little maternal clinical significance other than an increased risk of urinary tract infections.

Obvious genetic implications

Hgb SS: sickle cell anemia. Characterized by painful crises. Both maternal and fetal implications for poor outcome. Genetic implications

Hgb CA: hemoglobin C trait. Defect in the β -chain on one chromosome. No maternal clinical significance, mild microcytic anemia. Genetic implications for fetus if parent has child with partner with SA or SS or β -thalassemia

Hgb CC: hemoglobin C disease. Homozygous for Hgb C. No maternal clinical significance. More microcytic anemia compared with Hgb CA. Genetic implications for fetus if parent has child with partner with SA or SS or β -thalassemia

Hgb SC: hemoglobin SC disease. Milder form of sickle cell anemia, less crises when nonpregnant. Debatable whether maternal and fetal outcomes are worse, the same, or better than Hgb SS. Spleen is more functional, and hemolytic crises may be made worse because of acute splenic sequestration

Hgb EA: hemoglobin E trait. Defect in the β -globulin chain. Like Hgb C, no maternal clinical significance, mild microcytic anemia. Genetic implications for fetus if parent has child with partner with SA or SS or β -thalassemia. Found primarily in South-east Asians

Hgb EE: hemoglobin E disease. No maternal clinical significance. More microcytic anemia compared with Hgb EA. Genetic implications for fetus if parent has child with partner with SA or SS or β -thalassemia

Thalassemia disorders

α -Thalassemia minor. Deletion of one or two α -globulin genes. No maternal clinical significance, mild microcytic anemia. Genetic implications for fetus if parent has child with partner also with α -thalassemia minor

Hgb H: hemoglobin H. Composed of four β -globulin chains because of little α -chain. Hgb H disease patients have a three-gene deletion, and will have a mixture of Hgb H, Hgb A, and Hgb Bart. Severe hemolytic anemia, compatible with extrauterine life. Note that Hgb H disease is separate from Hgb H

Hgb Bart: hemoglobin Bart. Composed of four γ -globulin chains. Hgb Bart disease patients have no α -chain production at all because of a four-gene deletion. Not compatible with extrauterine life. No α -chain production at all

β -Thalassemia: decreased production of β -globulin usually because of a defect in the promoter region of the β -globulin gene. β^0 means that no β -chain is produced. β^+ means that little chain is produced. There are hundreds of mutations, and there is a spectrum of clinical findings and severity

β -Thalassemia major or Cooley's anemia: No fetal significance because Hgb F produced; however, after birth, neonate will fail to thrive and become anemic. Little maternal significance because females do not get pregnant often because of severity of disease

β -Thalassemia minor: heterozygote for β -thalassemia gene. Diagnosed because of elevated Hgb A2 levels ($> 3.5\%$). Hgb A2 has no β -chains

β -Thalassemia intermedia: applied to patients in between minor and major thalassemia in terms of clinical significance and severity

Combined abnormalities

Because the defects in hemoglobinopathies can combine with thalassemias, especially with β -thalassemias, a combined abnormality will be found on occasion, which may cause a hemolytic anemia (such as Hgb C/ β -thalassemia or Hgb E/ β -thalassemia). If β -thalassemia combines with Hgb S, a sickling hemoglobinopathy will result

rare: an extreme diet or malabsorption should be considered as potential etiologies.

Hemoglobinopathies

Normal adult hemoglobin consists of two α -chains and two β -chains (Hgb A), while the normal fetal hemoglobin consists of two α -chains and two γ -chains (Hgb F). Mutations, whether they result in decreased synthesis of hemoglobin (e.g., the thalassemias) or altered hemoglobin structure (structural hemoglobinopathies), can cause a wide range of problems. Hundreds of hemoglobin variants have been identified. These

hemoglobinopathies are genetic; there are implications for future childbearing. Hemoglobinopathy nomenclature can be confusing and is summarized in Table 48.2.

Thalassemias

The thalassemias are classified by the abnormal chain. The α -chain is encoded by four gene copies with two copies on each chromosome 16 ($\alpha\alpha/\alpha\alpha$). The severity of α -thalassemia depends on the number of gene copies that are deleted or defective. There is no clinical impact if one gene is missing. A mild microcytic anemia results if two genes are lost (α -thalassemia minor). A three gene deletion (hemoglobin H disease)

Blacks

The four possibilities of two Asian α -thalassemia minor parents result in one normal child, two α -thalassemia minor genotypes, and one Hemoglobin Bart disease.

results in a β -globulin tetramer called hemoglobin H (Hgb H). This disease is compatible with life, but is associated with profound hemolytic anemia. Hemoglobin Bart disease results if all four genes are missing; it is incompatible with life. Affected untreated fetuses die of hydrops, and their mothers often develop severe, early-onset preeclampsia. Survival is possible with repeated fetal transfusions followed by neonatal bone marrow transplantation.

In black people, α -thalassemia minor usually results from the loss of one gene from each chromosome ($\alpha-/ \alpha-$). In Asians, two gene deletions are more likely to occur on one chromosome ($\alpha\alpha/ -$). As a result, Asians have a higher risk of having a child with hemoglobin Bart or hemoglobin H disease (Fig. 48.2). A specific diagnosis should be made using DNA probes prior to further genetic counseling.

The β -thalassemias reflect mainly an underproduction of the β -globulin chains. Although less common, abnormalities of the β -globulin chain are transmitted in an autosomal dominant fashion.¹¹ β -Thalassemias occur in many parts of the world including the Mediterranean, Africa, southern China, the Malay Peninsula, and Indonesia. Over 150 mutations have been identified that affect the promoter region of the β -globulin gene.¹¹

The severity of the β -thalassemias is subclassified by the quantity of β -globulin produced. β^+ indicates that some β -

chains are being produced, whereas β^0 means that no chains are being produced. Homozygote patients for a defective β -thalassemia gene (thalassemia major or Cooley's anemia) have a markedly ineffective erythropoiesis and severe hemolysis. The disease is manifest postnatally, as the fetus produces hemoglobin F, which does not use the β -globulin chain. After birth, the hemoglobin type switches from hemoglobin F to the adult type and β -thalassemia appears. Heterozygotes for β -thalassemia require prenatal counseling, and antenatal diagnosis should be offered. Screening programs are effective in areas where β -thalassemia is prevalent. The combination during pregnancy of β -thalassemia with another abnormal hemoglobin variant can cause hemolytic and sickling anemias that confer higher rates of maternal and fetal morbidities and mortalities.

Sickle cell anemia, disease, and crisis

Sickle cell disease (SCD) is caused by an abnormal β -globulin resulting from a point mutation replacement of glutamic acid with valine at the sixth position (hemoglobin S). In times of stress (e.g., hypoxemia or infection), the abnormal β -globulin chain undergoes a conformational change causing sickling of the RBC. The sickled RBC have reduced deformability, causing microvascular occlusion, hemolysis, and increased susceptibility to infection.

A patient homozygous for hemoglobin S (hemoglobin SS) has sickle cell anemia. Heterozygote individuals (hemoglobin SA) have sickle cell trait. Other sickling hemoglobinopathies of importance during pregnancy include hemoglobin SC disease and hemoglobin S/ β -thalassemia. Patients with hemoglobin SC disease are double heterozygotes for both hemoglobin S and hemoglobin C. Hemoglobin C is a β -globulin chain that does not confer as much protection from sickling during pregnancy as does hemoglobin A. Hemoglobin S/ β -thalassemia is a “mild” form of sickle cell anemia that is managed similarly to hemoglobin SC disease. Sickle cell crises may occur especially in the third trimester with hemoglobin SC disease. Splenic infarction and vaso-occlusive disease do not occur outside pregnancy; as their spleens function normally, these patients can experience a more rapid and severe anemia than is expected with hemoglobin SS because of acute splenic sequestration. The management is similar to the patient with sickle cell anemia. Sickle cell trait individuals are not at risk of sequestration crises, nor are they at risk of excess obstetric complications with the exception of urinary tract infections.¹²

Pregnancy in a woman with one of these three sickling disorders exposes the mother and fetus to increased complication rates associated with vaso-occlusive disease, such as intrauterine growth restriction (IUGR), preterm labor, preeclampsia, and perinatal mortality.^{13–16} Complications of SCD are often exacerbated by pregnancy. The hallmark of disease is the sickle cell crisis in which the main complaint is severe pain in the back, chest, abdomen, and long bones. The treatment of sickle cell crisis has not changed significantly over the past decade, and consists of hydration, oxygenation, and pain relief. Pulmonary and urinary infections are common crisis triggers and must be ruled out. If present, infections must be treated aggressively. Alternative causes of pain should be considered. Symptomatic patients may benefit from transfusion therapy. General indications for transfusion are hemoglobin < 5g/dL, a hemoglobin drop of 30% or more, acute chest syndrome, and hypoxemia. The goal is to keep the hemoglobin S concentration at no more than 30–40% of the total hemoglobin. Regular antepartum fetal testing for fetal well-being and growth is strongly recommended.

Transfusion treatment for acute disease must be differentiated from prophylaxis, which is controversial. The goal of routine prophylactic transfusion therapy is to maintain the hematocrit above 25% and the hemoglobin S concentration below 60%. Two randomized trials compared routine transfusion versus transfusion only for an acute crisis.^{17,18} Patients transfused prophylactically had fewer crises and spent less time in hospital. However, perinatal outcome was not improved, and multiple transfusions were associated with a 25% rate of alloimmunization and a 20% prevalence of delayed transfusion reaction. The risks and benefits of routine prophylactic transfusion should be discussed with the patient. The use of prophylactic transfusion seems especially attractive in women with recurrent crises during pregnancy.

There are two particular complications of SCD that may be misdiagnosed during pregnancy. First, patients with SCD have a higher likelihood of a seizure disorder. Neurologic events secondary to SCD must be separated from pregnancy-associated events such as eclampsia. SCD neurologic events may result from thrombosis, hemorrhage, hypoxia, or meperidine use. Imaging studies and other clinical findings may help to differentiate neurologic events from complications of SCD and pregnancy.

The second SCD complication that may be misdiagnosed during pregnancy is acute chest syndrome (ACS). ACS is the leading cause of death in SCD patients and the second most common cause of hospitalization.¹⁹ The presentation is similar to pneumonia and consists of fever, cough, chest pain, pulmonary infiltrates, hypoxemia, and leukocytosis. Differentiation between the two diseases may be impossible. Pneumonia is implicated as a potential cause of ACS, being diagnosed concomitantly in 20% of ACS patients. The exact role of infection, thrombosis, or embolism in the development of ACS remains unclear. Exchange transfusion and antibiotic therapy is recommended if an SCD patient presents with severe respiratory symptoms; consultation with a pulmonologist and/or a hematologist would also be wise.

Routine screening for sickle cell trait is offered to at-risk women. If a woman is found to have sickle cell trait, her partner should be offered testing to determine whether the fetus is at risk of SCD. Women with an ‘at-risk’ pregnancy should be offered counseling and testing. Prenatal diagnosis can be accomplished by amniocentesis or by chorionic villus sampling (CVS). Many locales of high prevalence have effective postnatal screening programs in place.

Hemoglobin C and hemoglobin E

Hemoglobin C and hemoglobin E are both variants that cause microcytic anemia. Hemoglobin C is common in Africans, while hemoglobin E is more prevalent in South-east Asia. Patients may either have a trait form (hemoglobin CA, hemoglobin EA) or “disease” (hemoglobin CC, hemoglobin EE). The microcytic anemia is mild even in homozygous states and of little clinical significance. No additional maternal treatment or fetal testing is required. However, pregnant women are at higher risk for morbidity if they are a compound heterozygote. Hemoglobin E/ β -thalassemia and hemoglobin SE are each reported to cause a hemolytic anemia.²⁰

Hemolytic anemias

Structural, immunologic, and enzymopathic hemolytic anemias may each be exacerbated by pregnancy.

Structural hemolytic anemias include hereditary spherocytosis (HS), hereditary elliptocytosis (HE), hereditary pyropoikilocytosis (HPP), South-east Asian ovalocytosis (SAO), hereditary and acquired acanthocytosis, and hereditary and

acquired stomatocytosis. These diseases are distinguished by the morphology of the erythrocyte and result from defective erythrocyte membrane skeleton proteins that cause the deformed erythrocytes to be selectively sequestered and destroyed in the spleen.

Over 50 mutations affecting various membrane proteins such as spectrin or ankyrin are recognized. The symptomatology is varied and, in milder cases, the abnormality may not be identified until pregnancy. The diagnosis should be considered when unexplained splenomegaly, anemia, hemolysis, and unconjugated bilirubinemia present during pregnancy. The diagnosis is made using the osmotic fragility test. A peripheral blood smear may be falsely negative during a hemolytic episode when most of the abnormal erythrocytes have been destroyed in the spleen. Splenectomy is the treatment for the more severe forms of structural hemolytic anemia. However, splenectomy may be difficult during pregnancy and, if not feasible, supportive transfusion treatment and folate supplementation are recommended.

Autoimmune hemolytic anemia (AIHA) is caused by the production of antierythrocyte autoantibodies. Three forms of AIHA are described: IgM-mediated (cold-reactive) AIHA; IgG-mediated (warm-reactive) AIHA; and IgG Donath–Landsteiner antibody-mediated (paroxysmal cold-reactive). AIHA may occur as the primary disease, a secondary disease (often associated with hematological malignancy), or after the administration of various drugs. Penicillin, cephalosporins, and methyldopa are all implicated as causes of hemolytic episodes.^{21–25} Infection is another known trigger, but often no trigger is identifiable. The rate of autoantibody production increases during pregnancy over age-matched, nonpregnant subjects. Perhaps as a result, hemolytic episodes may be worse during pregnancy and improve after delivery. The diagnosis of AIHA is made after documentation of a hemolytic anemia associated with a positive direct Coombs’ test. The treatment is similar to that for immune thrombocytopenic purpura (ITP), and focuses on corticosteroid and intravenous immunoglobulin (IVIG) administration. A RBC transfusion should be performed if indicated, although crossmatching can be difficult because of the autoantibodies.

Glucose 6-phosphate dehydrogenase (G6PD) aids the synthesis of reduced glutathione (GSH), which protects the erythrocyte from oxidative damage. G6PD deficiency causes hemolytic anemia when the erythrocyte is exposed to oxidative stress, and is often associated with certain drugs such as nitrofurantoin and trimethoprim-sulfa, two drugs commonly used in obstetrics. The inheritance is X-linked. Up to 20% of African–American women are heterozygous and 1% homozygous.²⁶ The G6PD activity of heterozygote individuals ranges between deficient males and normal subjects, although some have little activity because of lyonization. Although rare, hemolytic episodes have been reported through “vertical” transmission.²⁷ Thus, while there is little chance that exposure to these drugs will cause a hemolytic episode in heterozygous carriers, pregnant and nursing women should avoid them

where possible in case their fetus/neonate is either an affected male or a homozygous female. The primary treatment during a hemolytic episode is to discontinue the offending drugs and transfuse if necessary.

Paroxysmal nocturnal hemoglobinuria (PNH) is a hematopoietic stem cell disorder in which the abnormal erythrocytes undergo intravascular complement-mediated hemolysis. The abnormal stem cells also produce abnormal leukocytes and platelets. The degree of hemolysis reflects the size of the abnormal clone, the degree of erythrocyte abnormality, and the amount of complement fixation. These patients are at increased risk for thrombotic events and for bone marrow failure. Prophylactic heparin should be considered beginning in the first trimester. One report described a 6% mortality rate in patients with PNH, primarily due to Budd–Chiari syndrome (thrombosis of the mesenteric vessels). The diagnosis is made after a positive Ham test demonstrates RBC vulnerability to complement. Referral to a hematologist is appropriate.

Coagulation disorders in pregnancy

Pregnancy changes in coagulation factors

Coagulation is a complex process that requires a delicate balance between prothrombotic factors and thrombolytic factors. Pregnancy tips the balance between thrombotic and thrombolytic factors toward a hypercoagulable state. Concentrations of both thrombotic and thrombolytic factors change during pregnancy, and most are estrogen dependent (Table 48.3). Fibrinopeptide A, the first peptide cleaved from

Table 48.3 Relative changes in coagulation factors in pregnancy.

Increased
Fibrinogen
vWF antigen, factor VIII function, and ristocetin cofactor activity
Factors III, XII, X
Fibrinopeptide A

Plasminogen
Prekallikrein

vWF, von Willebrand’s factor.

fibrinogen during thrombin-mediated fibrin generation, increases before the end of the first trimester.²⁸ The production of prostacyclin and nitric oxide, two potent inhibitors of platelet adhesion and aggregation, is increased by the endothelium during pregnancy.²⁹ Having a higher level of clotting activity predisposes the woman to disseminated intravascular coagulation (DIC) in pathologic states. Many of these same changes are observed in women taking oral estrogen-containing contraceptives. During pregnancy, a woman is four times more likely to suffer a thromboembolic event than a woman not taking oral contraceptives.³⁰ Each point of Virchow's triad is affected by pregnancy. Not only is there a relative hypercoagulable state, but there is also increased venous stasis in dependent limbs and vascular damage during delivery.

Laboratory workup of coagulation

A coagulation panel may include a complete blood count (CBC), prothrombin time (PT), partial thromboplastin time (PTT), fibrinogen, fibrin split products and, occasionally, a bleeding time. The bleeding time is a test of platelet function, and useful only in testing populations at risk of selected disorders. It should not be used as a test of overall coagulation function.³¹ The test itself is a poor predictor of surgical bleeding and a poor tool for following the response to therapy.³² Factors that influence the bleeding time include antiplatelet drugs, skin thickness, technologist skill and experience, and platelet count.

Thrombocytopenia

Thrombocytopenia may have major clinical consequences for the management of the pregnant woman. Although the diagnosis of thrombocytopenia is usually made on a routine CBC, a platelet disorder may be suspected should the patient present with spontaneous bleeding from mucous membranes, petechiae, easy bruising, and epistaxis. Concerns for maternal and fetal bleeding must be considered in determining a need for platelet transfusions, mode of delivery, and anesthesia.

The diagnosis of thrombocytopenia is made when the platelet count is below the lower laboratory reference limit. This value ranges among laboratories from 120 000 to 150 000/ μ L. However, management is not altered until the count drops below 100 000/ μ L. The "minimum" platelet count necessary for safely performing invasive procedures is listed in Table 48.4 as per the British Haematological Society.³³ Both they and the Red Cross agree that platelet transfusions are rarely indicated during Cesarean section when the count is above 50 000/ μ L and then only when there is evidence of abnormal function. Unnecessary platelet transfusion can lead to alloimmunization and may worsen immune-mediated thrombocytopenia.

The differential diagnosis for thrombocytopenia is listed in Table 48.5. The general causes of thrombocytopenia (like

Table 48.4 "Minimum" amount of platelets necessary for pregnancy-related procedures.

Procedure	Platelet count (/ μ L)
Minor surgery	> 50 000
Major surgery	> 80 000
Vaginal delivery	> 50 000
Cesarean section	> 80 000
Regional anesthesia	> 80 000

From the British Committee for Standards in Haematology General Haematology Task Force.³³ Note that these guidelines indicate 80 K as a cutoff. Discuss the use of regional anesthesia with the anesthesiologist who may have a different level of comfort if the platelet count is < 100 000.

Table 48.5 Differential diagnosis for thrombocytopenia.

Gestational thrombocytopenia
Immune thrombocytopenia purpura
Pregnancy-induced hypertension, HELLP syndrome
Drug-related thrombocytopenia (heparin, sulfonamides, see drug inserts)
Antiphospholipid syndrome, systemic lupus erythematosus
HIV infection
DIC, TTP, HUS
Pseudothrombocytopenia (laboratory artifact)

DIC, disseminate intravascular coagulation; HELLP, hemolysis, elevated liver enzymes, and low platelets; HIV, human immunodeficiency virus; HUS, hemolytic uremic syndrome; TTP, thrombotic thrombocytopenic purpura.

anemia) can reflect either increased platelet destruction/consumption or decreased production. Increased destruction/consumption accounts for most thrombocytopenia. The evaluation of thrombocytopenia begins with a careful history attempting to exclude a drug-induced thrombocytopenia, a CBC to rule out a pancytopenia, and a review of the peripheral smear to rule out pseudothrombocytopenia and microangiopathy. In a pregnant woman with no other medical or pregnancy problems, the most common causes of maternal thrombocytopenia are gestational thrombocytopenia (GT) and immune thrombocytopenic purpura (ITP).

Gestational thrombocytopenia

GT affects approximately 8% of all pregnancies.³⁴ The precise cause is unknown, although some authors attribute it to complement-mediated destruction of platelets as opposed to the antibody-mediated destruction that occurs in ITP.³⁵ It has no affect on pregnancy outcome. Neuraxial anesthesia is safe for the laboring patient with an unexplained thrombocytopenia with a platelet count from 100 000 to 120 000/ μ L.³⁶ Neurax-

ial anesthesia has also been administered when the platelet count was between 50 000/ μ L and 100 000/ μ L without complication,³⁶ although the anesthesiologist may decline to place an epidural catheter.

Immune thrombocytopenia purpura

ITP is the result of antibody-mediated destruction of platelets. The bone marrow responds to the shortened platelet lifespan by increasing production. The result is megakaryocyte hyperplasia in bone marrow smears and characteristically large (i.e., young) circulating platelets. The definitive cause of ITP was demonstrated by Harrington et al.³⁷ who observed that plasma from patients with ITP caused a severe thrombocytopenia when transfused into normal subjects. These autoantibodies bind to the platelet membrane glycoprotein, causing the platelets to be destroyed rapidly. The site of clearance is most likely in the spleen, as splenectomy induces a remission in about 60% of patients with chronic ITP, although there is some evidence for intravascular destruction.³⁸ Splenectomy is not generally recommended during pregnancy, but can be performed in the second trimester. Splenectomy does not remove the perinatal risk, and may actually increase it.

The goal of management during pregnancy is a platelet count of at least 50 000/ μ L by delivery. A platelet count of less than 20 000/ μ L is associated with spontaneous bleeding, and some form of treatment is necessary. Treatment of asymptomatic women with platelet counts between 20 000/ μ L and 50 000/ μ L who will not be delivering in the near future is unnecessary in most instances.

The first-line treatment is systemic corticosteroid administration. About two-thirds of patients with ITP will respond at least partially to corticosteroids.³⁹ The mechanism of action is unclear. Corticosteroids both increase the production and reduce the rate of platelet destruction.^{40,41} Prednisone is initially given at a dosage of 0.5–1.0 mg/kg/day in divided doses; it may take 3–10 days before a response is noted. If the platelet count rises to acceptable levels, the dose is tapered over a 2- to 4-week interval to the minimal effective dose.

In patients refractory or intolerant to corticosteroids, IVIG will often stimulate a transient increase within 48 h. Some centers use a regimen of IVIG of 1 g/kg/day for 1–2 days (Table 48.6). However, the dose most often described in the obstetric literature is 0.4 g/kg/day for 5 days. A single, randomized trial in nonpregnant subjects observed no difference between the two regimens. Approximately 80% of patients will respond to IVIG, and the duration of the response is 2–3 weeks.⁴² Pregnant women who fail corticosteroids and IVIG and who are in need of immediate treatment should be evaluated by a hematologist. Remaining therapeutic options include high-dose intravenous methylprednisolone with or without IVIG or azathioprine or splenectomy.

Many of the antibodies associated with ITP are IgG and can thus cross the placenta. The prevalence of fetal platelet counts at birth of less than 50 000/ μ L is 10–15%. It is less than

Table 48.6 IVIG protocol.

Indications:

- Treatment of ITP refractory to corticosteroid use
- Treatment of neonatal alloimmune thrombocytopenia purpura

Dosing recommendations:

- Usual dosage is 1 g/kg. IVIG solution often comes as 3% solution
- 30 mL/h \times 15 min, then
- 60 mL/h \times 30 min, then
- 120 mL/h \times 30 min, then
- 240 mL/h until completion of infusion.

Monitoring:

- Monitor maternal heart rate, respirations, blood pressure, and fetal heart rate
- Preinfusion baseline, then
- Every 15 min for first hour, then
- 2 \times per h, then
- Every 2 h until infusion is complete
- Anaphylaxis precautions: diphenhydramine, epinephrine, and hydrocortisone readily available for each dose

Adverse reactions:

- Chills, nausea, flushing, headache, myalgia, fatigue
- Anaphylaxis: generalized flush, urticaria, apprehension, dizziness, palpitations, respiratory distress, hypotension, arrhythmia

20 000/ μ L in 5%.^{43,44} Unlike alloimmune thrombocytopenia, the fetus of a woman with ITP is at no or minimal risk of a hemorrhagic complication *in utero* and during delivery.⁴⁵ ITP is an indication for neither a fetal blood sample nor a Cesarean delivery. However, prudence dictates the avoidance of either vacuum or forceps delivery. The morbidity of ITP occurs in the newborn period. Platelet counts may continue to decline during the first week of life.

Differentiating between GT and ITP

No test differentiates between GT and ITP. A prior history may suggest ITP, but the diagnosis remains problematic. Testing for antiplatelet antibodies to make the diagnosis of ITP is unreliable and is not recommended by the American College of Obstetricians and Gynecologists (ACOG). Many authors and ACOG take a pragmatic approach and suggest using the platelet count to differentiate between the two.⁴⁵ The diagnosis of GT is made when no other maternal disease can be identified and the platelet count is greater than 70 000/ μ L; the diagnosis of ITP is made when the platelet count is less than 100 000/ μ L. Although these ranges overlap, it has no clinical relevance. A platelet count of 70 000/ μ L unassociated with bleeding requires no treatment. The patient may receive routine prenatal care with platelet counts every month or two. A platelet count below 50 000/ μ L with no other identifiable cause can be attributed to ITP. The diagnosis of ITP is strengthened when the maternal platelet count remains below 100 000/ μ L for 3 months after delivery, and/or the neonate has thrombocytopenia without a difficult delivery.

Alloimmune thrombocytopenic purpura (AITP)

AITP is the platelet form of rhesus (Rh) disease. However, the behavior of the disease differs from RBC alloimmunization in two key ways. First, approximately half of affected fetuses occur in the first pregnancy. Second, there is no reliable screening method for AITP. The initial diagnosis is often made when a thrombocytopenic neonate is born to a woman with a normal platelet count. On occasion, the presentation is fetal intracranial hemorrhage. It remains unclear as to why the risk of hemorrhage is essentially nonexistent in the fetus affected by ITP and relatively high in the fetus with AITP despite equal platelet counts. The workup for AITP includes maternal and paternal platelet typing for human platelet antigen phenotype. At least 10 platelet antigens have been implicated in AITP, with human platelet antigen 1a accounting for most cases.

Because of the risk of intracranial hemorrhage, aggressive therapy is used to prevent severe fetal thrombocytopenia. Treatment options used in the past include corticosteroids, IVIG administration to both the fetus and the mother, and fetal platelet transfusion. No treatment strategy is perfect, although maternal treatment with high doses of IVIG weekly has consistently eliminated the risk of fetal hemorrhagic events.⁴⁶ These patients should be referred to a fetal medicine specialist for management.

The only reliable way to check the fetal platelet count is by cordocentesis. One management approach is to withhold IVIG until a fetal blood sample at 22–24 weeks confirms thrombocytopenia. The fetal platelet type should be determined if the count is normal. An alternative approach is to initiate IVIG around 12 weeks' gestation, and then to check the fetal platelet count around 26 weeks. This allows time for additional therapy if the fetus is found to have thrombocytopenia despite the IVIG. A final fetal platelet count is obtained around the time at which pulmonary maturity is likely and before the onset of labor to determine whether labor is contraindicated (generally considered to be when the count is < 50 000/ μ L).⁴⁷ Should the fetus be thrombocytopenic, a platelet transfusion can be performed and labor induced the following day.

Other causes of thrombocytopenia

Preeclampsia is another common cause of thrombocytopenia during pregnancy. The mechanism here is accelerated platelet destruction, although many potential etiologies have been suggested. The thrombocytopenia associated with hemolysis and elevated hepatic transaminases appears to respond to corticosteroid treatment.⁴⁸ Twelve milligrams of either dexamethasone or betamethasone given every 12 h for two doses improves platelet counts.⁴⁹ Additional doses of dexamethasone (6 mg intravenously q 12 h for two doses after the initial doses) have also been used. This strategy may help to increase the time available for fetal pulmonary maturity and reduce the risk of delivery. The platelet counts rise within a week of deliv-

ery when the explanation is preeclampsia. Preeclampsia is not a cause of fetal thrombocytopenia.

Thrombotic thrombocytopenic purpura (TTP) is characterized by a fever, microangiopathic hemolytic anemia, thrombocytopenia, central nervous system (CNS) symptoms, and renal impairment. Not all elements of the classic pentad must be present simultaneously. Hemolytic uremic syndrome (HUS) is clinically similar to TTP, only having a milder thrombocytopenia, no CNS changes, and worse renal dysfunction. Clearly, the outcomes and response to therapy are different, suggesting that they share only elements of the same pathophysiologic pathway. The diagnosis is often difficult in the third trimester when the default diagnosis is preeclampsia. The principal treatment for both TTP and HUS is plasmapheresis, which has increased survival by up to 90%.^{50,51} Plasma exchange should be initiated without delay once the diagnosis is made, exchanging one plasma volume in the first 24 h. If there is no or an inadequate response, corticosteroids (1–2 mg/kg/day of prednisone or equivalent) are added.

Other platelet disorders

Thrombocytosis

Thrombocytosis is defined as a platelet count greater than 450 000/ μ L. Most thrombocythemias are secondary to another process (Table 48.7). The diagnosis of essential thrombocytosis (ET) is suspected when all other underlying disorders appear to have been ruled out but the thrombocytosis persists. ET is a myeloproliferative disorder, and the diagnosis is made from a bone marrow aspiration. Thrombocytosis has a theoretical adverse effect on pregnancy because of a higher risk of thrombosis, and most reports suggest the use of aspirin (81 mg) to improve pregnancy outcome.⁵²

Table 48.7 Differential diagnosis for thrombocytosis.

Primary causes

- Myeloproliferative syndromes
- Essential thrombocytosis
- Polycythemia vera
- Chronic myelogenous leukemia
- Myelofibrosis

Secondary causes

- Infectious diseases
- Inflammatory diseases
- Rebound after recovery from thrombocytopenia
- Asplenia
- Iron deficiency
- Parturition
- Exercise

Platelet qualitative disorders

Poor platelet function can also result from inherited disorders such as Bernard–Soulier syndrome or Glanzmann thrombasthenia. These result from an abnormal platelet surface glycoprotein that interferes with platelet adherence and/or aggregation. These rare diseases are treated by platelet transfusions in case of hemorrhage. Both are identifiable prenatally by DNA studies.

A more common cause of qualitative platelet dysfunction is drug related, notably aspirin ingestion. Aspirin inhibits the platelet release reaction and prevents platelet aggregation by the irreversible acetylation of platelet cyclo-oxygenase (average platelet lifespan is 10 days). Impairment may occur after doses as small as 40 mg.⁵³ Larger, “clinical” doses of 60 mg/day are used extensively during pregnancy and are not associated with increased rates of maternal or neonatal bleeding complications.⁵⁴ This dose is also safe for neuraxial anesthesia. Other commonly used drugs in obstetrics that may affect platelet function include penicillin, cephalosporins, nitrofurantoin, nonsteroidal anti-inflammatory drugs (NSAIDs), calcium channel blockers, and ketanserin.⁵⁵

Inherited bleeding disorders

Inherited disorders of some soluble clotting factors will cause a hemorrhagic coagulopathy of varying degrees. The most commonly encountered inherited coagulopathy during pregnancy is von Willebrand’s disease (vWD). Other deficiencies of the coagulation cascade described during pregnancy include deficiencies in factor X, factor XI, and factor XIII. These deficiencies are rare and can be treated with blood products if complicated by clinically significant bleeding (Table 48.8).

von Willebrand’s disease

vWD is the most common inherited coagulopathy of clinical significance in the pregnant woman, affecting approximately 0.5–1% of the general population.⁵⁶ Von Willebrand’s factor (vWF) binds platelets to the damaged endothelium, and is a necessary cofactor for stabilizing factor VIII. vWD is divided into three types. The quantitative deficiency of normal vWF is called type 1. Abnormal structure and function but a normal concentration of vWF is called type 2. It can be further subdivided into type 2A and 2B and differentiated by how effectively the vWF binds to platelets. In type 2B, the vWF binds platelets very effectively, but does not bind endothelium. Type 3 vWD is a complete deficiency of vWF. It is important to differentiate among the three types to facilitate the prevention or treatment of bleeding, especially in labor or postpartum. Bleeding during pregnancy is uncommon. The greatest risk is postpartum as the pregnancy-stimulated rise in factor VIII component factors declines.

Medical management of vWD includes either vasopressin or blood products (cryoprecipitate or fresh frozen plasma). Vasopressin was developed to treat diabetes insipidus, but its extrarenal actions stimulate endothelial cells to release vWF and factor VIII. Type 1 vWD is the most common form of vWD and is responsive to vasopressin. Vasopressin can be administered either parenterally (0.3 µg/kg intravenously over 30 min) or intranasally (150 µg; one spray in each nostril or, if the patient is < 50 kg, one spray in one nostril). It is given at the onset of active labor to women with low vWF levels, and repeated every 12 h. Vasopressin is not as effective in patients with type 2A vWD, and it is contraindicated in patients with type 2B vWD. The administration of vasopressin to these patients will cause thrombocytopenia without improving clot function. Vasopressin has no effect on type 3

Table 48.8 Administration of blood products for coagulation deficiencies with major bleeding.

Disorder	Therapeutic material	Loading dose	Maintenance dose
Hemophilia A (factor VIII deficiency)	Cryoprecipitate	3.5 bags/10 kg	1.75/10 kg every 8 h for 1–2 days, then every 12 h
Hemophilia B (factor IX deficiency)	Purified factor IX	60–70 U/kg	20–40 U/kg every 24 h
vWD	Cryoprecipitate	Not usually required	1 bag/10 kg daily
Fibrinogen deficiency	Cryoprecipitate	1–2 bags/10 kg	1 bag/10 kg every other day
Prothrombin deficiency	FFP	15 mL/kg	5–10 mL/kg daily
Dysprothrombinemia	Purified prothrombin complex	20 U/kg	10 U/kg daily
Factor V deficiency	FFP	20 mL/kg	10 mL/kg q12–24 h
Factor VII deficiency	FFP	20 mL/kg	5 mL/kg q6–24 h
Factor X deficiency	FFP	20 mL/kg	5–10 mL/kg daily
Factor XI deficiency	FFP	20 mL/kg	5 mL/kg q6–24 h
Factor XIII deficiency	FFP	5 mL/kg q1–2 weeks	Not usually required

FFP, fresh frozen plasma.

vWD. The administration of blood products will be necessary for patients in whom vasopressin is ineffective or contraindicated.

Hemophilia

Factor VIII deficiency (hemophilia A) and factor IX deficiency (hemophilia B) are both sex-linked recessive traits and rarely cause significant maternal bleeding. Carriers of hemophilia A and B, however, should have a coagulation profile and factor VIII activity level tested. An activated PTT does not become abnormal until the factor VIII level is < 25%. As a result, some women at risk may be missed. The severity of hemophilia is classified by the activity levels of factors VIII and IX. Individuals with mild hemophilia have activity levels of 6–40%, those with moderate hemophilia 1–5%, and with severe hemophilia < 1%. If a carrier has clinically low factor VIII or IX level, they can be treated with either fresh frozen plasma or cryoprecipitate.

Male infants born to carriers have a 50% chance of having hemophilia. Prenatal detection is possible using DNA-based techniques. Carrier detection is based on family history, coagulation-based assays, and DNA testing. The gene mutation can be determined either by testing a known affected family member or after sequencing the maternal factor VIII or IX. Once the specific gene mutation is known and the mother is determined to be a carrier, amniocentesis or CVS can be performed to determine whether the fetus is affected. Without knowing the specific gene mutation, a hemophilia genetic test is less than ideal because of cost and a delay in results, although 98–99% of the hemophilias can be detected in this way. Known affected fetuses can safely deliver vaginally, but scalp monitoring and operative vaginal delivery should be avoided.

Disseminated intravascular coagulation (DIC)

DIC remains a serious obstetric complication. DIC may be compensated, hypercompensated, or decompensated. Hypercompensated DIC is associated with thrombosis. In decompensated DIC, excess thrombin generation results in the circulation of free thrombin, stimulating widespread microvascular thrombosis. Decompensated DIC can cause tissue ischemia and organ damage. Clinical laboratory findings include prolongation of the PT and activated PTT, decreased fibrinogen, elevated fibrin split products, an abnormal platelet count, and schistocytosis on a peripheral blood smear. A compensated DIC such as that which occurs in women with preeclampsia can become decompensated because of either worsening disease or another complication. Other causes of decompensated DIC include abruptio placentae, amniotic fluid embolus, saline abortion, dead fetus syndrome, and septic shock. Hemorrhage can also trigger a

decompensated DIC secondary to hypovolemia/hypoxemia. Management of DIC consists of two general steps. First, identify and remove the underlying pathological process and, second, prevent hypovolemia and hypoxemia. Occasionally, it is necessary to replace coagulation factors.

Abruptio placentae is the most common obstetric cause of decompensated DIC. The direct cause of clotting cascade activation is unclear, but may be related to the process of placental separation itself or the release of tissue thromboplastin. The diagnosis of a placental abruption associated with clinical laboratory abnormalities is an indication for rapid delivery. If the fetus is not in distress and the laboratory abnormalities are mild, a vaginal delivery may be considered, especially if the labor has occurred spontaneously. In cases of more severe laboratory abnormalities, a controlled Cesarean section should be considered with adequate blood replacement products available.

Intrauterine fetal demise (IUFD) routinely causes a compensated DIC that on rare occasions becomes decompensated. Clinical laboratory parameters do not change for at least 3–4 weeks after the demise, and some 80% of women with an IUFD will labor spontaneously within 2–3 weeks.⁵⁷ However, most patients do not wish to wait until spontaneous labor, and delay can compromise the search for a cause of the fetal death. Thus, even medically stable patients are typically delivered soon after the diagnosis.

One challenge is the singleton death in a preterm multiple gestation. There is no *a priori* indication for delivery regardless of whether the placentation is monochorionic or dichorionic. Delivery places the surviving fetus at risk from complications of prematurity. Close monitoring of the pregnancy with coagulation panels is recommended as well as other antenatal surveillance techniques. Concerns of neurologic and other organ damage to the surviving fetus from embolizing “thromboplastic” material from the dead fetus have been refuted. Should the placentation be monochorionic, perimortal blood pressure fluctuations cause shunt reversals and hypovolemia/hypotension in the survivor, making the risk of morbidity high.

Amniotic fluid embolism (AFE) is a relatively rare event, complicating approximately 1 in 250 000 pregnancies.⁵⁸ Unfortunately, the associated mortality rate ranges from 50% to 80% and has been attributed to 13–30% of all maternal mortality in industrialized countries. The pathophysiology of AFE is not well understood, in great part because of its rarity and unpredictability. The current theory is that the clinical picture of AFE reflects an anaphylactic response to materials present in the amniotic fluid. The term anaphylactoid syndrome of pregnancy is sometimes used synonymously and may represent a more accurate description of the pathophysiology underlying AFE. AFE occurs classically in the late stages of a rapid labor and presents with acute and profound hypotension and hypoxia (phase 1), followed in 0.5–2h by a coagulopathy (phase 2). Only 50% of patients survive phase 1. A standardized management protocol has not been estab-

lished, but therapy focuses on cardiovascular and ventilatory support. Basic and then advanced life support protocols should be initiated immediately in phase 1. A pulmonary artery catheter is essential, especially when pressors are needed to maintain the blood pressure and cardiac output. A perimortem Cesarean section or, if possible, an operative vaginal delivery should be considered immediately in phase 1 to preserve the neurologic status of the fetus. If a patient survives phase 1, she is at risk of developing severe coagulopathy and uterine atony. The administration of blood and blood products may be necessary to correct the coagulopathy if the bleeding cannot be controlled.

Septic abortion is another pregnancy-related diagnosis associated with decompensated DIC. Bacterial endotoxin is most likely the initiating mediator of DIC.^{59,60} Aggressive antibiotic treatment and evacuation of the uterus are the primary treatments. Removal of the source of infection leads to rapid resolution of the coagulopathy.

Heparin is useful for the treatment of DIC in specific scenarios. It requires a high enough antithrombin III level for function. Heparin is useful with an IUFD and possibly to prevent septic shock after a septic abortion has been evacuated. It is not appropriate in the setting of placental abruption and/or preeclampsia. It is unknown whether the use of heparin will prevent the coagulopathy associated with AFE.⁶¹ The dose of heparin described for the treatment of DIC with IUFD is 5000–10000U subcutaneously b.i.d. Therapeutic doses of heparin where the activated PTT is 1.5 time normal may be considered after the treatment of the underlying disorder is completed or if there is evidence of thrombosis causing endorgan damage.⁶² Fortunately, this scenario is uncommon, and consultation with a hematologist should be considered first. Other forms of therapy such as antithrombin, gabexate mesilate, and activated protein C are currently being studied as possible options for the treatment of obstetric DIC instead of heparin.⁶³

Thrombophilias in pregnancy

The possible effects of thrombophilias on pregnancy outcome have attracted interest and controversy. Unresolved questions include who should be tested, how the results are interpreted, and what therapeutic options are effective and indicated. Thrombophilias have variously been purported to increase the risks of IUGR, placental abruption, severe preeclampsia, fetal death, maternal deep venous thrombosis (DVT), and pulmonary embolus.^{64–67} Thrombophilias may be inherited or acquired, and major or minor in their impact.

Acquired thrombophilias

Perhaps the most common acquired thrombophilias are the group of antiphospholipid antibodies that includes the lupus anticoagulant (LAC) and anticardiolipin antibodies (ACA).

First identified obstetrically by Nilsson et al. in 1975,⁶⁸ these antibodies can be associated with both venous and arterial thrombosis in nonpregnant individuals. The diagnosis is suspected when paradoxically there is an elevated activated PTT that does not correct after a 1:1 mix with normal plasma, or when there is a false-positive rapid plasma reagin (RPR). The definitive diagnosis is made by repeated positive titers of antiphospholipid antibodies. A positive titer does not mandate treatment as there is a subset of women who have no obstetric complications despite a positive test. The diagnosis of obstetric antiphospholipid syndrome (APS) is made only when these antibodies are associated with recurrent pregnancy loss or a history of thrombosis (Table 48.9). The mechanisms responsible for the poor neonatal outcome remain to be determined, although thrombosis (either acute or chronic) at the maternal–fetal interface is believed to be involved.

Women with obstetric APS benefit from treatment. Several regimens have been compared in randomized trials. Lassere and Empson⁶⁹ summarized 13 randomized and quasirandomized trials. The studies were hampered by small sample sizes, absence of blinding to treatment, a lack of placebo control subjects, and highly variable disease definitions. The current recommendation based on these trials is to initiate in the early second trimester a combination of heparin (5000U to 10000U subcutaneously b.i.d.) plus low-dose aspirin (81 mg q.d.). Prednisone does not improve outcome and may actually be associated with a higher rate of preeclampsia.

Inherited thrombophilias

The inherited thrombophilias are listed in Table 48.10. They can be subgrouped into major or minor groups depending upon their impact on pregnancy. Inherited thrombophilias include factor V Leiden (activated protein C resistance), deficiencies in protein C, protein S, and antithrombin (III) activity, prothrombin gene mutation (G20210A), and hyperhomocysteinemia. Other inherited thrombophilias exist, such as plasminogen activator inhibitor mutation, elevated factor VIII levels, “sticky platelet” syndrome, and others, but their impact on pregnancy is not well described.

Factor V Leiden is the most studied. This mutation is common in northern Europeans (5–9%) and may well account for the increased risk of thrombosis in women taking third-generation oral contraceptives. This mutation prevents activated factor V from being neutralized by the activated protein C/protein S complex. Other mutations cause activated protein C resistance, and some authors suggest testing for activated protein C resistance, the functional assay, before checking for the factor V Leiden mutation. This suggestion may not be applicable to pregnancy, however, as pregnancy may increase activated protein C resistance, and factor V Leiden accounts for most of the activated protein C resistance mutations.^{70,71} The significance of factor V Leiden in pregnancy has been extensively debated. It is generally agreed that heterozygosity increases the likelihood of maternal thrombosis. However,

Table 48.9 Diagnostic criteria for antiphospholipid syndrome (APS).

Definite APS is considered to be present if at least one of the clinical criteria and one of the laboratory criteria are met.	
Clinical criteria:	
Vascular thrombosis:	one or more clinical episodes of arterial, venous, or small-vessel thrombosis in any tissue or organ confirmed by imaging or Doppler studies or histopathology, with the exception of superficial venous thrombosis. For histopathologic confirmation, thrombosis should be present without inflammation in the vessel wall.
Pregnancy morbidity:	(1) one or more unexplained deaths of a morphologically normal fetus beyond the 10th week of gestation with normal fetal morphology documented by sonography or by direct examination, or (2) one or more premature births of a morphologically normal neonate at or before the 34th week of gestation because of severe preeclampsia or eclampsia, or severe placental insufficiency, or (3) three or more unexplained consecutive spontaneous abortions before the 10th week of gestation with maternal anatomic or hormonal abnormalities and paternal and maternal chromosomal abnormalities excluded.
Laboratory criteria:	
Anticardiolipin antibody of IgG and/or IgM isotype in blood,	present in medium or high titer, on two or more occasions, at least 6 weeks apart, measured by a standardized enzyme-linked immunosorbent assay (ELISA) for β 2-glycoprotein-I-dependent anticardiolipin antibodies.
Lupus anticoagulant present in plasma on two or more occasions at least 6 weeks apart,	detected according to the International Society of Thrombosis and Hemostasis guideline/steps: (1) prolonged phospholipid-dependent coagulation demonstrated on a screening test (activated PTT, kaolin clotting time, dilute Russell's viper venom time, dilute PT, textarin time), (2) failure to correct the prolonged coagulation time on the screening test by mixing with normal platelet poor plasma, (3) shortening or correction of the prolonged coagulation time on the screening test by addition of excess phospholipids, (4) exclusion of other coagulopathies, e.g., factor VIII inhibitor or heparin as appropriate.

Table 48.10 Inherited thrombophilias.

“Greater” thrombophilias: consider therapeutic anticoagulation	
Compound heterozygosity with factor V Leiden and prothrombin G20210A gene mutation	
Homozygosity of factor V Leiden and prothrombin gene mutations	
Antithrombin deficiency (activity levels < 70%)	
“Lesser” thrombophilias: consider prophylactic anticoagulation	
Protein C deficiency	
Protein S deficiency	
Factor V Leiden	
Prothrombin G20210A gene mutation	
Antiphospholipid antibodies	
Other thrombophilias:	
Hyperhomocysteinemia	
Plasminogen activator inhibitor mutation	

there is ongoing debate as to whether heterozygosity is associated with recurrent pregnancy loss, placental abruption, and IUFD.⁷² Heterozygosity for factor V Leiden does not diminish life expectancy and, in the absence of thrombosis, nonpregnant individuals do not require lifelong anticoagulation.⁷³

Deficiencies in protein C, protein S, and antithrombin decrease the body’s ability to impede the coagulation process. Protein C and protein S deficiencies are autosomal-dominant traits that cause either quantitatively or qualitatively decreased activity. They are produced in the liver, and the activity levels are lowered by warfarin or acute thrombosis. Testing protein

C and S activities should occur at least 10 days after cessation of warfarin and not in the setting of acute thrombosis. If warfarin is started in a patient who has protein C or S without heparinization, this may cause enough of a decrease in activity to cause thrombosis. For protein C, activity levels of less than 55% off warfarin are suspicious of a genetic abnormality; ranges of 55–65% are borderline.⁷⁴ Protein C activity levels are unchanged by pregnancy. However, protein S activity and antigen are decreased by pregnancy; antigen levels < 60% are suspicious of a genetic abnormality in the nonpregnant subject not taking warfarin.⁷⁵ The analogous figure during pregnancy is < 20–25%.^{76,77}

The antithrombin molecule binds to serine protease clotting factors. After a conformational change, antithrombin becomes a potent anticoagulant, inhibiting factors IXa, Xa, XIa, and XII, and accelerates the dissociation of the tissue factor–factor VIIa complex. The antithrombin deficiency is divided into two types. In type I, there is a quantitative decrease in antithrombin. In type II, there is a mutation affecting the qualitative activity of antithrombin. The activity levels, in general, do not change significantly during pregnancy, although some decrease in activity has been reported in the third trimester. This inherited thrombophilia is considered by many as the most thrombogenic of the inherited thrombophilias. Antithrombin activity levels of heterozygotes range from 40% to 70%. Homozygotes are rare. Acute thrombosis, heparin, and systemic disease may decrease antithrombin activity during pregnancy, whereas warfarin may increase antithrombin activity. Experts disagree about the level of anticoagulation necessary for asymptomatic patients diagnosed because of a positive

family history, but most agree that heparin prophylaxis is indicated to prevent maternal thrombosis.

The prothrombin gene mutation increases the gene translation rate, causing elevated prothrombin levels. It may well be the second most common thrombophilia mutation, increasing the risk of thrombosis threefold in the nonpregnant state. This mutation is found in approximately 5–15% of patients being tested for thrombophilia.

Hyperhomocysteinemia (HHC) causes thrombosis by damaging the endothelium. The risk of stillbirth correlates with the homocysteine level. A twofold increase in the rate of stillbirth was reported in women with levels between 10 and 15 $\mu\text{mol/L}$; it was sevenfold in women with levels greater than 15 $\mu\text{mol/L}$.⁷⁸ There are two general causes of HHC: enzyme deficiencies or nutritional deficiencies. The enzyme deficiency most associated with hyperhomocysteinemia is an enzyme defect in methylenetetrahydrofolate (MTHFR), which clears homocysteine from the blood. Once an elevated hyperhomocysteinemia is documented, one may either check for the MTHFR mutation or simply administer additional folate.

A personal history of thrombosis in a woman of reproductive age requires a thrombophilia workup. However, there is a large group of women between the symptomatic group and those that are completely asymptomatic with no family history

of thrombosis. A study evaluating the cost-effectiveness of spending US\$1000 or more on the evaluation of every woman who experiences severe preeclampsia, placental abruption, IUGR, or unexplained IUFD needs to be done. No guidelines exist as to who might benefit from an inherited thrombophilia workup.

Existing recommendations are based on small studies and on theoretical grounds. Because of a lack of evidence, a discussion with the patient should take place once a thrombophilia has been diagnosed as to whether anticoagulation is of potential value. Some experts suggest stratifying risk for thrombosis into a “greater” risk and a “lesser” risk category.⁷⁹ Patients with a “greater” risk of thrombophilia are those with homozygous gene mutations for prothrombin and factor V Leiden, combined heterozygous mutations for prothrombin and factor V Leiden, and antithrombin deficiency. These patients will likely benefit from therapeutic anticoagulation as if the patient has already had a thrombosis. Those with “lesser” risk of thrombophilias may, in the presence of other risk factors (e.g., Cesarean delivery, preeclampsia), benefit from prophylactic anticoagulation. Treatment with heparin has its own inherent risks such as bleeding and osteoporosis, and these have to be considered and discussed with the patient prior to starting therapy.

Key points

Anemia

- 1 Pregnancy is subject to a disproportionate rise in plasma volume. The CDC defines anemia as hemoglobin levels less than 11 g/dL in the first and third trimesters and less than 10.5 g/dL in the second.
- 2 A basic workup depends on the reticulocyte count and MCV of the CBC.
- 3 The effect of anemia on pregnancy is dependent on the type and severity of anemia diagnosed.
- 4 Hemoglobinopathies in the mother are important to diagnose even if they have no effect on the pregnancy because of genetic implications.
- 5 Sickling hemoglobinopathies confer a high risk of maternal and fetal morbidity and mortality, and antepartum surveillance is recommended.
- 6 Neurologic and pulmonary symptoms of the sickling hemoglobinopathies need to be diagnosed very carefully, and prompt action taken. Acute chest syndrome is the major cause of morbidity in a patient with a sickling hemoglobinopathy.

Coagulation disorders

- 7 Pregnancy causes a heightened activation of the coagulation system of both the procoagulant and the

anticoagulant systems with a tendency toward thrombosis.

- 8 A coagulation panel may include a CBC, PT, activated PTT, fibrinogen, fibrin split products, and possibly a bleeding time.

Thrombocytopenia/platelet disorders

- 9 The most common cause of thrombocytopenia during pregnancy is gestational thrombocytopenia (GT), which rarely decreases platelet counts to less than 70 000/ μL . GT has little clinical significance.
- 10 Immune thrombocytopenic purpura (ITP) is another potential cause of thrombocytopenia and may be difficult to distinguish from GT. Treatment includes corticosteroids and IVIG.
- 11 Alloimmune thrombocytopenia purpura can be a devastating disease for the fetus/neonate. Management should be performed in conjunction with a fetal medicine specialist.
- 12 Drugs, especially aspirin, can cause platelet dysfunction. Doses higher than 81 mg/day should be used with caution and discussed with an anesthesiologist before regional anesthesia is given.

Inherited bleeding disorders

- 13 Von Willebrand's disease (vWD) is the most common inherited coagulopathy of clinical significance in the pregnant woman. Knowing the type of vWD has important management implications. Vasopressin should not be given in type 2B and type 3 vWD, and blood products should be given instead.
- 14 Hemophilia has X-linked inheritance with implications for the male fetus. Genetic counseling and testing are important for proper management.

DIC

- 15 Abruptio placentae is the most common cause of DIC, and prompt delivery, especially with laboratory abnormalities, should reverse changes. Heparin should not be given before delivery.
- 16 Intrauterine fetal demise and septic abortion cause DIC, and delivery of the fetus or evacuation of the uterus should be prompt.

- 17 Amniotic fluid embolus is a devastating complication that is treated with supportive measures.

Thrombophilias in pregnancy

- 18 There are many issues regarding thrombophilias in pregnancy that still need to be resolved, including impact, screening, and management issues.
- 19 Thrombophilias can be divided into acquired and inherited. Acquired thrombophilias are diagnosed by certain laboratory and clinical criteria. Inherited thrombophilias are diagnosed by laboratory criteria.
- 20 Management usually involves placing patients on heparin and aspirin. The amount of heparin (prophylactic versus therapeutic) depends on the thrombophilia and the past medical history.

Maternal alloimmunization and fetal hemolytic disease

Carl P. Weiner and Anita C. Manogura

Fetal hemolytic disease was first described in 1609 when a hydropic twin died shortly after birth and its co-twin succumbed of kernicterus a few days later. The cause and relationship between hydrops and kernicterus was unrecognized until 1932 when Diamond et al. noted that erythroblastosis fetalis was associated with fetal edema, neonatal anemia, and hyperbilirubinemia. They demonstrated that these were manifestations of a disease characterized by hepatosplenomegaly, extramedullary erythropoiesis, and erythroblastosis. Levine and Stetson in 1939 were the first to suggest that the hemolysis was due to the maternal development of a blood group antibody directed against a fetal blood group antigen. They observed atypical agglutinins in the serum of a woman who had just delivered a hydropic stillborn. These agglutinins were active against her husband's erythrocytes (same ABO blood group). Subsequently, Levine and Stetson postulated that an immunizing agent in the fetus, inherited from the father, entered the maternal circulation and caused her to develop the agglutinin. The discovery of blood group antigens by Landsteiner and Wiener in 1940 laid the foundation for the role of alloimmunization in the pathogenesis of fetal hemolytic disease.

Rhesus (Rh) blood group system

The Rh blood group system is the most common system causing serious alloimmunization. However, other blood group systems (so-called "minor antigens" of the erythrocyte membrane) are of growing importance as the prevalence of Rh alloimmunization declines secondary to prevention programs.

Nomenclature

The Fisher–Race system (first proposed in the 1940s) presumes the presence of three genetic loci, each with two major alleles – Dd, Cc, Ee.¹ An Rh gene complex is described by three letters – Cde, cde, cDE, cDe, Cde, cdE, CDE, CdE (the first three being the most common and the last one yet to be demonstrated).

The antigens produced by these alleles (located on chromosome 1p34–36) were originally identified by specific antisera.² No antiserum for the d antigen has been identified, and it is felt that the d antigen reflects in truth the absence of an allelic product. The presence or absence of the D antigen determines the Rh status. Approximately 45% of D-positive individuals are homozygous for D. If the Rh-positive husband of a Rh-negative woman is homozygous, all his children will be D positive; if he is heterozygous, there is an equal chance that the fetus will be D negative or D positive in each pregnancy.

There are alternative classification systems. The Wiener system is based on the theory that a single locus is occupied by a pair of complex agglutinogens.³ The eight genotypes are designated (in decreasing order of frequency in the white population) R¹, r, R², R⁰, r', r'', R², and r'. This system may be the most accurate. The Rosenfield system is based on the belief that neither of the two discussed systems explains the quantitative differences in the expression of Rh antigens.⁴ They also note that genetic concepts such as the operon model of gene function with nonlinked regulator genes are poorly accommodated by the mendelian model of Fisher–Race. Rosenfield proposed an updated system of nomenclature that numbered the Rh antigens as Rh1–Rh48.

Diversity and ethnicity

The Rh blood group system is complex; 42 antigens other than the five mentioned have been described.⁵ C^w, an allele for C, is relatively common. D^u, an allele for D, is more common in black populations than in other racial groups.

In most white populations, the incidence of Rh negativity is 15–16%. In Finland, it is 10–12%. It is 30–35% in the Basque population, but less than 1% in the Chinese and Japanese populations. Approximately 1–2% of North American Indians and Inuit are Rh negative, as are approximately 2% of Indo-Eurians. In the black population, the incidence ranges from 4% to 8%, being higher in North American than in African black people.

Immunology

The Rh antigens are embedded in the lipid phase of the erythrocyte membrane, and are expressed on fetal erythrocytes by day 38. Ten different antigenic epitopes have been identified to date. One theory suggests that the different epitopes are variably expressed within the erythrocyte membrane, and that this immunologic variation accounts for the spectrum of fetal hemolytic disease.

Rh functionality

The function of the Rh antigen is unclear, although it may have a role in maintaining erythrocyte integrity, plus contributing to electrolyte and volume flux across the erythrocyte membrane. For example, the red blood cells (RBCs) of individuals with Rh_{null} (lacking all Rh antigens) suffer multiple membrane defects, osmotic fragility, and abnormal shapes.

Pathogenesis of maternal alloimmunization

Blood transfusion was a common cause of Rh alloimmunization before the discovery of the Rh blood group system. It is still a common cause of non-D blood group alloimmunization. Although many non-D blood group antibodies have no clinical significance, some may cause severe erythroblastosis.

For Rh alloimmunization to occur:

- 1 The woman must be Rh negative and the fetus Rh positive.
- 2 Fetal erythrocytes must enter the maternal circulation in sufficient quantity.
- 3 The mother must be immune competent.

Transplacental hemorrhage

The prevalence of Rh alloimmunization declined only slightly after the discovery of the Rh blood group system and the introduction of transfusion of Rh D-compatible blood. In 1954, Chown proved Weiner's hypothesis that fetal-to-maternal transplacental hemorrhage (TPH) caused Rh immunization.^{6,7}

The Kleihauer acid elution test is an accurate and sensitive method of detecting TPH.⁸ Seventy-five percent of women have a fetal TPH some time during pregnancy or at delivery.⁹ The volume of the hemorrhage is usually small, but exceeds 5 mL in 1% and 30 mL in 0.25% of pregnancies. Antepartum hemorrhage, toxemia of pregnancy, Cesarean section, manual removal of the placenta, and external cephalic version each increase the risk and volume of TPH. The prevalence and volume of TPH rises with advancing gestation, from 3% (0.03 mL) in the first trimester to 12% (usually < 0.1 mL) in the second trimester, and to 45% (occasionally up to 25 mL) in the third trimester.⁹ Spontaneous abortion has a low risk of TPH (typically < 0.1 mL). However, the risk may be as high as 25% after therapeutic abortion, with volumes exceeding 0.2 mL in 4% of pregnancies.

Maternal response

At least two characteristics affect whether alloimmunization occurs. First, 30% of Rh-negative individuals act as immunologic nonresponders and do not become sensitized regardless of the Rh-antigen load. Second, ABO incompatibility has a protective effect. One explanation for this phenomenon is that the maternal anti-A or anti-B antibodies damage or alter the fetal Rh antigen so that it is no longer immunogenic. Another hypothesis holds that ABO-incompatible fetal cells are more rapidly cleared from the maternal circulation, so that maternal sensitization does not occur. Regardless of the mechanism, ABO incompatibility decreases the risk of alloimmunization to 1.5–2% after the delivery of a Rh-positive neonate.

Rh immune response

The primary Rh immune response develops slowly, typically over 6–12 weeks but sometimes up to 6 months. It is usually weak and predominantly IgM, which does not cross the placenta (molecular weight 900 000 kDa). Most immunized women convert quickly to IgG anti-D (molecular weight 160 000 kDa) production, which can readily cross the placenta. The IgG anti-D coats Rh-positive fetal erythrocytes and triggers hemolysis.

A second TPH, which may be very small, produces a very different secondary immune response. The response is rapid (days) and is usually IgG. Additional episodes of TPH may further increase the antibody titer. Long periods between Rh-positive erythrocyte exposures are associated with marked increases in Rh antibody titer along with increased binding avidity for the D antigen.¹⁰ The greater the avidity, the more severe the disease.

Antibody detection and measurement methods

Methods used to measure and detect antibodies include:

- 1 Saline – Rh-positive erythrocytes suspended in isotonic saline are agglutinated only by IgM anti-D. IgG anti-D cannot bridge the gap between erythrocytes suspended in saline. This method is no longer in use.
- 2 Colloid – Rh-positive red cells suspended in albumin are agglutinated by IgG anti-D.¹¹ Because IgM anti-D also agglutinates colloid-suspended Rh-positive erythrocytes, the albumin titer may not be an accurate measurement of IgG anti-D. Mixing the serum with dithiothreitol disrupts IgM disulfide bonds, destroying IgM but leaving IgG intact. Subsequent titration allows a true measurement of the IgG anti-D level. This method is rarely used.
- 3 Indirect antiglobulin test (IAT)¹² – antihuman globulin (AHG) antibody (Coombs' serum) is produced by the injection of human serum (or specific human IgG) into an animal.

IgG anti-D, if present, adheres to Rh-positive erythrocytes after incubation with the serum being screened for Rh antibody. The erythrocytes are then washed with isotonic saline and suspended in the AHG antibody serum. The erythrocytes agglutinate if coated with antibody (a positive IAT or indirect Coombs' test). The reciprocal of the highest dilution causing agglutination is the indirect antiglobulin titer. IAT screening is more sensitive than albumin screening. IAT titers are usually one to three dilutions higher than albumin titers. A critical titer is defined as the titer associated with a significant risk of fetal hydrops. This varies with the institution and methodology. Most centers have a critical titer between 8 and 32.

4 Enzyme – the incubation of erythrocytes with various enzymes (papain, trypsin, or bromelin) reduces the negative electrical potential of the cells. As a result, they are closer together in saline and are agglutinated by IgG anti-D. Enzyme techniques are the most sensitive available manual methods for detecting Rh immunization.¹³

5 AutoAnalyzer (AA) (Technicon Instruments Corp., Tarrytown, NY, USA) – AA methods (bromelin¹⁴ and low ionic¹⁵) are most sensitive for the detection of Rh antibody. They are so sensitive that, if manual methods fail to confirm the presence of Rh antibody, the mother may not be Rh immunized. Erythrocytes are mixed with agents to enhance agglutination by the anti-D antibodies. Agglutinated cells are separated from nonagglutinated cells and lysed. The amount of released hemoglobin is then compared with an international standard. A modification of the bromelin method is used to measure accurately ($\mu\text{g/mL}$) the amount of serum anti-D.¹⁶

Prevalence of Rh immunization

Rather small amounts of Rh-positive blood (as little as 0.3 mL) can produce Rh immunization in Rh-negative volunteers.¹⁷ The risk of Rh immunization is antigen-dose dependent: 15% after 1 mL, 33% after 10 mL, and 65% after 50–250 mL of Rh-positive erythrocytes.¹⁸ A secondary immune response may follow a small repeat challenge (0.05 mL of Rh-positive erythrocytes). The incidence of Rh immunization 6 months after delivery is 3% of Rh-negative women who, on serial Kleihauer tests, never had evidence of a TPH above 0.1 mL. If the volume is greater than 0.1 mL, the incidence is 14%;¹⁶ it is 22% if the volume is greater than 0.4 mL.¹⁹

The incidence of Rh immunization 6 months after delivery of the first Rh-positive ABO-compatible neonate is 8–9%. An equal number of women are immunized during their first pregnancy, but have an undetectable antibody level until challenged again, typically in their next pregnancy (“sensibilization”).²⁰ Therefore, the overall risk of Rh immunization following the first Rh-positive ABO-compatible pregnancy is 16%. An unimmunized Rh-negative woman faces approximately the same risk during a second such pregnancy. As parity increases and the ratio of good responders to poor

immune responders decreases, the risk becomes less. There is a 50% likelihood that she will be Rh immunized after five Rh-positive ABO-compatible pregnancies. In one study, five of 3533 Rh-negative women with Rh-positive fetuses (0.14%) were Rh immunized before 28 weeks' gestation, and 1.66% were immunized 3 days postpartum (total 1.8%).²¹ Because the total incidence of Rh immunization approximates 13% (16% in the 80% carrying ABO-compatible babies, 1.5–2% in the 20% carrying ABO-incompatible babies), 13–14% of all instances of Rh immunization [$1.8 \times (100/13)$] occur during pregnancy or within 3 days after delivery.

ABO incompatibility

ABO incompatibility between the Rh-positive fetus and the Rh-negative mother reduces the risk of immunization to 1.5–2%.¹⁸ The partial protection reflects, at least in part, rapid intravascular hemolysis of the fetal ABO-incompatible cells and their sequestration in the liver, where there are fewer antibody-forming lymphocytes than in the spleen. ABO incompatibility confers no protection once Rh immunization has developed.²²

Rh immunization caused by abortion

The woman who becomes Rh immunized after an abortion is a “good responder,” and frequently has very severely affected babies. The risk is approximately 2% after spontaneous abortion and 4–5% after therapeutic abortion.

Pathogenesis of fetal hemolytic disease

Fetal blood is produced in the yolk sac as early as the third week. The Rh antigen is detectable on the red cell membrane by the sixth week. Erythropoiesis begins in the yolk sac but moves to the liver and, finally, to the bone marrow by 16 weeks' gestation.

Maternal IgG anti-D crosses the placenta and coats the D-positive fetal red cells. The fetal red cells are destroyed extravascularly, primarily in the spleen, as anti-D does not fix complement. The resulting anemia stimulates fetal erythropoietin synthesis and release. A reticulocytosis occurs when the fetal hemoglobin deficit exceeds 2 g/dL compared with gestational age-appropriate norms. Should marrow red cell production fail to compensate, extramedullary erythropoiesis recurs, initially in the liver and spleen. Hepatomegaly may become extreme. Cardiac output increases, and 2,3-diphosphoglycerate levels are enhanced. Although the blood PO_2 is unaltered, tissue hypoxia results from the decreased carrying capacity. Umbilical arterial lactate begins to rise only after the fetal hemoglobin falls below 8 g/dL, while the umbilical venous lactate begins to rise after the hemoglobin falls below 4 g/dL.²³ Nucleated red cell precursors from normoblasts to primitive erythroblasts are released into the circulation (hence the term erythroblastosis fetalis coined by Diamond).

Degrees of Rh hemolytic disease

The severity of hemolytic disease reflects the amount of maternal IgG anti-D (the titer), its affinity or avidity for the fetal red cell membrane D antigen, and the ability of the fetus to tolerate hypoxemia before developing hydrops secondary to myocardial pump failure. When the globin chain is split from hemoglobin during hemolysis, the remaining heme pigment is converted by heme oxygenase to biliverdin, and then by biliverdin reductase to neurotoxic indirect bilirubin. The fetal and newborn liver is deficient in glucuronyl transferase and Y transport protein. Thus, the increased indirect bilirubin is deposited in the perinate's extravascular fluid compartments.

Indirect bilirubin is water insoluble and can remain in the plasma only when bound to albumin. When the albumin-binding capacity of the perinate's plasma is exceeded, "free" indirect bilirubin appears and diffuses into fatty tissues. The neuron membrane has a high lipid content, and the free indirect bilirubin penetrates the neuron where it interferes with cellular metabolism. Mitochondria swell, then balloon, and the neuron dies. The dead neurons with accumulated bilirubin appear yellow at autopsy (kernicterus).

Mild disease

Approximately 50% of affected fetuses do not require treatment postnatally. Their umbilical cord blood hemoglobin is above 12 g/dL, and their umbilical cord serum bilirubin is less than 68 $\mu\text{mol/L}$ ($< 4 \text{ mg}/100 \text{ mL}$). In the nursery, their hemoglobin does not drop below 11 g/dL, and their serum indirect bilirubin remains below 340 $\mu\text{mol/L}$ (20 mg/dL) or 260–300 $\mu\text{mol/L}$ (15–17.5 mg/dL) if preterm. Postdischarge hemoglobin remains above 7.5 g/dL.

Intermediate disease

Some 25–30% of affected fetuses have intermediate disease. They are born at or near term in good condition, with an umbilical cord blood hemoglobin between 9 g/dL and 12 g/dL. Extramedullary erythropoiesis is modest and liver function normal.

Some of these infants develop severe hyperbilirubinemia; those with kernicterus are deeply jaundiced. They become lethargic by day 3–5 and then hypertonic. They assume an opisthotonic position with their necks hyperextended, backs arched, and knees, wrists, and elbows flexed. Their vegetative reflexes disappear and apneic spells develop. The mortality rate is up to 90%. In the remaining 10%, the jaundice fades and spasticity lessens. However, they show severe central nervous system dysfunction over time with profound neurosensory deafness and choreoathetoid spastic cerebral palsy. Intellectual retardation may be relatively mild, but learning and functioning are hindered by deafness and spastic choreoathetosis.

Severe disease

The 20–25% of most severely affected fetuses, despite maximal RBC production, become progressively more anemic. Ascites with anasarca (generalized edema) occurs. Half these fetuses become hydropic between 18 and 34 weeks' gestation; the other half between 34 weeks and term.

The exact mechanism underlying hydrops has become clear over time. There is always a large hemoglobin deficit.²⁴ Hemoglobin concentration clearly rises with advancing gestational age. Hydrops, consequently, occurs at higher absolute hemoglobin levels during late compared with early gestation, and is extremely rare before 20 weeks' gestation. Cardiac dysfunction secondary to severe fetal anemia and the resultant inadequate oxygen-carrying capacity is evident in at least 90% of hydropic fetuses. Fetal cardiac dysfunction is characterized by an increase in the biventricular cardiac diameter, systolic atrial–ventricular valve regurgitation, and an elevated umbilical pressure for gestational age.²⁵ This cardiac dysfunction is detectable prior to the development of hydrops and, within 48 h of a RBC transfusion (and before the hydrops resolves), the umbilical venous pressure decreases into the normal range for gestation.^{26,27} Although hepatomegaly was once thought to cause portal hypertension and decrease cardiac return, it is clear that this is not the typical mechanism. Additionally, while hypoalbuminemia (secondary to fetal liver failure) was once thought to be a contributing factor, fetal studies reveal that the albumin concentration is normal for all but premoribund, hydropic fetuses.^{28,29}

Monitoring the mother and fetus at risk

A blood sample is obtained from every woman during her first prenatal visit for blood type and antibody screening. Ideally, all women should have two blood type determinations on record that are in agreement. Mistyping of a Rh-negative woman may have occurred in a prior pregnancy, and a Rh-positive woman, particularly if she has been transfused, may have developed a dangerous atypical blood group antibody.

The Rh-positive woman without blood group antibodies at her first prenatal visit is not likely to develop dangerous atypical blood group antibodies later in her pregnancy. Frequent retesting is not cost-effective.³⁰

The Rh-negative woman without Rh antibodies should be ABO grouped, and the Rh status of her husband should be determined. If he is Rh negative, her fetus will be Rh negative if paternity is correct. Rh status should, however, be confirmed at birth. If the father is Rh positive, his ABO group and Rh phenotype should be determined. Depending on his Rh phenotype, the likelihood of his Rh zygosity can be determined. If he is heterozygous, there is a 50% chance that the fetus is Rh negative. If the husband is ABO incompatible with his wife, there is roughly a 60% chance that the baby is ABO incompatible. If the fetus is ABO incompatible, the risk of Rh immunization is reduced from 16% to 1.5–2%.

The Rh-negative pregnant woman whose husband is Rh positive should undergo additional testing to exclude isoimmunization during the pregnancy. Cesarean section and manual removal of the placenta increase the frequency and size of fetal-maternal TPH, increasing the risk of immunization if the fetus is Rh positive. Amniocentesis for genetic purposes or for the determination of pulmonary maturity carries a 2% risk of immunization if performed under constant ultrasound guidance.³¹ At delivery, umbilical cord and maternal blood are tested: umbilical cord blood for ABO, Rh type and the direct Coombs' status, and maternal blood for the presence of Rh antibody and fetal red cells. Although most instances of Rh immunization occur after small or undetectable fetal TPH [maternal Rh prophylaxis being readily provided by one dose of Rh immune globulin (120–300 µg)], approximately one woman in 400 has a fetal TPH of more than 30 mL of whole blood and will not be protected by a single prophylactic dose.

Predicting the severity of Rh hemolytic disease

History

Hemolytic disease may remain similar from pregnancy to pregnancy (mild, moderate, or severe), but it is more likely to progress with each Rh-positive pregnancy. The risk of hydrops is 8–10% in a first sensitized pregnancy. If a woman has had a hydropic fetus, there is a 90% chance that the next affected fetus will also develop hydrops without intervention, typically at the same or an earlier time in gestation.

Rh antibody titers

If Rh antibody titers are measured in the same laboratory by the same experienced personnel using the same methods, the results are reproducible and of some value in predicting the risk of severe hemolytic disease. Because the binding constant of the Rh antibody varies, as may the density of Rh antigen on the RBC membrane and the ability of the fetus to compensate for RBC hemolysis, the titer indicates only which fetus is at risk. The maternal antibody titer that puts the fetus at risk must be determined for each laboratory. Generally speaking, an albumin titer of 16 or an indirect antiglobulin titer of 32–64 carries a 10% risk that the fetus will become hydropic without intervention. Titers of at-risk women should be repeated monthly after the first prenatal visit.

Maternal history and antibody titer alone are inadequate for the proper management of the Rh-immunized pregnancy. In one study of 426 Rh-immunized women managed at one hospital between 1954 and 1961 using amniocentesis and maternal titers, the severity of disease was predicted accurately in only 62% of the 121 affected fetuses.³² If prediction of severity of hemolytic disease had been completely accurate,

50% of the 67 deaths would have been prevented by the interventions available at the time.

Amniotic fluid analysis

Amniotic fluid of severely affected fetuses is stained yellow with bilirubin that absorbs visual light at 450 nm. The bilirubin reaches the amniotic fluid primarily by excretion into fetal pulmonary and tracheal secretions and diffusion across the fetal membranes and umbilical cord. Bevis was the first to report that spectrophotometric determinations of amniotic fluid bilirubin correlated with the severity of fetal hemolysis.

Liley reported a method in 1961 that allowed comparisons between one laboratory and another.³³ Although this technique remains important in some locales, it has been largely displaced by noninvasive techniques discussed later.

Optical density readings of centrifuged amniotic fluid (protected from light which can destroy the bilirubin) are made over the visual wavelength spectrum from 700 to 350 nm. The readings are plotted on semilogarithmic graph paper (with wavelength as the horizontal linear coordinate and optical density as the vertical logarithmic coordinate). The deviation from linearity at 450 nm (the ΔOD 450 reading) correlates directly with disease severity. An increase at 405 nm, if present, is due to heme. The heme peak may be another indication of severe disease if the fluid has not been contaminated with blood.

Liley divided a plot of single amniotic fluid sample ΔOD 450 readings from 101 pregnancies after 28 weeks' gestation into three zones and related them to neonatal outcome. Readings in zone 1 indicated mild or no disease, but did not exclude the possibility that treatment would be required after birth. Readings in zone 2 were felt to indicate intermediate disease, increasing in severity as the zone 3 boundary was approached. There was no control group, i.e., women with a Rh-negative fetus. The zone boundaries slope downward because of the diminishing amount of bilirubin normally produced after 25 weeks' gestation. Before 25 weeks, the zone boundaries are almost certainly parabolic rather than linear, probably reaching their highest levels at 24 weeks (Fig. 49.1). Extrapolating the Liley curves to pregnancies before 27 weeks has proved erroneous. Nicolaides et al.,³⁴ in 1986, correlated fetal hematologic values in 59 Rh D-sensitized pregnancies between 18 and 25 weeks' gestation with ΔOD 450 values on a Liley curve extrapolated to 18 weeks' gestation. If intervention were reserved for fetuses with ΔOD 450 values in zone 3, 70% of anemic fetuses would not have been detected.

A modified ΔOD 450 curve for such situations was proposed by Queenan et al.³⁵ in 1993 and, in 1998, Scott and Chan³⁶ conducted a prospective evaluation of this curve. The Queenan curve was predictive of severely affected fetuses (more than 7 g/dL deficit in hemoglobin) with a sensitivity of 100% and a specificity of 79%. The sensitivity for detecting moderate anemia (hemoglobin deficit of 3–7 g/dL) was 83% with a specificity of 94%. With further study, it became clear

Figure 49.1 Modification of Liley's ΔOD 450 reading zone boundaries before 24 weeks' gestation (From ref. 78).

that a single measurement of ΔOD 450 was poorly predictive of the fetal status unless it was extremely high or extremely low. Liley emphasized the need for repeating the amniotic fluid analyses to establish the ΔOD 450 trend. Thus, a decision to rely on amniotic fluid ΔOD 450 measurements is a decision to do at least two invasive procedures.

Serial ΔOD 450 readings increase the accuracy of the identification of severity. From examination of 3177 amniotic fluids obtained from 1027 immunized women, the following observations can be made:

- 1 A ΔOD 450 reading of 0.400 or higher at any period of gestation is associated with hydrops fetalis in 65% of instances.
- 2 Hydrops may be present with readings of 0.200–0.250 at 28 weeks' gestation.
- 3 Once serial readings reach 80–85% of zone 2, hydrops may be present by the time the reading reaches zone 3 without therapy.
- 4 Disease may be fulminant. For example, readings of 0.160 at 23 weeks and 0.240 at 27 weeks can be followed 2 weeks later by readings of 0.385 and 0.370 with hydrops present at the time of the second amniocentesis.
- 5 Conversely, readings of 0.200–0.250 at 20–22 weeks may occur in the presence of a negative, unaffected fetus.

Other spectrophotometric measurements of amniotic fluid have been developed. Bartsch concluded that none is better than the Liley method, and some are worse.³⁷ The experience and judgment of the individual assessing the amniotic fluid findings are more important than the method of measurement used. Clearly, amniocentesis is a less than desirable tool for the management of Rh disease.

Hazards of amniocentesis

The risks of amniocentesis include placental trauma causing TPH, rising titers, and increasing severity of fetal hemolytic

disease, amnionitis, and premature rupture of membranes. Any invasive procedure should be performed under continuous ultrasound visualization.

Sources of error

Maternal or fetal blood produces sharp 580-, 540-, and 415-nm oxyhemoglobin peaks that obscure the ΔOD 450 readings (Fig. 49.2). Small amounts of blood do not mask the ΔOD 450, but small amounts of plasma, particularly fetal plasma, can increase the ΔOD 450 reading, giving a falsely high reading. Heme produces a 405-nm peak, which may obscure the 450-nm peak, but can itself be indicative of severe hemolytic disease. Meconium in amniotic fluid distorts and increases the 450-nm peak. Exposure of the sample to light (particularly fluorescent light) decolorizes bilirubin, reducing the ΔOD 450 peak. Maternal urine produces no ΔOD 450-nm peak. Ascitic fluid is clear, bright yellow, and more viscous than amniotic fluid because of a higher protein level. It has a much higher ΔOD 450 level.

Congenital anomalies, such as anencephaly, open meningocele, and upper gastrointestinal obstruction, produce hydramnios and markedly elevated ΔOD 450 readings, which may be misleading if the mother is immunized.

Fetal blood sampling

Cordocentesis is available in many tertiary perinatal centers.³⁸ This procedure, which usually precedes fetal intravascular transfusion (IVT), allows the measurement of all blood parameters that can be measured after birth (i.e., hemoglobin, hematocrit, serum bilirubin, direct and indirect platelet count, leukocyte count, serum proteins, and blood gases). Fetal blood sampling is by far the most accurate means of determining the degree of severity of hemolytic disease, in the absence of hydrops fetalis.

Fetal blood sampling has an associated mortality rate of less than 1%²⁷ (0.2% in the authors' hands for Rh disease using a needle guide). Other morbidity occurs in approximately 5% of patients sampled using a freehand technique: prolonged bradycardia, umbilical cord hematoma, amnionitis with maternal adult respiratory distress syndrome, and placental abruption are each described. Cordocentesis is recommended when a screening tool such as measurement of the middle cerebral artery (MCA) peak velocity is abnormal. Cordocentesis can be performed as early as 16–18 weeks; it is usually feasible by 20–21 weeks.

Ultrasound

Ultrasound has a central role in the management of the alloimmunized pregnancy. First, it is used early to accurately establish gestational age. Second, many investigators have searched for alternative ultrasound parameters that could predict mild to moderate anemia. Such studies include:

Figure 49.2 Spectrophotometric curve (Liley method) of amniotic fluid grossly contaminated with blood. Note sharp peaks at 580, 540, and 415 nm that obscure the 450-nm rise (Bowman JM. Hemolytic disease of the newborn. In: Conn HF, Conn RB, eds. *Current diagnosis* 5. Philadelphia: W.B. Saunders; 1977:1107).

1 Nicolaides et al.³⁹ in 1988 investigated the fetal abdominal circumference, head-to-abdomen circumference ratio, intraperitoneal volume, intrahepatic and extrahepatic umbilical vein diameter, and placental thickness to predict a fetal hemoglobin less than 5 g/dL. Placental thickness and intraperitoneal volume detected only 25% of cases; the other parameters detected < 10% of severe cases.

2 Vintzileos et al.⁴⁰ in 1986 and Roberts et al.⁴¹ in 2001 used ultrasound to assess the fetal liver, reasoning that it is the principal site of extramedullary hematopoiesis. The length of the right lobe of the liver reportedly detected 93% of anemic fetuses.

3 Oepkes et al.⁴² in 1993 and Bahado-Singh et al.⁴³ in 1998, measured splenic perimeter (length + width \times 1.57), reasoning that the spleen is another site of extramedullary hematopoiesis. In two series, a splenic perimeter greater than two standard deviations was predictive of severe fetal anemia (94% and 100% respectively).

Despite this experience, hepatic length and splenic perimeter have not been widely used in alloimmunization management.

Lastly, hydrops fetalis can easily be detected with ultrasound.

Doppler ultrasonography

A number of investigators have reasoned that decreasing fetal hemoglobin levels would be associated with a lower blood vis-

cosity and increased cardiac output, producing higher blood velocities. Sites studied include the descending aorta, the umbilical vein, the splenic artery, the common carotid artery, and the MCA.

Vyas et al.⁴⁴ in 1990 was the first to apply MCA Doppler velocity for the detection of fetal anemia. They found the best correlation with fetal hemoglobin levels using the intensity-weighted time-averaged mean velocity of the MCA; unfortunately, only 50% of the anemic fetuses were identified.

The peak systolic velocity in the fetal MCA has proved more accurate. Mari⁴⁵ established normative data for gestational age. Using a threshold value of 1.5 multiples of the mean to predict moderate to severe anemia, more than 70% of invasive tests were avoided. Since 2000, multiple reports have confirmed the high sensitivity of the peak MCA velocity in detecting moderate to severe fetal anemia.

The fetal MCA closest to the maternal skin should be evaluated using a minimal angle of insonation. The Doppler gate is placed over the vessel just as it bifurcates from the carotid artery; placement on the more distal aspects of the MCA can falsely depress the real peak systolic velocity.

Deti et al.⁴⁶ in 2002 examined the time trend of MCA velocities as a tool to identify fetal anemia. The slope of a regression line based on three consecutive Doppler measurements greater than 1.95 was predictive of the subsequent development of moderate to severe fetal anemia. They proposed the following scheme:

- 1 Doppler assessment weekly.
- 2 If the MCA peak velocity remains < 1.5 MoM, calculate the slope of the increase between the three measurements.
- 3 If the slope is less than 1.95, repeat studies at 10- to 14-day intervals.
- 4 If the peak MCA velocity is at least 1.5 MoM and there are other ultrasound findings consistent with fetal anemia, proceed with cordocentesis. If there are no sonographic signs of anemia, repeat the peak MCA Doppler measurement within 24 h to confirm elevation; if persistent, proceed with cordocentesis.
- 5 Do not use the MCA after 35 weeks' gestation.

Cell-mediated maternal antibody functional assays

Because of the relatively poor correlation between blood group antibody and severity of hemolytic disease, various functional assays were developed to reflect the antibody-binding avidity for the RBC membrane antigen. These assays include the monocyte monolayer assay (MMA),⁴⁷ antibody-dependent cellular cytotoxicity (ADCC) using lymphocytes,⁴⁸ ADCC using monocytes,⁴⁹ and monocyte chemiluminescence.⁵⁰ Each assay has its proponents. A survey of nine European laboratories revealed that they correctly predicted disease outcome in about half of the cases. The assays are perhaps more helpful in predicting mild disease than very severe disease. In a recent study, there was no correlation between the hematocrit at cordocentesis and the MMA in 41 pregnant women with potentially dangerous blood group antibodies who delivered affected babies.⁵¹ All tests are incapable of differentiating the unaffected antigen-negative fetus from the affected antigen-positive fetus. In summary, these tests appear to have modest clinical value as currently formulated.

Determination of fetal D antigen status by polymerase chain reaction

The cloning of the CcEe and D complementary DNA allows for the determination of the fetal Rh D genotype from DNA obtained by chorionic villus biopsy or amniocentesis.⁵² Although highly uncommon, point mutations can result in the occasional incorrect diagnosis. Thus, it is possible to determine the D status of a fetus whose mother is Rh d and whose father appears to be heterozygous for D and, if negative, no further testing will be required. Probes are also available for Kell.

It is also possible to determine D antigen fetal status from maternal blood using the polymerase chain reaction (PCR). The fetal nucleated hematopoietic stem cells present in the maternal circulation are subjected to PCR.⁵³ Finning et al.⁵⁴ in

2002 followed a series of 137 sensitized pregnancies. Fetal typing using DNA from maternal serum was 100% accurate in determining the Rh D type in 94 Rh D-positive and 43 Rh D-negative cases.

Management of the Rh-immunized woman and her fetus

Clinical management is dependent on the available diagnostic tools, the patient and her history of fetal/neonatal manifestations of hemolytic disease, and on the clinical condition of the fetus. As a rule, the patient's first Rh D-sensitized pregnancy results in minimal fetal/neonatal disease; subsequent pregnancies are associated with a worsening outcome.

Nonsensitized women

Management of the newly sensitized woman begins upon identification. The practitioner cannot predict fetal risk accurately relying on the obstetric history and serology. The caregiver must be familiar with their laboratory's maternal indirect Coombs' antibody titers (assuming the results are reproducible) and threshold. Antibody titers have their greatest utility during the first sensitized pregnancy; in later pregnancies, they are of limited value.

When the maternal indirect Coombs' antibody titers are below the threshold (below which severe fetal hemolytic disease does not occur), they should be repeated monthly. Once the critical titer is exceeded, the fetus is followed with serial measurements of the peak MCA velocity. It is important to remember that a determination of the fetal PCR Rh genotype should be standard in any at-risk women undergoing chorionic villus sampling (CVS) or second-trimester amniocentesis because a negative result eliminates the need for further testing.

The timing of invasive fetal testing is now determined by ultrasound evidence of fetal anemia as several investigators have found an association between fetal anemia and increased MCA velocities.^{44,45,55}

Invasive fetal evaluation following a positive Doppler finding consists of cordocentesis. With the declining incidence of maternal isoimmunization, these patients should be referred to maternal-fetal medicine specialists with experience in the field.

The principal concern with cordocentesis is safety – vascular accidents and maternal sensitization are known to occur. As described earlier, this technique accounts for at least 30% of fetal losses and, by using a needle guide, the loss rate is decreased to approximately 0.3%.⁵⁶ The first cordocentesis should be performed when the peak MCA velocity becomes elevated or (if applicable) a few weeks before the last sensitized fetus required a transfusion. Laboratory tests performed on the first fetal specimen include type and Rh status, direct Coombs' test, complete blood count (CBC), manual reticulo-

cyte count, and total bilirubin. Laboratory tests sent on subsequent fetal specimens include CBC, manual reticulocyte count, and total bilirubin. If the fetus is not anemic when first sampled, a strongly positive direct Coombs' test or a manual reticulocyte count outside the 95% confidence interval are strong risk factors for the development of anemia *in utero*. Approximately 50% of isoimmunized women will require only one cordocentesis and, with the use of Doppler ultrasound, delivery may be safely deferred until term.

Rh-immunized woman with a previously affected fetus or infant

Patients should be referred to a tertiary care center if they have documented isoimmunization. Maternal titers are not predictive of the degree of fetal anemia. If the paternal phenotype is heterozygous, an amniocentesis is performed at 15 weeks to determine fetal Rh D status. If the fetus is antigen positive, initiate serial MCA Doppler measurements by 18 weeks to monitor these pregnancies. Testing should be repeated every 1–2 weeks as long as they are normal. If a rising value for peak MCA Doppler velocity greater than 1.5 MoM is found, a cordocentesis is performed and the fetus transfused if the hematocrit is < 30%.

Intrauterine fetal transfusion

Preterm delivery is associated with increased perinatal morbidity and mortality. This can be avoided for the most part using modern techniques for fetal transfusion. Fetal intraperitoneal transfusion is rarely necessary, and the techniques will only be mentioned briefly. Fetal transfusion therapy should never be undertaken in the absence of hydrops without first confirming that the fetus has significant anemia (fetal hematocrit < 30%, a value less than the 2.5 percentile at all gestational ages above 20 weeks). These procedures should only be performed by individuals with considerable experience.

Intraperitoneal fetal transfusions

This is the original, but least preferred, method of fetal transfusion. Red cells placed in the peritoneal cavity of any animal with a diaphragm are absorbed intact into the circulation via the subdiaphragmatic lymphatics and the right thoracic duct. Diaphragmatic contractions are necessary for the absorption.⁵⁷ In the absence of hydrops, 10–12% of transfused red cells are absorbed each day after transfusion. Absorption is greatly diminished and unpredictable in the presence of hydrops.⁵⁸

The volume of blood injected is limited by the capacity of the peritoneal space. If the volume transfused is such that intraperitoneal pressure exceeds umbilical venous pressure, blood flow from the placenta to the fetus stops and the fetus dies.⁵⁹ The intraperitoneal transfusion (IPT) volume can be calculated by the following formula: IPT volume = (weeks'

gestation–20) × 10 mL (i.e., 50 mL at 25 weeks, 90 mL at 29 weeks). Calculation of residual donor hemoglobin concentration is necessary to space IPTs optimally so that the fetus undergoes the minimal number of procedures. After IPT, 80% of the infused red cells are in the fetoplacental circulation (based on a fetoplacental blood volume of 125 mL/kg fetal body weight). The residual donor hemoglobin concentration is calculated according to the following formula: residual hemoglobin concentration (g/L) = $[(0.80 \times a)/(125 \times b)] \times [(120 - c)/(120)]$ where "a" is the amount of donor red cell hemoglobin transfused in grams, "b" is the estimated fetal weight according to gestation (i.e., 1 kg at 27 weeks' gestation, 1.5 kg at 30 weeks' gestation), "c" is the interval in days after the IPT, and 120 days is the lifespan of the donor red cell. For example, 10 days after IPT of 55 mL of blood with a hemoglobin concentration of 280 g into a fetus of 27 weeks' gestation (weight 1 kg), there would be a residual donor hemoglobin concentration of $[(0.80 \times 55 \times 280)/(125 \times 1)] \times [(120 - 10)/(120)] = 90.3$ g/L. A second IPT is performed as soon as the first is absorbed, and every 4 weeks thereafter.

IPT has several disadvantages. There is slow correction of the fetal anemia and a higher risk of trauma. There is the added risk of obstructing cardiac return if the intra-abdominal pressure becomes too high.

Direct intravascular fetal transfusion

In 1981, Rodeck et al. introduced direct fetal blood sampling and intravascular transfusion (IVT) through a needle introduced down a fetoscope.⁶⁰ The presence of blood (common after a first IVT), meconium, or turbidity (common in later gestation) in amniotic fluid creates major problems with visualization of fetal vessels through the fetoscope. Fetal blood sampling and direct IVT are now carried out in most, if not all, tertiary level centers under ultrasound. Transfusion therapy is initiated when the fetal hematocrit is < 30%, a value less than the 2.5 percentile at all gestational ages above 20 weeks.

The blood should be from a fresh donor, group O, and negative for the antigen (or antigens) to which the mother is sensitized (D negative if the mother is Rh negative with anti-D). It should also be negative for hepatitis B surface antigen (HBsAg), anti-human immunodeficiency virus (HIV), anti-hepatitis C virus (HCV), and anti-cytomegalovirus (CMV). Alloimmunized Rh-negative women are functional hyperresponders. They frequently develop other blood group antibodies, such as M, S, s, Jk^a, Fy^a, and so on. A second antibody may become manifest after one or two intrauterine transfusions (IUTs), jeopardizing the lifespan of the donor red cells transfused next if not corrected. The blood unit is centrifuged, and the supernatant plasma with its buffy coat is discarded. Gamma irradiation of the donor red cells is recommended. Sterile isotonic saline is added to the packed red cells immediately before the IUT raising the hematocrit to between 70% and 75%. Transfused blood with a higher hematocrit mixes much more slowly.

Technique of intravascular transfusion

The mother is made comfortable with pillows placed under her knees (to take pressure off the lower spine) and a pillow positioned on the left to displace the uterus to avoid supine hypotension. Diazepam 5–10 mg intravenously is used to foster relaxation during the procedure. The maternal abdomen is surgically prepared. Prophylactic antibiotic administration is neither effective nor cost-efficient. The unit of blood at room temperature is attached to a blood filter and then a three-way valve. A length of extension tubing is attached to the stopcock end and filled with donor red cells, taking great care to insure that no air bubbles are in the tubing, stopcock, or syringe.

Once prepared, the operator selects the easiest approach to the umbilical vein and, under real-time ultrasound guidance (the transducer being enclosed in a sterile drape), directs a 10-cm, 22-gauge spinal puncture needle into the umbilical vein. The selected skin site is infiltrated with 1% lidocaine. If the artery is inadvertently punctured, the needle should be removed and redirected to the vein unless there is no other option. When the needle appears within the vessel, the stylet is withdrawn and, upon free return of blood, the fetus is paralyzed with pancuronium, 0.3 mg/kg estimated fetal weight (EFW) intravenously, to insure fetal quiet, as any fetal movement may cause catastrophic events such as vessel laceration or cord hematoma. Pancuronium is also advantageous for transfusion specifically because its sympathomimetic effect helps to maintain cardiac output as the fetus is volume loaded. After fetal paralysis, the umbilical venous pressure is measured. It provides definitive identification of the vessel punctured and allows for the monitoring of the fetal response to volume loading. The author also administers furosemide (3 mg/kg EFW); however, research has failed to show a clear benefit.⁶¹ The donor blood is injected in 20-mL aliquots over 2–3 min. The transfusion is monitored continuously by ultrasound (streaming turbulence is seen as the donor red cells pass down the vein). Meanwhile, the assistant must be ready to halt the infusion if there is any abrupt change in the resistance to flow. Because only 2–3 mm of needle is in the fetal vessel, there is a significant risk of dislodgement, either into the amniotic cavity (easily recognized and not hazardous) or into the cord substance producing a cord hematoma with risk of umbilical venous compression and vasospasm-induced bradycardia. Excluding the first transfusion of a hydropic fetus, the target for the post-transfusion fetal hematocrit is 48–55%. Consequently, the volume infused depends on the gestational age and the initial hematocrit.

A variety of options exist to monitor the fetus during the transfusion. First, many physicians will image the fetal heart to rule out bradycardias, but this is of limited value. A second option is to periodically measure the umbilical venous pressure. If the fetus does not tolerate the transfusion, the umbilical venous pressure will increase (fetal bradycardias also increase the umbilical venous pressure); an increase of

> 10 mmHg is associated with increased perinatal mortality, and the transfusion should be stopped and, if needed, blood volume should be removed to reduce the fetal preload. Another option is Doppler ultrasound to evaluate fetal well-being during the transfusion.

The fetal hematocrit declines slowly over time after transfusion therapy is begun. It is more rapid and variable between the first and the second transfusion compared with subsequent transfusions. Except for the hydropic fetus, the second transfusion is generally performed 2 weeks after the first transfusion. The decline in fetal hematocrit thereafter is more predictable and generally, by 34–35 weeks, delivery may be delayed 4–5 weeks without another transfusion.⁶²

Transfusion therapy suppresses fetal erythropoiesis, and the average reticulocyte count is usually < 1% by the third transfusion. The complications of hyperbilirubinemia are less if at least two transfusions are performed 3 weeks apart. The last transfusion is done between 34 and 35 weeks' gestation, and delivery is planned at 38–39 weeks. Transfusion therapy is not an indication for Cesarean delivery.

Intrauterine transfusion in the presence of hydrops fetalis

Most hydropic fetuses have myocardial dysfunction. As a result, they frequently fail to tolerate the typical volume load.²⁸ Thus, their target hematocrit after the first transfusion should be no more than 25%. A day later, the hematocrit can safely be brought up to the target 48–55% with a second transfusion.

Umbilical vein pH (UVpH) maintenance is especially important in the hydropic fetus. During a transfusion, the UVpH normally declines because the pH of the transfused blood is 6.98–7.01. The RBC is the principal buffer in the human fetus. In the authors' experience, all losses of hydropic fetuses after the era of umbilical venous pressure measurement began were associated with profound acidemia and occurred hours after the transfusion. Consequently, the author now infuses bicarbonate in 1-mEq increments to maintain UVpH above 7.30. The overall survival rate for hydrops (since beginning IVT) now exceeds 94%.

The blood volume transfused is dependent on gestational age and the starting hematocrit. Several formulae exist to calculate the volume needed; however, none is reliable enough to terminate the procedure without first checking the hematocrit. Donor blood with a hematocrit < 75% equilibrates rapidly (likely because of the rapid fluid exchange across the placenta) whereas donor blood with a hematocrit > 80% does not equilibrate as rapidly (likely because of increased viscosity).

Survival after fetal transfusion

Survival after IUT varies with center experience and with the presence or absence of hydrops. Overall survival in one review

was 84%. However, fewer hydropic fetuses survived after IUT (70%) compared with fetuses who were not hydropic (92%). One treatment center looking at 213 fetuses receiving 599 IUTs had similar results. Survival with any degree of hydrops was 78% compared with 93% for nonhydropic fetuses. These investigators further classified hydrops into mild (mild ascites) and severe (significant ascites with scalp edema, pericardial effusion, or pleural effusion). Mild hydrops reversed in 88% of cases, whereas severe hydrops only reversed in 39%, a finding clearly linked to overall perinatal survival: 98% of fetuses survived after reversal of hydrops. With persistent hydrops, only 39% of fetuses survived; if the hydrops was severe and persisted, only a quarter survived.

Delivery of the fetus after intrauterine transfusion

Generally, the last transfusion is administered around 34–35 weeks' gestation. If the fetal hematocrit at the end of the last transfusion was approximately 50%, then it will still be above 35% at delivery 4 weeks later. Consequently, there is no justification for preterm induction of labor if a transfusion can be performed.

Infants who have received *in utero* transfusion therapy do well after birth. Generally, the neonatal capillary hematocrit increases about 15% within the first few hours of life (likely secondary to fluid shifts) and then decreases slowly to a level at or below the umbilical cord hematocrit level at delivery over the next few days to weeks. As these infants are now delivered at term, they have a higher tolerance to bilirubin levels and can usually be managed with phototherapy alone. The infant may develop anemia by 5 weeks after delivery; this is expected as the transfused blood is nearing the end of its lifespan. This neonatal anemia is also likely indicated by a low reticulocyte count. These neonates should have their hematocrit and reticulocyte count monitored weekly. The therapeutic goal is to maintain them with a modest anemia; small transfusions will keep the infant asymptomatic but leave the erythropoietic stimulus unblunted. Once reticulocytosis is observed, the neonate will no longer need further transfusion therapy.

Suppression of Rh immunization

Plasma exchange

Large amounts of maternal antibody-containing plasma (3L/day, 5 days/week) are removed and replaced with saline, 5% albumin, and intravenous gammaglobulin to reduce the circulating maternal blood group antibody levels by 75–80%. Such reductions are transient and at best delay the need for IUT by 2–3 weeks. The procedure is costly in both professional time and resources. With the advent of fetal blood sampling and IVT as early as 18–20 weeks' gestation, intensive plasmapheresis is only rarely indicated.

Intravenous immune serum globulin

Intravenous immunoglobulin (IVIG) has been reported to reduce the severity of hemolytic disease.⁶³ The dose used is 1g/kg maternal body weight administered weekly. IVIG may exert a beneficial effect by negative feedback, reducing maternal antibody levels by 50%, or by saturating the trophoblastic Fc receptor sites to impede placental transfer of antibody to the fetus, or by saturating fetal splenic Fc receptor sites, preventing the destruction of antibody-coated fetal RBCs.

Prevention of Rh immunization

The development of Rh immunization prophylaxis was a major advance in the management of the Rh-negative pregnant woman. In 1900, Von Dungern showed that administration to rabbits of antibody from ox red cells along with ox red cells prevented the development of rabbit anti-ox red cell antibodies.⁶⁴ He proved that the presence of antibodies to an antigen, in sufficient amount, suppresses active immunization to the antigen. This information was used 60 years later in New York,⁶⁵ Liverpool,⁶⁶ and Winnipeg.¹⁶ In the initial experiments, Rh-negative male volunteers were given Rh-positive red cells and Rh antibody in the form of Rh immune globulin (RhIG, anti-D IgG); the anti-D IgG prevented Rh immunization.

Clinical trials were performed in which Rh-negative unimmunized women were given RhIG after the delivery of a Rh-positive infant. All such trials were successful. As a result of these trials, RhIG was licensed in 1968 for use in North America. The standard dose in the United States is 300 µg given intramuscularly (i.m.). Smaller doses of 100–125 µg i.m. are used in Canada, Europe, and Australia. All these doses appear to be effective.

RhIG prevents Rh immunization with two provisos: it must be given in an adequate amount, and it must be given before Rh immunization has begun. RhIG administration does not suppress Rh immunization once it has begun, no matter how weak the immunization.⁶⁷

RhIG mechanism of action

The precise mechanism of action of RhIG is unknown. There are three theories: antigen deviation, antigen blocking-competitive inhibition, and central inhibition. The first theory, antigen deviation, was proposed by Race and Sanger. Rh-positive cells bound by RhIG succumb to intravascular hemolysis that destroys or alters the Rh antigen so as to prevent anti-D antibody production. It is now known, however, that IgG anti-D does not cause intravascular hemolysis of Rh-positive cells. Instead, the antibody-coated fetal cells are removed from the circulation in the spleen and lymph nodes (the site of antibody production). Consequently, antigen deviation is likely not the mechanism of action of RhIG.

The second theory, antigen blocking–competitive inhibition, is also likely not the mechanism of RhIG action. Antibody preparations that lack the Fc portion also avidly bind the antigen, but do not suppress the immune response. Consequently, this also is not the mechanism of action.

The most likely mechanism of action for RhIG is that of central inhibition, proposed by Gorman and elaborated by Pollack. Fetal erythrocytes are coated with anti-D IgG and are filtered out by the spleen and lymph nodes. The increase in local concentrations of anti-D IgG bound to the D antigen appears to suppress the primary immune response by interrupting the commitment of B cells to IgG-producing plasma cell clones. The binding of anti-D–D antigen complexes releases cytokines that inhibit the proliferation of B cells specific for the antigen. This process is dependent on the presence of the IgG Fc receptor.

Because the half-life of RhIG is approximately 16 days, 15–20% of patients receiving it at 28 weeks have a very low anti-D titer at term delivery. It is recommended in the United States that 300 µg of RhIG be administered within 72 h of delivery of a Rh-positive infant. This dose will protect against sensitization from a fetal–maternal hemorrhage (FMH) of 30 mL of fetal whole blood. Approximately 1 in 1000 deliveries will exceed this volume, and risk factors identify only 50%. Therefore, routine screening at delivery for excessive FMH is indicated. The rosette test, a qualitative yet sensitive test for FMH, is performed first. A negative test result implies that the patient should receive only the standard dose of RhIG. A Kleihauer–Betke stain is performed if the rosette test is positive. The percentage of fetal blood cells is multiplied by 50 to estimate the FMH volume, and additional vials of RhIG are administered to prevent maternal sensitization. No more than five units of RhIG should be administered intramuscularly in a 24-h period. Should a large dose of RhIG be required, the entire calculated dose may be given using an intravenous preparation.

Standard Rh prophylaxis recommendations

One prophylactic dose unit of RhIG is administered to a Rh-negative nonimmune woman as soon as her infant is determined to be Rh positive, and no later than 72 h postpartum. If the Rh status of the baby remains unknown at 72 h, the woman should be given RhIG regardless. It is better to treat unnecessarily than to fail to treat an at-risk woman. ABO status is not part of the decision paradigm as ABO incompatibility is only partially protective. If there is a failure to administer RhIG within 72 h, Rh prophylaxis may still be beneficial up to 28 days postpartum, although the experimental evidence suggests that RhIG will provide some protection only up to 13 days after exposure to Rh-positive red cells.⁶⁸

Rh prophylaxis problems

Postpartum Rh prophylaxis programs have greatly reduced, but not entirely eliminated, Rh immunization. Residual problems still exist^{69,70} and include the following:

- 1 Failure of compliance after delivery.
- 2 Failure to give prophylaxis after abortion.
- 3 Failure to give prophylaxis after amniocentesis.
- 4 Failure to protect after massive fetal TPH.
- 5 Failure to protect against Rh immunization during pregnancy.
- 6 The question of augmentation of the risk of Rh immunization.
- 7 The question of Rh immunization during infancy.
- 8 The question of the D^u mother.
- 9 The question of suppression of weak Rh immunization.
- 10 Reactions to i.m. RhIG–ion exchange and RhIG–monoclonal RhIG.

Failure of protection after massive fetal transplacental hemorrhage

The protection provided by RhIG is dose dependent. Experimentally, 300 µg of RhIG given i.m. prevents Rh immunization after an exposure of up to 30 mL of Rh-positive blood (12–15 mL of red cells).¹⁷ The protection is only partial if the volume of blood is greater. Rh immunization occurred in 30% of Rh-negative male volunteers given up to 450 mL of blood with 300 µg of RhIG i.m.⁷¹ Because only about 1 woman in 400 is exposed to more than 30 mL, Rh immunization failure due to undiagnosed massive fetal TPH occurs rarely (1 in 1400 Rh-negative women carrying Rh-positive babies). Nevertheless, screening the Rh-negative woman for massive fetal TPH after delivery is recommended.

If massive TPH is diagnosed after delivery of a Rh-positive baby, 600 µg (two vials) should be administered if the TPH is greater than 25 mL but less than 50 mL, 900 µg (three vials) if the TPH is greater than 50 mL but less than 75 mL, and so on. Up to 1200 µg (four vials) i.m. can be given every 12 h until the total dose has been administered.

Not only is there a risk of Rh immunization, but there is also a risk of fetal exsanguination if a massive TPH occurs antenatally and exceeds 100 mL (nearly always in the third trimester).⁷² There is a risk of fetal red cell hemolysis from the large amounts of RhIG that must be given before delivery. If the TPH does not exceed 50 mL of blood, the dose required (600 µg) does not cause significant fetal red cell hemolysis.

It is prudent to consider delivery after the TPH exceeds 50 mL if the fetus is 33 weeks or greater and there is evidence of pulmonary maturity. If the baby is Rh positive, the mother should be given an appropriate amount of RhIG. The baby should be examined immediately and, if pale and shocky or with significant anemia, transfused immediately.

If a fetal TPH greater than 50 mL is diagnosed early in pregnancy before evidence of fetal lung maturity, cordocentesis should be performed, and a transfusion carried out if a significant anemia is discovered. RhIG (600 µg) should be given to the mother if the fetus is Rh positive. Thereafter, the fetus should be followed by serial ultrasound examinations. If gestation and lung maturity are such that delivery is not prudent

within 14 days of the transfusion, a second fetal blood sampling procedure should be performed to insure stability of the fetal hematocrit.

Rh immunization during pregnancy

Rh immunization during pregnancy accounts for approximately 13% of all Rh immunization if no prophylaxis is given. In Manitoba, 1.8%⁵⁷ of 3533 mothers carrying Rh-positive fetuses who had no evidence of Rh immunization at the beginning of their pregnancies were Rh immunized during pregnancy or within 3 days after delivery.²⁰ Similar prevalence figures were reported from Hamilton, Ontario,⁷³ and Sweden.⁷⁴ Rh immunization during pregnancy has also been reported in the United States.⁷⁵

A clinical trial of antenatal Rh prophylaxis with 300 µg of RhIG given i.m. at 28 and again at 34 weeks' gestation reduced the incidence of Rh immunization from 1.8% to 0.1%.²⁰ As a result, antenatal Rh prophylaxis is accepted practice in many locales, although most give a single injection of 300 µg of RhIG at or as close to 28 weeks' gestation as possible. The single dose at 28 weeks' gestation has been highly successful.⁷⁶ Universal antenatal prophylaxis combined with universal postpartum, postabortion, and postamniocentesis prophylaxis will reduce the prevalence of Rh immunization by 97% from the preprophylaxis incidence of approximately 13 to 0.27%.⁷⁷

The administration of RhIG during pregnancy does not harm the fetus. When 300 µg is given at 28 and 34 weeks' gestation, one-third of neonates have red cells that are weakly direct antiglobulin positive, but none shows any evidence of anemia or hyperbilirubinemia. Only very rare babies have direct antiglobulin-positive red cells after their mothers have received 300 µg just once, at 28 weeks' gestation.

Reactions to intramuscular RhIG – newer forms of RhIG

Ion-exchange RhIG

RhIG is most often prepared by the Cohn cold ethanol precipitation process. Although it is effective and carries a low risk of adverse reactions, it does contain small amounts of IgA, IgM, and other plasma proteins. Because it is anticomplementary, it can be given i.m. only. The efficacy of yield of anti-D IgG from the starting plasma is quite low (35–45%). Severe anaphylaxis has been reported.⁷⁸

Hoppe et al. prepared RhIG by ion-exchange chromatography.⁷⁹ This method produces a very pure product with low total protein, no demonstrable IgM, and an IgA content only 0.3% of that in the Cohn prepared RhIG. It also has very low anticomplementarity and can be given safely intravenously (i.v.). It is twice as effective when given i.v.; thus only half the dose is needed after delivery (120 µg). However, the antenatal prophylaxis dose must be the same (300 µg) because its half-life is the same.

Clinical trials and service programs in which hundreds of thousands of doses of ion-exchange RhIG have been given (either i.v. or i.m.) demonstrate it is at least as successful in preventing Rh immunization as the Cohn prepared RhIG.

The advantages of ion-exchange prepared RhIG are greater purity, less likelihood of an adverse reaction, greater efficiency of yield (and, therefore, lower cost), lower dose, and less discomfort when given i.v.

Monoclonal RhIG

At present, RhIG is manufactured from the plasma of hyperimmunized Rh-negative donors, either from the plasma of sterile women initially immunized by pregnancy or from the plasma of Rh-negative deliberately immunized male donors. The former population, the best source of Rh immune plasma, is decreasing in number because of Rh prophylaxis. Deliberate Rh immunization of male volunteers has been questioned on moral and ethical grounds as the majority of those exposed to Rh-positive red cells do not produce acceptable Rh antibody levels. Within the next few years, RhIG will be produced in tissue culture. Monoclonal anti-D has been produced by Epstein-Barr virus transformation of lymphoblastoid cell lines taken from Rh-immunized donors^{80,81} and by the fusion of similarly transformed cell lines with mouse-human heteromyelomas (hybridomas).^{82,83} Once sufficient stable monoclonal anti-D is produced, tissue-culture RhIG will replace plasma-prepared RhIG.

Current recommendations for Rh prophylaxis

- 1 Every Rh-negative unimmunized woman who delivers a Rh-positive baby must be given one prophylactic dose of RhIG as soon as possible after delivery.
- 2 Every Rh-negative unimmunized woman who aborts or threatens to abort must be given RhIG, unless her husband (or father of the baby) is known to be Rh negative.
- 3 Every Rh-negative unimmunized woman who undergoes amniocentesis or CVS, unless her husband (or father of the baby) is known to be Rh negative, must be given 300 µg of RhIG at the time of the procedure, with subsequent doses at 12-week intervals until delivery.
- 4 Every Rh-negative unimmunized woman whose husband (or father of the baby) is either Rh positive or Rh unknown should be given 300 µg of RhIG at 28 weeks' gestation. A second dose should be given 12.5 weeks later if delivery has not taken place, but then need not be repeated postpartum if delivery occurs within 3 weeks.
- 5 If massive TPH is diagnosed, 300 µg of RhIG should be given i.m. for every 25 mL of fetal blood or fraction thereof in the maternal circulation. The dose may be reduced by one-third if RhIG is given i.v.
- 6 One prophylactic dose of RhIG should be given antepartum to the mother who has an Rh antibody detectable only by AA

methods and again after delivery, if she delivers a Rh-positive baby. If the antibody is detectable by a manual enzyme method, administration of RhIG will not prevent progressive immunization. However, it should be given if there is any question about the specificity of the enzyme reactions.

NonRh D blood group immunization

ABO hemolytic disease

Although ABO-incompatible hemolytic transfusion reactions are intravascular and much more serious than extravascular Rh-incompatible hemolytic transfusion reactions, ABO hemolytic disease is much milder than Rh hemolytic disease. Kernicterus due to ABO hemolytic disease is reported, but hydrops caused by ABO hemolytic disease is extremely rare.⁸⁴ In another case, neonatal death due to hydrops fetalis occurred in an ABO-incompatible newborn who had direct antiglobulin-positive red cells but whose umbilical cord blood hematocrit was 43%, rendering it most unlikely that this was alloimmune hydrops fetalis.⁸⁵

ABO hemolytic disease is mild because A and B antigens are not well developed on the fetal red cell membrane, because most anti-A and anti-B is IgM and does not cross the placenta, and because most of the small amounts of IgG anti-A and anti-B that do cross become attached to numerous other tissue and fluid A or B antigens. Thus, only a small amount of A or B antibody traversing the placenta binds to red cell antigenic sites. This explains why the umbilical cord blood direct antiglobulin test is only weakly positive and may even be negative unless a sensitive test is used. Even with the most sensitive test, red cells taken from a 1- or 2-day old baby with ABO hemolytic disease may be direct antiglobulin negative.

ABO hemolytic disease is by far the most common hemolytic disease. From 1954 to 1965, of 45 000 deliveries at the Winnipeg General Hospital, 9000 ABO-incompatible babies were born. Of the 9000, 2500 had weakly direct antiglobulin-positive cord blood red cells and therefore had serologic ABO erythroblastosis. Of those 2500, only 41 (less than 2%) required exchange transfusion.⁸⁶ The management of ABO erythroblastosis is entirely a pediatric concern. Amniocentesis and other fetal investigative measures are not required in the ABO-incompatible pregnancy.

Hemolytic disease caused by atypical blood group antibodies

Anti-D in the Rh blood group system remains the most common antibody causing severe hemolytic disease. Rh immunization preventive measures have produced a marked reduction in Rh immunization, however.

In Manitoba (population 1 million), the mean annual occurrence of D alloimmunization in pregnant women dropped from 194 in the 5-year period ending October 31, 1967 to 22 in the 5-year period ending October 31, 1995. In the same

two periods, the mean annual occurrence of detected nonD alloimmunization in pregnant women, excluding ABO alloimmunization, increased from 14 to 116. This increase is partly because of the increased screening of pregnant D-positive women. It may also be because of a real increase in the occurrence of nonD alloimmunization because of the increased frequency of blood transfusion (transfused blood being only ABO and D compatible).

NonD alloantibodies, therefore, have assumed greater significance in the etiology of hemolytic disease. The alloantibodies causing hemolytic disease of the newborn outlined by Mollison et al. are numerous.⁸⁷ However, the only antibodies implicated in moderate to severe disease are all those in the Rh blood group system plus anti-K, -Jk^a, -Jk^b, -Jk^c, -Ku, -Fy^a, -M, -N, -s, -U, -PP₁^p, -Di^b, -Lan, -LW, -Far, -Good, -Wr^a, and -Zd. Although this list seems overwhelming, it must be considered in conjunction with the frequency with which such antibodies occur and the frequency with which they cause significant hemolytic disease of the newborn (Table 49.1).

Of the nonD alloantibodies observed in one hospital during the 34-year period ending September 30, 1996, anti-E and anti-K were the most common, although only 20 of the 171 affected infants due to anti-E and 8 of the 17 affected infants due to anti-K required exchange transfusion or phototherapy. Two, due to anti-Kell, were very severely affected. Anti-C, when present, is more likely to cause hemolytic disease (54% versus 24% and 3.3% for anti-E and anti-K respectively) and, in those affected, is more likely to cause disease requiring treatment than anti-E (29% versus 12%), but not so for anti-Kell, where 47% who were affected required treatment.⁸⁸ Anti-C, anti-Kell, and anti-Fy^a were the only nonD alloantibodies in the 34-year period that caused disease so severe that it resulted in either severe

Table 49.1 Association of hemolytic disease with maternal blood group antibodies.

Common	c(cE) – incidence high, disease common, may be severe Kell – incidence high, disease uncommon but, if present, may be severe E – incidence high, disease uncommon, usually mild, rarely severe C(Ce, C ^w) – incidence moderate, disease common, usually mild
Uncommon	K – rarely present but, when present, may be very severe Kp ^a (Kp ^b) – rare, disease may require treatment, very rarely severe Jk ^a – uncommon, may require treatment, rarely severe Fy ^a – uncommon, usually mild, may require treatment, rarely severe S – uncommon, usually mild, may require treatment, rarely severe
Rare	s, U, M, Fy ^b , N, Do ^a , Di ^a , Di ^b , Lu ^a , Yt ^a , Jk ^b – rarely cause hemolytic disease
Never	Le ^a , Le ^b , P – never cause hemolytic disease

anemia requiring IUT or neonates born with hemoglobin levels less than 60 g/dL.

Pregnant women with atypical antibodies [i.e., c(cE), Kell, E, C(Ce, C^w), k, Kp^a(Kp^b), Jk^a, Fy^a, S] should be managed in exactly the same manner as if they were Rh negative and Rh D immunized. Although some of these antibodies are common and only occasionally (or rarely) cause dangerous hemolytic disease (i.e., anti-E), and although others are very rare but, if present, may cause severe disease (i.e., anti-K), the potential remains for severe disease. Antibodies that never cause hemolytic disease (i.e., Le^a, Le^b, P) may be disregarded, as for the most part may those that rarely, if ever, cause hemolytic disease (i.e., s, U, M, Fy^b, N, Do^a, Di^a, Di^b, Lu^a, Yt^a, Jk^b).

However, if in the latter group, the antibody appears very potent and of high titer, ultrasound evaluation and possibly amniocentesis or fetal blood sampling is warranted.

Anti-Kell alloimmunization is a special case. There are several reports of severe Kell alloimmune disease with low, misleading ΔOD 450 values.^{89,90} Anti-Kell has been postulated to cause destruction of poorly hemoglobinized marrow erythroid precursors,⁹¹ which may explain the reports of more severe Kell hemolytic disease of the newborn than was predicted from the ΔOD 450 readings.^{83,84} The management of Kell isoimmunization is the same as for Rh disease, and based on serial MCA peak velocity measurements and cordocentesis when abnormal.

Key points

- For Rh alloimmunization to occur:
 - The woman must be Rh negative and the fetus Rh positive.
 - Fetal erythrocytes must enter the maternal circulation in sufficient quantity.
 - The mother must be immune competent.
- The primary maternal Rh immune response is slow (typically over 6–12 weeks) – it is usually weak and predominantly IgM (which does not cross the placenta). The second TPH in an immunized woman produces a rapid (within days) secondary immune response – IgG anti-D, which can readily cross the placenta, coat fetal erythrocytes, and trigger hemolysis.
- ABO incompatibility between a Rh-positive fetus and a Rh-negative mother reduces the risk of immunization to 1.5–2%. This protection is in part because of rapid intravascular hemolysis of the fetal ABO-incompatible cells and their sequestration in the liver. Remember ABO incompatibility confers no protection once Rh immunization has developed.
- Fetal blood is produced as early as the third week in the yolk sac, but moves to the liver and, finally, to the bone marrow by 16 weeks' gestation. The Rh antigen is detectable on the red cell membrane by the sixth week.
- Pathogenesis – maternal IgG anti-D crosses the placenta (TPH) and coats the D-positive fetal red cells. These fetal red cells are destroyed extravascularly, resulting in anemia, which stimulates the synthesis of fetal erythropoietin. Reticulocytosis occurs when fetal hemoglobin deficit exceeds 2 g/dL (compared with gestational age-appropriate norms). Nucleated red cell precursors from normoblasts to primitive erythroblasts are released into the circulation (erythroblastosis fetalis).
- During hemolysis, the globin chain is split from hemoglobin. The remaining heme pigment is converted by heme oxygenase to biliverdin, and then by biliverdin reductase to neurotoxic indirect bilirubin. The fetal and newborn liver is deficient in glucuronyl transferase and Y transport protein; therefore, the increased indirect bilirubin is deposited in the extravascular fluid. Indirect bilirubin is water insoluble and, when the albumin-binding capacity is exceeded, the excess indirect bilirubin diffuses into fatty tissues (i.e., the neuron), where it interferes with cellular metabolism causing the mitochondria to swell, balloon, and then the neuron dies.
- Bilirubin reaches the amniotic fluid primarily by excretion into fetal pulmonary and tracheal secretions and diffusion across the fetal membranes and umbilical cord. Spectrophotometric determinations of amniotic fluid bilirubin correlate with the severity of fetal hemolysis. The deviation from linearity at 450 nm (the ΔOD 450 reading) correlates directly with disease severity. (An increase at 405 nm, if present, is due to heme.)
- The Liley curve emphasizes the need for repeating the amniotic fluid analyses to establish the ΔOD 450 trend. Readings in zone 1 indicate mild or no disease, but did not exclude the possibility that treatment would be required after birth. Readings in zone 2 are felt to indicate intermediate disease, increasing in severity as the zone 3 boundary is approached.
- Cordocentesis is the most accurate means of determining degree of severity of hemolytic disease, in the absence of hydrops fetalis – it allows the measurement of all blood parameters that can be measured after birth (hemoglobin, hematocrit, serum bilirubin, direct and indirect platelet count, leukocyte count, serum proteins, and blood gases). Cordocentesis has an associated mortality rate of 1% and approximately 5% morbidity (prolonged bradycardia, umbilical cord hematoma, amnionitis with maternal adult respiratory distress syndrome, and placental abruption). Consequently, cordocentesis is recommended when a screening tool such as the measurement of the MCA peak velocity is abnormal.

- 10 Ultrasound is invaluable in the management of alloimmunization. First, it establishes accurate dating criteria for gestational age. Second, many ultrasound parameters exist that help to predict fetal anemia. Lastly, hydrops fetalis can be detected with ultrasound.
- 11 Doppler ultrasound – the peak systolic velocity in the fetal MCA has proved very accurate, and normative data have been established for gestational age. Using a threshold value of 1.5 MoM to predict moderate to severe anemia, more than 70% of invasive tests were avoided. The fetal MCA closest to the maternal skin should be evaluated using a minimal angle of insonation. The Doppler gate should be placed over the vessel just as it bifurcates from the carotid artery.
- 12 Management of the newly sensitized woman begins with identification. If titers are below the threshold (below which severe fetal hemolytic disease does not occur), they should be repeated monthly. Once the critical titer is exceeded, the fetus is followed with serial measurements of the peak MCA velocity. The timing of invasive fetal testing (cordocentesis) is determined by ultrasound evidence of fetal anemia (when the peak MCA velocity becomes elevated).
- 13 Management of the woman with a previously sensitized fetus again begins with identification. If the fetus is deemed to be at risk, initiate serial MCA Doppler measurements by 18 weeks to monitor these pregnancies. Testing should be repeated every 1–2 weeks as long as they are normal. If a rising value for peak MCA Doppler velocity of more than 1.5 MoM is found, a cordocentesis should be performed and the fetus transfused if the hematocrit is < 30%.
- 14 Transfusion therapy is initiated when the fetal hematocrit is < 30%, a value less than the 2.5th percentile at all gestational ages above 20 weeks.
- 15 The blood used for fetal transfusion should be from a fresh donor, group O, and negative for the antigen (or antigens) to which the mother is sensitized. It should also be negative for HBsAg, anti-HIV, anti-HCV, and anti-CMV.
- 16 Intraperitoneal fetal transfusion is the original, but now least preferred, method of fetal transfusion. It has several disadvantages: there is slow correction of the fetal anemia and a higher risk of trauma. There is the added risk of obstructing cardiac return if the intra-abdominal pressure becomes too high.
- 17 Transfusion therapy suppresses fetal erythropoiesis, and the average reticulocyte count is usually < 1% by the third transfusion. The complications of hyperbilirubinemia are less if at least two transfusions are performed 3 weeks apart. The last transfusion can be done between 34 and 35 weeks' gestation and delivery planned at 38–39 weeks. (Transfusion therapy is not an indication for Cesarean delivery.)
- 18 Neonates affected by alloimmunization should have their hematocrit and reticulocyte count monitored weekly. The therapeutic goal is to maintain them with a modest anemia; small transfusions will keep the infant asymptomatic but leave the erythropoietic stimulus unblunted. Once reticulocytosis is observed, the neonate will no longer need further transfusion therapy.
- 19 RhIG prevents Rh immunization with two provisos: it must be given in adequate amounts, and it must be given before Rh immunization has begun. RhIG administration does not suppress Rh immunization once it has begun, no matter how weak the immunization.
- 20 In the United States, it is recommended that 300 µg of RhIG be administered within 72 h of delivery of a Rh-positive infant. This dose will protect against sensitization from TPH of 30 mL of fetal whole blood. Approximately 1 in 1000 deliveries will exceed this volume. Therefore, routine screening at delivery for excessive TPH is indicated. The rosette test is performed first; if negative, the patient need only receive the standard dose of RhIG and, if positive, a Kleihauer–Betke stain is performed to determine the number of additional vials of RhIG that are needed to prevent maternal sensitization.

Maternal infections, human immunodeficiency virus infection, and sexually transmitted diseases in pregnancy

Richard L. Sweet and Howard Minkoff

Maternal infections during pregnancy

The altered immune state of pregnancy increases the risk of infection for the adult host. This is a paradox. The blunting of the immunologic response in a pregnancy is beneficial because it permits the maintenance of a foreign protein graft, the placenta and the fetus. At the same time, it can be detrimental to the pregnant women when she is exposed to such foreign antigens as viruses and bacteria. Both the frequency and the severity of infection can be increased.

There are conflicting laboratory data about a reduced immunologic response during pregnancy. For the purposes of this discussion, evaluation of immunity is divided into two categories: humoral and cellular. Most of the studies of humoral immune response in pregnancy show reactions similar to those found in nonpregnant women.¹ In contrast, the cellular immune response has generally been diminished. Although the mechanism remains in question, pregnancy has generally been associated with a depressed cell-mediated immunity.

The most important test of the hypothesis of diminished cell-mediated immunity in pregnancy is clinical observation. If infection in pregnant women is more frequent or severe, this should settle the issue. There have been many studies with a multitude of varied pathogens that document a diminished host response in pregnant women. For example, Finland and Dublin's² detailed study, published in 1939, of a large number of Boston women who had a pneumococcal pneumonia documented a death rate that was higher in pregnant than in nonpregnant women, particularly when the disease was contracted in the third trimester. The increased severity of infection in pregnant women is not limited to bacterial infections. Viruses are also a problem. In the influenza pandemic of 1957, death was much more common among pregnant women.³ Protozoal disease and systemic fungal disease can also be serious. For example, pregnant women have an increase in both the incidence and the complications of malaria and, in endemic

regions, coccidioidomycosis is a leading cause of maternal death.⁴ All these different disease entities, caused by bacteria, viruses, protozoa, and fungi, share two similar traits: they are normally held in check by cell-mediated immune mechanisms, and all are more serious in pregnancy.

The control of maternal infection during pregnancy requires two strategies. The traditional approach is the treatment of an established infection, and this takes up the bulk of the presentation in this chapter. Of equal or greater importance is prevention. Up to now, this has been a neglected subject for obstetricians. Comprehensive prevention of infection implies two target patient populations: those women before pregnancy (preconception) and those women during pregnancy.

Obstetricians must take a more active role in the immunization of adult women.⁵ When young women become sexually active, they switch their primary care from the pediatrician to the obstetrician-gynecologist. In the future, we will need to become more attuned to preventive medicine strategies in women.

The preconception period is a window of opportunity for the prevention of infections in women. This should be a familiar theme for obstetricians because it applies to other problems. For infectious disease control, the strategies fit into three major groupings: treatment, immunization, and prevention strategies.

Treatment is included here as a preventive measure, because of the clinically silent nature of most *Chlamydia trachomatis* infections in women. Screening for *C. trachomatis* should be applied to sexually active women, particularly those younger than age 25 years who are at most risk of acquiring this infection. As discussed in the section on sexually transmitted diseases (STDs), chlamydial infection is associated with adverse prognosis complications. In addition, undetected *C. trachomatis* infection can have myriad untoward long-term effects on the future health of women including infertility,⁶ ectopic pregnancy,⁷ and abortion.⁸ Diagnosis and treatment of chlamydial infections are discussed in the section on STDs.

Immunization of adult women

Immunization programs are a major part of our infectious disease prevention strategy. Of critical importance is the recognition that adult immunization programs are an integral part of this strategy.^{9,10} It has been estimated that over 60 000 adults die annually in the United States from vaccine-preventable diseases with influenza and pneumococcal disease the most common.¹¹ Gonik et al.¹⁰ have recently emphasized the important role that obstetrician–gynecologists play in adult immunization.

Tetanus–diphtheria

Tetanus is a rare problem in the United States, with only 50–65 cases per year, but it is a serious disease that can cause death.⁹ The Centers for Disease Control (CDC) recommends that adults, including pregnant women with uncertain history of a complete primary vaccination series, should receive a primary series of tetanus and diphtheria (Td).⁹ This includes a series of three doses with the first two doses given at least 4 weeks apart and the third dose 6–12 months after the second. For those women who have received the primary series, one booster dose should be administered every 10 years.⁹ The most important fact in the physician’s care decision is that tetanus can be prevented by immunization. New nonpregnant patients in the childbearing age group should be asked about their tetanus immunization status. If they have not had a booster dose in the last 10 years, they should be given tetanus toxoid. This should be a lifetime concern of obstetrician–gynecologists because 60% of tetanus cases and 75% of deaths occur in the elderly, especially women.¹²

Measles, mumps, and rubella

The next three preventable diseases, measles, mumps, and rubella, are discussed together because a vaccine that protects against them is commercially available. Antibody testing should be done to confirm susceptibility. If the patient has no antibodies, she should be offered immunization. Because this is an attenuated live virus, the patient should be counseled to avoid getting pregnant for 3 months after the immunization. These women should be advised before the injection that adult women have a much higher incidence of migratory arthritis than men.¹³ Fortunately, this is a transient, not a permanent, problem. Unfortunately, the symptoms can last up to 9 months.

Hepatitis B

Hepatitis B is an important disease for American women. It occurs with a greater frequency in the United States than other vaccine-preventable communicable diseases.¹⁸ More importantly, it causes short-term illness and, for those chronic carriers of the virus, there is the possibility of serious long-term morbidity with cirrhosis or a hepatic carcinoma. The Advisory Committee on Immunization Practices (ACIP) has developed recommendations for the prevention of hepatitis B virus

(HBV) transmission in the United States.¹⁴ Pre-exposure vaccination to prevent HBV infection addresses three groups of patients: (1) routine vaccination of all newborns/infants; (2) catch-up vaccination of susceptible children and adolescents; and (3) vaccination of high-risk adults (Table 50.1).^{9,14} Despite the frequency of hepatitis B compared with rubella,¹⁸ American obstetricians are predisposed to immunize against rubella, a very rare disease, but not hepatitis B, which is much more common and a greater threat to the long-term health of women. This is a problem of education and awareness for physicians and patients. This is a three-shot immunization regimen. The first two are given 1 month apart, with the third administered 6 months later.⁹ These women should be reassured. This vaccine is a recombinant DNA vaccine derived from yeast and is safe in pregnancy.

Hepatitis B vaccine is recommended for all newborns/infants; those born to mothers who are hepatitis surface antigen-positive should receive the first dose of vaccine within 12 h of birth and a concomitant injection of hepatitis B immune globulin (HBIG).

Varicella

Varicella is a potentially serious illness for adults, resulting in pneumonia in some cases, and progressing to death in a few, especially in pregnant women. In addition, acquisition during pregnancy can be damaging to the fetus. As some women are unclear about a prior history of varicella, susceptibility should be determined by antibody testing. If susceptible, immunization should be offered. It is a live attenuated virus vaccine that is usually well tolerated by adults. For adults, the best response is achieved by two injections, 4–8 weeks apart.

Varicella vaccine is a live attenuated virus vaccine and thus, because of a theoretical risk, should not be given to pregnant women or those planning on becoming pregnant in the next

Table 50.1 Groups at high risk of hepatitis B infection.

Sexually active heterosexual persons with recent STD, identified as prostitutes, having more than one sexual partner in the past 6 months, or seen in STD clinic
Homosexual or bisexual men
Household contacts and sexual partners of HbsAg-positive persons
Intravenous drug abusers
Persons at occupational risk through exposure to blood or infected body fluids (i.e., healthcare workers, public safety workers)
Clients and staff of institutions for the developmentally disabled
Patients on hemodialysis
Patients receiving clotting factor concentrate
Adoptees from countries where HBV infection is endemic
International travelers to areas where HBV is endemic who will have close contact with the local population
Inmates of long-term correctional facilities

STD, sexually transmitted disease; HbsAg, hepatitis B surface antigen; HBV, hepatitis B virus.

1 (ACIP) to 3 (Merck) months.^{9,15} However, to date, no evidence of the congenital varicella syndrome has been reported among offspring of mothers inadvertently vaccinated in the first trimester. Breastfeeding is not a contraindication to varicella vaccine.

Influenza

Influenza vaccines are inactivated viral vaccines and, as a result, are safe to use during any trimester of pregnancy.¹⁶ Pregnant women suffered excess deaths due to influenza during the pandemics of 1918–1919 and 1957–1958.¹⁷ Thus, the benefits of influenza vaccination in pregnant women clearly outweigh the potential risks. Women who will be pregnant during the influenza season should be inoculated with the influenza vaccine prior to the influenza season, regardless of the stage of pregnancy.

Pneumococcal pneumonia

Pneumococcal infections caused by *Streptococcus pneumoniae* are a major source of morbidity and mortality.¹⁸ *S. pneumoniae* is the leading cause of community-acquired pneumonia in the United States requiring hospitalization,¹⁸ and is associated with an overall mortality rate of 5–10% and mortality rates as high as 30% in patients ≥ 65 years of age.¹⁹ The ACIP recommends pneumococcal vaccine for all persons ≥ 65 years of age and for those individuals between 2 and 65 years of age who are at increased risk of serious pneumococcal infection.⁹ Those at increased risk include: (1) persons with functional or anatomic asplenia; (2) persons with chronic cardiovascular or pulmonary disease; (3) those with diabetes mellitus; (4) alcoholics and those with chronic liver disease; (5) persons with cerebrospinal fluid leaks; and (6) persons living in special environments (e.g., nursing homes, chronic-care facilities, homeless shelters) or social settings (Native Alaskan, Native American).²⁰ While the safety of pneumococcal vaccine use in pregnancy has not been determined, there is no reason to suspect that the vaccine would have an adverse effect on the fetus or mother, and thus pneumococcal vaccine is not contraindicated during any stage of pregnancy.

Hepatitis A

Hepatitis A vaccine is recommended for those ≥ 2 years of age who are at increased risk of hepatitis A virus (HAV) infection.⁹ Those at high risk include: (1) international travelers to countries where hepatitis A is endemic; (2) military personnel; (3) high-risk ethnic or geographic populations (e.g., Native Americans, Native Alaskans); (4) men who have sex with men; (5) intravenous drug abusers; (6) regular recipients of blood or plasma-derived products; (7) persons engaged in high-risk employment (primate handlers, employees of institutions for the developmentally challenged, day-care staff); and (8) persons chronically infected with hepatitis C.

Hepatitis A vaccine is an inactivated virus, and thus is not specifically contraindicated during pregnancy and is safe when breastfeeding. However, it is recommended by the CDC that

hepatitis A vaccine should be given in pregnancy only if clearly indicated (e.g., exposure to infected contact or travel to endemic region).⁹

Preventive care for pregnant women

The antepartum time-frame is critical for the obstetrician who practices preventive medicine. Many strategies of prevention are in harmony with preconception care. There are many patients who will first see their healthcare provider when they are pregnant. In these instances, the whole process of education should be part of their care. Finally, preventive strategies that work will be beneficial to the mother and the fetus. For pregnancy, strategy follows three lines: treatment, prevention, and immunization.

Treatment should be directed at silent infections that could adversely affect the pregnant woman. There are eight disease entities that require attention. Two are discussed in this section; six others are presented elsewhere. Asymptomatic bacteriuria and patients with positive skin test results for tuberculosis are discussed under specific organ systems, the urinary and respiratory tract. Human immunodeficiency virus (HIV), *Neisseria gonorrhoeae*, *C. trachomatis*, syphilis, and trichomoniasis and bacterial vaginosis are discussed in other sections.

Although we think of them as symptomatic diseases, both bacterial vaginosis (BV) and *Trichomonas* vaginitis can be asymptomatic in many women. Their discovery is important, because these vaginal infections have been associated with an increased rate of premature labor and delivery.^{22,23} There are currently no recommended techniques for screening asymptomatic women for the presence of these diseases. At the time of the initial pelvic examination, a vaginal pH and a whiff test with potassium hydroxide should be done. If both these test results are positive, a microscopic examination of a saline preparation should be done for the presence of clue cells. The positive whiff test and the presence of more than 20% clue cells in the vaginal preparation is the most sensitive screening test for BV.²⁴ Although the Vaginal Infection in Pregnancy study emphasizes the use of the Gram stain of a vaginal smear and one more recent study supports its sensitivity,²⁵ it is probably unlikely that this will be a popular screening test for clinicians.

While epidemiologic studies have demonstrated an association between BV and preterm birth, published randomized control studies have been inconsistent. Detection and treatment of asymptomatic BV in pregnant women with a previous preterm birth has significantly reduced the rate of preterm births.^{26–28} In contradistinction, treatment of asymptomatic BV in low-risk women (i.e., no previous history of preterm birth) did not reduce the preterm birth rate.^{28,29} Currently, the CDC does not recommend screening and treatment of asymptomatic pregnant women for BV.³⁰ For symptomatic pregnant or high-risk pregnant women, metronidazole 250 mg orally t.i.d. for 7 days or clindamycin 300 mg orally b.i.d. for 7 days

is recommended.³⁰ Intravaginal topical preparations are not recommended for the treatment of BV during pregnancy.

Even less is known about a pregnancy strategy for *Trichomonas*. The hanging drop microscopic examination is not a sensitive test.³¹ In contrast, a higher yield of positive test results was obtained in an urban population when the screening was done with the polymerase chain reaction (PCR) technique.³² Although the presence of *Trichomonas* is associated with an increased rate of preterm delivery, there is no consensus on screening and treatment. Paradoxically, a large prospective, randomized, placebo-controlled treatment trial of asymptomatic *T. vaginalis* infection in pregnancy, by the National Institutes of Health (NIH)-supported Maternal-Fetal Medicine network, reported an increased risk of preterm delivery (< 37 weeks' gestation) in the metronidazole-treated patients.³³

Screening for asymptomatic bacteriuria and tuberculosis is discussed in the sections on urinary tract and respiratory tract infections.

Toxoplasmosis is not a common disease in pregnancy, but it is important because the first maternal infection during pregnancy can result in fetal infection and morbidity. Any preventive strategy requires knowledge of the patient's susceptibility. For those antibody-negative women, printed recommendations should be provided (Table 50.2).³⁴ These measures are not difficult to understand or to follow. A similar set of recommendations given in patient education sessions significantly lowered the incidence of toxoplasmosis acquisition in Belgium.³⁵

Cytomegalovirus (CMV) requires a very different emphasis by obstetricians because of its frequency. It is the most common cause of congenital viral infections, with an estimated 30 000–40 000 infected newborns born each year in the United States, 9000 of whom have permanent serious sequelae.³⁶ The starting point of preventive care is to determine the antibody status of the patient. If the patient is susceptible,

there is a wide range of behavioral modifications that will decrease the risk of acquisition of this virus during pregnancy (Table 50.3).³⁴ The first applies to patients who remain in non-monogamous sexual relationships after they are pregnant. They should have their male sexual partners use condoms. The second measure, handwashing, is especially applicable to the CMV-susceptible working mother who has young children in a childcare center, nursery school, or kindergarten. These procedures should be easily followed. The third reminder is for physicians to remember to counsel patients.

The rest of this chapter addresses problems of maternal infection during pregnancy, with an emphasis on organ systems.

Vulvovaginal infections

A frequent problem for pregnant women is the development of an increased vaginal discharge. Often, this is accompanied by other uncomfortable symptoms, such as itching or vulvar burning.

Changes in physician attitudes are needed to care properly for these women. Altered strategies are needed because of new information now available to physicians. In the past, the defining obstetric dogma was that pregnant women had an increased incidence of yeast vaginitis that was related in theory to a range of events from pregnancy hormonal changes to the glycosuria so commonly seen in pregnant women. The accepted therapeutic pattern among obstetricians was to prescribe a local antifungal agent or to have the patient medicate herself with over-the-counter antifungal preparations. Neither of these strategies mandated a vaginal examination, and it was frequently not done. Instead, the vaginal secretions were evaluated in patients who remained symptomatic despite treatment. This approach is no longer acceptable for a number of reasons. Practitioners have observed and it has been reported that patient self-diagnosis of a yeast vaginitis is often incorrect.³⁷ Physicians and patients should not assume that a symptomatic vaginal discharge in pregnancy is due to yeast. This is

Table 50.2 Toxoplasmosis, uncommon disease.

Patients should be tested for the presence of <i>Toxoplasma</i> antibodies.
If the antibody is negative:
Patients should be advised not to eat raw or undercooked meat, particularly pork, lamb, or venison. Specifically, meat should be cooked to an internal temperature of 150°F; meat cooked until no longer pink inside generally has an internal temperature of 165°F.
Patients should be advised to wash their hands after contact with raw meat and after gardening or contact with soil; in addition, they should wash fruit and vegetables well before eating them raw.
If the patient owns a cat, someone else should change the litter box daily; alternatively, the patient should wash her hands thoroughly after changing the litter box. Patients should be encouraged to keep their cats inside and not to adopt or handle stray cats.

Table 50.3 Cytomegalovirus (CMV), common disease.

Patients should be tested for the presence of CMV antibodies. If the antibody is negative:
Patients should be advised that CMV is shed in semen, cervical secretions, and saliva. Latex condoms should be used during sexual contact if the patient is not in a monogamous relationship.
Providers of childcare or parents of children in childcare centers should be informed that they are at increased risk of acquiring a CMV infection. The risk of CMV infection can be diminished by avoiding mouth-to-mouth kissing and by handwashing, particularly after changing diapers.
If a blood transfusion is needed, these patients should receive only CMV antibody-negative blood or leukocyte-reduced cellular blood products in nonemergency situations.

important, because the Vaginal Infection in Pregnancy study noted two outcomes of other vaginal infections that are important to obstetricians. Patients with BV²² and *Trichomonas* vaginitis²³ have a higher than expected incidence of preterm labor and delivery. These new correlates change the diagnostic demands on physicians caring for pregnant women. A physical examination and necessary laboratory testing need to be done to confirm the etiology of the vaginal discharge.

This physical and laboratory examination of the pregnant patient with a troublesome vaginal discharge does not require any new expensive office equipment or specialized clinical expertise. The approach to these women is simple and straightforward. The physician has to examine the vulva and vagina and do some immediate testing in the office environment. Cotton swabs, pH paper, solutions of saline, potassium hydroxide, and dilute acetic acid, as well as slides, coverslips, and a usable microscope, should be on hand. Physicians have to evaluate the pH paper reading, assay the scent emanating when vaginal secretions are added to the dilute potassium hydroxide solution, and be able to identify fungal forms, trichomonads, white blood cells, vaginal epithelial cells, and survey the bacterial background of the wet mount smears at the time of the immediate microscopic examination. This is the required office workup of every pregnant patient with vulvovaginal symptoms. Unfortunately, as reported by Wiesenfeld and Macio,³⁸ many obstetrician-gynecologists do not perform these simple office-based tests for determining the etiology of vaginitis symptoms and signs.

A frequent diagnosis of the pregnant patient with a troublesome vaginal discharge is a *Candida* vaginitis. The evaluation of these patients is straightforward. The vaginal pH is tested and is usually acidic. Vaginal secretions are added to a drop of saline on one slide and a drop of dilute potassium hydroxide on another. The physician should determine if an odor is present. A portion of the secretions is put in a sterile microbiological culture kit, which may or may not be sent to the laboratory. The diagnosis is usually made by microscopic examination of the saline and the potassium hydroxide preparation. If this is the first vaginal infection and *Candida* forms can be identified, a culture is not needed. If the diagnosis of *Candida* vaginitis cannot be confirmed on microscopic examination or the patient has recurrent vaginal yeast infections, the culture should be sent to the laboratory,³⁹ and on the specimen slip, a request made that, if yeast is present, it should be speciated.⁴⁰

Candida albicans vaginitis is usually easy to treat, because it is not resistant to the available, local antifungal agents, nystatin and the azoles, all of which can be prescribed or obtained over the counter. These local agents should be the drugs of choice for pregnant women for three reasons. The systemic absorption of the topical azoles is minimal,⁴¹ their use in the first trimester has been documented with no detectable evidence of teratogenicity,⁴¹ and congenital anomalies (craniofacial, skeletal, and cardiac) have been reported in women who

received fluconazole in the first trimester.⁴² The reported ossification defects resemble those seen in pregnant animals given fluconazole.⁴² There is no evidence that patients with a recurrent *C. albicans* vaginal infection have an improved clinical cure rate if their male sexual partners are treated.⁴³ Other strains of yeast are a more serious problem, and this is one reason for obtaining cultures in women with recurrent or persistent problems.

Torulopsis glabrata may be resistant to local azole antifungals. Treatment with a local boric acid preparation is often effective in nonpregnant women,⁴⁰ but its safety in pregnancy has not been studied. Routine antepartum glucose screening of all obstetric patients will reveal any with a problem of glucose metabolism. Another reason for culture in women with persistent vaginal symptoms is the awareness that some of these symptomatic women do not have a chronic vaginal yeast infection. Many patients become sensitive to the propylene glycol present in most vaginal creams and suppositories⁴⁴ and are helped if these local treatments are discontinued.

Another common cause of troublesome vaginal discharge for a pregnant woman is BV. In addition to a persistent copious discharge, many of these women report an unacceptable odor, particularly after intercourse. This is an important entity to recognize because it has been associated with a higher than expected incidence of preterm labor and delivery.²² The diagnosis is simple and is immediately apparent to the physician at the time of the patient's office visit. The first test to perform is the vaginal pH, which is usually alkaline, that is > 4.5 in women with BV. These women invariably have a positive whiff test result when vaginal secretions are added to the dilute potassium hydroxide solution, and more than 20% of the vaginal squamous cells are clue cells when the saline preparation is examined immediately under the microscope. The two most sensitive tests for an immediate accurate diagnosis are a positive whiff test result and the presence of clue cells on the microscopic examination of the saline preparation.²⁴

For symptomatic BV in pregnancy, the CDC recommends metronidazole 250 mg t.i.d. for 7 days or clindamycin 300 mg orally b.i.d. for 7 days.³⁰

Some women complain of a troublesome vaginal discharge that is due to the organism *Trichomonas vaginalis*. Although textbooks have in the past described the typical clinical presentation of a patient with this infection, which includes a frothy vaginal discharge and "strawberry" spots on the vaginal surface, the problem for the physician is that these signs are not sensitive indicators of a *Trichomonas* vaginitis.³¹ As with previously described vaginal syndromes, the diagnosis is straightforward. The pH of the vagina is usually alkaline, there is often a positive whiff test result and, on microscopic examination of the saline preparation, there is an abundance of white cells, and motile trichomonads are often seen. If trichomonads are not seen, these patients should have either a culture or a PCR test for *T. vaginalis* performed.³² Unlike BV, the diagnosis may not be obvious at the time of the initial physician evaluation. This is an important

diagnosis to confirm because these vaginal infections are associated with a higher than expected incidence of premature delivery.²³ In those women in whom the diagnosis is established, there are two available treatment regimens with metronidazole. The woman can be prescribed either 2.0g orally in a single dose or 500mg b.i.d. for 7 days.³ Obviously, the male sexual partner should be treated concomitantly with the same dose.

If office pH, microscopy, and selective microbiological studies do not delineate the infection as BV, *Candida* vaginitis, or *Trichomonas* vaginitis, there are a variety of other problems that should be suspected, including vulvar vestibulitis, allergic vaginitis, desquamative vaginitis, and cervicitis.⁴⁴ There are signs associated with these alternative diagnoses that are apparent to the physician at the time of seeing the patient. The patient with vulvar vestibulitis has point tenderness with a cotton-tipped applicator applied at the vaginal entry sites of 3:30 and 8:30, if the vaginal entrance is oriented as the face of a clock; the patient with cervicitis has mucous present. None of these patients is helped with local antifungal preparations and, if these women have an allergic vaginitis, their symptoms can be magnified by the use of local preparations containing propylene glycol. Desquamative vaginitis is effectively treated with clindamycin vaginal cream. A patient with cervicitis should have microbiological tests for the presence of *N. gonorrhoeae* or *C. trachomatis*. They should be treated for both gonorrhea and chlamydia if they are a member of a patient population with a high prevalence of infection, treated for chlamydia if the prevalence of gonorrhea is low and the likelihood of chlamydia is substantial, or await test results if the likelihood of either is low.³ The treatment for both gonorrhea and chlamydia has been noted in the preventive section of this chapter.

Urinary tract infections

Increased stasis of urine during pregnancy and the fact that urine is an excellent growth medium for bacteria makes the urinary tract the most common site of infection. Urinary stasis is caused by the convergence of a number of normal pregnancy changes. The capacity of the urinary tract is usually increased. In spite of the fact that few radiologic observations have been made of the urinary tract in normal pregnant women, the available data indicate that dilation is mild in the first half of pregnancy, but this is not a uniform phenomenon. After mid-pregnancy, the right side is dilated in three-quarters of cases, and the left side is dilated in a third.⁴⁵ There is also expansion of the renal pelves and calices as well as an increase in bladder capacity. While this anatomic expansion occurs, more urine is delivered to this excretion system as renal blood flow and glomerular filtration rate increase. Increased progesterone production also affects urinary tract function. Ureteral peristalsis slows, and the transit time from kidneys to bladder is prolonged. The bladder is hypotonic and has an increase in the residual volume of urine. The sum of these changes results in

stagnant urine, an environment that encourages overgrowth of bacteria and subsequent clinical infection. The bacterial nidus for infection is present in the 2–10% of pregnant women with asymptomatic bacteriuria.⁴⁶ It is small wonder that urinary tract infections are seen so frequently in pregnant women.

Prevention is the appropriate starting place for any discussion of the therapy of urinary tract infections in pregnancy. Successful prevention eliminates the morbidity of symptomatic infections. This can be achieved in most instances and is described below.

Prevention of pyelonephritis

An estimated 25–30% of women with asymptomatic bacteriuria at the time of their first antepartum visit who are not treated will subsequently develop pyelonephritis in pregnancy.⁴⁷ These women are the focus of programs of detection and therapeutic intervention. Eighty percent of all cases of pyelonephritis in pregnancy could be eliminated if this population was identified and treated.⁴⁸ Harris⁴⁹ reported that, when an effort was made to identify and treat pregnant women with asymptomatic bacteriuria (ASB), there was a five-fold decrease in the annual incidence of acute antepartum pyelonephritis from 4.0% to 0.8%. In addition, ASB has been associated with an increased risk of preterm delivery and low birthweight.⁴⁷ Romero et al.⁵⁰ performed a meta-analysis that demonstrated a strong association of untreated ASB with preterm delivery or low birthweight.

These results buttress the idea of a uniform approach to all pregnant women seen for the first time. They should have a voided urine culture obtained to screen for significant bacteriuria. The health team caring for these women should advise them on how to produce a clean voided urine sample, and the specimens should be either processed immediately or refrigerated until they can be transported to the laboratory (this prevents bacterial overgrowth and false-positive urine cultures).

Although other screening tests are available, they lack sensitivity, and the standard remains the screening culture. When voided urine culture tests are employed, a significant test result has more than 100 000 colonies/mL of one bacterial species. If multiple bacterial isolates are obtained, the specimen was contaminated at the time of collection, and another clean voided urine sample should be obtained and cultured. The treatment of women who are culture positive is based on the recognition that, as in nonpregnant women, *Escherichia coli* is the predominant pathogen isolated (80–90% of cases).⁴⁷ Other important pathogens include *Staphylococcus saprophyticus* and group B streptococci. Those women who are positive on urine culture for the group B streptococci early in pregnancy have been identified as a high-risk population for newborn group B streptococcal infection and should be treated with penicillin or ampicillin during labor.⁵¹

When the presence of ASB is identified, empiric treatment is instituted based on the above described causative microor-

ganisms. Treatment is instituted with a 3-day course of trimethoprim-sulfamethoxazole (TMP-SMX, one double-strength tablet b.i.d.) or nitrofurantoin 100 mg b.i.d. In geographic areas where *E. coli* remains sensitive to ampicillin, amoxicillin 500 mg t.i.d. is an alternative. Continuous monitoring of patients for recurrent or persistent ASB is critical. If infection recurs, treatment should be based on antimicrobial susceptibility studies, and the patient should be maintained on suppressive antimicrobials (nitrofurantoin 100 mg h.s.) for the remainder of the pregnancy.⁴⁷

Cystitis and pyelonephritis

Despite universal screening and treatment of women with ASB, unlike the prevention of pyelonephritis, the incidence of cystitis remains the same.⁵² Fortunately, acute cystitis in pregnancy has not been associated with preterm birth, low birth-weight, or acute pyelonephritis.⁵²

The diagnosis of cystitis should be suspected in any pregnant woman with frequency and dysuria. *E. coli* is the most commonly isolated organism in the urine of patients with acute cystitis, followed by other Gram-negative bacteria such as *Klebsiella* and *Proteus*.⁴⁷ Gram-positive organisms, including group B streptococcus and *S. saprophyticus*, are less common.⁴⁷ Whereas in nonpregnant women with acute cystitis, empiric treatment without a culture is appropriate, in pregnancy, a culture should be obtained before commencing empiric therapy, and antibiotic therapy adjusted as indicated.⁴⁷ While $\geq 100\,000$ colonies/mL is the gold standard, Stamm et al.⁵³ demonstrated that, in acutely dysuric women, a quantitative count of 100 organisms/mL was sufficient for diagnosing acute cystitis.

For acute cystitis, the duration of therapy is 3 days. The antimicrobial agents suggested for the treatment of acute cystitis are the same as those utilized for the treatment of ASB including TMP-SMX 160/800 mg b.i.d. for 3 days and nitrofurantoin 100 mg b.i.d. for 3 days.

Acute pyelonephritis is one of the most frequent medical complications of pregnancy, occurring in 1–2.5% of obstetric patients.⁴⁷ The treatment of patients with pyelonephritis during pregnancy is much more intense. These patients are sicker and usually benefit from intensive therapy, so that problems of fever, hydration, and electrolyte imbalance, as well as the infection, can be treated. In addition, premature labor can occur in these women. This increase in uterine activity can be due to actions of the bacterial products causing the pyelonephritis, fever, or decreased intravascular volume. Therapy can modify these changes, and the uterus can be monitored to see whether a contraction pattern is becoming established. If necessary, tocolytic therapy may be indicated in addition to the antibiotics. Occasionally, some of these women become critically ill. In a series with a large number of pregnant women with pyelonephritis, 3 out of 99 (3%) had evidence of septic shock.⁵⁴ In addition, adult respiratory distress syndrome has been reported in pregnant women with

pyelonephritis.^{55–57} These women require close medical supervision.

All these potential problems require a broad therapeutic approach to the pregnant patient with pyelonephritis. Clinically, the diagnosis is usually obvious. These patients look ill, are febrile, and usually have flank pain. The uterus should be assessed immediately to be sure there is not a pattern of uterine contractions, and there should be immediate fetal heart rate monitoring to ascertain the health of the fetus. A vaginal examination should be done to insure there is no cervical dilation and cultures obtained to rule out maternal colonization with group B streptococcus, *C. trachomatis*, and *N. gonorrhoeae*. As soon as a voided urine sample can be obtained from the patient, a portion should be examined microscopically for the presence of bacteria. Uncentrifuged urine samples have been used, but a survey of laboratory studies in patients with bacteriuria recommended oil immersion microscopy of a Gram-stained centrifuged urine sample.⁵⁸ A portion of the urine should be sent for culture. If the clinical diagnosis has been made, treatment should begin. Fluid replacement should be an important part of therapy because some of these women are dehydrated, which is further aggravated because they are febrile with an increased insensible fluid loss. This is probably the reason why some investigators have noted diminished renal function in the first 24 h of treatment of pregnant women with pyelonephritis.⁵⁹ They need sufficient intravenous fluid replacement with a balanced electrolyte solution to insure a urine output of at least 50 mL/h. Because septic shock and respiratory distress have been reported in these women, they should be observed frequently, with regular monitoring of vital signs. In addition, these patients must be monitored for premature labor. If it occurs, tocolytic agents can be employed. Because respiratory distress can occur when these agents are used, an electrocardiogram should be obtained before treatment begins. If the patient has unrelenting flank pain, an ultrasound evaluation for the presence of urinary tract calculi should be done. If electrolyte abnormalities are noted in the initial screening blood chemistries, these can be corrected and repeat electrolyte determinations done until they are normal. Intravenous fluid electrolytes can be modified and repeat electrolyte determinations done until they are normal.

Initially, treatment for acute pyelonephritis is empiric with antimicrobial therapy dictated by knowledge of the most common etiologic organisms and the need for bactericidal drugs. The organisms most commonly recovered from pregnant women with acute pyelonephritis include *E. coli* (80–85%) and, less commonly, the *Klebsiella-Enterobacter* group.⁴⁷ Gram-positive bacteria, such as group B streptococcus and enterococci, have increasingly been recognized as pathogens in acute pyelonephritis in pregnant women.⁴⁷ Because of increasing resistance to *E. coli*, ampicillin and first-generation cephalosporins, which had been favored regimens for acute pyelonephritis in pregnancy, are generally no longer recommended for empiric therapy.^{47,60} The authors recommend that empiric therapy for acute pyelonephritis during

pregnancy be instituted with ceftriaxone 1–2 g intravenously as a single daily dose; it provides coverage against most major uropathogens other than *Enterococcus* and, because of once-daily administration, facilitates home parenteral therapy after initial in-hospital treatment and stabilization. TMP-SMX 160/800 mg intravenously b.i.d. is also appropriate in geographic areas where *E. coli* resistance to this agent has not occurred. A combination of either ampicillin (1–2 g intravenous q6h) or cefazolin (1–2 g intravenous q8h) in combination with gentamicin (1 mg/kg q8h) is an alternative approach. All patients should have a repeat culture done at 48 h after the initiation of treatment. If bacteria are still recovered, consideration should be given to switching antibiotics to an agent more effective against the organism to avoid later recurrence of infection. When patients have been afebrile for 24–48 h, they can be switched to an oral agent or home parenteral therapy to complete 10 days of therapy. All these women should have a post-treatment culture obtained and, if it is positive, they should be treated with a different agent that is effective against the isolates. In those women who remain culture positive after a full course of treatment, an ultrasound examination should check for the presence of urinary tract calculi.

Economic pressures have altered this inpatient treatment emphasis, and there is evidence suggesting that selected patients might be treated as outpatients. Brooks and Garite⁶¹ examined 34 patients as outpatients with uncomplicated initial episodes of pyelonephritis. Low-risk patients were identified by the absence of any sepsis, an oral temperature of greater than 39°C, severe nausea and vomiting, presence of diabetes or HIV infection, concomitant preterm labor, multiple gestation, severe penicillin allergy, history of renal disease or urinary tract anomalies, or the presence of an indwelling bladder catheter. After 2 h of observation, the patients had an initial dose of 2 g of ceftriaxone given intravenously, followed by 2 g of daily outpatient intramuscular ceftriaxone, until resolution of fever and flank pain, followed by a 10-day course of oral antibiotics. These carefully selected low-risk patients did well. Of the 34 in the outpatient treatment group, only four (12%) required subsequent hospital admission and one developed an upper urinary tract recurrence. None had premature delivery or any other serious complications.

Angel et al.⁶² suggested that treatment with oral antimicrobial agents only for acute pyelonephritis during pregnancy is appropriate and safe. They reported equal efficacy in a randomized trial of oral cephalexin versus intravenous cephalothin (91% versus 93% respectively). However, 13 (14.4%) of their patients had bacteremia and were excluded from the study. With inclusion of the bacteremic patients, oral therapy was less effective than parenteral therapy (71% versus 87%).⁶² Millar et al.⁶⁰ undertook a randomized controlled trial comparing inpatient and outpatient management of acute pyelonephritis in pregnancy prior to 24 weeks of gestation. All patients were observed in the emergency department to insure that they were stable and able to tolerate oral intake. The

ambulatory group received ceftriaxone 1 g intramuscularly (i.m.) in the emergency department and 1 g i.m. within 18–36 h after discharge, followed by oral cephalexin (500 mg q.i.d.) to complete a 10-day course. In addition, home-health nurses monitored the ambulatory patients for 48–72 h. Patients with severe pyelonephritis were excluded. The rates of persistent or recurrent bacteriuria and recurrent pyelonephritis were similar. However, the study was biased in favor of the outpatient arm because 10% of inpatients required the addition of gentamicin for failure to respond to cefazolin monotherapy; 12% of *E. coli* isolates were resistant to cefazolin.⁶⁰ Wing et al.⁶³ studied pregnant women with pyelonephritis at more than 24 weeks' gestation. After all patients received two 1-g doses of ceftriaxone i.m. during a 24-h observation period, women were discharged (if stable) on oral cephalexin (500 mg q.i.d.) to complete a 10-day course. Inpatients received oral cephalexin until they were afebrile for 48 h and then were discharged to complete a 10-day course of cephalexin. There were no significant differences in clinical response or pregnancy outcomes between the groups.⁶³ However, 30% of outpatients could not complete their course of therapy, and the majority of women with acute pyelonephritis were excluded because of suspected sepsis, signs of acute respiratory distress syndrome (ARDS), serious underlying medical disorders, renal or urologic abnormalities, or inability to tolerate oral intake.

As a result of the concerns described above with these studies advocating oral ambulatory treatment of acute pyelonephritis in pregnancy, the authors recommend that all pregnant women, at any gestational age, should be hospitalized for initiation of antimicrobial therapy, rehydration, close monitoring for complications, and monitoring for preterm labor. Once stabilized and afebrile for 24–48 h, they may be discharged to complete a 10-day course of oral antibiotics.

If the follow-up culture result is negative, there is controversy about the subsequent care of these women for the rest of the pregnancy. Both antibiotic suppression of these women for the remainder of the pregnancy (i.e., nitrofurantoin, 50–100 mg/day) and urine culture at frequent intervals with short courses of treatment in women who are culture positive have been suggested.⁴⁷ Either of these approaches for the prevention of recurrent pyelonephritis is acceptable. The authors utilize the suppression approach for the duration of pregnancy.

Respiratory tract infections

Upper respiratory tract

Upper respiratory infections occur frequently in the winter. Many are viral in origin, and antibiotic treatment will not be beneficial. Women complaining of a sore throat should be examined and, if the throat is inflamed or if tonsillitis is present, a culture for group A streptococcus should be

obtained. If the physician suspects a group A infection, penicillin should be prescribed instead of waiting for culture results. If the patient is allergic to penicillin, erythromycin can be given. If the clinician suspects a viral cause for a sore throat, it is appropriate to wait for a culture report before starting therapy.

Lower respiratory tract

The incidence of lower respiratory tract infection varies from service to service, many different risk factors have been determined, current methods of precisely defining the microbiological etiology of this disease are not specific, and there are a multitude of suggested treatment regimens. Clearly, a scientific consensus for a uniform approach to this disease has not been reached. Everyone does agree that this is a serious disease that has associated morbidity and mortality for both the mother and the fetus.^{64,65}

The frequency of pneumonia has varied widely over the years but, in general, the incidence has decreased since the introduction of antibiotics into clinical practice. However, there has been an increase in numbers since HIV was identified in women in the mid-1980s. HIV positivity in women is a major risk factor in the high frequency of pneumonia.⁶⁶

Although it is not a common disease in pregnant women, the physician should be alert to risk factors for pneumonia. Several risk subgroups have been identified.⁶⁴⁻⁶⁸ Poor urban women are at highest risk. In addition to HIV infections, maternal smoking, excessive alcoholic intake, and cocaine crack use are also risk factors. Pneumonia is usually seen in the winter months.

Prevention is the starting point in the respiratory tract care of pregnant women. High-risk patients should be immunized against organisms that can cause serious respiratory infections. All pregnant women should receive the influenza vaccine as discussed previously. For HIV-positive pregnant patients, preventive respiratory tract care is important because lower respiratory infections can be fatal. One strategy is the influenza vaccine. This seems logical except for troubling reports that the viral load of HIV is increased after immunization with an antigen.⁶⁹ These women are also candidates for a single dose of 23 valent polysaccharide pneumococcal vaccine.⁷⁰ All patients should be skin tested for tuberculosis and, if positive, they should have chest radiography performed with appropriate shielding of the pregnant abdomen. If the chest radiography result is normal, these HIV-positive women should receive 12 months of chemoprophylaxis with isoniazid.³⁴ For the immunocompetent patient, the treatment interval is 6 months. TMP-SMX administered daily can be effective as an agent for *Pneumocystis carinii* pneumonia prophylaxis in HIV-positive women. All these preventive strategies should reduce their risk of developing pneumonia.

In those patients who develop pneumonia, the prognosis has markedly improved since the introduction of antibiotics. In the preantibiotic era, maternal death from pneumococcal pneumonia occurred in approximately one-third of cases.² In

another series, the death rate in pregnant women with all types of pneumonia was 20%.⁷⁰ Since antibiotics have become available, the death rate is much lower, ranging from 0% to 8.6%.^{64-68,71,72} Part of this improvement was due to early diagnosis and less severe disease. Additional therapeutic advantages include better ventilatory aids and more precise techniques to monitor vital signs and fluid balance. Because of the increasing numbers of HIV-positive women in the child-bearing age groups, more seriously ill patients with pneumonias will be seen by obstetricians in the future.

There is no consensus about the care of patients with a community-acquired pneumonia.⁷⁰ There is concern that increasing numbers of *S. pneumoniae* strains in the United States are resistant to penicillin.⁷³ This fact, combined with a diverse variety of encountered pneumonia pathogens, has resulted in conflicting opinions about the care of pregnant patients with community-acquired pneumonia.

The key to the care of women with pneumonia in pregnancy is an early and accurate diagnosis. Patients with respiratory symptoms need a meticulous evaluation to determine if they have a lower respiratory tract infection. The evaluation begins with careful percussion and auscultation. A carefully obtained sputum sample for microscopic examination and culture before treatment is advised. A microscopic examination of a Gram-stained specimen showing polymorphonuclear leukocytes and the absence of squamous epithelial cells indicates that the specimen is expectorate and not saliva. A chest radiograph should be obtained with appropriate shielding of the abdomen. This serves as a guide to both the diagnosis and the severity of the disease. Blood studies should include a complete blood count and an arterial PO_2 . Patients sick enough to require hospitalization should have a blood chemistry panel performed and blood cultures before antibiotics are begun.

In general, the most frequent organism causing a community-acquired pneumonia is *S. pneumoniae*. This pathogen should be suspected at the time of admission in the febrile patient with lobar consolidation on chest radiography and white cells with Gram-positive diplococci present on microscopic examination of a smear of sputum.

In immunocompetent nonpregnant patients with community-acquired pneumonia, the decision whether to treat on an ambulatory or a hospitalized basis remains a key clinical decision that determines both the selection and the route of administration of antimicrobial agents.⁷⁴ However, pregnant women with this diagnosis should be admitted because of the potential for premature labor. In one study of 22 women with pneumonia, preterm labor was seen in five, and three had a preterm delivery.⁷² They will need intravenous hydration and close monitoring of uterine activity.

Currently, the Infectious Disease Society of America's recommendation for hospitalized patients with community-acquired pneumonia, with no recent antibiotic therapy, includes an advanced macrolide (e.g., azithromycin or clarithromycin) plus a beta-lactam antibiotic such as cefotaxime,

ceftriaxone, or ampicillin-sulbactam.⁷⁴ For those with a history of recent antibiotic use, similar type antibiotics are recommended with selection dependent on the nature of recent antibiotic use.⁷⁴ While respiratory fluoroquinolones are an alternative recommended therapy in nonpregnant patients, these agents are best not used in pregnancy.

A variety of other organisms can be implicated in the patient with pneumonia in pregnancy who is febrile. Three other pathogens are isolated with some frequency and should be considered by the physician: *Haemophilus influenzae*, the coagulase-positive staphylococcus, and Gram-negative bacilli.^{73,75} *H. influenzae* and Gram-negative bacilli should be suspected if Gram-negative rods are seen on the Gram stain of the expectorate. *H. influenzae* is a fastidious organism and will not be isolated if the culture specimen is obtained after antibiotic therapy has begun. Because 30% of the strains of *H. influenzae* are resistant to ampicillin, the cephalosporins are a good choice for treatment if this organism is suspected.⁷³ Pneumonia due to the coagulase-positive staphylococcus can be serious. It should be considered as a potential pathogen as a complication of influenza.⁷⁵ This organism should be suspected when clumps of Gram-positive cocci are seen on the Gram stain. In this situation, the drug of choice is a cephalosporin. Pneumonia due to the group A beta-hemolytic streptococcus is quite rare, but it should be suspected if chains of Gram-positive cocci are seen on the Gram stain of the expectorate and if a pleural effusion is seen on chest radiography, which when aspirated is found to be an empyema.⁷⁶

Another category of patients, which constitutes a segment of pregnant women with pneumonia, is made up of those with an atypical clinical presentation. These are the patients with roentgenographic evidence of pneumonia who may not be febrile. The most important diagnostic clue to these atypical pneumonias is the microscopic examination of the expectorate. If few or no bacteria are found, *Legionella pneumophila*,⁷⁷ *Mycoplasma*,⁷⁸ and *Chlamydia pneumoniae*⁷⁰ are prime concerns. Despite physician awareness, these are difficult diagnoses to make. The positive culture result confirms the diagnosis of *Legionella*, but it requires invasive procedures to get appropriate culture material.⁷⁷ For *Mycoplasma* and *C. pneumoniae*, culture and PCR testing are available. Other testing is available to help confirm the diagnosis. Blood can be drawn for serologic testing for *Legionella*, *Mycoplasma*, and *C. pneumoniae*. Repeat titers should be drawn in 4 weeks. The antibiotics of choice for these organisms are erythromycin, clarithromycin, and azithromycin. All these are safe for use during pregnancy.

There are other rare pneumonias that will tax the diagnostic and therapeutic skills of the obstetrician. Varicella is a serious disease for susceptible pregnant women. Antepartum antibody screening and a history to determine whether they have received the varicella vaccine will identify susceptible women. Although a varicella pneumonia can be life-threatening, acyclovir is a potent antiviral agent for treatment during pregnancy. Oral acyclovir can be given to pregnant women

when they first develop cutaneous manifestations of varicella to lessen the frequency and severity of a subsequent pneumonia.⁷⁹ In women with respiratory symptoms, the diagnosis of pneumonia can be confirmed by roentgenographic examination.⁴⁷ These seriously ill women should be admitted and given intravenous acyclovir and assisted ventilation if indicated. The fetus will receive passive immunity from the transplacental passage of IgG from the mother, so long as the delivery occurs at an interval long enough from the maternal viral exposure for maternal antibody formation to occur.

There are other pneumonias that are not as immediate a threat to the mother but have serious implications. The first is tuberculosis. This disease is a threat to pregnant women even though a recent study showed no evidence that pregnancy increased the risk that a woman of childbearing age infected with *Mycobacterium tuberculosis* will develop active tuberculosis.⁸⁰ In the United States, the incidence of tuberculosis has increased over the past 20 years, particularly among poor urban women. In this population, a tuberculin skin test will be performed and, in those women who have positive skin test results, a chest roentgenographic examination should be performed. In HIV-positive patients, a screening chest roentgenographic examination should be performed in patients who have negative skin test results if chest roentgenography has not been done in the past year. If there are apical changes, sputum should be sent for *M. tuberculosis* culture. The organisms isolated need to be evaluated for antibiotic susceptibilities. This will determine the combination of antibiotics to be prescribed. The most popular combination treatment now in use is isoniazid and ethambutol, but antibiotic susceptibility studies may alter the choice.^{81,82} Multidrug-resistant tuberculosis (MDR-TB) has become a major public health problem.^{82,83} Unfortunately, little information is available about the safety of the drugs used to treat MDR-TB during pregnancy. In a small study, Shin et al.⁸³ reported that, in seven cases of MDR-TB during pregnancy, excellent treatment outcomes were obtained for all seven women and their children. As a result, these authors stressed that MDR-TB can be successfully treated during pregnancy. The reader is referred to references 84 and 85 for more details on the treatment of MDR-TB. *P. carinii* pneumonia is seen with some frequency in urban obstetric services with a high incidence of HIV-positive pregnant patients. These patients usually have high fever, a lowered PO_2 , and can have no changes initially on chest radiography, but are subsequently found to have diffuse bilateral alveolar disease. A definitive diagnosis is made by isolation of the organism from material from the lung. The usual treatment is TMP-SMX, but trimethoprim-dapsone, clindamycin-primaquine, and atovaquone can be used. In endemic areas, pulmonary infection due to a yeast can occur. The most common pathogens in these patients are *Coccidioides immitis* and *Histoplasma capsulatum*. The diagnosis can be confirmed by specific culture techniques. In the case of *Coccidioides*, systemic treatment with antifungal agents such as amphotericin B can be life-saving.⁴

Central nervous system infections

Central nervous system infections during pregnancy are uncommon but can be life-threatening when they occur. Because they are infrequent, the obstetrician has to be alert for early signs and symptoms. Treatment is most successful when initiated early. A physician's suspicion of a central nervous system infection should be high in any patient who has had general malaise for a period of time, followed by headache, nausea, vomiting, and hyperthermia. A serious sign is convulsions in a woman with normal blood pressure and no history of epilepsy.

Recent medical advances have increased our ability to make an accurate diagnosis of central nervous system pathology. Imaging techniques, such as the computed tomographic study (CT scan) or magnetic resonance imaging (MRI) give detailed views of the brain, in which brain abscesses can be diagnosed and evidence of ventricular enlargement can be documented. In the febrile patient without any gross imaging abnormalities who has nuchal rigidity, a diagnostic spinal tap should be performed. The fluid should be examined immediately under the microscope after Gram staining, and a portion of the sample sent for culture and biochemical studies. If the Gram stain reveals Gram-negative diplococci, the presumptive diagnosis is *Neisseria meningitidis* meningitis, and a broad-spectrum cephalosporin should be prescribed.⁸⁴ If Gram-positive diplococci are seen, the presumptive diagnosis is *Streptococcus pneumoniae* meningitis, and vancomycin and a cephalosporin should be begun.⁸⁴ *H. influenzae* meningitis, common in children, is rarely seen in adults.
