Preface to the second edition

This new edition, like the first, aims to present a comprehensive account of clinical psychiatry with reference to its scientific basis and to the ill person's perspective. As in the first edition, the authors are drawn from many countries, including the UK, the USA, 12 countries in continental Europe, and Australasia. The favourable reception of the first edition has led us to invite many of the original authors to revise their chapters for this second edition but 50 chapters are the work of new authors, many concerned with subjects that appeared in the first edition, while others are completely new. The forensic psychiatry section has the most new chapters, followed by the section on psychology as a scientific basis of psychiatry.

The overall plan of the book resembles that of the first edition (see preface to the 1st edition, reprinted on pages vii and viii). One important feature is that information about treatment appears in more than one place. The commonly used physical and psychological treatments are described in Section 6. Their use in the treatment of any particular disorder is considered in the chapter concerned with that disorder and the account is in two parts. The first part is a review of evidence about the effects of each of the treatments when used for that disorder. The second part, called Management, combines evidence from clinical trials with accumulated clinical experience to produce practical advice about the day to day care of people with the disorder.

Although much information can now be obtained from internet searches, textbooks are still needed to provide the comprehensive account of established knowledge into which new information can be fitted and against which recent findings can be evaluated. As well as seeking to provide an authoritative account of essential knowledge, each chapter in the new edition includes a brief list of sources of further information, including where appropriate, regularly updated web sites.

An essential component of good practice is the need to be aware of patients' perspectives, to respect their wishes, and to work with them, and often their families, as partners. The book opens with an important chapter on the experience of being a patient, and there are chapters on stigma, ethics, and the developing topic of values-based practice.

We are grateful to the following who advised us about parts of the book; Professor John Bancroft (Psychosexual Disorders), Professor Tom Burns (Social and Community Psychiatry), Professor William Fraser (Intellectual Disability), Professor Keith Hawton (Suicide and Deliberate Self Harm), Professor Susan Iversen (Psychology), Professor Robin Jacoby (Old Age Psychiatry), Professor Paul Mullen (Forensic Psychiatry), Sir Michael Rutter (Child and Adolescent Psychiatry), and Professor Gregory Stores (Sleep Disorders).

The editors

Preface to the first edition

Three themes can be discerned in contemporary psychiatry: the growing unity of the subject, the pace of scientific advance, and the growth of practice in the community. We have sought to reflect these themes in the *New Oxford Textbook of Psychiatry* and to present the state of psychiatry at the start of the new millennium. The book is written for psychiatrists engaged in continuous education and recertification; the previous, shorter, *Oxford Textbook of Psychiatry* remains available for psychiatrists in training. The book is intended to be suitable also as a work of reference for psychiatrists of all levels of experience, and for other professionals whose work involves them in the problems of psychiatry.

The growing unity of psychiatry

The growing unity in psychiatry is evident in several ways. Biological and psychosocial approaches have been largely reconciled with a general recognition that genetic and environmental factors interact, and that psychological processes are based in and can influence neurobiological mechanisms. At the same time, the common ground between the different psychodynamic theories has been recognized, and is widely accepted as more valuable than the differences between them.

The practice of psychiatry is increasingly similar in different countries, with the remaining variations related more to differences between national systems of health care and the resources available to clinicians, than to differences in the aims of the psychiatrists working in these countries. This unity of approach is reflected in this book whose authors practise in many different countries and yet present a common approach. In this respect this textbook differs importantly from others which present the views of authors drawn predominantly from a single country or region.

Greater agreement about diagnosis and nosology has led to a better understanding of how different treatment approaches are effective in different disorders. The relative specificity of psychopharmacological treatments is being matched increasingly by the specificity of some of the recently developed psychological treatments, so that psychological treatment should no longer be applied without reference to diagnosis, as was sometimes done in the past.

The pace of scientific advance

Advances in genetics and in the neurosciences have already increased knowledge of the basic mechanisms of the brain and are beginning to uncover the neurobiological mechanisms involved in psychiatric disorder. Striking progress has been achieved in the understanding of Alzheimer's disease, for example, and there are indications that similar progress will follow in uncovering the causes of mood disorder, schizophrenia, and autism. Knowledge of genetics and the neurosciences is so extensive and the pace of change is so rapid that it is difficult to present a complete account within the limited space available in a textbook of clinical psychiatry. We have selected aspects of these sciences that seem, to us and the authors, to have contributed significantly to psychiatry or to be likely to do so before long.

Psychological and social sciences and epidemiology are essential methods of investigation in psychiatry. Although the pace of advance in these sciences may not be as great as in the neurosciences, the findings generally have a more direct relation to clinical phenomena. Moreover, the mechanisms by which psychological and social factors interact with genetic, biochemical, and structural ones will continue to be important however great the progress in these other sciences. Among the advances in the psychological and social sciences that are relevant to clinical phenomena, we have included accounts of memory, psychological development, research on life events, and the effects of culture. Epidemiological studies continue to be crucial for defining psychiatric disorders, following their course, and identifying their causes.

Psychiatry in the community

In most countries, psychiatry is now practised in the community rather than in institutions, and where this change has yet be completed, it is generally recognized that it should take place. The change has done much more than transfer the locus of care; it has converted patients from passive recipients of care to active participants with individual needs and preferences. Psychiatrists are now involved in the planning, provision, and evaluation of services for whole communities, which may include members of ethnic minorities, homeless people, and refugees. Responsibility for a community has underlined the importance of the prevention as well as the treatment of mental disorder and of the role of agencies other than health services in both. Care in the community has also drawn attention to the many people with psychiatric disorder who are treated in primary care, and has led to new ways of working between psychiatrists and physicians. At the same time, psychiatrists have

worked more in general hospitals, helping patients with both medical and psychiatric problems. Others have provided care for offenders.

The organization of the book

In most ways, the organization of this book is along conventional lines. However, some matters require explanation.

Part 1 contains a variety of diverse topics brought together under the general heading of the subject matter and approach to psychiatry. Phenomenology, assessment, classification, and ethical problems are included, together with the role of the psychiatrist as educator and as manager. Public health aspects of psychiatry are considered together with public attitudes to psychiatry and to psychiatric patients. Part 1 ends with a chapter on the links between science and practice. It begins with a topic that is central to good practice—the understanding of the experience of becoming a psychiatric patient.

Part 2 is concerned with the scientific foundations of psychiatry grouped under the headings neurosciences, genetics, psychological sciences, social sciences, and epidemiology. The chapters contain general information about these sciences; findings specific to a particular disorder are described in the chapter on that disorder. Brain imaging techniques are discussed here because they link basic sciences with clinical research. As explained above, the chapters are selective and, in some, readers who wish to study the subjects in greater detail will find suggestions for further reading.

Part 3 is concerned with dynamic approaches to psychiatry. The principal schools of thought are presented as alternative ways of understanding the influence of life experience on personality and on responses to stressful events and to illness. Some reference is made to dynamic psychotherapy in these accounts, but the main account of these treatments is in Part 6. This arrangement separates the chapters on the practice of dynamic psychotherapy from those on psychodynamic theory, but we consider that this disadvantage is outweighed by the benefit of considering together the commonly used forms of psychotherapy.

Part 4 is long, with chapters on the clinical syndromes of adult psychiatry, with the exception of somatoform disorders which appear in Part 5, Psychiatry and Medicine. This latter contains more than a traditional account of psychosomatic medicine. It also includes a review of psychiatric disorders that may cause medical symptoms unexplained by physical pathology, the medical, surgical, gynaecological, and obstetric conditions most often associated with psychiatric disorder, health psychology, and the treatment of psychiatric disorder in medically ill patients.

Information about treatment appears in more than one part of the book. Part 6 contains descriptions of the physical and psychological treatments in common use in psychiatry. Dynamic psychotherapy and psychoanalysis are described alongside counselling and cognitive behavioural techniques. This part of the book contains general descriptions of the treatments; their use for a particular disorder is considered in the chapter on that disorder. In the latter, the account is generally in two parts: a review of evidence about the efficacy of the treatment, followed by advice on management in which available evidence is supplemented, where necessary, with clinical experience. Treatment methods designed specially for children and adolescents, for people with mental retardation (learning disability), and for patients within the forensic services are considered in Parts 9, 10, and 11 respectively.

Social psychiatry and service provision are described in Part 7. Public policy issues, as well as the planning, delivery, and evaluation of services, are discussed here. Psychiatry in primary care is an important topic in this part of the book. There are chapters on the special problems of members of ethnic minorities, homeless people, and refugees, and the effects of culture on the provision and uptake of services.

Child and adolescent psychiatry, old age psychiatry, and mental retardation are described in Parts 8, 9, and 10. These accounts are less detailed than might be found in textbooks intended for specialists working exclusively in the relevant subspecialty. Rather, they are written for readers experienced in another branch of psychiatry who wish to improve their knowledge of the special subject. We are aware of the controversy surrounding our choice of the title of Part 10. We have selected the term 'mental retardation' because it is used in both ICD-10 and DSM-IV. In some countries this term has been replaced by another that is thought to be less stigmatizing and more acceptable to patients and families. For example, in the United Kingdom the preferred term is 'learning disability'. While we sympathize with the aims of those who adopt this and other alternative terms, the book is intended for an international readership and it seems best to use the term chosen by the World Health Organization as most generally understood. Thus the term mental retardation is used unless there is a special reason to use another.

In Part 11, Forensic Psychiatry, it has been especially difficult to present a general account of the subject that is not tied to practice in a single country. This is because systems of law differ between countries and the practice of forensic psychiatry has to conform with the local legal system. Although many of the examples in this part of the book may at first seem restricted in their relevance because they are described in the context of English law, we hope that readers will be able to transfer the principles described in these chapters to the legal tradition in which they work.

Finally, readers should note that the history of psychiatry is presented in more than one part of the book. The history of psychiatry as a medical specialty is described in Part 1. The history of ideas about the various psychiatric disorders appears, where relevant, in the chapters on these disorders, where they can be considered in relation to present-day concepts. The history of ideas about aetiology is considered in Part 2, which covers the scientific basis of psychiatric aetiology, while the historical development of dynamic psychiatry is described in Part 3.

Acknowledgements from the first edition

We are grateful to the many colleagues who have advised us about certain parts of the book.

The following helped us to plan specialized parts of the book: Dr Jeremy Holmes (Section 3, Psychodynamic Contributions to Psychiatry); Professor Richard Mayou (Section 5, Psychiatry and Medicine); Professor Robin Jacoby (Section 8, Psychiatry of Old Age); Sir Michael Rutter (Section 9, Child and Adolescent Psychiatry); Professor William Fraser (Section 10, Intellectual Disablity); Professor Robert Bluglass (Section 11, Forensic Psychiatry).

The following helped us to plan certain sections within Section 4, General Psychiatry: Professor Alwyn Lishman (delirium, dementia, amnestic syndrome, and other cognitive disorders); Professor Griffith Edwards (alcohol use disorders); Dr Philip Robson (other substance use disorders); Professor Guy Goodwin (mood disorders); Professor John Bancroft (sexuality, gender identity, and their disorders); Professor Gregory Stores (sleep–wake disorders); Professor Keith Hawton (suicide and attempted suicide). In Section 6, Professor Philip Cowen advised about somatic treatments, Dr Jeremy Holmes about psychodynamic treatments, and Professor David Clark about cognitive behavioural therapy. Dr Max Marshall provided helpful advice about forensic issues for Section 7. We also thank the many other colleagues whose helpful suggestions about specific problems aided the planning of the book.

Finally, we record our special gratitude to the authors and to the staff of Oxford University Press.

SECTION 1

The Subject Matter of and Approach to Psychiatry

This page intentionally left blank

1.1

The patient's perspective

Kay Redfield Jamison, Richard Jed Wyatt,† and Adam Ian Kaplin

It is difficult to be a psychiatric patient, but a good doctor can make it less so. Confusion and fear can be overcome by knowledge and compassion, and resistance to treatment is often, although by no means always, amenable to change by intelligent persuasion. The devil, as the fiery melancholic Byron knew, is in the details.

Patients, when first given a psychiatric diagnosis, are commonly both relieved and frightened—relieved because often they have been in pain and anxiety for a considerable period of time, and frightened because they do not know what the diagnosis means or what the treatment will entail. They do not know if they will return to the way they once were, whether the treatment they have been prescribed will or will not work, and, even if it does work, at what cost it will be to them in terms of their notions of themselves, potentially unpleasant side-effects, and the reactions of their family members, friends, colleagues, and employers. Perhaps most disturbing, they do not know if their depression, psychosis, anxieties, or compulsions will return to become a permanent part of their lives. Caught in a state often characterized by personal anguish, social isolation and confusion, newly diagnosed patients find themselves on a quest to regain a sense of mastery of themselves and their surroundings. One of the main goals of therapies of all types is to empower the patient and give them some control back over their world.

The specifics of what the doctor says, and the manner in which he or she says it, are critically important. Most patients who complain about receiving poor psychiatric care do so on several grounds: their doctors, they feel, spend too little time explaining the nature of their illnesses and treatment; they are reluctant to consult with or actively involve family members; they are patronizing, and do not adequately listen to what the patient has to say; they do not encourage questions or sufficiently address the concerns of the patient; they do not discuss alternative treatments, the risks of treatment, and the risks of no treatment; and they do not thoroughly forewarn about side-effects of medications.

Most of these complaints are avoidable. Time, although difficult to come by, is well spent early on in the course of treatment when confusion and hopelessness are greatest, non-adherence is highest, and the possibility of suicide substantially increased. Hope can be realistically extended to patients and family members, and its explicit extension is vital to those whose illnesses have robbed them not only of hope, but of belief in themselves and their futures. The hope provided needs to be tempered, however, by an explication of possible difficulties yet to be encountered: unpleasant side-effects from medications, a rocky time course to meaningful recovery which will often consist of many discouraging cycles of feeling well, only to become ill again, and the probable personal, professional, and financial repercussions that come in the wake of having a psychiatric illness.

It is terrifying to lose one's sanity or to be seized by a paralysing depression. No medication alone can substitute for a good doctor's clinical expertise and the kindness of a doctor who understands both the medical and psychological sides of mental illness. Nor can any medication alone substitute for a good doctor's capacity to listen to the fears and despair of patients trying to come to terms with what has happened to them. A good doctor is a therapeutic optimist who is able to instill hope and confidence to combat confusion and despair. Great doctors are able to provide the unwavering care to their patients that they would want a member of their own family to receive, blending empathy, and compassion with expertise.

Doctors need to be direct in answering questions, to acknowledge the limits of their understanding, and to encourage specialist consultations when the clinical situation warrants it. They also need to create a therapeutic climate in which patients and their families feel free, when necessary, to express their concerns about treatment or to request a second opinion. Treatment non-adherence, one of the major causes of unnecessary suffering, relapse, hospitalization, and suicide, must be addressed head-on. Young males, early in the course of their illness, are particularly likely to stop medication against medical advice, and the results can be lethal.[1,2] Unfortunately, doctors are notoriously variable in their ability to assess and predict adherence in their patients.[3]

Asking directly and often about medication concerns and side-effects, scheduling frequent follow-up visits after the initial diagnostic evaluation and treatment recommendation, and encouraging adjunctive psychotherapy, or involvement in patient support groups, can make a crucial difference in whether or not a patient takes medication in a way that is most effective. Aggressive treatment of unpleasant or intolerable side-effects, minimizing the dosage and number of doses, and providing ongoing, frequently repetitive

†Deceased.

education about the illness and its treatment are likewise essential, if common-sense, ways to avert or minimize non-adherence.

Education is, of course, integral to the good treatment of any illness, but this is especially true when the illnesses are chronic. The term 'doctor' derives originally from the Latin word for teacher, and it is in their roles as teachers that doctors provide patients with the knowledge and understanding to combat the confusion and unpredictability that surrounds mental illness. Patients and their family members should be encouraged to write down any questions they may have, as many individuals are intimidated once they find themselves in a doctor's office. Any information that is given orally to patients should be repeated as often as necessary (due to the cognitive difficulties experienced by many psychiatric patients, especially when acutely ill or recovering from an acute episode) and, whenever feasible, provided in written form as well. Additional information is available to patients and family members in books and pamphlets obtainable from libraries, bookstores, and patient support groups, as well as from audiotapes, videotapes, and the Internet.[2,4] Visual aids, such as charts portraying the natural course of the treated and untreated illness, or the causes and results of sleep deprivation and medication cessation, are also helpful to many.[5–7] Finally, providing the patients with self-report scales to monitor their daily progress, such as mood charts in affective disorder, not only provides invaluable clinical data, but also teaches patients to better understand their own illness and its response to therapeutic interventions as well as exacerbating stressors. Patients, when they are well, often benefit from a meeting with their family members and their doctor, which focuses upon drawing up contingency plans in case their illness should recur. These meetings also provide an opportunity to shore up the support system the patient has by educating their caregivers about the nature, cause, manifestations, and treatment of their loved one's mental illness. Such meetings may also include what is to be done in the event that hospitalization is required and the patient refuses voluntary admission, a discussion of early warning signs of impending psychotic or depressive episodes, methods for regularizing sleep and activity patterns, techniques to protect patients financially, and ways to manage suicidal behaviour should it occur. Suicide is the major cause of premature death in the severe psychiatric illnesses,[8,9] and its prevention is of first concern. Those illnesses most likely to result in suicide (the mood disorders, comorbid alcohol and drug abuse, and schizophrenia) need to be treated early, aggressively, and often for an indefinite period of time.[2,10] The increasing evidence that treatment early in psychiatric illness may improve the long-term course needs to be considered in light of the reluctance of many patients to stay in treatment.[10,11]

No one who has treated or suffered from mental illness would minimize the difficulties involved in successful treatment. Modern medicine gives options that did not exist even 10 years ago, and there is every reason to expect that improvements in psychopharmacology, psychotherapy, and diagnostic techniques will continue to develop at a galloping pace. Still, the relationship between the patient and doctor will remain central to the treatment, as Morag Coate wrote 35 years ago in *Beyond All Reason*:[12]

> Because the doctors cared, and because one of them still believed in me when I believed in nothing, I have survived to tell the tale. It is not only the doctors who perform hazardous operations or give life-saving drugs in obvious emergencies who hold the scales at times between life and death. To sit quietly in a consulting room and talk to someone would not appear to the general public as a heroic or dramatic thing to do. In medicine there are many different ways of saving lives. This is one of them.

Public attitudes and the challenge of stigma

Graham Thornicroft, Elaine Brohan, and Aliya Kassam

Introduction

The starting point for this discussion is the idea of stigma. This term (plural stigmata) was originally used to refer to an indelible dot left on the skin after stinging with a sharp instrument, sometimes used to identify vagabonds or slaves.[1–4] In modern times stigma has come to mean 'any attribute, trait or disorder that marks an individual as being unacceptably different from the 'normal' people with whom he or she routinely interacts, and that elicits some form of community sanction.'[5–7]

Understanding stigma

There is now a voluminous literature on stigma.[5,8] [9–13,13–19] The most complete model of the component processes of stigmatization has four key components:[20]

i) Labelling, in which personal characteristics, which are signalled or noticed as conveying an important difference.

ii) Stereotyping, which is the linkage of these differences to undesirable characteristics.

iii) Separating, the categorical distinction between the mainstream/normal group and the labelled group as in some respects fundamentally different.

iv) Status loss and discrimination: devaluing, rejecting, and excluding the labelled group. Interestingly, more recently the authors of this model have added a revision to include the emotional reactions which may accompany each of these stages.[21,22]

Shortcomings of work on stigma

Five key features have limited the usefulness of stigma theories. First, while these processes are undoubtedly complex, academic writings on stigma (which in the field of mental health have almost entirely focused upon schizophrenia) have made relatively few connections with legislation concerning disability rights policy[23] or clinical practice. Second, most work on mental illness and stigma has been descriptive, overwhelmingly describing attitude surveys or the portrayal of mental illness by the media. Very little is known about effective interventions to reduce stigma. Third, there have been notably few direct contributions to this literature by service users.[24] Fourth, there has been an underlying pessimism that stigma is deeply historically rooted and difficult to change. This has been one of the reasons for the reluctance to use the results of research in designing and implementing action plans. Fifth, stigma theories have de-emphasized cultural factors and paid little attention to the issues related to human rights and social structures.

Recently there have been early signs of a developing focus upon discrimination. This can be seen as the behavioural consequences of stigma, which act to the disadvantage of people who are stigmatized.[23,25–27] The importance of discriminatory behaviour has been clear for many years in terms of the personal experiences of service users, in terms of devastating effects upon personal relationships, parenting and childcare, education, training, work, and housing.[28] Indeed, these voices have said that the rejecting behaviour of others may bring greater disadvantage than the primary condition itself.

Stigma can therefore be seen as an overarching term that contains three important elements: [29]

- problems of knowledge ignorance
- problems of attitudes prejudice
- problems of behaviour discrimination

Ignorance: the problem of knowledge

At a time when there is an unprecedented volume of information in the public domain, the level of accurate knowledge about mental illnesses (sometime called 'mental health literacy') is meagre.[30] In a population survey in England, for example, most people (55 per cent) believe that the statement 'someone who cannot be held responsible for his or her own actions' describes a person who is mentally ill.[31] Most (63 per cent) thought that fewer than 10 per cent of the population would experience a mental illness at some time in their lives.

There is evidence that deliberate interventions to improve public knowledge about depression can be successful, and can reduce the effects of stigmatization. At the national level, social marketing

campaigns have produced positive changes in public attitudes towards people with mental illness, as shown recently in New Zealand and Scotland.[32,33] In a campaign in Australia to increase knowledge about depression and its treatment, some states and territories received this intensive, co-ordinated programme, while others did not. In the former, people more often recognized the features of depression, were more likely to support help seeking for depression, or to accept treatment with counselling and medication.[34]

Prejudice: the problem of negative attitudes

Although the term prejudice is used to refer to many social groups, which experience disadvantage, for example minority ethnic groups, it is employed rarely in relation to people with mental illness. The reactions of a host majority to act with prejudice in rejecting a minority group usually involve not just negative thoughts but also emotion such as anxiety, anger, resentment, hostility, distaste, or disgust. In fact prejudice may more strongly predict discrimination than do stereotypes. Interestingly, there is almost nothing published about emotional reactions to people with mental illness apart from that which describes a fear of violence.[35]

Discrimination: the problem of rejecting and avoidant behaviour

Surveys of attitude and social distance (unwillingness to have social contact) usually ask either students or members of the general public what they would do in imaginary situations or what they think 'most people' who do, for example, when faced with a neighbour or work colleague with mental illness. Important lessons have flowed from these findings. This work has emphasized what 'normal' people say without exploring the actual experiences of people with mental illness themselves about the behaviour of normal people towards them. Further it has been assumed that such statements (usually on knowledge, attitudes, or behavioural intentions) are congruent with actual behaviour, without assessing such behaviour directly. Such research has usually focussed on hypothetical rather than real situations, neglecting emotions, and the social context, thus producing very little guidance about interventions that could reduce social rejection. In short, most work on stigma has been beside the point.

Global patterns

Do we know if discrimination varies between countries and cultures? The evidence here is stronger, but still frustratingly patchy.[36] Although studies on stigma and mental illness have been carried out in many countries, few have been comparison of two or more places, or have included non-Western nations.[37]

In Africa one study described attitudes to mentally ill people in rural sites in Ethiopia. Among almost 200 relatives of people with diagnoses of schizophrenia or mood disorders, 75 per cent said that they had experienced stigma due to the presence of mental illness in the family, and a third (37 per cent) wanted to conceal the fact that a relative was ill. Most family members (65 per cent) said that praying was their preferred of treating the condition.[38] Among the general population in Ethiopia schizophrenia was judged to be the most severe problem, and talkativeness, aggression, and strange behaviour were rated as the most common symptoms of mental illness.[39] The authors concluded that it was important to work closely with traditional healers.

In South Africa,[40,41] a survey was conducted of over 600 members of the public on their knowledge and attitudes towards people with mental illness.[42] Different vignettes, portraying depression, schizophrenia, panic disorder, or substance misuse were presented to each person. Most thought that these conditions were either related to stress or to a lack of willpower, rather than seeing them as medical disorders.[43] Similar work in Turkey,[44] and in Siberia and Mongolia[45] suggests that people in such countries may be more ready to make the individual responsible for his or her mental illness and less willing to grant the benefits of the sick role.

Most of the published work on stigma is by authors in the USA and Canada,[11,27,46,47] but there are also a few reports from elsewhere in the Americas and in the Caribbean.[48] In a review of studies from Argentina, Brazil, Dominica, Mexico, and Nicaragua, mainly from urban sites, a number of common themes emerged. The conditions most often rated as 'mental illnesses' were the psychotic disorders, especially schizophrenia. People with higher levels of education tended to have more favourable attitudes to people with mental illness. Alcoholism was considered to be the most common type of mental disorder. Most people thought that a health professional needs to be consulted by people with mental illnesses.[49]

A great deal of work has studied the question of stigma towards mentally ill people in Asian countries and cultures.[50–52] Within China,[53] a large scale survey was undertaken of over 600 people with a diagnosis of schizophrenia and over 900 family members.[54] Over half of the family members said that stigma had an important effect on them and their family, and levels of stigma were higher in urban areas and for people who were more highly educated.

In the field of stigma research we find that schizophrenia is the primary focus of interest. It is remarkable that there are almost no studies, for example, on bipolar disorder and stigma. A comparison of attitudes to schizophrenia was undertaken in England and Hong Kong. As predicted, the Chinese respondents expressed more negative attitudes and beliefs about schizophrenia, and preferred a more social model to explain its causation. In both countries most participants, whatever their educational level, showed great ignorance about this condition.[55] This may be why most of population in Hong Kong are very concerned about their mental health and hold rather negative views about mentally ill people.[56] Less favourable attitudes were common in those with less direct personal contact with people with mental illness (as in most Western studies), and by women (the opposite of what has been found in many Western reports).[57]

Little research on stigma has been conducted in India. Among relatives of people with schizophrenia in Chennai (Madras) in Southern India, their main concerns were: effects on marital prospects, fear of rejection by neighbours, and the need to hide the condition from others. Higher levels of stigma were reported by women and by younger people with the condition. [58] Women who have mental illness appear to be at a particular disadvantage in India. If they are divorced, sometimes related to concerns about heredity,[59] then they often receive no financial support from their former husbands, and they and their families experience intense distress from the additional stigma of being separated or divorced.[60]

In Japan mental illnesses are seen to reflect a loss of control, and so are not subject to the force of will power, both of which lead to a sense of shame.[61–63] Although, it is tempting to generalize about the degree of stigma in different countries, reality may not allow such simplifications. A comparison of attitudes to mentally ill people in Japan and Bali, for example showed that views towards people with schizophrenia were less favourable in Japan, but that people with depression and obsessive-compulsive disorder were seen to be less acceptable in Bali.[64]

What different countries do often share is a high level of ignorance and misinformation about mental illnesses. A survey of teachers' opinions in Japan and Taiwan showed that relatively few could describe the main features of schizophrenia with any accuracy. The general profile of knowledge, beliefs, and attitudes was similar to that found in most Western countries, although the degree of social rejection was somewhat greater in Japan.[65]

In a unique move aimed to reduce social rejection, the name for schizophrenia has been changed in Japan. Following a decade of pressure from family member groups, including Zenkaren, the name for this condition was changed from *seishi buntetsu byo* (split-mind disorder) to *togo shiccho sho* (loss of co-ordination disorder).[66,67] The previous term went against the grain of traditional, culturally-valued concepts of personal autonomy, as a result of which only 20 per cent of people with this condition were told the diagnosis by their doctors.[68–70] There are indications from service users and family members that the new term is seen as less stigmatizing and is more often discussed openly.

Little is written in the English language literature on stigma in Islamic communities, but despite earlier indications that the intensity of stigma may be relatively low,[52] detailed studies indicate that on balance, it is no less than we have seen described elsewhere.[71–74] A study of family members in Morocco found that 76 per cent had no knowledge about the condition, and many considered it chronic (80 per cent), handicapping (48 per cent), incurable (39 per cent), or linked with sorcery (25 per cent). Most said that they had 'hard lives' because of the diagnosis.[75] Turning to religious authority figures is reported to be common in some Moslem countries.[76,77] Some studies have found that direct personal contact was not associated with more favourable attitudes to people with mental illness,[78,79] especially where behaviour is seen to threaten the social fabric of the community.[80,44]

What sense can we make of all these fragments of information? Several points are clear. First there is no known country, society, or culture in which people with mental illness are considered to have the same value and to be as acceptable as people who do not have mental illness. Second, the quality of information that we have is relatively poor, with very few comparative studies between countries or over time. Third, there do seem to be clear links between popular understandings of mental illness, if people in mental distress want to seek help, and whether they feel able to disclose their problems.[81] The core experiences of shame (to oneself and for others) and blame (from others) are common everywhere stigma has been studied, but to differing extents. Where comparisons with other conditions have been made, then mental illnesses are more, or far more, stigmatized,[82,83] and have been referred to as the 'ultimate stigma' [9]. Finally, rejection and avoidance of people with mental illness appear to be universal phenomena.

Conclusions

If we deliberately shift focus from stigma to discrimination, there are a number of distinct advantages. First attention moves from attitudes to actual behaviour, not if an employer *would* hire a person with mental illness, but if he or she *does*. Second, interventions can be tried and tested to see if they change behaviour towards people with mental illness, without *necessarily* changing knowledge or feelings. The key candidates as active ingredients to reduce stigma are: (i) at the local level, direct social contact with people with mental illness;[84–86] and (ii) social marketing techniques at the national level. Third, people who have a diagnosis of mental illness can expect to benefit from all the relevant anti-discrimination policies and laws in their country or jurisdiction, on a basis of parity with people with physical disabilities. Fourth, a discrimination perspective requires us to focus not upon the 'stigmatized' but upon the 'stigmatizer'. In sum, this means sharpening our sights upon human rights, upon injustice, and upon discrimination as actually experienced by people with mental illness.[7,24,87,88]

1.3

Psychiatry as a worldwide public health problem

Contents

1.3.1 Mental disorders as a worldwide public health issue

Benedetto Saraceno

Magnitude and burden of mental disorders

The twentieth century has witnessed significant improvements in somatic health in most countries. A number of key public health threats have been eradicated or brought under control under the leadership of WHO. Priority was given to communicable diseases in view of their inherent potential to spreading.

At the present time, a focus on non-communicable diseases and mental health would now appear as the next natural step in public health priorities. In the case of mental health, this is due to the capacity of mental disorders to proliferate not only as a result of complex and multiple biological, psychological but also social determinants. WHO estimates that at any given time 450 million people suffer from some form of mental or brain disorder, including alcohol and substance use disorders. In other words, one in four of the world's population suffer from different forms of mental, behavioural, and neurological disorders.[1]

The World Development Report: investing in health[2] and the development of the disability-adjusted life-year for estimating the global burden of disease, including years lost because of disability[3,4] and the World Health Report 2001, have all raised the awareness of the global burden of mental disorders. Mental disorders already account for more than 13.46 per cent of the GBD. Furthermore, it is estimated that by the year 2015, the GBD from all neuropsychiatric illnesses will reach 14.14 per cent and by 2030, 14.42 per cent. According to WHO, mental disorders accounted for 6 of the 20 leading causes of disability worldwide for the 15–44 age group, the most productive section of the population.[1] While a greater proportion of the burden is found in high-income countries (21.4 per cent) including those with formerly socialist economies (16.4 per cent), low- and middle-income countries are greatly affected and are likely to see a disproportionately large increase in the burden attributable to mental disorders in the coming decades as infectious diseases are brought under better control and as the population ages. The growing burden of mental, neurological, and substance use disorders is exacerbated in low and middle-income countries due to a projected increase in the number of young people entering the age of risk for the onset of certain mental disorders. An estimated 849 000 people commit suicide every year. This figure represents 1.4 per cent of the global burden of disease as estimated using Disability Adjusted Life Years (DALY) methodology. The proportion of the global disease burden due to suicide varies from 0.2 per cent in Africa up to 2.5 per cent in the Western Pacific region. In the European, South East Asian, and Western Pacific regions, this proportion exceeds the world average. Suicide among young people is of significant concern; in some regions, suicide is the third leading cause of death in the age group of 15–35 years. Suicide is the leading cause of death for this age group in China and the second in the European region. Alcohol consumption alone is responsible for 4 per cent of the global disease burden.[5] In 2000, the global use of alcohol was estimated to have caused 1.8 million deaths or 3.2 per cent of the total deaths from all causes that year. It is estimated that 2.2 million people died from alcohol-related causes in 2005 and increase of 22 per cent from 2000. The population of injecting drug users comprises approximately 10 million people worldwide. Globally, 4–12 per cent of all HIV cases are due to injection drug use, a driving force behind the HIV/AIDS epidemic in many parts of the world.

Economic and social costs of mental disorders

The economic and social costs of mental disorders fall on societies, governments, people with mental disorders, and their carers and families. Given the long-term nature of mental disorders, the most

evident economic burden is that of direct treatment costs. For example, the most important contributor to direct costs of depression is hospitalization, accounting for around half of the total in the United Kingdom and three-quarters in the United States.[6] However a common finding from studies of the economic burden of mental disorders in high-income countries is that the 'indirect' costs of lost productivity and premature mortality outweigh the 'direct' costs of treatment and care.[7] Three recent mental health economic studies carried out in India have likewise shown that lost production and other time costs greatly exceed the costs of targeted clinical intervention.[8–10]

In most countries, families bear a significant proportion of these economic costs because of the absence of publicly funded comprehensive mental health service networks. However, ultimately governments and societies pay a price in terms of reduced national income and increased expenditure on social welfare programmes. Thus, the economic logic for societies and countries is simple: treating mental disorders is expensive but leaving them untreated can be more expensive.

In addition to the obvious suffering caused by mental disorders there is a hidden burden of stigma and discrimination and human rights violations. Rejection, unfair denial of employment opportunities and discrimination in access to services, health insurance, and housing are common as are violations of basic human rights and freedoms, as well as denials of civil, political, economic, and social rights, in both institutions and communities. Much of this goes unreported and therefore the burden remains unquantified. Families and primary care providers also incur social costs, such as the emotional burden of looking after disabled family members, diminished quality of life, social exclusion, stigmatization, and loss of future opportunities for self-improvement.

Global resources for mental health

The WHO survey of mental health resources (Project Atlas) highlighted the huge existent gap between the burden of mental disorders and available resources.[11,12]

Mental health policy and legislation

Mental health services and strategies must be well coordinated with other services, such as social security, education, and public interventions in employment and housing through an adequate mental health policy. In spite of this, only 62 per cent of countries have a policy in the mental health field (see Table 1.3.1.1). Mental health legislation is essential to guarantee the dignity of patients and protect their fundamental human rights, though 22 per cent of countries do not have legislation in the field of mental health.

Table 1.3.1.1 Policy and legislation on mental health in WHO regions and the world—countries (%)

WHO regions	Policy (N: 190)	Legislation (N: 173)
Africa	50%	80%
Americas	73%	75%
Eastern Mediterranean	73%	57%
Europe	71%	92%
South-East Asia	55%	64%
Western Pacific	48%	76%
World	62%	78%

Source: The World health report 2001–Mental Health: New Understanding, New Hope, © 2001, World Health Organization, www.who.int

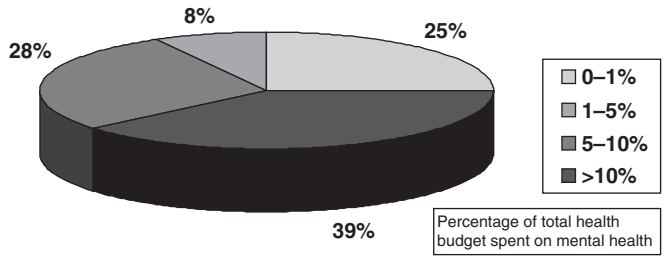

Fig. 1.3.1.1 Percentage of total health budget spent on mental health—countries (%) (*N* = 101). Taken from The World health report 2001–Mental Health: New Understanding, New Hope © 2001, World Health Organization, www.who.int

Mental health budget

In spite of the importance of mental health burden in the world (representing more than 13.46 per cent of global burden of diseases), out of only 101 countries that reported having a specific budget, 25 per cent spend less than 1 per cent of the total health budget on mental health (Fig. 1.3.1.1).

Methods of financing mental health care

The tax-based method is the preferred method for financing mental health care present in 63 per cent of countries (Fig. 1.3.1.2), while all the countries with out-of-pocket financing as the primary method are low- or middle-income countries. However, families of people with severe chronic mental disorders are often among the poorer and, in addition to the family burden, can access to basic mental health care.

Community care for mental health

Community care has a better effect than institutional treatment on the outcome and quality of life of individuals with chronic mental disorders. Globally, 68 per cent of countries reported to have at least some community care facilities for mental health. Community care facilities in mental health are only present in 52 per cent of the low-income countries versus 97 per cent of high-income countries.

Though community-based services are recognized to be most effective, 65 per cent of all psychiatric beds are still in mental hospitals—eating away the already meagre budgets while providing largely custodial care in an environment that violates basic human rights of inmates.[10]

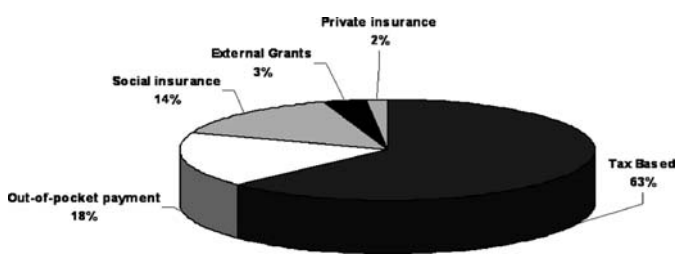

Fig. 1.3.1.2 Methods of financing mental health care in the world—countries (%) (*N* = 180). Taken from The World health report 2001–Mental Health: New Understanding, New Hope, © 2001, World Health Organization, www.who.int

Psychiatric beds

The distribution of psychiatric beds by setting across different income countries also varies. In low-income countries 74 per cent of the psychiatric beds are located in mental hospitals, while in high-income countries only 55 per cent. Across different regions, south-east Asia has 83 per cent of its psychiatric beds in mental hospitals compared with 64 per cent in the European region (see Table 1.3.1.2). The Western Pacific region has the highest proportion of psychiatric beds in general hospitals (35 per cent), followed by Europe with 22 per cent of their total psychiatric beds. In approximately 41 per cent of countries there is less than one psychiatric bed per 10 000 of the population. The proportion of beds which are not located in mental hospitals or in general hospitals includes those in private and military hospitals, hospitals for special groups of population or long-term rehabilitation centres.

Professionals working in mental health

All the countries in the south-east Asia region and most of countries in the African region have less than one psychiatrist per 100 000 population compared to 10 psychiatrist per 100 000 populations in the European region (see Table 1.3.1.3).

The median number of psychiatric nurses per 100 000 population varies from 0.10 in the south-east Asia region to 25 in the European region.

The median number of psychologists in mental health per 100 000 population varies from 0.03 in the south-east Asia and Western Pacific region to 3.10 in the European region and 2.80 in the American region.

In the world there is less than one psychologist per 100 000 population in 61.6 per cent of countries and in low-income countries almost all the population has access to less than one psychologist per 100 000.

The median number of social workers working in mental health per 100 000 population varies from 0.04 in the south-east Asian region to 1.50 in the European region. In about 64 per cent of countries there is less than one social worker per 100 000 population. In the African and Eastern Mediterranean regions more than 85 per cent of the population has access to less than one social worker per 100 000 population.

Table 1.3.1.2 Psychiatric beds per 10 000 population and proportion of psychiatric beds in mental hospitals in WHO regions and the world (*N* = 185)

WHO regions	Median per 10,000 population	Mental hospitals (%)
Africa	0.34	73.0
Americas	2.60	80.6
Eastern Mediterranean	1.07	83.0
Europe	8.00	63.5
South-East Asia	0.33	82.7
Western Pacific	1.06	60.1
World	1.69	68.6

Treatment gap for mental disorders

A large proportion of the individuals who suffer from mental disorders do not receive any health care for their condition. The treatment gap for most mental disorders is high. According to a recent review done by WHO from published sources, originating from the United States, Europe, Brazil, Chile, China, India, Zimbabwe, and others,[13] the percentages of people in need for treatment not receiving it are as follows (see Table 1.3.1.4).

Improving mental health care

The mental health infrastructure and services in most countries is grossly insufficient for the large and growing needs. In order to deliver a high standard of mental health treatment and care, WHO emphasizes the adoption of an integrated system of service delivery which attempts to comprehensively address the full range of psychosocial needs of people with mental disorders. A number of policy recommendations for service organizations have been highlighted in the World Health Report 2001.[1] They include (i) shifting care away from large psychiatric hospitals, (ii) developing community mental health services, and (iii) integrating mental health care into general health services.

Table 1.3.1.3 Median number of psychiatrists, psychiatric nurses, psychologists and social workers working in mental health per 100 000 population in WHO regions and the world

WHO regions	Psychiatrists (N=176)	Psychiatric nurses (N=187)	Psychologists in mental health (N=177)	Social workers in mental health (N=161)
Africa	0.04	0.2	0.05	0.05
Americas	2	2.6	2.80	1.00
Eastern Mediterranean	0.95	1.25	0.60	0.40
Europe	9.8	24.8	3.10	1.50
South-East Asia	0.2	0.1	0.03	0.04
Western Pacific	0.32	0.5	0.03	0.05
World	1.2	2	0.60	0.40

Table 1.3.1.4 Treatment gap for some mental and substance use disorders

Schizophrenia	32.2%
Depression	56.3%
Bipolar disorder	50.2%
Panic disorder	55.9%
Obsessive compulsive disorder	57.3%
Alcohol abuse and dependence	78.1%

Source: Taken from The World health report 2001–Mental Health: New Understanding, New Hope, © 2001, World Health Organization, www.who.int

Essentially, ethical and scientific considerations have given impetus to the movement to transfer mental health care from mental hospitals to primary health care, general hospitals, and a range of community services in the expectation of enhancing accessibility and acceptability of services, achieving better 'mental' and 'physical' health outcomes, and also a better rationalization of resources.

A large part of mental health care can be self-managed and/or managed by informal community mental health services and low-cost resources can be made available in the community to this effect. Where additional expertise and support is needed a more formalized network of services is required. In ascending order these include primary care services, followed by psychiatric services based in general hospitals and formal community mental health services and lastly by specialist and long stay mental health services.

The mental health field is developing rapidly. There is an evolving information base to guide policy, legislation, service development, and clinical practice. However, there remains a gap between what we know in terms of what works and what is actually occurring in practice in countries around the world. This gap needs to be closed by continued advocacy efforts to raise mental health on the agenda of governments, by continued dissemination of information on effective policies, service development and clinical practice, and the dissemination of international human right standards.

1.3.2 Transcultural psychiatry

Julian Leff

Clinical relevance of transcultural psychiatry

With the mass movements of populations that have characterized the second half of the twentieth century, there can be few psychiatrists who do not encounter members of an ethnic minority group in their practice. The principles of transcultural psychiatry are obviously of relevance to this type of psychiatrist–patient interaction, but they are also of central importance even when the psychiatrist and patient share the same ethnic background. This is because within a particular ethnic group there are invariably many subcultures, for example based on religious affiliation, which encompass a diversity of beliefs. It is essential that the psychiatrist be aware of the common belief systems likely to be encountered, not simply to enhance rapport with patients and relatives, but in order to avoid serious mistakes in ascribing pathology to experiences that are accepted as normal by the subculture. For example, it is important to be aware that between 10 and 17.5 per cent of the

general population report experiencing psychotic symptoms.[1,2] The political repercussions of ignorance of such subcultural phenomena are illustrated by the accusations of misdiagnosis of Black patients by White psychiatrists which have come from both outside and within the profession. It is somewhat reassuring that the only published scientific study of this contention fails to support it.[3]

There are two main streams of thought and enquiry that have shaped the development of transcultural psychiatry: social anthropology and psychiatric epidemiology. In a number of ways these disciplines are opposed; the former is concerned with qualitative data and emphasizes cultural relativity (see Chapter 2.6.2.), while the latter relies on quantitative data and prioritizes a search for universal disease categories (see Chapter 2.7). The tools of the epidemiologist are standardized interview schedules which are linked with definitions of symptoms and signs, and rules for reaching a diagnosis. These have been introduced in an attempt to reduce the subjectivity of the psychiatrist's judgement to a minimum. By contrast, it is the person's subjective experience of illness that is the prime focus of the anthropologist. Consequently the use of standardized psychiatric interviews has been criticized by anthropologists as imposing a western biomedical model of disease on the rich variety of experience of illness and distress. The two approaches are not mutually exclusive and are best viewed as contributing complementary material to our understanding of psychiatric morbidity.[4]

The contribution of psychiatric epidemiology

Cultural influences on the psychoses

Epidemiologists have been keen to discover whether psychiatric conditions are universal and appear with the same incidence across human populations. Universality would minimize the role of culture in shaping the form of a condition, while a uniform incidence would indicate that biological factors played a major role in aetiology. Schizophrenia has been the focus of many epidemiological surveys, especially the cross-national studies conducted by the World Health Organization (WHO). The International Pilot Study of Schizophrenia[5] showed that it was possible to conduct a psychiatric epidemiological study across a wide variety of cultures and languages.[6] The use of standardized assessment and diagnostic techniques revealed that the core symptoms of schizophrenia were subject to few cultural variations. The most striking difference in the form of the illness was that catatonic symptoms were relatively frequent in patients from developing countries, but rare in the other centres.

The success of this study led to an even more ambitious project—the Determinants of the Outcome of Severe Mental Disorders. The main aim was to collect epidemiologically based samples of psychotic patients making a first contact with health services in centres around the world. It was found that the incidence of narrowly defined schizophrenia was remarkably uniform across a diversity of countries.[7] However, when patients with a broad diagnosis of schizophrenia but lacking the core Schneiderian symptoms were considered, the incidence rates across centres showed a threefold difference which was highly significant. This suggests that socio-cultural factors are likely to play a much greater role in the aetiology of non-Schneiderian schizophrenia than in the narrowly defined form, although the nature of these factors remains to be determined.

Dramatic differences in outcome at a 2-year follow-up were found, patients with schizophrenia in developing centres faring considerably better than those in developed centres despite a paucity of psychiatric personnel and facilities. This was not explained by a higher proportion of cases with an acute onset in the developing centres, raising intriguing questions about the beneficial aspects of traditional cultures. Explanations that have been proposed include beliefs that the causes of illness are external to the patient, the low demands for productivity and punctuality in an agrarian economy enabling the employment of disabled patients, and the quality of traditional family life. Only the latter has been investigated and appears to make an important contribution, since family carers in India are far less critical and more tolerant of patients with schizophrenia than their counterparts in Britain.[8]

The existence of relatively large populations of people of ethnic minority status in developed countries has facilitated the study of cultural influences on psychoses. Such research has revealed a remarkably elevated incidence of both schizophrenia and mania in some of these groups.[9,10] Of a number of possible explanations, the most likely lie in the social environment.[11]

Mania has been the focus of much less transcultural research than schizophrenia, but what little there is suggests that psychotic experiences are more common in Nigerian and African–Caribbean patients than in patients from European countries.[12,13]

Cultural influences on the neuroses

(a) Variations in frequency across cultures

Whereas neither the form nor the incidence of psychoses vary much across cultures, neuroses show dramatic variations in both respects. So-called culture-bound syndromes are an extreme example of variation in frequency since it is claimed that they are confined to specific cultural groups (see Chapter 4.16.). It is an error to think of these as exotic manifestations in traditional societies, since eating disorders, while increasingly common in developed countries are infrequent elsewhere.[14] Even with common conditions such as depression, the range of prevalence rates from studies across cultures is extremely wide.[15] This is partly attributable to a greater focus on bodily symptoms in patients in developing countries. The significance of somatic symptoms may well be missed by standardized interviews designed to detect the cognitive experiences of depression.

The emphasis on the measurement of prevalence of neuroses as opposed to incidence is due to the small proportion of new cases of neurosis that present to psychiatric services. In order to detect the majority of new cases of neuroses it is necessary to conduct population surveys, which are costly in terms of time and trained personnel. The few population surveys that have been conducted in both developed and developing countries using the same methods of interviewing and case ascertainment have shown either no difference in the prevalence of neuroses[16,17] or a higher rate in the developing country.[18,19]

(b) Variations in form across cultures

One of the most striking transcultural aspects of the neuroses is the great variation in the frequency of classical conversion hysteria. Whereas this condition is rarely seen in psychiatric and neurological services in developed countries today, it is still a common form

of presentation in developing countries.[20] This is another manifestation of the tendency to present emotional distress in bodily terms that prevails in those cultures. Somatization is by no means uncommon in patients in developed countries, particularly in individuals of lower socio-economic status, but somatic symptoms are more likely to dominate the picture in patients in a developing country. This is determined partly by beliefs about illness (see Chapter 2.6.2.) and partly by mutual expectations of patients and doctors and of traditional healers, who treat the majority of people with neuroses in developing countries.

Contributions of anthropology

Help-seeking behaviour

In general people seek help from healers who hold the same beliefs as they do (see Chapter 7.3). Traditional healers in developing countries have the advantage of sharing the same belief system about illness with their clients, so that they can take for granted a great deal of common ground and do not need to embark on long explanations. Clients of traditional healers often present their distress in terms of somatic symptoms. Skilled healers are adept at understanding the relationship problems that underlie the client's bodily complaints, and their prescription of rituals is aimed at involving the client's social network and regularizing relationships.[21] Problems in communication arise when the patient brings somatic symptoms to the western trained doctor, who may fail to detect the emotional distress generating the symptoms[22] and is unable to recognize the relationship difficulties that have prompted the comlaints.

Traditional healers are by no means confined to developing countries or to ethnic minority groups in developed countries. Alternative medicine flourishes where western biomedicine is perceived by the public to be ineffective, and psychiatry is one of those areas. Patients with psychiatric conditions are very likely to seek help from acupuncture, spiritual healing, homeopathy, or herbal remedies, in addition to consulting the general practitioner or psychiatrist. Sympathetic questioning of psychiatric patients will elicit their use of a number of sources of alternative medicine in their neighbourhood.

The concept of depression

At the same time as the evidence for a biological basis for depression appears to be strengthening, the western concept of depression has been criticized by transcultural researchers. Obeyesekere[23] considers that each culture has developed its own methods for dealing with painful emotions, for example, the Buddhists of Sri Lanka cope with the loss of a loved person by meditating on the illusory nature of the world of sense, pleasure, and domesticity. Obeyesekere[23] refers to these coping measures as 'the work of culture' and views the construction of a disease known as depression as a western cultural resource. Its incorporation into international classifications of diseases could be viewed as 'the imposition of western cultural standards that are presented as universal and inseparable parts of an emerging new world order'.[24] If a biological basis for the neuroses was firmly established such a formulation could be readily dismissed, but the efficacy of non-biological treatments for depression and anxiety, such as cognitive therapy, couple therapy, and behaviour therapy, indicates that Obeyesekere's view deserves serious consideration. It represents a specific example of the general premise that western biomedicine is itself a cultural construction and needs to be seen as one of many different ways of dealing with the experience of illness and distress.[24] The achievement of biomedicine in ridding the world of smallpox and other fatal diseases is undeniable, but in the field of psychiatry in particular we need to remain open to the ways other cultures have developed for helping people with what we would term psychiatric illness.

1.4

The history of psychiatry as a medical specialty

Pierre Pichot

Introduction

In 1918, Emil Kraepelin wrote:[1]

> A hundred years ago, they were practically no alienists. The care of the mental patients was nearly everywhere in the hands of head supervisors, attendants and administrators of the houses for the mentally ill and the role of the physicians was limited to the treatment of the physical illnesses of the patients.

He pointed out that, in the first decades of the 19th century, many of the books dealing with psychiatric themes were still written by medical doctors, such as Reil (who coined the word psychiatry), who had few contacts with mental patients or even by philosophers and theologians, and that only in the great scientific centres had specialists appeared 'who had decided to spend their life in the study and treatment of mental diseases'.

The history of psychiatry as a medical specialty has to be distinguished from the history of psychiatric medical knowledge which began in ancient Greece with the birth of medicine as a science. For more than 2000 years, only physicians observed and treated mental illnesses, and institutions were created in which the 'lunatics' and the 'insane' were received. But, as rightly pointed out by Kraepelin, the truth is that psychiatry was not really a medical specialty. One can argue about the precise date of the appearance of psychiatry as a specific field of medicine and of the psychiatrist as a specialist, devoting his professional competence exclusively to the care of the mentally ill. Denis Leigh recognizes that 'some degree of specialization occurred [in England] among respectable physicians' in the middle of the eighteenth century when the monopoly of Bethlem was broken and new 'lunatic hospitals', such as St Luke's were opened.[2] On the other hand, the American historian Jan Goldstein stresses that in France the language, as an exact reflection of the underlying reality, began to use expressions such as *homme spécial* to describe a physician specializing in a branch of medicine such as psychiatry only around 1830.[3]

Pinel and the birth of psychiatry as a branch of medicine

Despite those divergences, it is generally accepted that the work of Philippe Pinel constitutes a turning point. His role has several aspects. He is known worldwide as the physician who 'liberated the insane from their chains' in a dramatic initiative he started in 1793, at the height of the French revolution, at the Bicêtre asylum, and completed 3 years later at the Salpêtrière asylum. However, the reality is more complex.

Pinel, who was born in 1745, had studied medicine, translated Cullen's books into French, and published scientific papers on various subjects. He acted as a physician in a small Parisian 'madhouse', the Pension Belhomme, in which wealthy lunatics were confined at the request of their families. At that time most of the Parisian insanes were confined for a few weeks in the general hospital—the Hôtel Dieu. If their state did not rapidly improve, they were considered as incurable and send to Bicêtre or the Salpêtrière, built a century before, which also received other social deviants like beggars and prostitutes. Pinel, who was known by his politically influential friends for his progressive scientific ideas, was appointed physician to Bicêtre. The division for the insane was under the direction of an overseer (*surveillant*), Pussin, who had already introduced humanitarian reforms in the care of the patients. Pinel's merit was to approve and systematically develop Pussin's empirical measures and to propose an explicit scientific theory for their mode of action. Inspired by Crichton's views about the nature of the 'passions' by Condillac's psychology, and by the ideas of Jean-Jacques Rousseau, he created the *traitement moral* which he claimed to be effective with patients previously considered as incurably ill.

The improvement of the conditions in which the insane were cared for, supported and expanded by Pinel, was not an isolated French phenomenon. In Tuscany, Chiarugi in 1789 had already asserted that the basis of the extensive reforms he had introduced in the local asylum for the insane was that 'it is a supreme moral duty and a medical obligation to respect the mental patient as a person'. In England, where public had been shocked by the inhuman treatment to which King George III had been submitted during his mental illness; and where, a pious Quaker, William Tuke, deeply affected by the conditions in which the wife of a member of the Society of Friends had died in York lunatic asylum, decided to set up a special institution under the government of the Friends 'for the care and accommodation of their own members'. At the Retreat, opened in 1796 near York, physical restraints were largely abolished, and religious and moral values were emphasized in relations with the patients.

Chiarurgi's reforms did not survive the upheavals caused by subsequent wars and the political divisions of Italy, and Tuke's creation of the Retreat had not been prompted by medical considerations but was the expression of religious humanitarian purposes. The role played by Pinel was decisive, not so much because of the changes he promoted in the conditions of the patients, although they had a profound influence, but because he made the study and treatment of mental disorders a branch of medicine.

In 1801, Pinel published the *Medico-philosophical Treatise on Mental Alienation*. In it, he presented the various clinical manifestations he had observed; proposed a simple nosological system largely borrowed from older authors; examined possible aetiological factors; and described his 'moral treatment' in detail. The book has remained a landmark in the history of psychiatry, even being considered by the philosopher Hegel as a 'moment of capital importance in the history of humanity'. For Pinel, insanity was a disease and the patient affected by it remained, despite the loss of his reason, a human being. Its study, like the rest of medicine, had to be 'a science which consists of carefully observed facts'. Goldstein[3] has shown that Pinel's main preoccupation was to prove this scientific nature of the new medical specialty by repudiating the previous practices of the 'empirics' and 'charlatans'—the two terms being practically synonymous. He had accepted the method Pussin had developed empirically and transformed it in his moral treatment by providing a scientific theory of its mode of action. A curiously premonitory aspect of his emphasis on the necessity of a scientific methodology is to be found in his *Tables to Determine How Probable is the Curability of Alienation*, published in 1808. He provided statistical data on the efficacy of his therapeutic method according to the types of mental disorders and in comparison with spontaneous evolution, and concluded that medicine can only be a true science through the use of the calculus of probability!

Psychiatry as a profession: Esquirol and the clinical approach

If, because of the international influence of the ideas expressed in his book, Pinel is the founder of psychiatry as a medical discipline, he was not a psychiatric specialist in the strict meaning of the term. Although he retained his position at the Salpêtrière until his death in 1826 and is known today for his contributions to mental medicine, he had many other medical interests which gave him, in his time, a leading position among the Paris physicians; his *Philosophical Nosology*, published in 1796 and a classical reference for several decades, deals with general pathology. The case of his pupil and successor, Esquirol, who became the prototype of the psychiatric specialist was very different. At the Salpêtrière he was only in charge of the 'section of the insane'. He was later appointed medical director of the Charenton psychiatric asylum near Paris and owned in addition a small clinic, in which he treated his private patients. All his activities were exclusively dedicated to the study and treatment of mental disorders and the teaching of psychiatry. His book, *On Mental Diseases* published in 1838, in which he collected his previous publications, acquired a fame as great as Pinel's *Treatise*. In 1913, Karl Jaspers recognized that the later great representatives of German psychiatry, such as Griesinger and Kraepelin, were strongly indebted to Esquirol. He, and the school he founded, effectively developed one of the basic tenets of the new medical specialty. For Esquirol, careful objective observation and analysis of the symptoms and the behaviour of the patients were fundamental. He originated the descriptive clinical approach expanded by his pupils. Even more than Pinel, he was suspicious of unproved theories and when he eventually suggested relations between pathogenic factors and syndromes, he remained extremely cautious in his interpretations. Zilboorg, the psychoanalytically oriented historian of psychiatry, has accused this predominantly descriptive approach of creating a 'psychiatry without psychology' because, lacking psychodynamic concepts, its attempted objectivity remained at an allegedly superficial level.[4] The truth is that it laid the foundations of the present description of the mental disorders. The 'atheoretical' descriptive approach adopted in the present nosological systems—both the American *Diagnostic and Statistical Manual* and the *International Classification of Diseases*—whose proclaimed purpose is to emphasize the medical character of psychiatry is, in this respect, a return to Esquirol's principles.

The social aspects of psychiatry and the asylum system

By the end of the eighteenth century it was recognized that the study of mental alienation was part of medicine. However, mental diseases were of such a nature that it was not possible to treat the insane in the same conditions as patients affected by other diseases. Their most obvious manifestations had social consequences. According to the prevailing philosophical view, the mentally ill were deprived of free-will by their illness. In practice, they were unable to participate in the normal life of the society and were often considered as potentially dangerous. Because of this, they had generally been confined in madhouses of various kinds. One of the aspects of the reforms initiated by Pinel had been to make more explicit the difference in nature between the socially deviant behaviour of the insane, which, being the consequence of an illness, belonged exclusively to medicine, and the other deviations which society had to control and eventually to repress. The implementation of this fundamental distinction during the first half of the 19th century helped to give psychiatry its specific shape as a profession by being at the origin of forensic psychiatry and by leading to the formulation of precise rules concerning the commitment of the insane to institutions of a strictly medical character.

The legal code promulgated by Napoleon in 1810 stipulated that 'no crime or delict exists if commited in a state of dementia', with the old term dementia being used as a synonym of Pinel's mental alienation. This legal provision, introduced in similar forms in other countries, opened an important domain of activity to the medical profession of psychiatrist. Because of their now recognized specialized knowledge, the alienists were to help the judges in determining whether the mental state of an individual convicted of a 'crime or delict' was normal or pathological, with decisive consequences on the subsequent decision. The title of Esquirol's *Treatise* mentions explicitly that it describes mental diseases 'in their medical, hygienic and medico-legal aspects'. The conflict (which still exists) between the judges, usually supported by public opinion, who took a restrictive view of the concept of mental disease; and the psychiatrists, who tended to expand it to include new types of deviant behaviour, is illustrated by the violent controversies provoked by Esquirol's description of 'homicidal monomania'. They had an even more famous counterpart in England. J.C. Pritchard, an admirer of

Esquirol, had isolated 'moral insanity' as a specific mental disorder in two books published in 1837 and 1842; in the second, he examined its 'relations to jurisprudence'. Half a century later, in 1897, Henry Maudsley, who was in favour of the use of this diagnosis, recognized that this category, although internationally accepted by the psychiatrists, corresponded to

> . . . a form of mental alienation which has so much the look of vice and crime that may persons regard it as an unfounded medical invention'. Judges have repeatedly denounced it from the bench as a 'most dangerous medical doctrine', 'a dangerous innovation' which, in the interest of society, should be reprobated.

The general acceptance of the new medical concept of mental alienation implied the existence of adequate facilities for the treatment of the patients. The creation of new asylums—the term was retained—and the reorganization of the old ones were the answers. The French law of 1838 that fixed the detailed rules for the expansion of the new system to the whole country and for its functioning and financial support had a model character. Similar results were obtained in, for example, England with the Asylum Act 1828 and the Lunacy Act 1845. Outwardly, the new system was the extension, under more humane conditions, of the previous institutional practices. However, it had radically original features. While recognizing the necessity of protecting society, it stressed the fact that the insane had a fundamental right to be protected and medically treated in a competent way. The deprivation of liberty for the patients which it still implied, was strictly controlled to prevent possible misuse and was anyway justified, according to Esquirol and most contemporary psychiatrists, not only by the loss of free will, which was a consequence of the illness, but also by the therapeutic value of separation from a pathogenic milieu.

The asylum system became the central element of psychiatric care and was both the consequence and determining factor of the emergence of psychiatry as a medical specialty to which it gave, until the end of the 19th century and even beyond, an original character. The asylums acquired a quasi-monopoly in the care of the mentally ill. The few private institutions reserved for the wealthier members of the population, which often belonged to alienists in charge of the asylum, were generally submitted to the same legal rules. Private practice with ambulatory patients, as existing today, was exceptional or dealt with cases which were not then considered to belong to mental alienation. As a result, the study of mental illness was predominantly restricted to the more severe forms of disorder. Another consequence was that the alienists in charge of patients committed to the asylums had a dual function, a fact that differentiated them from other hospital physicians. In addition to their medical duties, they were involved in legal procedures which determined the conditions of admission, stay, and eventually release of the mentally ill. As superintendents, they also often had economic and financial responsibilities, being in charge of the material as well as the medical aspects of the functioning of their institutions.

Despite the fact that the laws now strictly differentiated the nature of the limitations of liberty in asylums and in prisons, the participation of the alienist in a form of social control was eventually perceived negatively by the public, and often by other physicians, and contributed to accentuating the specificity of psychiatry inside medicine. During the third and the fourth decades of the 19th century, which saw the birth of the asylum system, the psychiatrists became really conscious of their identity as a professional group. In England, France, Germany, and the United States they founded societies and began to publish journals with specialized scientific goals. Such a description oversimplifies an evolution which was progressive and in some cases took different directions. The creation and the extension of the asylum system took many years; it did not reach its classical form until the last part of the century, as testified by the famous campaign conducted in the United States during the 1840s by Dorothea Dix who complained that many of the mentally ill were still incarcerated in almshouses and prisons. The moral treatment practized in the institutions was eventually used to justify brutal measures, alleged to be therapeutic, and the behaviour of the attendants, who were not usually medically trained (significantly, they were known as *surveillants* in France), was too often of a purely repressive character. It was a long time before the proposals made in 1856 by the British psychiatrist John Conolly in his book, *The Treatment of the Insane without Mechanical Restraints* were put into practice everywhere.

The biological and the psychological model

The clinical orientation of Pinel, Esquirol, and their followers was basically empirical. By concentrating on describing observable symptoms and abnormal behaviours, it avoided theoretical controversies. However, many believed that if psychiatry was to become a branch of the medical sciences and to progress, it had to adopt models similar to those accepted by the rest of medicine. According to the anatomoclinical perspective, which was now dominant, diseases were distinct entities. Each disease was defined by a characteristic pattern of symptoms provoked by a lesion or eventually, a dysfunction of an organ to be discovered at autopsy. In 1821, Bayle, following this scheme, described the typical clinical symptoms and lesions of the brain in the general paralysis of the insane. Despite the disappointing results of the further anatomopathological studies (brain lesions were observed in only a small proportion of cases), there was increasing conviction that, with better investigation methods, mental disorders, like other diseases, could be explained by somatic causes. The degeneration theory, proposed in 1857 by Morel, which attributed many forms of insanity to the hereditary transmission of dysfunction of the nervous system produced by the noxious effects of environmental factors, and whose influence lasted until Kraepelin, is another expression of this biological orientation whose aim was to give psychiatry an undisputed medical status.

The biological and the purely clinical approaches were concerned with different conceptual levels—the discovery of the causes of insanity and the description of its manifestations respectively. Therefore, they could easily coexist. Even when the followers of Pinel and Esquirol expressed reservations about the applicability of the biological model to every type of mental disorder, they still believed in the medical nature of psychiatry. The situation created in the German-speaking countries by the school of the 'mentalists' (the term *Psychiker* by which they were known means 'psychologically oriented'), who were predominant during the first half of the 19th century, was very different. Influenced by philosophical, religious, and romantic trends, these psychiatrists took a radical dualistic position, postulating the absolute difference between the physical body and the spiritual soul. The soul was the source of the whole psychic life and hence eventually of its abnormal aspect—insanity. A term such as disease, appropriate for the somatic illness,

could only be used metaphorically in psychiatry. The sins of the patients were the origin of the mental disorders, and psychiatry belonged more to moral philosophy than to medicine. These ideas were developed in various related forms by the majority of the German psychiatrists of the period (Heinroth, Ideler, Langerman, and many others). Their ideological position had two consequences: scientific relations with other schools, such as the French and the English who saw in the publications of the mentalists obscure philosophical theories devoid of medical character, were largely cut off, and they provoked a violent reaction in Germany itself. The most extreme representatives of the contending group of 'somatists' (*Somatiker*), such as Jakobi and Friedreich, saw the mental disorders as symptoms of somatic diseases, not necessarily of the brain. In fact for them mental diseases as such did not exist. They defended aggressively their biological and sometimes bizarre hypotheses, such as the aetiological role of intestinal worms, against the mentalists. Finally, around 1850, they gained the upper hand. The publication in 1845 of *Pathology and Therapy of the Nervous Diseases* by Wilhelm Griesinger, an heir to their school who was also influenced by the French alienists, is a landmark in the history of the German psychiatry. With his appointment in 1865 as professor of psychiatry in Berlin, where he succeeded the mentalist Ideler, medical psychiatry was definitely established in Germany as a branch of the natural sciences.

The rise of neuropsychiatry

Romberg's *Lehrbuch der Nervenkrankheiten* symbolizes the birth of neurology as an autonomous medical specialty studying and treating the diseases of the nervous system. It was published 5 years after Griesinger's *Textbook* in which, adopting and expanding Bayle's anatomoclinical model he had affirmed: 'Mental diseases are diseases of the brain'. If both psychiatric and neurological symptoms originated in the nervous system, some form of association between the two specialties was a logical step, at least at the conceptual level. One aspect of their complex relationship was the creation of neuropsychiatry which developed its most characteristic aspects in the German-speaking countries.

The universities acquired considerable power and influence in the second half of the 19th century. From the 1850s on, chairs were created for the teaching of the new common discipline and special institutions, the university clinics, were built with hospital beds for psychiatric patients (if their disorders became chronic they were sent to the nearest asylum), laboratories for research on neurophysiology and neuroanatomy, and special wards for the neurological cases were developed. Griesinger's first move when he took over the chair of psychiatry at Berlin was the creation of neurological wards at the Charité. The leading neuropsychiatrists in charge of these institutions often performed research in both fields with equal competence, as shown by the work of Wernicke and Westphal, and later of Kleist and Bonhöffer, in Germany and of Meynert in Austria.

The concept of neuropsychiatry, appearing at a period during which the German school was progressively gaining influence, had a deep impact on psychiatric thought and on the psychiatric profession, even if its institutional driving force, the university clinic system, was not developed everywhere to the same extent as in Germany. For example, it was conspicuously absent in England, despite the fact that the theoretical position taken by the most important psychiatrist of the time, Henry Maudsley, was very close to that of Griesinger. The National Hospital in Queen's Square, London, founded in 1860, retained a virtual monopoly on the teaching of neurology for many decades, and psychiatry, taught essentially in hospitals, was not represented at university level until the 1930s. However, in most countries, neuropsychiatric institutions coexisted with the asylums where the alienists had the unenviable task of caring for chronic mental patients, often with inadequate means. The concept of neuropsychiatry reflected a basically biological perspective on the aetiology of the mental illnesses, expressed in the creation of a new specialty associating competence in the two previously separated domains of medicine. However, it provoked ideological and professional tension between the 'pure' psychiatrists, mainly those in charge of asylums, and the neuropsychiatrists, predominantly involved in teaching and research. In the long term, this conflict was one of the factors which finally led, in the 1960s, to the almost complete administrative and institutional separation of the two specialties in countries such as France where they had been, at least formally, associated. But many traces of the old situation remain. The most influential scientific journal published in German, *Nervenarzt*, still deals equally with neurology and psychiatry, and the term 'neuropsychiatric' survives in the titles of many teaching and research institutions.

The neuroses and the birth of the psychotherapies

The study of the neuroses, in which the relation between psychiatry and neurology was also involved, resulted in completely different, but equally important changes to psychiatry as a medical specialty. The term neurosis had been coined in 1769 by Cullen to describe a class of diseases he attributed to a dysfunction of the nervous system. In this very heterogenous group, two entities of very ancient origin, hysteria and hypochondriasis, had predominantly psychological manifestations. Since the affected patients were not usually commited to asylums, they were not normally studied by alienists, but by specialists in internal medicine such as Briquet, who in 1859, wrote the classical *Treatise on Hysteria*. Because of the assumed nature of the neuroses, the new discipline of neurology rapidly took an interest in them.

Charcot, the founder of the French neurological school, was responsible for the internal medicine wards at the Salpêtrière—they were not associated with the 'divisions of the insane' at the same hospital, the domain of the alienists. In about 1880, he became interested in hysterical patients who, because of their seizures, were admitted to the same ward as the epileptics. He developed a purely neurological theory of the disease which he described and studied using hypnosis. This was the former 'animal magnetism', long fallen into disrepute, but to which he gave a new scientific status. Charcot's descriptions of the *grande hystérie*, which he demonstrated on selected patients in his famous public lectures, were justly criticized later, but his international fame attracted students from all over the world. One of them, was a young lecturer in neuropathology at the University of Vienna, Sigmund Freud, who, impressed by Charcot's lectures, decided to devote all his energies to the study and the treatment of the neuroses. Another was a French professor of philosophy (psychology was then a branch of philosophy), Pierre Janet, who had become interested in the psychological aspects of the neuroses. He was later to develop, in parallel with Freud, a

psychopathological theory which, despite the traces it has left (the concepts of psychasthenia and the dissociative processes in hysteria) was not to be as internationally successful as Freud's psychoanalysis. Charcot's ideas were opposed by Bernheim, the professor of internal medicine at the Nancy Medical School and also an adept of hypnosis. He attacked the neurological interpretations of the Salpêtrière and claimed that suggestion played a central role in the phenomena described by Charcot.

The general interest in the neuroses, which extended beyond medicine to *fin de siècle* literature, was an international phenomenon. In 1880, Beard, an American neurologist, described a new neurosis, neurasthenia, which soon aroused even more interest than Charcot's hysteria. Psychiatry had played almost no part in this evolution, but this was to change under the influence of three related developments: the changes which took place within the concept of neurosis, the birth of the psychotherapies, and the incorporation in the field of psychiatry of psychopathological manifestations, even if they were of minor intensity.

The transformation of the concept of neurosis is apparent in the position taken by Kraepelin in the 1904 edition of his *Textbook*. He introduced a chapter,'The psychogenic neuroses', on the grounds that 'among the neuroses, to which belong epilepsy and chorea, one must isolate a sub-group characterized by the purely psychological cause of the apparition of the symptoms'. The disintegration of the old concept left to neurology, which from now on abandoned the generic term, diseases (such as epilepsy and chorea) whose somatic manifestations could be shown to express a dysfunction of a precise part of the nervous system. Psychiatry took charge of hysteria, hypochondriasis, neurasthenia, and the related phobic, obsessional, and anxious disorders, which constituted the new neuroses. This concept was justified by the psychological nature of the symptoms and the causes recognized even by a biologically oriented psychiatrist such as Kraepelin. This redrawing of the frontier between the neurological and psychiatric specialties also testified to the extension of the limits of psychiatry. Pinel's insanity, until then defined by the necessity of commitment to special institutions, was replaced by a broader concept. A new class corresponding to our present personality disorders had already appeared in the 1894 edition of Kraepelin's *Textbook*. It had been isolated for the first time in 1872–1874 by the psychiatrist Koch. Like the neuroses, the cases were rarely observed in asylums but, nevertheless, they were now considered as belonging to the psychiatric field of study.

This field was further modified by the birth of the psychotherapies. In fact, they had a long history. In 1803, one of the first German mentalists, Reil, had described under the name of 'psychic therapy' (*psychische Curmethode*) a number of procedures, including very violent somatic ones, which could influence the 'perturbed passions of the soul', and Pinel's moral therapy contained psychotherapeutic elements. However, psychotherapies as techniques whose formal rules were based on an explicit theory about their psychological mechanisms of action, derived mainly from Mesmer's animal magnetism as rehabilitated by Charcot. The emergence of the psychotherapies, characteristic of the last decades of the 19th century, was intimately related to the renewed study of the neuroses. After he had abandoned hypnosis, Freud developed psychoanalysis, but many other techniques evolved during the same period, which were as well or even better known at the time, although they were to have a less lasting success. One of these was the method of Janet, who still occasionally used hypnosis. In 1904, Dubois, a Swiss neuropathologist from Bern, introduced a technique influenced by Bernheim's theory of suggestion in *The Psychoneuroses and their Moral Treatment*, and claimed to produce a 'psychological re-education' by a combination of rational and persuasive elements. His international reputation brought him patients from all over the world. The 'rest cure', proposed in 1877 by the American neurologist S. Weir Mitchell for the treatment of hysteria and later of neurasthenia, was combined with Dubois' method by Dejerine, Charcot's successor as the professor of neurology in Paris.

This very incomplete summary illustrates the striking fact that, because of their intimate connections with the neuroses, the psychotherapies originated inside neurology. When the study and treatment of the neuroses were incorporated into psychiatry, the psychiatrists considered that they were an integral part of their activity and tried to retain the monopoly of their practice. They never completely succeeded. Already Freud had, according to his biographer Jones, 'warmly welcomed the incursion in the therapeutic field of suitable people from another walk of life than medicine'. The problem of the 'lay analysts', a source of conflict within the psychoanalytic movement, is only an aspect of a broader question which was later to involve the relations of the medical specialty of psychiatry with the new professional group of clinical psychologists.

From the beginning of the 20th century to the Second World War

During the first half of the 20th century, psychiatry developed in many directions. Kraepelin's monumental synthesis[5] established around 1900, a nosological system which, in its broad outlines, has remained valid until today. Without being radically altered it was completed, to mention only a few contributions, in 1911, by Bleuler's description of schizophrenia and in 1913, by Jaspers' psychopathological perspective, developed by the Heidelberg school and Kurt Schneider, and by other psychiatrists working in academic institutions. However, the old conflict between the 'mentalists' and the 'somatists' reappeared in a modified form. The mainstream of psychiatry had abandoned the extreme positions of the 'brain pathologists' of the Meynert-Wernicke type but, while recognizing a limited influence of psychological factors, admitted in a general way the biological origin of the more severe mental disorders—the psychoses. The empirical discoveries of biological treatments—of general paralysis by malaria therapy (Wagner von Jauregg in 1917), of schizophrenia by insulin coma (Sakel in 1933) or by chemically induced seizures (von Meduna in 1935), and of depression by electroconvulsive therapy (Cerletti in 1938)—not only helped to dispel the prevailing therapeutic pessimism, but provided supporting arguments. However, an opposing ideological current represented by psychoanalysis had arisen from the study of the neuroses. Its attention was concentrated on the study of complex psychopathological mechanisms postulated to be at the origin of the neurotic, and later also of the psychotic symptoms, favoured psychogenetic aetiological theories, and advocated psychotherapy as the fundamental form of treatment. Psychoanalysis expanded steadily during this period and gained enthusiastic adherents in many countries. However, partly because of the suspicion and even hostility of many members of the psychiatric establishment, they remained isolated in close-knit groups with their own teaching

system independent of the official medical curriculum, and the use of their therapeutic technique was restricted to a small number of mostly neurotic patients seen in outpatient clinics or, more often, in private practice.

The great majority of patients suffering from mental disorders were still confined in asylums, and the enormous increase in their number, mainly related to the social changes accompanying industrialization and urbanization, although other factors have been invoked, was striking. In Great Britain it grew from 16 000 in 1860 to 98 000 in 1910, three times more rapidly than the population. A similar phenomenon was observed in all countries and persisted until the end of the 1940s despite the introduction of the first biological therapies. In the United States, there were already 188 000 patients in mental hospitals in 1910, and by the end of the Second World War, 850 000 were lodged in huge institutions which were overpopulated, understaffed, and could only provide custodial care. This obvious degeneracy of the asylum system, contrasting with the progresses in the scientific field, stimulated efforts to improve the practice of psychiatry and its institutional framework. Most of these improvements took place after 1920 and, although their results remained relatively limited, they were the forerunners of later more drastic changes.

The education of psychiatric specialists, which had varied widely from country to country, was improved and systematized. A convergence of evolution is apparent during this period which can be said, to some extent, to have seen the formal administrative recognition of psychiatry as a medical specialty. Educational programmes and controls of the level of competence were introduced which extended beyond psychiatrists in academic positions. A limited teaching of psychiatry became compulsory even in the general medical curriculum. In France, psychiatrists for public asylums and, in some cases, residents in psychiatry were selected by a competitive examination system. In England, the Board of Control recommended in 1918, that a leading position in a psychiatric institution could only be occupied by a physician who had obtained a Diploma in Psychological Medicine awarded by the Royal College of Physicians and by five universities. In the United States, the moving force behind the reforms was Adolf Meyer, the Director of the Henry Phipps Clinic at Johns Hopkins University from 1913 to 1939, who organized a systematic residency system and promoted the creation of the Board of Neurology and Psychiatry. This Board was established in 1936 and awarded a diploma which it became necessary to hold, to be recognized as a specialist.

The changes were reflected in the vocabulary. The term psychiatry, originating in the German-speaking countries and mostly used there, was adopted everywhere at the beginning of the century. In France, the health authorities officially substituted '*hôpital psychiatrique*' for '*asile d'aliénés*' and '*psychiatre*' for '*aliéniste*' in the 1930s. In England, a Royal Commission used the words 'hospital', 'nurse', and 'patient' instead of 'asylum', 'attendant', and 'lunatic' for the first time between 1924 and 1926. However, efforts were also made to dissociate, when possible, the social protection function of the institutions from their medical role by allowing them to admit patients under the same conditions as the general hospitals. In 1923, a special section was created in the Paris Sainte-Anne asylum which provided treatment to voluntary patients and had both hospital beds and a large outpatient department. In England, the Mental Health Act of 1930 made voluntary admissions to psychiatric hospitals possible; by 1938, they already constituted 35 per cent of all admissions.

Social considerations had always been evident in psychiatry, but their traditional expressions had mainly been of a negative nature, i.e., the confinement of patients in asylums. The new possibility of free admissions reflected an increase in tolerance towards the disturbing character of mental illness. At the same time, a differently oriented and broader social perspective appeared. The concept of mental hygiene originated in the United States in 1919 with the creation by a former patient, Clifford Beers, of an organization whose internationally growing influence was manifested by well-attended congresses held in Washington in 1930 and in Paris in 1937. From its beginning, the movement was not purely medical and was influenced by various humanitarian philosophical trends. It emphasized the role of social factors, such as living conditions or educational practices, in the origin of mental disturbances and promoted their prevention and treatment by the close co-operation of psychiatrists and nurses with non-medical groups in the community. One of the institutional consequences of these ideas was the creation of the profession of social worker. They began their activity in Adolf Meyer's clinic (Adolf Meyer had been an early supporter of the mental hygiene movement whose principles converged with his own ideas) at the Sainte-Anne Hospital in Paris, in England where the London School of Economics opened a special training course in 1929, and elsewhere.

Contemporary with the emergence of psychiatric social work was the expansion of clinical psychology. The Binet-Simon scale for the measurement of intelligence, developed in 1905, was the first application to psychiatry of the new discipline of experimental psychology which had originated at the end of the previous century. This initial contribution led to the creation of a professional class of clinical psychologists who were initially concerned with the development and use of psychological assessment instruments and with theoretical research in a few psychiatric centres. Their number initially remained low; in 1945 the United States, where they were most numerous, had about 4 000 psychiatrists but only 200 clinical psychologists.

The expansion of psychiatry after 1945

The Second World War coincided with a major transformation of the psychiatric specialty. The war had vividly demonstrated the frequency of mental disorders in the United States; they had proved to be the leading cause of medical discharges from the military service and the primary cause of almost 40 per cent of selective service rejections. The previously prevailing view that psychiatry was a minor and often somewhat despised medical discipline, concerned primarily with the custodial care of psychologically deviant and potentially troublesome individuals, was progressively dispelled. The preservation and the restoration of mental health—an expression from now on often used by national and international institutions—began to be considered by governments as an important task. The fundamental changes which took place after 1945 and shaped psychiatry as we know it today were the result of this new atmosphere and of the emergence of new perspectives in the three traditional domains— the psychological, the social, and the biological. Some appeared in slightly different forms at different times, their relative influence was submitted to variations, and eventually they came into conflict. The result has been an impressive expansion and increase of the efficacy of psychiatry, profound institutional transformations, and successive ideological waves

which have had a major impact on the professional position of the psychiatrist.

The demographic data reflect the new importance of psychiatry in medicine. In the United States, the proportion of psychiatrists in the medical profession was 0.7 per cent in 1920, 1.4 per cent in 1940, and 5.5 per cent in 1970, the rate of growth having doubled after the Second World War. In France, at present there are 18 psychiatrists for 100 000 habitants; they constitute 6 per cent of all physicians. Similar levels were reached during the postwar decades in the developed countries and remain relatively stable today. Even before this spectacular increase in numbers, psychiatrists had been becoming conscious of the necessity to affirm the identity of their discipline. The First World Congress of Psychiatry, held in Paris in 1950, has been followed by periodic meetings and by the creation of the World Psychiatric Association to which almost every national society of psychiatry belongs. The health authorities of various countries have become conscious of the necessity to provide adequate financial means to support research and training in the discipline. In 1946, the United States government created the National Institutes of Mental Health for such a purpose, and similar efforts were made in many countries although the structures of the organizations formed were different. To promote the same goals at the international level, the World Health Organization, created immediately after the Second World War, had a Section (later Division) of Mental Health which, among other co-ordinating activities, tried to overcome the difficulties of communication between the national schools by establishing a common nosological language.

While the changes affected almost all countries, they were most spectacular in the United States. From the end of the 19th century until the 1930s, the concepts developed in the German-speaking countries had been the most influential. This disappeared with the advent of the National Socialist regime which, under cover of racist theories, expelled many of the leading psychiatrists from Germany and Austria, introduced compulsory sterilization for several varieties of mental illnesses, and promoted the voluntary killing in psychiatric hospitals of mentally-retarded children and chronic patients. The United States, which had emerged from the Second World War as the most powerful country in the world, began to exert a widespread influence in psychiatry as in the rest of medicine. Because of the prestige of its research and teaching institutions and the worldwide influence of its scientific publications, reinforced by the progressive adoption of English as the language of international scientific communication, American psychiatry became a model in many countries, even though many of the theoretical trends and technical advances it adopted and developed had originated in Europe. However, in the United States, with a local colouring, they took on a special intensity.

The psychodynamic wave

An important factor in the spread of the doctrine of psychoanalysis was the emigration of a relatively large number of German and Austrian psychoanalysts to the United States from 1933 onwards. They had been compelled to leave their home countries for racial reasons—psychoanalysis had been condemned by the National Socialist regime as Jewish and Freud's books had been publicly burned. Many of the young psychiatrists trained in large numbers to answer the demands of the armed forces adopted psychoanalysis under the influence of some of those in charge of the programmes. For a generation, until the end of the 1960s, psychoanalysis became the dominant ideology in American psychiatry.

The American form of psychodynamism often deviated from Freudian orthodoxy, but it emphasized the role of psychogenetic factors, the value of the study of intrapsychic mechanisms, and the basic importance of psychotherapy, while giving little consideration to the traditional clinical approach and to nosology. The domination of this essentially psychological orientation, sometimes compared with the success of the German mentalist school during the first half of the 19th century, had important consequences. Although the disorders of hospitalized psychotics were eventually interpreted according to psychoanalytic theory, psychotherapy was mostly used, as it has been since its beginning, on ambulatory neurotic patients. As early as 1951–1952, 3 000 of the 7 500 American psychiatrists identified private practice as their main activity, and in 1954, the number of private psychiatrists exceeded that of their salaried colleagues for the first time, with a quarter of the former devoted exclusively to psychotherapy. However, with the initial encouragement of official institutions such as the Veterans Administration, the clinical psychologists began to engage in psychotherapeutic activities. The number of members of the Clinical Psychology Section of the American Psychological Association reached 20 000 in 1980, at a time when they were 26 000 psychiatrists in the United States. In public opinion, and to a certain extent in general medical opinion also, psychiatry was assumed to consist only of psychotherapy and psychology.

In most other countries the developments that occurred in the United States were not as intense, generally appeared later, and were modified by local traditions and influences. In the German-speaking countries they were delayed by the still powerful neuropsychiatric perspective and the temporary vogue for existential phenomenology. In the United Kingdom, the eclectic current fostered by the influential London Institute of Psychiatry during the decades following the war restricted the advance of psychodynamism; in 1956, *Time Magazine* could affirm, as a conclusion of a survey, that 'all of Great Britain [had] half as many analysts as New York City'. In France, the psychoanalyst Jacques Lacan gave the doctrine a special colouring. On the whole, however, the rise of psychodynamism was a general phenomenon, except in the communist countries where Freud's doctrine had been condemned on ideological grounds.

A reaction began in the 1960s with the successes of the new pharmacotherapies. Clinical psychologists had developed alternative radically different psychotherapeutic methods based on learning theories, especially the behaviour therapy introduced in 1958 by Wolpe, supported in the United Kingdom by Eysenck, and the cognitive therapy often associated with it. These methods competed successfully with the psychodynamic techniques and conquered a large part of the field. Psychodynamism did not disappear; many of its concepts retained their place in psychiatry and psychotherapeutic methods continued to be practized, but it lost its predominant ideological position. In addition to its theoretical contributions, when its influence on the professional aspect of psychiatry is considered from a historical perspective, it has been an important factor in the further expansion of the activity of psychiatrists in the treatment of relatively minor disorders and has also encouraged clinical psychologists to play an active and independent role in this field.

The social wave

At the end of the Second World War there was a great desire for social change; one of its aspects was the belief that everyone had a 'right to health' or at least the right to receive adequate medical care regardless of the ability to pay. This resulted in the creation of the National Health Service in the United Kingdom in 1948 and the Social Security system in France, together with similar developments in other countries. The social perspective, which was one of the basic principles underlying these developments, initiated major institutional changes in psychiatry. They were the result of a number of factors—the necessity to give to the whole population an easy access to psychiatric care, and also the belief that social elements played an important role in the aetiology of the mental disorders and that they could greatly contribute to the healing process, with the aim of progressively reintegrating the patient in the community.

The most spectacular aspect of the new policy was the decline of the asylum system, still in a dominant position in psychiatry; in fact, the number of patients in psychiatric hospitals in the developed countries reached its peak in 1955. The criticisms of the 'degeneration' of the functioning of psychiatric hospitals and the segregation of patients in institutions, often located far from their homes and families, were not new. However, the previous partial improvements, such as the decrease in the number of compulsory commitments or the creation of outpatient departments, were replaced by the creation of completely new structures. Ideally, the country would be divided into geographical zones or sectors with a population of about 100 000, and each zone would have a multidisciplinary team of psychiatrists, nurses, clinical psychologists, social workers, and occupational therapists responsible for mental health. Visits and therapeutic interventions in the patient's home and easily accessible outpatient departments were to play an increasingly important role. If hospitalization was necessary, it should be as far as possible in small units located in a general hospital where the time of stay was to be reduced to the absolute minimum. Special institutions such as day hospitals, night hospitals, and specially adapted workshops would contribute to the progressive readaptation of the patient to the life in the community. The introduction of this 'community care', which was expected to work in close co-operation with general practitioners and various public and private institutions, would result in the disappearance of the traditional psychiatric hospital and to 'deinstitutionalize' psychiatry. The new system was introduced in various forms in most countries after 1969. In the United States, the Community Mental Health Center Act was promulgated in 1967. In the United Kingdom, which had strong traditions of social psychiatry, plans for the implementation of community care were discussed in the 1960s, and in 1975, the Government White Paper *Better Services for the Mentally Ill* encouraged the formation of multidisciplinary 'primary care teams' which also included general practitioners. In France, an official directive in 1960 created the *psychiatrie de secteur* which was expected to result in the progressive elimination of *hospitalocentrisme*. The World Health Organization (WHO) encouraged all its member countries to adopt similar practices.

Although, in the last 40 years community care has become the official doctrine everywhere, except in Japan where the rate of hospitalization in mostly private hospitals has grown continuously, its implementation has not been easy despite the major therapeutic improvements brought about by pharmacotherapy. In some parts of the United States, the sudden closure of public psychiatric hospitals combined with the inadequacies of the Community Mental Health Centers were for a time at the origin of an appalling lack of care for a number of mentally ill people. The expected 'fading out' of hospitalization has been slow. According to the WHO, in 1976 the number of mental health beds (including beds for the mentally retarded) per 1 000 population was 6.5 in Sweden, 5.5 in the United Kingdom, 3 in France, and 2 in Germany. These figures have since decreased and the types of hospitalization have changed. In 1955, 77 per cent of the 'psychiatric care episodes' in the United States occurred in public psychiatric hospitals, compared with 20 per cent in 1990. In 1994, 1.4 million mental patients were hospitalized, but only 35 per cent in public psychiatric hospitals compared with 43 per cent in general hospitals and 11 per cent in private psychiatric hospitals, which increased in number from 150 in 1970 to 444 in 1988. In France, where the total number of psychiatric patients treated in public institutions (including children) is now about a million, 60 per cent are seen exclusively on an ambulatory basis, but the number of hospital beds has only been reduced by half.

Reflecting the increasing influence of social perspectives, the organizational changes modified psychiatry as a profession. The increase in the number of psychiatrists in private practice was paralleled, in general to a lesser extent, by an increase in the public sector where their role was modified. In the traditional asylum, the authority of the psychiatrist was unchallenged and limited only by the legal provisions related to the procedures of commitment. The nurses, and later the clinical psychologists, social workers, and occupational therapists, were 'paramedical auxiliaries' in a subordinate position. The creation of multidisciplinary teams, working in various settings, gave the psychiatrist a function of co-ordination made increasingly complex by the claims of professional autonomy made by the former auxiliaries. In some cases, such as in the American Mental Health Centers, the psychiatrists who were a small minority in the team and had less and less control over its functioning, resented what they considered to be the loss of their medical status.

The importance given to social factors was not limited to the system by which care was delivered. Sometimes, combined with radical ideological and political attitudes, it took more extreme forms. The criticisms, which first centred on the inadequacies of the existing institutions, extended to the concept of mental disease itself. The antipsychiatric movement claimed that mental diseases were artificial constructs which were not related to diseases in the medical meaning of the term. The allegedly pathological behaviours, such as those conceptualized as schizophrenia, were in fact normal reactions to an inadequate social system. The so-called treatments were techniques used by the ruling classes to preserve the social order of which they were the beneficiaries. The only solution was a drastic reform of society. Such theses varied in their content and in the arguments used. They were developed by authors such as Szasz, Laing, and Cooper in the English-speaking world, the philosopher Foucault in France, and the psychiatrist Basaglia in Italy. They reached their greatest influence in the 1960s and a few attempts were made to put their ideological principles into practice. Although they attracted much attention at the time, they were very limited and short lived. One of the few countries where this movement had a practical impact was Italy. Basaglia's strongly politically oriented theories were influential in the later legal reform of the antiquated asylum system, but, despite the apparently

revolutionary character of some of the new administrative provisions, the changes made were very similar to those taking place in other countries.

The biological wave

Psychotropic drugs, such as opium, had been used since the origin of the medical treatment of psychiatric patients. During the 19th and the first half of the 20th century, synthetic drugs such as the bromides, the barbiturates, and the amphetamines were developed. Some of them, especially the sedatives and hypnotics, had a real but in practice, marginal value in alleviating some symptoms. They had never constituted an effective treatment of mental disorders. Modern psychopharmacology not only initiated what has been rightly called a therapeutic revolution in psychiatry but also gave a powerful new impulse to the biological perspective. Its date of birth is usually considered to be 1952, when the remarkable activity of chlorpromazine on the symptoms of schizophrenia and mania was discovered. This had been preceded in 1949 by the demonstration of the value of lithium salts in manic states. A few years later, it was shown that the continuous administration of lithium salts prevented the recurrence of manic and depressive phases in the mood disorders. This was followed by the introduction of drugs acting on the depressive manifestations (imipramine and the monoamine oxidase inhibitors in 1957) and on anxiety (including chlorediazepoxide, the prototype of the benzodiazepines, in 1960). In one decade, clinicians had empirically discovered the fields of application of the main classes of psychoactive drugs—the neuroleptics, the antidepressants, the anxiolytics, and the mood stabilizers—which had been synthesized by biochemists and previously tested by pharmacologists on animal models. The scale and rapidity of the spread of their use had major repercussions.

The first was a modification of the image of psychiatry. The layman generally expected a physician to prescribe drugs to treat the disease from which he suffered. In part, because it did not conform to the expected therapeutic behaviour, psychiatry had been seen as an atypical and almost non-medical specialty. In addition to the specificity of the institutions in which it was generally practized, psychological techniques were unknown in the rest of medicine, and even the recently introduced biological techniques (the shock therapies and the lobotomy) had a somewhat strange and frightening character. The establishment of pharmacotherapy contributed strongly to modifying this perception, even if it did not completely remove the traditional prejudices.

The second consequence was even more important. There were, at least initially, controversies about the roles of pharmacotherapy and of the new social perspectives in the restructuring of the mental health care system. In fact, the number of inpatients in psychiatric hospitals began to decrease from 1955 on, and it seems obvious that the main cause was the therapeutic efficacy of the drugs. They reduced the mean length of hospitalization and eventually even made it unnecessary. Although some types of patients did not benefit from them and the mental state of others was only improved, many who had previously been condemned to long stays in the hospital were able to return to the community, with their treatment eventually being continued in rehabilitation settings and often on an ambulatory basis. Pharmacotherapy had made possible the practical implementation of social trends. In addition to this basic contribution to the 'deinstitutionalization' movement, pharmacotherapy was an essential factor in the growth of private practice. The success of psychotherapy had been one contribution to this, but the complexity of its techniques, the length of the treatment, its applicability to only a few types of disorders, and the uncertainty of the results limited its use to a relatively small number of selected patients, even in the United States during the period of the greatest popularity of psychodynamism. Pharmacotherapy could be used much more easily, on a much larger number of patients, and did not require a long and complex training. Some of the drugs, such as the anxiolytics, had an immediate symptomatic effect, and others (the antidepressants and the neuroleptics) could attenuate or suppress the pathological manifestations in a few weeks and, outside the acute phase requiring hospitalization, could be used on an ambulatory basis. It was not only private psychiatrists who were able to treat many of their patients successfully; general practitioners also began to prescribe psychotropic drugs on a large scale.

The third consequence was the explosive development of biological research in psychiatry. The first therapeutic discoveries were largely empirical, but new biochemical techniques allowed some of the modes of action of the drugs to be elucidated. From 1960 on, studies of the influence of these drugs on various aspects of neurotransmission in the brain stimulated hypotheses about the abnormal biochemical mechanisms considered to be the physical substrate of the mental disorders. Meanwhile new methods had been introduced for examination of morphological modifications of the living brain and even of the nature and localization of the biochemical processes taking place in its different parts. The discovery by Watson and Crick in 1953, of the chemical basis of heredity and the subsequent spectacular advances in molecular biology gave a fresh impulse to psychiatric genetics, which had been partly discredited by their misuse by the National Socialist regime. Under the name of neurosciences, these new fields of enquiry progressively acquired a dominant role in psychiatric research at the same time as the introduction of an ever-increasing number of drugs, eventually more potent, usually with less inconvenient side-effects, and sometimes with new therapeutic indications.

'Remedicalization' of psychiatry

In 1983, Melvin Sabshin, the Director of the American Psychiatric Association, summarized the overlapping chronologies of the psychodynamic, biological, and social waves as follows:[6]

> Psychoanalysis surged through the United States during the 1940s and the 1950s. During the 1950s, a new psychopharmacological approach emerged which had great impact on psychiatric practice generally . . . The 1960s saw the dawning of a community psychiatric approach which attempted to accomplish a massive desinstitutionalization of patients from public psychiatric hospitals.

Although less radical and not strictly identical, the general picture was similar in other countries. The 1960s saw an often uneasy coexistence of three schools. 'During that decade', wrote Sabshin, 'American psychiatry enlarged its boundaries and its practices so broadly that many critics grew increasingly concerned with the 'bottomless pit' of the field'. The extension of the practice of psychotherapy, frequently to cases with no clear pathological character, tended to blur the limits of the mental disease concept and to neglect the traditional diagnostic approach. Social work was also tempted to concern itself with problems with no obvious medical nature, such as those still described in 1978 in the United States by the President's Commission of Mental Health, which asserted

that 'American mental health cannot be defined only in terms of disabling mental illness and identified mental disorders' and identified as a domain of concern for workers in the field 'unrelenting poverty and unemployment and the institutionalized discrimination that occurs on the basis of race, sex, class, age . . .'. In sharp contrast, the new biological psychiatry recognized only a strictly medical model, stressing the necessity of an accurate diagnosis for the prescription of the drugs and for the testing of their efficacy, and advocated restrictive limits in the definition of the mental diseases.

Around 1970, a profound change took place. Although the institutional modifications of the care system favoured by the generalization of drug therapy continued and expanded under its various forms everywhere, the influence of psychodynamism began to decline within the psychiatric profession. According to the Director of the National Institutes for Mental Health 'it was nearly impossible in 1945 for a non-psychoanalyst to become Chairman of a Department of Psychiatry (in the United States)' but by the mid-1970s the situation was reversed. The publication by the American Psychiatric Association of the Third Revision of the Diagnostic and Statistical Manual of Mental Disorders (DSM-III) is often considered as the symbolic expression of the change. This took place in 1980, but its origins were more than a decade previously, and it was significantly presented by its apologists, such as Klerman, as 'a decisive turning point in the history of American psychiatry . . . an affirmation of its medical identity'. The new nosology, which was categorical in nature and which introduced diagnostic criteria borrowed from experimental psychology in the delimitation of the categories, did not allow any reference to 'unproven' aetiological factors or pathogenic mechanisms, unless 'scientifically demonstrated'. It claimed to be purely descriptive and therefore acceptable as a means of communication by all psychiatrists, whatever their individual orientation may be. It was in fact perceived, not only in its country of origin, as a reaction against the extreme socio-psychological positions—the deletion of the term neurosis because of its usual association with the psychoanalytic theory of intra-psychic conflicts raised violent controversies—and, despite its proclaimed 'a-theorism', as favouring the biological medical model. Although initially exclusively devised for the use of the American psychiatrists, to the surprise of its authors it was rapidly accepted in all countries and the WHO adopted finally its principles in its own nosological system, the International Classification of Diseases. Originally the result of a brutal reversal of trends in the American psychiatry, it expressed a general change of direction in the psychiatric way of thinking towards the affirmation, against the forces believed to threaten it of the medical character of psychiatry.

Crisis in psychiatry?

At first glance, the new status of psychiatry seems to have taken firm root in the last three decades. It rests on the general acceptance of the medical definition of the concept of mental disease and of the progressive realization of a diversified but co-ordinated institutional system of mental health care. The biological perspective, even if it has taken a prominent place in research and therapy, is now combined with psychological and social approaches in the bio-psychosocial model. The psychiatrist, in accordance with his medical professional responsibilities, occupies a central position in a multidisciplinary team whose members contribute their special competences to the common goal.

This idyllic picture is far from a reflection of reality, even in the developed countries, and the existence of a crisis in psychiatry is evoked with increasing frequency. An indication of the loss of prestige of psychiatry in the medical profession is the alarming decrease of the proportion of American medical students choosing a psychiatric residency; it fell to 2 per cent in 1990, a level much too low to ensure the maintenance of the present demography. Under the pressure of economic constraints, efforts are made everywhere to control the rising burden of medical care. They have taken different forms according to the country—from the managed care system in the United States to the *numerus clausus* system in France, in which the number of internships available is determined by the government—but their common aim is to limit the number of psychiatrists and the cost of their activities. Paradoxically, the recognition of the frequency of the mental disorders and the growing demand for psychiatric treatments has been associated with a reduction in the domain of action of psychiatrists, who are now often vastly outnumbered by clinical psychologists and social workers. In the United States, by 1990, 80 000 'clinical' social workers were active in the psychiatric socio-psychological domain, a quarter of them in part- or full-time private practice. The claims of these powerful professional groups are not limited to a completely autonomous status but, in the case of the clinical psychologists, extend to the demand for a legal recognition of such typical 'medical privileges' as the right to hospitalize patients and to prescribe drugs. Even within medicine, psychiatry is under attack. In Germany, a medical psychotherapeutic specialty distinct from psychiatry has been created. The most impressive change has been in the proportion of mental disorders being now treated by general practitioners as a result of the availability of psychotropic drugs with fewer side-effects; in France, 60 per cent of antidepressants are now prescribed by general practitioners. These examples may not be a fair representation of the global picture, but there is undoubtedly a movement towards a limitation of the psychiatric specialty to the care of the most severe cases—in practice, the psychotic cases. However, some neuroscientists raise doubts about the usefulness of maintaining psychiatry as a specialty even in this field. Influential biologically oriented psychiatrists have recently proposed on theoretical and practical grounds, that psychiatry should be absorbed into a new medical discipline, akin to the former neuropsychiatry, and all or most of its socio-psychological aspects should be left to non-medical professions.

Since psychiatry has emerged as a specialty, it has been submitted to conflicting forces. The demands of society, changes in the concept of mental disorder and of its limits, variations in the role played by different theoretical perspectives, and successive scientific discoveries have been responsible for an evolution reflected in the professional status and role of the psychiatrist. Displacements of the centre of gravity of a complex structure in which biological, psychological, and social factors interact have modified the image of psychiatry. The threat of being incorporated in other medical specialties or being deprived of its medical character is but another transitory episode in its history.

Ethics and values

Contents

1.5.1 Psychiatric ethics

Sidney Bloch and Stephen Green

A myriad of ethical problems pervade clinical practice and research in psychiatry. Yet with few exceptions,[1–3] psychiatric ethics has generally been regarded as an addendum to mainstream bioethics. An assumption has been made that 'tools' developed to deal with issues like assisted reproduction or transplant surgery can be used essentially unmodified in psychiatry. These tools certainly help the psychiatrist but the hand-me-down approach has meant that salient features of psychiatric ethics have been prone to misunderstanding. Psychiatric ethics is concerned with the application of moral rules to situations and relationships specific to the field of mental health practice. We will focus on ethical aspects of diagnosis and treatment that challenge psychiatrists, and on codes of ethics. Resolution of ethical dilemmas requires deliberation grounded in a moral theoretical framework that serves clinical decision-making, and we conclude with our preferred theoretical perspective.

Diagnostic issues

Conferring a diagnosis of mental illness on a person has profound ethical sequelae since the process may embody substantive adverse effects, notably stigma, prejudice, and discrimination (e.g. limited job prospects, inequitable insurance coverage). Furthermore, those deemed at risk to harm themselves or others may have their civil rights abridged. These consequences justify Reich's[4] call for the most thorough ethical examination of what he terms the clinician's 'prerogative to diagnose'.

Psychiatrists strive to diagnose by using as objective criteria as possible and information gained from previous clinical encounters. The process is relatively straightforward when findings such as gross memory impairment and life-threatening social withdrawal strongly suggest severe depression. Other situations are not so obvious. For instance, the distress felt by a bereaved person may incline one clinician towards diagnosing clinical depression whereas another may construe the picture as normal grief. Expertise, peer review, and benevolence combine to protect against arbitrariness and idiosyncrasy. Notwithstanding, psychiatrists must, to some extent, apply what might be termed as 'reasoned subjectivism'. Thus, specified criteria in the American Psychiatric Association's (APA) DSM-IV[5] and the World Health Organization's ICD-10[6] do not preclude debate about the preciseness or legitimacy of syndromes like Attention Deficit Hyperactivity Disorder (ADHD) and sexual orientation disturbance. Concern about the intrusion of value judgements into contemporary classification has led to the contention that some diagnoses reflect pejorative labelling rather than scientific decisions. For example, charges of sexism were leveled against DSM-III[7] on the grounds that masculine-based assumptions shaped criteria, resulting in women receiving unwarranted diagnoses like premenstrual dysphoria.[8]

The issue central to this debate is whether certain mental states are grounded in fact or value judgements. Szasz[9] takes a radical position, arguing that disordered thinking and behaviour are due to objective abnormalities of the brain whereas mental illness *per se* is a 'myth', created by society in tandem with the medical profession in order to exert social control. The 'anti-psychiatrist movement'[10,11] posits that mental illnesses are social constructs, reflecting deviations from societal norms. This argument is supported by the role of values in both defining homosexuality in the past as a psychiatric disorder, then reversing that position, in the case of American psychiatry through a ballot among members of the APA in 1973.[12] Legitimate diagnoses necessarily combine aspects of fact and value, as Wakefield[13] avows in his conception of 'harmful dysfunction'. He views 'dysfunction' as a scientific and factual term, based in biology, which refers to the failure of an internal evolutionary mechanism to perform a natural function for which it is designed and 'harmful' as a value-oriented term which covers the consequences of the dysfunction deemed detrimental in socio-cultural terms. Applying this notion to mental functioning, Wakefield describes beneficial effects of natural mechanisms like those mediating

cognition and emotional regulation, and judges their dysfunction harmful when it yields effects disvalued by society (e.g. self-destructive acts). Diagnosable conditions occur when the inability of an internal mechanism to perform its natural function causes harm to the person. DSM-IV[5] rightly emphasizes that mental disorders should not be diagnosed solely by reference to social norms. The deterioration of functioning by which schizophrenia is (partly) defined under Criterion B, or the norm violations of antisocial personality disorder, must therefore be, in DSM-IVs phrase, 'clinically significant'. What this amounts to, then, is that a negative value judgement is insufficient to diagnose. The repercussions of these issues can be considerable, (e.g. exposing children erroneously labelled as ADHD to long-term medication with its attendant risks).[14] A related matter, so-called 'cosmetic psychopharmacology', involves the use of medication to enhance psychological functioning. As Kramer[15] notes, fluoxetine may modulate emotions like anxiety, guilt, and shame, raising ethical questions regarding a person's capacity to possess 'two senses of self'. Psychiatric diagnosis may also mitigate legal and personal results of one's actions (e.g. interpreting excessive sexual activity as a variant of obsessive-compulsive disorder rather than as wilful).

Some of the worst perversions of psychiatry, in which it has been deployed as a form of social control, have been driven by misuse of its diagnostic concepts. In the former Soviet Union, for example, thousands of political, religious, and other dissidents were committed to psychiatric hospitals on the basis of 'delusions of reformism' and other similar tainted concepts.[16]

Treatment issues

Assessing and treating patients require a working alliance in conjunction with informed consent. Many psychiatric patients are in a position to understand and appreciate the nuances of treatment options, to express an informed preference, and to feel allied with a therapist in the task. When the process of informed consent is responsibly handled, particularly with reference to benefits and risks of therapeutic options, mentally ill people are in a comparable position to their counterparts in general medicine. This comparability is grounded in two concepts—competence[17] and voluntarism. [18] The former satisfies the required criterion that the person facing choices in treatment has the 'critical faculties' to appreciate the implications of each course of action. Voluntarism refers to a state in which the process of consent is devoid of any form of coercion. Obviously, given that the organ of decision-making is the same one that is impaired in many psychiatric conditions, profound ethical complications may ensue when seeking informed consent.

Other issues also present themselves in this context; these have been conveniently examined as a series of rights—to treatment, effective treatment, and refusal of treatment—and involuntary treatment.

The right to treatment

The asylum revealed tragically how this right was never actualized; the overcrowded institution became little more than a warehouse.[19] Its custodial nature persisted even after the advent of psychotropics and psychosocial therapies. It took a plaintiff[20] to determine that a person committed involuntarily had the 'right to receive treatment that would offer him a reasonable opportunity to be cured or to improve his mental condition'. Diagnosed with schizophrenia in 1957, Kenneth Donaldson received minimal treatment for the next decade and a half. The US Supreme Court concluded in 1975 that a patient who does not pose a danger to himself or to others and who is not receiving treatment should be released into the community.

The right to effective treatment

The right to treatment has been revisited in subsequent judgements, predominantly in the United States.[21] However, the right has lacked a guarantee that patients will receive effective treatment, reflected vividly in Osheroff v Chestnut Lodge (a private psychiatric hospital in the United States). In this case, the plaintiff sued the staff for their failure to provide antidepressant treatment in the face of his deteriorating depression. Klerman[22] subsequently argued that the clinician is duty-bound to use only' 'treatments for which there is substantial evidence' 'or seek a second opinion in the absence of a clinical response. Stone[23] countered this position which he averred was tantamount to '. . . promulgating more uniformed scientific standards of treatment in psychiatry, based on . . . opinion about science and clinical practice'. Moreover, he posited that legal standards of care should not be established by one 'school' for the whole profession, even if enveloped in science. Instead, we should depend on 'the collective sense' of psychiatry, as well as apply the 'respectable minority rule', namely that a relatively small group within psychiatry can legitimately devise novel therapies.

The right to refuse treatment

As a voluntary patient, Osheroff could have refused treatment of any type as part of informed consent. He pinpointed the institution's alleged failure to offer him an alternative treatment in the face of his worsening state with the therapy that was administered. If principles of informed consent had been applied correctly, his freedom to choose one treatment over others, and to withdraw consent at any stage thereafter, would have prevailed.

The situation differs radically when the patient is committed involuntarily to hospital or community treatment. The right to refuse treatment then looms large.[24] A key event in this context was another US legal judgement when a court ruled that detained patients have a right to refuse treatment.[25] This coincided with changing commitment laws in many jurisdictions from criteria linked to need for treatment to those highlighting the danger posed to oneself and/or others. The ethical repercussions are profound. If psychiatrists are empowered to detain a patient, is it not a contradiction if they are then powerless to provide treatment should the person refuse? The argument rests on the premise that someone disturbed enough to warrant involuntary admission is axiomatically entitled to treatment, and the psychiatrist well placed to give it. Without this arrangement, the psychiatrist's functions are reduced to the custodial.

A countervailing argument is grounded in constitutional rights. Merely because people are committed does not mean they are incapable of participating in the process of informed consent. In the event they cannot appreciate the rationale for a course of action, a form of substituted judgement should be employed thereby ensuring that their rights remain prominent.

An assortment of legal remedies has emerged in response to this ethical quandary, ranging from a full adversarial process to reliance

on a guardian. Appelbaum[24] has contributed a lucid account of available options and a predilection for a treatment-driven model in which patients are committed because their capacity to decide about their medical care is lacking as part of their disturbed mental functioning. His own research demonstrates that most 'refusing' patients voluntarily accept treatment within 24 h.[26]

In another pragmatically oriented account Stone[27] proposes that presumption of competence should be dealt with before admission to hospital. Dealing with commitment and competence together obviates the problem of compulsory admission without the powers to treat. The snag is the fluidity of the mental state. What patients think about treatment during the maelstrom of being detained may well change once they settle in and are suitably cared for.

Involuntary treatment

A consensus has prevailed universally that a proportion of psychiatric patients lack the capacity for self-determination. They are prone to harming themselves and/or others, acting in ways they will later regret (e.g. a manic patient's sexual indiscretions); and suffer from self-neglect (e.g. malnourished and physically ill schizophrenic patients). What is not universally agreed is how best to deal with such vulnerable people. Society has, generally, devised laws as the vehicle to respond to the thorny issue of how to protect this group. However, variations in legislation and its application are legion, reflecting, in part, the ethical underpinnings of the process. Psychiatrists and society need to establish coherent arguments concerning relevant moral principles. A good start is Mill's[28] contention that the 'only purpose for which power can be rightfully exercised over any member of a civilized community, against his will, is to prevent harm to others. His own good, either physical or moral, is not a sufficient warrant'. Mill's caveat that an exception must be made in the case of children and mentally disturbed people (i.e. 'delirious' or in a 'state of excitement or absorption incompatible with the full use of the reflecting faculty') suggests they can legitimately be assisted.

Chodoff[29] has addressed the awesome question of compulsorily treating a person on the grounds of mental illness. He finds classical moral theory wanting and therefore proposes a 'chastened and self-critical' paternalism, one 'willing to commit to strong safeguards against abuse'. This humanism is epitomized in a concluding sentiment: involuntary treatment is not a conflict of right versus wrong but one over the right to remain at liberty against the right 'to be free from dehumanizing disease'.

Our account hitherto has referred to patients as a homogeneous group. Loss of critical faculties may be a unifying feature but ethical factors will vary according to particulars of the clinical state. One noteworthy example is suicidal behaviour. Szasz[30] sees suicide as the act of a moral agent. The State should therefore not assume power to prevent self-killing although it may opt to advise for or against. This argument is a libertarian one, with the corollary that everyone should have the right to end their life. Szasz has, however, neglected Mill's[28] point that when respecting a person's right to liberty, a possible exception is loss of critical faculties. This is not to aver that all suicidal behaviour is the product of a disordered mind. Suicide in the wake of debilitating illness and a long-standing commitment to euthanasia, seems rational—for example, the British author, Arthur Koestler, left a suicide note demonstrating that he arrived at his decision authentically and competently in terms of psychological function.[31]

The suicidal patient epitomizes the psychiatrist's dilemma in having no choice but to impose treatment in various circumstances and having to declare a person's incapacity, by dint of mental illness, to make rational judgements about what is in their best interests.[32] Van Staden and Kruger[33] cover this topic by highlighting its dimensions, namely the failure to understand relevant information, choose decisively between options, and accept that the need for treatment prevails. They refer to the utility of a 'functional approach' in determining capacity, especially the temporal factor, so that a patient incapable of consenting at one point in their illness may become able at another. Ethical arguments to justify detention in a hospital can be extrapolated into the community setting. Similar restrictions on liberty lie at the heart of the moral dilemma and the psychiatrist again has to consider patients' competence. Munetz and his colleagues[34] apply three ethical arguments in a compelling fashion—utilitarian, communitarian, and beneficence—concluding that all three support the use of compulsory treatment in the community setting. Advance directives are a means to obviate some of the ethical complications of compulsory treatment. In summary, patients prone to recurrence of their illness during which they may be too disturbed to provide informed consent reach an agreement with their psychiatrist about what constitutes the best course of action should they suffer an episode in the future and be unable to decide appropriately what treatment is in their best interest. Given that several mental illnesses have a recurring course and are associated with incapacity, advanced directives would appear, on the face of it, to have a useful role. Empirical studies to examine this potential are a clear option; promising results have been achieved in work carried out hitherto.[35]

Codes of ethics

The development of codes of ethics in the history of medicine reflects their possible role in promoting sound clinical practice (and research). Some codes have been a direct response to the collapse of professional standards—the Nuremberg Statement, for instance, was formulated in the aftermath of the Nazi medical crimes—but they obviously also have positive functions.

Promoting professional cohesion is one such function. Despite George Bernard Shaw's depiction of professions as 'conspiracies against the laity' and the risk that professional codes may indeed be self-serving—a charter for restrictive practices, protectionist rather than protective—a profession can only function effectively if it is cohesive and acts in a collegial way. Thus, a code which sets out its members' obligations to one another can contribute substantially to achieving this goal. Most codes have emphasized medicine's tradition of commitment and dedication to society; some even call for 'whistle blowing' in appropriate circumstances.

A second function of codes is to enhance high standards of practice. Professions are characterized, in part, by a corpus of specialized knowledge and skills, not readily available to others, and offered to a dependent, often vulnerable clientele.[36] To the extent, therefore, that it takes an expert to judge relevant expertise, a degree of self-regulation is essential. But this must be balanced by external monitoring. Where bad practice becomes the norm, self-regulation may reinforce it: the abuse of psychiatry to suppress dissent in the former Soviet Union was, in effect, promoted by leaders of the profession.[16] It can be argued that a prescriptive ethical code is

unnecessary, since implicit discipline and a shared ethos suffice to maintain standards. As we have noted, history contradicts this, with codes often appearing as a response to compromised care. What kind of codes best promote sound practice will vary with circumstances. They have therefore differed widely in form and content, ranging from aspirational principles to practice guidelines which are set out in considerable detail. The latter are pertinent, especially for education and training. The code of the Royal Australian and New Zealand College of Psychiatrists[37] and the American Psychiatric Association[38] combine general principles with a series of annotations on specific areas such as confidentiality, respect for professional boundaries, and informed consent. Codes also vary in ethical focus, some are virtue-driven, emphasizing character traits which support best possible practice whereas others are duty-based in that they lay out specific responsibilities and obligations.

Codes thus have several meritorious purposes. Furthermore, these support one other. For instance, their inherent educational quality serves to enhance sound ethical clinical practice and their stipulation of potential hazards in ethical decision-making may prevent compromised care, even misuse of expert knowledge.

Conclusion

We have readily noted how the psychiatrist faces ethical quandaries at several levels, both diagnostically and therapeutically, and the potential role of codes of ethics to grapple with them. Diverse moral theories have also been promulgated to aid the practitioner[1,2] and we conclude with our own preferred approach, a combination of principlism[39] and care ethics.[40] Principlism (or principle-based ethics) relies on a set of well-recognized moral principles to identify and analyse ethical problems: respect for autonomy (literally self-government), non-maleficence (first of all, do no harm), beneficence (acting in peoples' best interests), and justice (treating people fairly). The essence of care ethics revolves around the 'natural' propensity of health professionals to extend care to dependent, vulnerable people and to react with such 'moral' feelings as compassion, sensitivity, and trustworthiness.[40] The approach fits well with psychiatry since its practitioners depend day in, day out, on empathy in order to understand the interests and needs of patients and their families. A synthesis of care ethics and principlism permits sound moral reflection within an emotionally based environment in which connectedness between patient and therapist is paramount. We believe this approach, a complementarity between feeling and reason, acknowledges and best exploits the role of 'moral emotions'[41] when clinicians are presented with the many, nuanced ethical conundrums of psychiatric practice.

1.5.2 Values and values-based practice in clinical psychiatry

K. W. M. Fulford

Introduction

Values-based practice is a new skills-based approach to working more effectively with complex and conflicting values in health and social care. This chapter illustrates some of the ways in which combining values-based with evidence-based approaches supports the day-to-day practice of the clinical psychiatrist, particularly in the context of multidisciplinary teamwork.

What are values?

Perhaps one of the most familiar ways in which values impact medicine is by way of ethics. But values are wider than ethics. Ethical values are indeed one kind of value. But there are many other kinds of values, such as aesthetic and prudential values. Values also extend to needs, wishes, preferences, indeed to any and all of the many different ways in which we express negative or positive evaluations and value judgments. Within each and all of these areas, moreover, there are wide differences in the particular values held by different individuals, by different cultures, and at different historical periods.

Given the breadth and complexity of values, it is small wonder that the term 'values' means different things to different people. This is illustrated by Table 1.5.2.1 which lists the responses of a group of trainee psychiatrists when asked, at the start of a training session on values-based practice, to write down three words or short phrases that they associate with 'values'. As the table shows, although there is some overlap, every member of the group came up with a different set of associations.

If our values are diverse, however, they are not completely idiosyncratic. To the contrary, there are many values that are widely shared, at least within a given group at a particular period. The values of patient autonomy (freedom of choice) and of acting in the patient's best interests, for example, are shared values that underpin contemporary medical ethics, and these two values are indeed among the values evident in Table 1.5.2.1.

It is the diversity of human values, and how this can be linked with the shared ethical values underpinning clinical practice, that is the starting point for values-based practice. There is a sense in which medicine has always been values-based just as there is a sense in which it has always been evidence-based.(1) The need for values-based practice in contemporary practice, again like the need for evidence-based practice, arises from the growing complexity of medicine; the growing complexity of the evidence underpinning medicine has led to the need for the new tools of evidence-based medicine; the growing complexity of the values underpinning medicine has led to the need for the new tools of values-based medicine.

The growing complexity of values, as well as evidence, is particularly evident in psychiatry. 'Autonomy' and 'best interests', for example, although both shared ethical values, are often in tension. In the past, most people were content to allow doctors to decide what is in their best interests and this is still the case in many parts of the world.(2) Increasingly though, at least in Europe and North

Table 1.5.2.1 What are values?

Faith Internalization Acting in best interests	How we treat people Attitudes Principles Autonomy
Integrity Conscience Best interests Autonomy	Love Relationships
Respect Personal Difference . . . diversity	Non-violence Compassion Dialogue
Beliefs Right/wrong to me What I am	Responsibility Accountability Best interests
Belief Principles Things held dear	What I *believe* What makes me tick What I won't compromise
Subjective merits Meanings Person-centred care	'Objective' core Confidentiality Autonomy
A *standard* for the way I conduct *myself* Belief about how things *should* be Things you would not want to change	Significant Standards Truth

America, a growing emphasis on patient autonomy has led to complex interactions between these two values in clinical care. In particular, autonomy and best interests come into direct conflict in relation to issues of compulsory treatment (Chapter 1.5.1). Then again, even considered in isolation, 'best interests' have highly complex applications in practice, in the sense that what is 'best' for one person may be very different from what is 'best' for another, according to differences in their personal values and the values of others concerned. Establishing 'best interests' thus presents particular challenges in areas such as old age psychiatry, for example, where patients may lack the decision-making capacity to exercise genuine autonomy on their own behalf.

One response to the growing complexity of the values bearing on clinical practice is to write ever more detailed rules aimed at fixing in advance the 'right outcomes' for any given clinical situation. It is this response that is driving the growing volume of ethical codes and regulatory bodies concerned with medicine. Values-based practice offers quite a different albeit complementary response. It switches the focus from pre-set *right outcomes* to a reliance on *good process*. Values-based practice, that is to say, focuses not so much on *what* is done but on *how* it is done. Starting from the 'democratic' ethical premise of respect for differences of values, values-based practice relies on good process (in particular good clinical skills, see below) to support balanced decision-making within the framework of shared values defined by codes of ethical practice.[3]

Values-based and evidence-based medicine

As a process-based approach to clinical decision-making, values-based practice is complementary not only to regulatory ethics but also to evidence-based practice. The processes of values-based practice and of evidence-based practice are of course very different. Evidence-based practice, as John Geddes describes (Chapter 1.10), relies on statistical and other methods for combining evidence from methodologically sound research. Values-based practice, by contrast, relies primarily on learnable clinical skills. There are other components of the process of values-based practice, including a number of specific links between values-based and evidence-based practice.[3] But at the heart of values-based practice are four areas of clinical skill. As set out more fully in Table 1.5.2.2, these are, raised awareness of values and of differences of values, reasoning about values, knowledge of values, and communication skills.

The close interdependence of values-based and evidence-based approaches has been well recognized by many of those involved in the development of evidence-based medicine. Indeed, there is perhaps no clearer statement of this inter-dependence than the very definition of evidence-based medicine given by David Sackett and his colleagues in their book, *Evidence-Based Medicine: How to Practice and Teach EBM*.[1] Evidence-based medicine is standardly thought to be concerned only with research evidence, as outlined above. To the contrary, Sackett *et al.* say (p. 1), evidence-based medicine combines three distinct elements. The first element is, certainly, best research evidence. In clinical practice, however, best research evidence has to be combined with the experience and skills of practitioners, and, crucially, with patients' values. 'By patients' values', Sackett *et al.* continue, 'we mean the unique preferences, concerns and expectations each patient brings to a clinical encounter and which must be integrated into clinical decisions if they are to serve the patient'. Furthermore, they conclude, it is only 'when these three elements (best research 'evidence, clinicians' experience and patients' values) are integrated, (that) clinicians and patients form a diagnostic and therapeutic alliance which optimizes clinical outcomes and quality of life.'

Table 1.5.2.2 The four key skills areas underpinning values-based practice

Skills area	Applications in values-based practice
1. Raising Awareness of Values	Values, our own and those of others, are often implicit: thus a first step towards balanced decision-making is to raise awareness, 1) of values as such, 2) of differences of values, (See text)
2. Reasoning about Values	In ethics and law, various methods of reasoning are used to derive ethical conclusions. In values-based practice, the same range of methods is used but primarily to explore and open up the range of values bearing on a given situation. These include principles, casuistry (case-based reasoning), utilitarianism (balancing utilities, used especially in health economics), and deontology (rule-based reasoning, used especially in law). (See Further information)
3. Knowledge of Values	Values-based practice draws on evidence about values derived from, 1) the full range of empirical methods (including qualitative social science methods), 2) a range of philosophical methods, 3) combined methods (see text, also Further Reading).
4. Communication Skills	In values-based practice, communication skills are central to, 1) eliciting and understanding individual values, 2) resolving conflicts of values, for example by negotiation and conflict resolution (see text).

Values in the multidisciplinary team

In many parts of the world, psychiatric services are increasingly delivered through multidisciplinary and multi agency teams (Chapter 1.8.1). The move to multidisciplinary team-working reflects a broadly evidence-based recognition that different professional groups offer different but complementary resources of knowledge and skills. It was realized early on, however, that differences of perspective (which include different value perspectives) between different professional groups may lead to communication and other problems of effective team-working.[4,5] This is where values-based practice can help to support the leadership role of the clinical psychiatrist in the multidisciplinary team. To anticipate a little, values-based practice, as we will see in this section and the next, 1) helps to make differences of perspective between team members more transparent, thus improving communication and shared decision-making; and 2) converts these differences of perspective between team members from a barrier into a positive resource for decision-making that is sensitive to the particular and

often very different values—the needs, wishes, preferences, etc.—of individual patients and their families.

First, then, what are the differences of perspective between different team members? The perhaps surprising extent of these differences is illustrated by Table 1.5.2.3. This is based on a study, led by the British social scientist, Anthony Colombo, of multidisciplinary teams in the UK concerned with the community care of people with long-term schizophrenia.[6] To understand the significance of Table 1.5.2.3, we need to look briefly at the background to Colombo's study and how it was carried out.

Colombo was interested in implicit models of disorder and how such models might influence the processes of decision-making in day-to-day clinical care within multidisciplinary teams. Asked directly, most team members, from whatever professional background, will indicate that they share much the same broadly biopsychosocial model of schizophrenia. This is their shared *explicit* model, then. The hypothesis guiding Colombo's study, however, was that, notwithstanding their explicit commitment to a shared biopsychosocial model, in actual practice different team members would be guided by different *implicit* models. These different implicit models reflected different weightings or priorities (hence values), in turn reflecting differences of professional background and training, that different team members might attach to the different aspects of a given case. Their different implicit models, furthermore, just in being implicit rather than explicit, could help explain the difficulties of communication and other problems of shared decision-making within multidisciplinary teams that had been identified in the literature (as above).

The aim of Colombo's study, therefore, was to access the *implicit* models (including values) guiding different professional groups in their responses to patients with schizophrenia. Colombo's method, correspondingly, was indirect rather than direct. He presented subjects with a standardized case vignette, of a man called 'Tom', with features of schizophrenia (though without using that term as such), and then explored their responses using a semi-structured interview and carefully validated scoring system. In previous work, Colombo had shown how different models of disorder (six of which are represented by the columns in Table 1.5.2.3) could be analysed

Table 1.5.2.3 Comparison of models grids for psychiatrists and social workers (shared elements of models shown highlighted)

	Models - Psychiatrists					
Elements	**Medical (Organic)**	**Social stress**	**Cognitive behaviour**	**Psychotherapeutic**	**Family (interaction)**	**Political**

11. Duties of the Patient			**S**			
12. Duties of Society		S				

and compared along 12 key dimensions (diagnosis, causal factors, etc.) as represented by the lines in Table 1.5.2.3. Responses to the semi-structured interview thus allowed a profile to be developed for each subject, and cumulatively for each professional group, of their implicit models. These profiles, or 'models grids', gave an overall picture of the implicit model on which an individual or group was drawing in their responses to Tom.

It is the 'models grids' for psychiatrists and psychiatric social workers respectively that are compared in Table 1.5.2.3. As this shows, notwithstanding their shared explicit commitment to a biopsychosocial model, psychiatrists and social workers, working in similar teams in the same area of the UK, had widely different *implicit* models. Direct comparison of the two models grids shows that psychiatrists and approved social workers coincided on only six out of a total possible of 72 elements! Small wonder, then, given that team members were unaware of these differences of implicit models, that difficulties of communication and of shared decision-making often arose. They all accepted an explicitly biopsychosocial approach. But their different professional perspectives, including value perspectives, led them to attach very different priorities to different aspects of 'Tom', and, by extension, to the real patients with whom they were concerned in the real world of day-to-day multidisciplinary care.

Values-based practice in the multidisciplinary team

Colombo's study illustrates how careful research may improve our knowledge of values (skills area 3, Table 1.5.2.2 above) and his research has subsequently been adapted and developed as part of a training manual for values-based practice.[7] Research is as important in values-based practice as in any other aspect of medicine. There is a widespread assumption that understanding each other's values is a matter of relatively transparent intuition. But in addition to empirical studies, surveys,[8] patient narratives,[9] and other sources all point to the extent to which our perceptions of each other's values are often *mis*perceptions. Colombo's study also illustrates the inter-dependence of the four skills areas. As a contribution to skills area 3 (knowledge), the study also contributes to raising awareness of values and of differences of values (skills area 1) in the specific context of multidisciplinary team working.

Merely raising awareness of differences of implicit models may itself be enough to improve communication between team members and hence, shared decision-making as the basis of effective multidisciplinary care. There are circumstances, however, in which raising awareness may not be sufficient. Where team values are directly conflicting, for example, raising awareness may even have the effect of accentuating rather than reducing difficulties of shared decision-making. So, how should differences of values be managed? Different responses are possible here. One approach is to try to create a homogenized composite model. At a relatively abstract level, this is what the biopsychosocial model offers. A different response is to seek to establish a 'top' model that takes priority over all other models. It is a natural enough assumption of any given professional group that their own particular model should be the 'top' model.

Rather than either a composite model or a 'top' model, values-based practice suggests that differences of value perspective, as incorporated into implicit models of disorder, far from being suppressed should be acknowledged and built on as a positive resource for effective multidisciplinary teamwork. This is essentially because, as the models grids in Table 1.5.2.4 show, differences in implicit models between different team members reflect corresponding differences among *patients themselves*.

The models grids in Table 1.5.2.4 were derived in Colombo's study using precisely the same methods as the models grids for the professional groups (i.e., using the same standardized case vignette, interview schedule, etc.). The patients involved in Colombo's study, however, were not recruited through multidisciplinary teams. Rather, they were recruited as volunteers from local MIND, a mental health NGO in the UK that 'advocates for patients' rights. To volunteer for the study, a patient had to have had a diagnosis of schizophrenia for at least three years. There was no requirement that they should agree with the diagnosis. Rather, the aim was to explore the implicit models of a group of subjects who had had this diagnosis 'willing or no' for an extended period. The expectation in the study was that this group of patients, recruited in this way, would include a significant number with a 'political', or 'anti-psychiatric', model of disorder, represented by the right-hand column of the models grids. In fact, as Table 1.5.2.4 shows, the patient group divided naturally into two sub-groups, one with implicit models very close to those of the psychiatrists in the study, the other with implicit models very close to those of the social workers.

The correlation in Colombo's study between different professional models and different patient models, gives a whole new values-based rationale for multidisciplinary teamwork. From an evidence-based perspective, multidisciplinary team working offers a diversity of knowledge and skills in meeting patients' needs. From a values-based perspective, multidisciplinary team working brings, in addition to different knowledge and skills, different value perspectives. In a well-functioning multidisciplinary team, these different value perspectives can help to ensure that professionals' knowledge and skills are matched appropriately to the different values—the needs, wishes, preferences, etc.—of individual patients and their families.

In helping to bring together the different perspectives of team members in a positive and well-balanced way, values-based practice thus, directly supports the leadership role of the consultant psychiatrist in the multidisciplinary team. Again, all four skills areas of values-based practice are closely interdependent here. In addition to knowledge of values, the reasoning skills noted in Table 1.5.2.2 may be helpful. Good communication skills are also crucial. As Table 1.5.2.2 indicates, these include in particular, skills for eliciting and understanding values, and where values conflict, skills of negotiation and conflict resolution.

Conclusions

This chapter has introduced a number of key points about values-based practice (summarized in Table 1.5.2.5) as a new skills-based approach to working more effectively with complex and conflicting values. The importance of values-based as well as evidence-based approaches has been illustrated particularly by reference to the leadership role of the consultant psychiatrist in the multidisciplinary team. Multidisciplinary team-working is of course not unique in its requirement for values-based as well as evidence-based approaches. As Sackett *et al.*[1] reminded us at the start of this chapter, it is only by combining best research evidence with practitioners' knowledge and skills and with patients' values, that we can

build the 'diagnostic and therapeutic alliance' on which in any area of medicine, good clinical care crucially depends.

Two further points are worth adding in conclusion. The first is that values-based practice as introduced here, as being based primarily on learnable clinical skills, is only one among a number of new disciplinary resources supporting more effective ways of working with complex and conflicting values in healthcare. Further and quite different resources are provided by such empirical disciplines as decision theory,[10] for example, and health economics, an innovative use of which has recently been developed by a group at the Centre for Value-Based Medicine in the States.[11] Values-based practice itself is so underpinned by a branch of analytic philosophy, called philosophical value theory (see Further Reading, below) that, as an analytic discipline, it is a natural partner both of empirical research, as in Colombo's study,[12] and of other philosophical disciplines more familiar in psychiatry, notably phenomenology.[13] As Andreasen[14] has argued, these and other philosophical disciplines, have a growing practical importance not only in clinical psychiatry, as illustrated in this chapter, but also in the new neurosciences.

The second concluding point has to do with the place of psychiatry as a science-led medical discipline in the 21st century. As the most value-laden area of medicine, psychiatry was widely stigmatized in the 20th century as being, at best, scientifically underdeveloped,[15] at worst outwith medicine altogether;[16] and debates about eliminate values from psychiatric diagnostic concepts continue in the context of current revisions of the ICD and DSM classifications.[17,18] Philosophical value theory, as the discipline underpinning values-based practice, shows to the contrary that the value-ladenness of psychiatry, far from reflecting any deficiency in its science, is a direct consequence of the fact that psychiatry, in being concerned with the higher functions of emotion, desire, volition, sexuality, and so forth, is by the same token concerned with areas of experience and behaviour where human value themselves are highly diverse ([19], especially chapters 4 and 5, building on[20]).

Table 1.5.2.5 Key points about values-based practice for clinical psychiatry

1. Values are wider than ethics and include all the many ways in which we express positive and negative evaluations, i.e., preferences, needs, wishes, etc. as well as ethical values
2. Values-Based Practice is a new skills-based approach to working with complex and conflicting values in medicine
3. Ethical principles provide a framework of shared values – such as 'best interests' and 'autonomy of patient choice' - that guide the *outcomes* of clinical decision-making supported by codes of practice and regulatory bodies
4. Values-based practice is complementary to regulatory ethics in focusing on the *process* of clinical decision-making: ethics focuses on 'right outcomes' (reflecting shared values); values-based practice focuses on 'good process' (reflecting complex/conflicting values)
5. In focusing on process rather than outcomes, values-based practice (concerned with complex and conflicting values) is fully complementary to evidence-based practice (concerned with complex and conflicting evidence) in clinical decision-making
6. At the heart of the 'good process' on which values-based practice depends are four key areas of clinical skills: 1) awareness of values and of diversity of values, 2) reasoning about values, 3) knowledge of values, and 4) communication skills (including skills in such areas as negotiation and conflict resolution)
7. Among other applications, values-based practice supports the role of the consultant psychiatrist in multidisciplinary teams by, 1) improving understanding of differences of values between different team members (thus improving communication and shared decision-making), and 2) improving understanding of the particular and often very different values of individual patients and carers (thus improving the extent to which care and treatment are appropriately matched to the particular needs, preferences and wishes of each individual patient and their families)
8. Values-based practice is research-based, drawing in particular on the resources of philosophical value theory and a number of other areas of the philosophy of psychiatry, such as phenomenology, in addition to empirical social science methods, patient narratives and other sources
9. In clinical work, values-based practice is supported by a wide range of training materials and is the basis of a number of both national and international developments in psychiatry aimed at building a strong diagnostic and therapeutic alliance between professionals and patients in mental health and social care
10. The skills-based approach of values-based practice is one of a number of disciplinary resources for working with complex and conflicting values in medicine: in addition to ethics, other important disciplines include health economics and decision theory

Psychiatry, therefore, in addition to being *scientifically* complex, is shown by philosophical value theory to be *evaluatively* complex. This is why it has been appropriate that values-based practice, as a skills-based approach to working with complex and conflicting values, should have developed first in psychiatry. But with the growing complexity of the values bearing on all areas of medicine, it seems likely that, as Sackett *et al.* anticipated (as above), values-based as well as evidence-based approaches will become increasingly crucial in the 21st century not only in psychiatry but across the board. The effect of this will be to reverse the 20th century stigmatization of psychiatry. Instead of being perceived as a scientific also-ran, psychiatry, by being first in the field with values-based practice as an essential partner to evidence-based practice, will be seen to have led the way with a 21st century model of medicine that is not only fully science-based but also genuinely patient-centred.

Acknowledgments

The information on which Tables 1.5.2.3 and 1.5.2.4 are based is derived from the study of models of disorder described in the text and first published in Colombo *et al.* 2003. (6)

1.6

The psychiatrist as a manager

Juan J. López-Ibor Jr. and Costas Stefanis

Introduction: integrating two perspectives

The past years have witnessed the introduction and implementation of strict macro and micro economical principles in the planning and delivery of health care. The change is a consequence of the limitation of resources and the obligation to optimize their utilization in the delivery of health care to those in need. This has led to the birth of a new domain of management science dealing with hard choices and with the selection of priorities in the delivery of health care.[1] Even Western European countries, where a tradition of equity presides over health care and developing countries, with a tradition of care based on welfare system are adopting strategies built upon managed care principles. Of course, the private health care present in many forms in the different countries has been a driving force in this movement.

The new management perspective is based on the standards of management discipline but has to adapt to the main ethical concerns of delivery of care to suffering human beings. Because management has oftentimes been imposed as an 'external' mandate to the clinical community, clinicians, lacking understanding for the basics behind management, are reluctant to accept it; they often feel degraded by managers and develop negative attitudes towards them.

The objective of the present chapter is to provide clinicians with some input on how to manage the resources at hand and how to understand and communicate with managers in order to reach priorities closer to the needs of patients.

Health professionals and managers differ in many aspects. They belong to two different cultures which are summarized in Table 1.6.1.

However, many managerial skills are extremely useful to deal with psychiatric diseases, because they are chronic, they are accompanied by high degrees of disability, they require an interdisciplinary perspective, and they have important interactions with the social environment. Nowadays, most psychiatrists work as members of a multidisciplinary team, need to develop collaborative working relationships with other professionals, should have an understanding of the roles and the limits and extent of involvement of other agencies, and lastly, of the lines of accountability. Furthermore, the concerns about the competence of psychiatrists that is the framework for training programmes include some such as: the psychiatrist is a medical expert, a communicator, a collaborator, a manager, a health promoter, a professional and somebody able to tolerate ambiguity and uncertainty. In most of those, managerial skills are essential. Unfortunately, those skills are not taught in most medical schools.

There are three levels at which there is a parallel between a manager and a psychiatrist: a) the psychiatrist as a manager of the interventions needed to implement an individualized treatment plan for his patient, b) the psychiatrist as a manager of the involvement of other professionals in clinical settings, and c) the psychiatrist as a manager of health care resources available to his practice.

The psychiatrist as a manager of his patient's needs is a consequence of the introduction of processes of disease and patient management by most health care organizations. These play an increasing emphasis on prioritizing health care provision on the basis of limited resources and increased sensitivity to specialized patient needs. Therefore, the clinician has to keep a delicate balance between cost containment principles and quality in care provided. It is crucial for the psychiatrist to be able to identify and implement practices that assure quality of care without sacrificing this to any external pressures for containment of cost within his clinical practice. The *Madrid Declaration* of the World Psychiatric Association (WPA)[2] has one item on the rights of psychiatrists that in essence

Table 1.6.1 Two different cultures

	Health professionals	**Managers**
Values	Health and fighting diseases	Economy and administration
Main interest	1. Patients 2. The profession	1. Organization 2. Management
Principal loyalty	The profession	The institution
Main concern	Patients	Health policy
Persons are	Patients	Clients, stakeholders
Terminology	Medical	Business-like
Training in management	No	Yes
Clinical training	Yes	No
Worries about costs	No	Yes
Stability in working places	Long	Short

declares that the first right of the psychiatrist is to be able to practice the profession without external constraints of any kind.

The psychiatrist as a manager of other professionals in clinical settings is consequently working as an element of a multidisciplinary team. Everybody in a team should at least possess an understanding of the essence, the extent and the limitations of cooperation and accountability. Managing other professional also largely refers to managing other psychiatrists within the same clinical settings. Management goes beyond the simple 'coordination' of various roles and steps in the process of providing health care, in the professional education of colleagues, the training of young professionals and the sharing of experience.

The psychiatrist as a manager of health care services has to struggle to reach a satisfactory degree of equity and in order to do so, the clinician has to become familiar with issues such as human resource management, customer satisfaction and change, crisis and conflict management.

What is management?

The word management derives from the Italian *maneggiare* 'to handle' (i.e., a horse), from *mano* 'hand', from Latin *manus*. Management is 'the art of getting things done through people';[3] it is the act (sometimes the art) of conducting or supervizing something (initially a business) and the thoughtful use of means to accomplish an end. Management needs to direct and to control a group of people or entities for the purpose of coordinating and harmonizing that group towards accomplishing a goal and it often encompasses the deployment and handling of human, financial, technological, and other resources.

Management in health care is not new. Physicians have a long tradition of being supervisors or conductors of a team. The simplest form of management is the partnership, an essential model for the doctor–patient relationship.

Management can also refer to the person or people who perform the acts of management; in this sense management has to do with power by position, whereas leadership involves power by influence.

From a functional perspective, management consists of measuring a quantity on a regular basis and of adjusting some initial plan in order to reach an intended goal. This applies even in situations where planning does not take place.

Functions of management

Management has several functions, which are summarized as following:

Planning: deciding what needs to happen in the future and generating plans for action.

Organizing: making optimum use of the resources required to enable the successful carrying out of plans.

Leading and motivating: exhibiting skills in these areas for getting others to play an effective part in achieving plans.

Coordinating: making different people or equipments work together for a goal or effect.

Controlling (**monitoring**): checking progress against plans, which may need modification based on feedback.

Basic managerial concepts

Although in the following paragraphs we will, as often as possible, replace managerial jargon by one more pleasant to clinicians, there some basic concepts which need a definition.

Efficacy is the ability to produce a desired effect and it is measured by the closeness to an achievable goal.

In clinical settings, efficacy is the degree of the benefit for patients, induced by an intervention (treatment, procedure or service) in ideal research conditions (i.e., in a controlled trial). It indicates that the therapeutic effect is acceptable. 'Acceptable' refers to a consensus that it is at least as good as other available interventions to which it will have ideally been compared to in a clinical trial.

Effectiveness, on the contrary, refers to the impact in real world situations.

Efficiency is the achieved results or effects related to the effort invested in terms of money, time and other resources. It is the maximization of some desired output or effect for the least amount of input, means or effort. Usually, the larger the ratio, the greater the efficiency.

Efficiency is not a pure scientific concept as it carries a value judgement. Efficiency is achieved through design, the process by which intelligence is substituted for matter and energy in technological systems.

Productivity is a measure of efficiency; it is the amount of output created (in terms of goods produced or services rendered) per unit input used. For instance, labour productivity is measured as output per worker or output per labour-hour.

Equity is social justice, the way of providing services according to the needs of each individual in a defined population. It is not an equalitarian principle because each individual should not get the same, but what he or she would need in a specific situation.

The light bulb example: the efficacy is the amount of visible light measured in lumens; the efficiency is the ratio of lumens to the amount of energy consumed to produce them, measured in Watts. Equity will measure the reach of the lumens to the needs of, let's say, the passers by on a street.

Ethical aspects of management in clinical settings

Health care and economic management are two different cultures. Cultures are defined by their values and peculiarities, among them ethics. Specific values are part of the property of a culture and belong to the identity of every social group.

There are three stages in the development of medical ethics,[4] each one adding value to the previous one without replacing it totally. In each one of them particular managerial skills are helpful.

The **ethics of welfare** is the traditional medical ethics, first appeared in Hippocratic writings. According to it, the doctor's primary goal and duty are the well-being of the patient and as much as possible, harm avoidance. The doctor is perceived and behaves as a good father, to be fully trusted, convinced that the physician will act adequately to the benefit of the patient. To meet this obligation, the doctor has to increase to the maximum his own medical knowledge and to assume a series of obligations. The scientific advances increase the paternalism of the professional who has to learn how to manage information. The ***Madrid Declaration***

of the WPA expressed this notion in the following way: *Psychiatry is a medical discipline concerned with the provision of the best treatment for mental disorders. Psychiatrists serve patients by providing the best therapy available consistent with accepted scientific knowledge and ethical principles. It is the duty of psychiatrists to keep abreast scientific developments of the specialty.*

The USA influence, with its strong emphasis on autonomy and individualism, has lead to the **ethics of autonomy**. The ethics of autonomy considers the patient as an autonomous human being, adult and free and consequently, able to take his/her own decisions. The values and beliefs of the patient are the background for the moral responsibilities of the doctor. As a consequence, doctors have to truly inform patients about all possible diagnoses and treatments so that patients are able to decide. The basic element of this new way of establishing the doctor-patient relationship is the informed consent.[5] From this perspective, patient-doctor relationship is defined in new terms: *The patient should be accepted as a partner by right in therapeutic process. The therapist-patient relationship must be based on mutual trust and respect to allow the patient to make free and informed decisions. It is the duty of psychiatrists to provide the patient with relevant information so as to empower the patient to come to a rational decision according to his or her personal values and preferences* (WPA *Madrid Declaration*).

The **ethics of equity** is a consequence of the impact of economic factors in medicine. The need of equal access to health care resources for all patients, including those suffering from mental illnesses and the principle of equity in a period of intrinsic and extrinsic limitations to health care cost, is leading to a third stage of bioethics which has also been called the **ethics of management**. The main reasons for the increase or imbalance of the costs are partially due to the successful developments of modern medicine: health care by itself is increasingly expensive (implementation of new and expensive technologies, incorporation of new professions into medicine, financing research in biomedical sciences, and applying resources for the training of physicians and specialists); the better control of acute diseases which increases the proportion of chronic illness requiring care; the increased demand due to ageing of the population and in social security systems, the change in the population pyramid, decreases the population of those paying compared to those making the expenses.

Resources to be invested in health care are limited. The first one to ask for limits was President Carter in the USA, during his first public speech after assuming the presidency, when he claimed for a ceiling of the 7 per cent of the GNP to be devoted to health care. This was in 1977. But, why such a limit? Why could it not be possible for an enlightened society to decide to devote 10, 20 or even 50 per cent of its GNP to health care and less, for instance, to defence? President Carter expressed it very well: too much spending in this area would decrease investments in education and care of the environment, which would lead to a deterioration of health.[8] In Europe, the cost of brain disorders (to be precise brain diseases and mental disorders) is more than the double of the cost of all cancers and diabetes together.[7]

The fact that more is not better is evident when comparing health indexes, and among them the bottom line, which is life expectancy. This is much lower in the US which dedicate over twice the percentage of their GNP to health care, than countries such as Japan, France, Italy, or Spain.

Economic factors can limit the access to health care, either because individuals lack sufficient insurance coverage or because of waiting lists. In the last few years, limitations have been imposed by governments which through different approaches try to control the access of patients to interventions which are not considered economically worthy. Again the WPA has addressed these issues in several documents such as the *Hawaii Declaration* (rev.), the *WPA Statement and Viewpoints on the Rights and Legal Safeguards of the Mentally Ill*, the first official document on the rights of mentally ill, and the *Madrid Declaration* of the WPA. This last code of ethics states *'As members of society, psychiatrists must advocate for fair and equal treatment of the mentally ill, for social justice and equity for all. While doing so, psychiatrists should be aware of and concerned with the equitable allocation of health resources'.*

Therefore, the goal of cost control should not be considered in isolation from other goals, such as quality assurance and equity. Here a managerial approach is useful, when based on three pillars: Information (to know what we physicians do, how patients behave on long-term outcome of medical interventions and on the impact on quality of life), consensus (on the right approaches to decide interventions), and a new social contract on sustainable health care. This approach is not limited to health care, it has a great influence on the culture of modern enterprises and in post-modern perspectives.[9,10]

Nature of managerial activity

Workplace democracy has become more common and advocated. Management is based on classical military type of command-and-control but it should not throw itself to the other extreme here all management functions are distributed among all workers, each of whom takes on a portion of the work, and the institution is run by assemblies of staff and of patients as was common in some anti-psychiatry experiences. Management relies increasingly more on facilitating, promoting and supporting collaborative activity, which is essential in health care. Modern management embraces democratic principles, in that, in the long term, workers must give majority support to management; otherwise they leave to find other work, or go on strike.

In for-profit organizations, the primary function of management is the satisfaction of a range of stakeholders. This typically means making profit (for the shareholders), creating valued products at a reasonable cost (for customers), and providing rewarding employment opportunities (for employees). In non-profit management, other functions are added, such as keeping the faith of donors, attaining social and political goals such as increasing health and fighting diseases.

In most models of management, shareholders vote for the board of directors, and the board then appoints senior management. This model is rarely applied in health care (or in Academic life).

Management also has the task of innovating and improving the functioning of organizations.

Categories of management

There are many categories of management. The most important are: human resource management, production (operations) management, strategic management, marketing management, financial management, and information technology management.

Nevertheless, as more and more processes simultaneously involve several categories, it is better to think in terms of the various processes, tasks, and objects subject to management.

Management science and organizational psychology

Whether management is rightly claiming a scientific status is debatable. It is more appropriate to classify it as a branch of economic sciences often confounded with its practical arm, operations research. Management science is the discipline of using analytical methods, to help make better decisions. Among others methods are decision-making analysis, optimization, simulation, forecasting, game theory[11] (which had a strong impact in psychotherapy[12]), network (transportation) forecasting models, mathematical modelling, data mining, probability and statistics, morphological analysis, resources allocation, and project management.

Industrial and organizational psychology consists of the application of psychological theories, research methods, and intervention strategies to workplace issues in order to hire suitable employees for the job, to reduce absenteeism, to improve communication and to increase job satisfaction.

Information systems

An information system is the array of persons, data records and activities that process the data and information in a given organization, including manual processes or automated processes. Information systems are also social systems whose behaviour is heavily influenced by the goals, values and beliefs of individuals and groups, as well as the performance of the technology. An information system consists of three components: human, technology, and organization.[13]

The systems rely on data from the unit as well as data acquired outside it (such as literature research, scientific meetings, consensus documents and others) and data provided by others (i.e. the Health Care System, partners, suppliers, and customers).

A computer based information system is a technologically implemented medium for recording, storing, and disseminating linguistic expressions, as well as for drawing conclusions from such expressions.[14]

Managerial levels and styles

The management of a large organization usually has three self-evident levels: senior management, middle management, and low-level management.

There are several management styles that can be applied depending on the nature of the activity, the type of the task, the characteristics of the workforce, and the personality and skills of the leaders. As the style of leadership is dependent upon the prevailing circumstance, leaders should exercise a range of leadership styles and should deploy them as appropriate.[15]

An **autocratic** or authoritarian manager makes all the decisions and keeps the information and decision-making among the senior management. Objectives and tasks are set and the workforce is expected to do exactly as required. The communication involved with this method is mainly downward, from the leader to the subordinate. The main advantage of this style is that the direction of the business is stable and the decisions are similar and comparable. This in turn projects the image of a trustworthy and well managed business. However, this method can lead to a decrease in motivation of employees and subordinates who may become highly dependant on the leaders and close supervision may be unavoidable.

A **paternalistic** approach is also dictatorial; however, the decisions tend to be in the best interests of the employees rather than the business. This can help balance out the lack of worker motivation caused by an autocratic management style. Feedback is again generally downward; however, feedback to the management will occur in order for the employees to be kept happy. This style can be highly advantageous, and can engender loyalty from the employees, leading to a lower labour turnover, thanks to the emphasis on social needs. It shares the same disadvantages of the authoritarian style; employees becoming highly dependant on the leader, and if wrong decisions are made, then employees may become dissatisfied with the leader.

In a **democratic** style, the manager allows the employees to take part in decision-making; therefore everything is agreed by the majority. The communication is extensive in both directions (from subordinates to leaders and vice-versa). This style can be particularly useful when complex decisions that require a range of specialized skills need to be made. From the overall business point of view, job satisfaction and quality of work will improve. However, the decision-making process is severely slowed down, and the need of a consensus may avoid taking the 'best' decision for the business. It can go against a better choice of action.

In a **laissez-faire** leadership style, the leader's role is peripheral and the staffs manage their own areas of the business; the leader therefore evades the duties of management leading to an uncoordinated delegation. The communication in this style is horizontal, meaning that it is equal in both directions; however, very little communication occurs in comparison with other styles. The style brings out the best in highly professional and creative groups of employees; however, in many cases it is not deliberate and is simply a result of poor management. This leads to a lack of staff focus and sense of direction, which in turn leads to much dissatisfaction, and a poor company image.

Roles and responsibilities of heads of clinical units and leaders

The head of a clinical unit is a managing director. In business, the principal leader is the Managing Director, who is in charge of the definition, the development and implementation of the strategic plan of their unit or service in the most cost-effective and time-efficient manner.

The managing director is responsible for both the day-to-day running of the company and developing business plans for the long-term future of the organization. In business, the managing director is accountable to the board and the shareholders of the company. It is the board that grants the managing director the authority to run the company. In clinical settings, the head of a unit is accountable to and gets the power from the health authorities.

A head of a unit may or may not have direct clinical responsibilities and is usually burdened by much office-based work, but he or she is the leader of the organization, chairing different sorts of meetings, motivating the workforce and developing the culture and style of the organization.

As the title suggests, the managing director needs to manage everything. This includes the staff, the patients, the budget and the

resources to make the best use of them and increase the company's profitability.

Strategic planning

Strategic planning is the process of defining the goal of an organization and of making decisions on allocating resources to pursue the goal. In order to determine where it is going, the organization needs to know exactly where it stands, then determine where it wants to go (over the next years, typically 3 to 5) and how it will get there.[16] The resulting document is called the 'strategic plan'.

Strategic planning deals with at least one of three key questions: 1 'What do we do?' 2. 'For whom do we do it?' and 3. 'How do we excel?'

There are many approaches to strategic planning. Typically it is done in a stepwise manner:

1 Vision (define the vision and set a mission statement with a hierarchy of goals);

2 SWOT analysis (strengths, weaknesses, opportunities and threats);

3 Formulation (of the actions and processes to be taken to attain these goals);

4 Implementation (of the agreed upon processes);

5 Controlling (to get full control of the operation); and

6 Monitoring (to get feedback from implemented processes).[17]

Situational analysis. When developing strategies it is important to analyze the organization and its environment in the present moment and how it may develop in the future. The analysis has to be executed both at internal as well as at external levels to identify all opportunities and threats of the new strategy. Analysis of the external environment normally focuses on the customer (the needs of patients).

Goals, objectives and targets: Vision, mission and values. These are essential components of strategic planning. They are specific, time-bound statements of intended future results, and general and continuing statements of intended future results.

A **Vision statement** outlines what a clinical unit wants to be in the future; it is a source of inspiration and provides clear decision-making criteria. It reflects the optimistic, perhaps utopic view of the organization's future.

A **Mission statement** describes what the unit or service is at present. It defines the customers (kinds of patients), critical processes and it informs about the desired level of performance.

A vision statement is different from a mission statement. The Vision describes a future identity and the Mission describes why it will be achieved.

A **Values statement** describes the main values protected by the organization during the progression, reflecting the organization's culture and priorities.

Management by objectives

Management by Objectives (MBO)[18] is a method of agreeing on objectives within an organization. The management and the head of clinical units reach a consensus on the objectives to attain in a certain time period (typically one year). The objectives have to comply with some criteria, usually described by the acronym SMART (Specific, Measurable, Achievable, Realistic, and Time-Specific). They usually represent an increased level of performance than the one attained during the previous period of time. The objectives of each clinical unit are part of the global objectives of the hospital or the higher level organization (i.e., the health care area) which are the result of the consensus between the organization and the health care authorities. Some objectives are collective, while others can be individualized. Ideally, the responsible of a clinical unit shares and divides the objectives among the responsible staff under his authority.[19]

The achievement (or non-achievement) of the objectives should lead to incentives (or penalties). In health care, significant pay incentives (bonuses) are not common, and this is an advantage because high bonuses trigger unethical behaviour such as distorting financial figures to achieve short term individual targets. This is the main criticism of management by objectives.

Quality management

Quality management is an exceptionally useful tool for the running of clinical services. It is based on scientific excellence which includes research on efficacy and efficiency. In can include systems to control costs but accompanied by methods to sustain and increase quality. The basic assumption is that cost control and quality of care can run in parallel. Of the several approaches, we have chosen for this chapter, the European Foundation for Quality Management (EFQM)[20] model, because it is increasingly been used by health care administration in many countries and not only by Europeans, and although developed for the management of very large companies it soon became evidence of their advantages for the public sector.

The EFQM model relies on the strive over Excellence, which is defined as the *outstanding practice in managing the organization and achieving results*. Truly Excellent organizations are those that strive to satisfy their stakeholders by what they achieve, how they achieve it, what they are likely to achieve, and the confidence they have that the results will be sustained in the future. Being excellent requires total leadership commitment and acceptance of the fundamental concepts, a set of principles on which the organization bases its behaviours, activities, and initiatives.

Excellence relies on a few fundamental concepts (Fig. 1.6.1):

1 Results Orientation: Excellence is achieving results that delight all the organization's stakeholders.

2 Customer Focus: Excellence is creating sustainable customer (patient) value.

3 Leadership and Constancy of Purpose: Excellence is visionary and inspirational leadership, coupled with constancy of purpose.

4 Management by Processes and Facts: Excellence is managing the organization through a set of interdependant and interrelated systems, processes and facts.

5 People Development and Involvement: Excellence is maximizing the contribution of employees through their development and involvement.

6 Continuous Learning, Innovation and Improvement: Excellence is challenging the status quo and effecting change by utilizing learning to create innovation and improvement opportunities.

7 Partnership Development: Excellence is developing and maintaining value-adding partnerships.

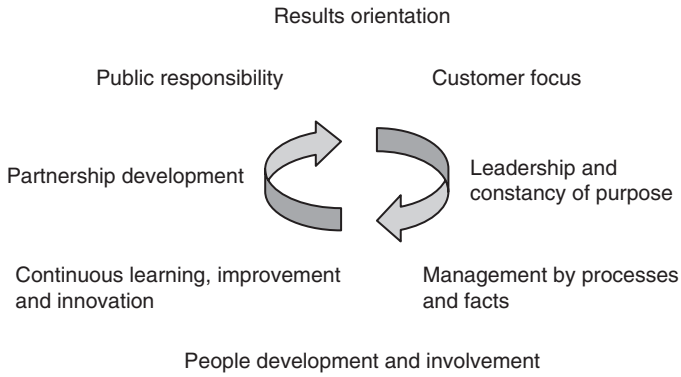

Fig. 1.6.1 Concepts of excellence.

8 Corporate Social Responsibility: Excellence is exceeding the minimum regulatory framework in which the organization operates and strives to understand and respond to the expectations of their stakeholders in society.

The EFQM Excellence Model is a practical tool that can be used in a number of different ways: as a tool for self-assessment; as a way to benchmark with other organizations; as a guide to identify areas for improvement; as the basis for a common vocabulary and a way of thinking; as a structure for the organization's management system.

The EFQM Excellence Model is a non-prescriptive framework based on nine criteria (Fig. 1.6.2). Five of these are 'Enablers' and four are 'Results'. The 'Enabler' criteria covers what an organization does. The 'Results' criteria covers what an organization achieves. 'Results' are caused by 'Enablers' and 'Enablers' are improved using feedback from 'Results'.

Risk management

Risk management is a discipline for living with the possibility that future events may cause adverse effects. The term is increasingly been used in the health sector.

Risk analysis includes risk assessment (identifying sources of potential harm, assessing the likelihood that harm will occur and the consequences if harm does occur), risk management (evaluation of the risks identified that require action and selection and implementation of the procedures to control those risks), and risk communication (interactive dialogue between all parties involved in the risk).

There are seven principles in the management of risk:

1 Global perspective (recognizing both the potential value of opportunities and the potential impact of adverse effects);

2 Forward-looking view (identifying uncertainties, anticipating potential outcomes);

3 Open communication (encouraging free-flowing information at and between all levels);

4 Integrated management (risk management is an integral part of management);

5 Continuity (maintaining constant vigilance);

6 Shared vision (common purpose, collective communication, and focusing on results); and

7 Teamwork (pooling talents, skills, and knowledge).

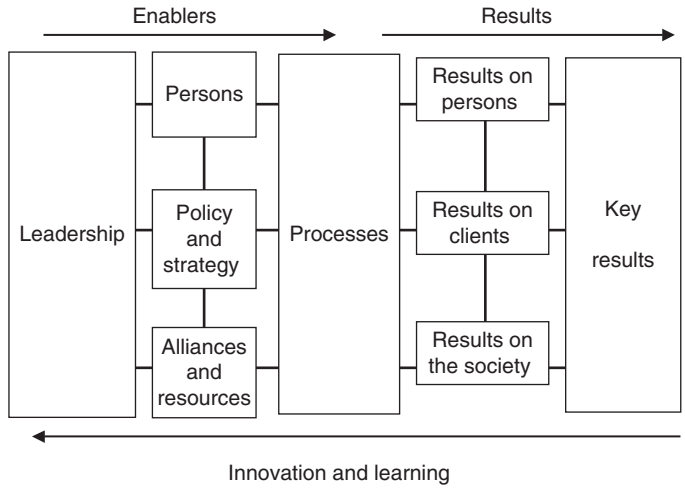

Fig. 1.6.2 European Foundation for Quality Management.

The experience of psychiatrists in disaster and traumatic events has made them highly valuable experts in risk management.

Types of health care and management systems

Health Systems throughout the world share the same, although sometime distant, goals: accessibility, equity, and extensive range of coverage. But there is also a wide array of organizational and financing types (taxation, employer-employee based private insurance, mixed), which have a strong impact on their efficiency, effectiveness, equity, and productivity. On the basis of financial policy, the following three main health care systems can be distinguished:

1 The social insurance system: It is also known as Bismarck model. It is based on obligatory insurance funded by both the employer and the employees. It guarantees collectivity, bilateral consent, and social solidarity. There is only marginal interference by the state, which however, is the main provider of health care facilities. Patients are free to choose their primary care physician, who is either a free professional or salaried to an insurance agency. In some countries, this system has evolved into the next one.

2 Government-state controlled through taxation system: Introduced by Beveridge in the U.K., it guarantees free of charge access of all citizens to health care services. Planning, programming, financing, and administration of services, as well as prevention and public health policy are centrally controlled. The system is financed through taxes as health care is considered a right of the citizens. Interestingly enough, it often co-exists with a non-negligible private insurance sector, which offers reduced waiting lists, better accommodation facilities, a more free election of the doctors and other privileges. In both cases, there are some limitations to access such as, having the primary care physician as the first contact and gate-keeper.

3 The private health system: The system is financed either through private insurance or by direct (out of the pocket) payment by the patient. Population insurance is not obligatory. Both, the patients and the physicians preserve the right of choice and payment is based on fee per service. The private system flourishes in the USA where about 2/3 of Health Services belong

to private or to managed care for profit or non-profit organizations. Governmental contribution to health care free of charge for patients is limited to the uninsured, very poor, and elderly as well as to patients in emergency through the Medicare and Medicaid Federal Government programs.

The more recent trend is towards adopting a mixed system of financing of health services, with an increasing collaboration of the private sector both in financing the services and in providing medical care.

Managed care

Managed care is the use of business managerial principles, strategies and techniques in health care. As it started in the USA during the presidency of Ronald Reagan, in a restricted sense is only applied to this country as a way to control Medicare and Health Maintenance Organizations' (HMO's) payouts. However, nowadays every system including those more controlled by governments use the same approach to control costs. Governmental run systems are just big nationwide HMO's and confront clinicians with the same restrictions to their work, patients with limitations of access, be it only waiting lists, conflicts of interests and confrontation of cultures. Essentially, it is a reform of health care from its longstanding not-for-profit business principles into a for-profit model that would be driven by the insurance industry or governmental bodies ruled by the same principles.

The reason for the beginning of managed care is the need to control cost and to reduce the so-called medical inflation which in the 1980s and 90s, was running at twice or thrice the general inflation rate. Nevertheless, managed care has not been so successful at this role, but has brought rationality in the use of public resources in health care, and often into attracting private resources to a successful for-profit business model.

There are several forms of managed care. Plans range from more restrictive to less restrictive, and include:

Health Maintenance Organization (HMO)

An HMO is an insurance plan under which an insurance company gears most aspects of the health care of the insured person. Each insured person is assigned a 'gatekeeper', usually a primary care physician who is responsible for the overall care of members assigned to him/her. Specialty services require a specific referral from the primary care physician to the specialist. Non-emergency hospital admissions also require specific pre-authorization by the PCP. Typically, services are not covered if performed by a provider not an employee of or specifically approved by the HMO, unless it is an emergency as defined by the HMO. The HMO concept was introduced in 1960 by Dr. Paul Elwood[21] and was adopted by the Nixon Administration.

Preferred Provider Organization (PPO)

PPO is a coinsurance system, which provides patients a co payment (generally around 80 per cent) of the costs of care, for an insurance fee. The deductible is the first part of the coverage and is paid by the patient. After the deductible is met, the coinsurance portion applies. Because the patient is picking up a substantial portion of the 'first dollars' of coverage, PPO is the least expensive type of coverage.

Point of Service (POS)

A POS plan utilizes some of the features of each of the above plans. Members of a POS plan do not make a choice about which system to use until the point at which the service is being used. For example, if the patient stays in a network of providers and seeks a referral to use a specialist, they may have a co payment only. However, if they use a network provider, but do not seek a referral, they will pay more.

Conclusions

It is clear that the modern role of both the physicians, in general, and psychiatrists, in particular, requires intensive decision-making which is helped by management principles.

Psychiatrists, in addition to their clinical qualifications and skills are asked to occupy positions and undertake responsibilities as clinical executives, directors of health care facilities, administrators of Academic units and even Mental Health Commissioners, all of them requiring managerial knowledge and leadership qualities.

Increased pressure by patients for improved quality of services and access to new and innovative treatments needs to be balanced against the expectation of the health care system of the physician to act 'economically', following cost containment guidelines and staying within expenditure ceilings.

Such decisions require specialized knowledge and a deep understanding of the principles and the functions of management and health economics. Such knowledge is only gained through specialized training by introducing management teaching, either at the undergraduate level or preferably at the residency level, as part of the core curriculum or as an elective which may include items such as administration principles, quality assurance, budgeting, resource allocation, accreditation procedures and what is close to the psychiatrist's clinical background the personnel management. This may be extended to ongoing professional education programmes for psychiatrists who are already active in the field.

Descriptive phenomenology

Andrew Sims

Principles of descriptive phenomenology

Definitions and explanations

Psychopathology is the systematic study of abnormal experience, cognition, and behaviour. It includes the **explanatory psychopathologies**, where there are assumed causative factors according to theoretical constructs, and **descriptive psychopathology**, which precisely describes and categorizes abnormal experiences as recounted by the patient and observed in his behaviour.[1] Therefore the two components of descriptive psychopathology are the observation of behaviour and the empathic assessment of subjective experience. The latter is referred to by Jaspers as **phenomenology**,[2] and implies that the patient is able to introspect and describe what these internal experiences are, and the doctor responds by recognizing and understanding this description. Descriptive phenomenology, as described here, is synonymous with phenomenological psychopathology, and involves the observation and categorization of abnormal psychological events, the internal experiences of the patient, and consequent behaviour. The attempt is made to observe and understand this psychological event or **phenomenon** so that the observer can, as far as possible, know what the patient's experience must feel like.

Mental phenomena in health and cultural variation

It is not surprising that the identification and classification of the phenomena of mental illness is a difficult task as there is no consensus concerning what would be acceptable as normal healthy experiences. Mental illness has variously been considered as the products of a diseased brain, the symptoms that doctors treat, or a statistical variation from the norm carrying biological disadvantage, and mental illness often has legal implications. It is best to retain the use of the word 'normal' in a statistical sense; thus a phenomenon, such as hypnagogic hallucination, may be statistically abnormal but not an indicator of ill health or mental disease. Similarly, it is unwise to extrapolate from a population of mentally ill people and make assertions about the origins of behaviour in those who are not mentally ill.

It is important to recognize the effect of **culture** on subjective experience, the expression of psychological symptoms, and their manifestation in behaviour. In some cultures the very expression of subjective experience and emotion is discouraged and censored, in others feelings tend to be somatized, and in yet others the subjective experience of the individual tends to be subjugated to the sense of well being of the immediate social group. There are specific culture-bound expressions of subjective distress concerning body image in those who suffer from anxiety disorders. For delusions of passivity, although the psychopathological form remains relatively constant, the description of content will vary according to culture; for example, 'the djinn made me do it', 'my thoughts are controlled by the television'. Similarly, for possession state, although the psychopathological description remains similar, the actual cultural expression is very different between a member of a fundamentalist sect in the American Appalachian Mountains and a Buddhist girl in Sri Lanka.

Understanding the patient's symptoms

Although in internal medicine a clear distinction is made between **symptom** (the complaint which the patient makes) and **sign** (the indicator of specific disease observed or elicited on examination), in psychiatry both are contained within the speech of the patient. He complains about his unpleasant mood state, therefore identifying the *symptom*; he ascribes the cause of the pain in his knee to alien forces outside himself, thus revealing a *sign* of psychotic illness. Because both symptoms and signs emanate from the patient's conversation, in psychiatric practice the term symptom is often used to include both. For a symptom to be used diagnostically, its occurrence must be typical of that condition and it must occur relatively frequently.

Fundamental to psychiatric examination is the use of **empathic understanding** to explore and clarify the patient's subjective experiences. The method of empathy implies using the ability to 'feel oneself into' the situation of the other by proceeding through an organized series of questions, rephrasing, and reiterating where necessary until one is quite sure of what is being described by the patient. The final stage is recounting back to the patient what you, the psychiatrist, believe the patient's experience to be, and the patient recognizing that as indeed an accurate representation of their own internal state. Empathy uses the psychiatrist's capacity, as a fellow human being, to experience what the patient's subjective state must feel like as it arises from a combination of external environmental and internal personal circumstances.

Identifying phenomena as specific indicators of defined psychopathology may be difficult. It may require hearing much conversation from the patient for significant words and sentences to be revealed. The psychiatrist, when in the role of psychopathologist, has to assume that all speech of the patient, all behaviour of the patient, and every nuance has meaning, at least to the patient at the time the speech or behaviour takes place; it is not just an epiphenomenon of brain functioning.

Jaspers has contrasted **understanding** with **explaining**; descriptive phenomenology is concerned with the former. Understanding is the perception of personal meaning of the patient's subjective experience and involves the human capacity for empathy. That is, I understand because I am able to put myself into my patient's situation and know for myself how he is feeling, I feel those feelings of misery myself. Explanation is concerned with observation from outside and working out causal connections as in scientific method. In psychopathology, the terms *primary* and *secondary* are based upon this important distinction between meaningful and causal connections. That which is primary can be reduced no further by understanding, i.e. by empathy. What is secondary emerges from the primary in a way which can be understood by putting oneself into the patient's situation at the time; that is, if I were as profoundly depressed as my patient, I could have such a bleak feeling that I believed the world had come to an end—a nihilistic secondary delusion.

Subjective experience and its categorization

Within certain limits subjective experience is both predictive and quantifiable. When an individual loses a close relative it can be predicted that he or she will experience misery and loss. It is possible to quantify depressive symptoms and compare the degree of depression at different times in the same individual or differences between individuals at the same time. An important distinction for psychopathology is that between form and content. The **form** of psychological experience is the description of its structure in phenomenological terms (e.g. a delusion). Its **content** is the psychosocial environmental context within which the patient describes this abnormal form: 'Nurses are coming into the house and stealing my money'. The form is dependent upon the nature of the mental illness, and ultimately upon whatever are the aetiological factors of that condition. Content is dependent upon the life situation, culture, and society within which the patient exists. The distinction is important for diagnosis and treatment; determining the psychopathological form is necessary for accurate diagnosis, whereas demonstrating the patient's current significant concerns from the content of symptoms will be helpful in constructing a well-directed treatment regime.

Whereas most science is concerned with objectivity and with trying to eliminate the observer as far as possible from being a variable within the experiment, descriptive phenomenology tries to make evaluation of the subjective both quantifiable and scientific. It is a mistake to discredit subjectivity in our clinical practice. Inevitably we use it all the time and we should learn to use it skilfully and reliably. When I make an assessment that my patient is depressed, I am, at least to some extent, making a subjective judgement based upon the experienced and disciplined use of empathy: 'If I felt as my patient looks and describes himself to be, I would be feeling sad'. In psychopathology the distinction is also made between **development**, where a change of thinking or behaviour can be seen as emerging from previous patterns by understanding what the individual's subjective experience is, and **process**, where an event is imposed from outside and this cannot be understood in terms of a natural progression from the previous state. Anxiety symptoms could be seen as a development in a person with anankastic personality confronted with entirely new external circumstances; epilepsy and its psychiatric symptoms would be a process imposed upon the individual and not understandable in terms of previous life history.

Theoretical bases of descriptive phenomenology

There are important theoretical differences from dynamic psychopathology. Descriptive psychopathology does not propose explanations accounting for subjective experience or behaviour, but simply observes and describes them. Psychoanalytic psychopathology studies the roots of current behaviour and conscious experience through postulated unconscious conflicts and understands abnormalities in terms of previously described theoretical processes. The distinction between form and content and between process and development is not seen as important in psychoanalysis, but symptoms are considered to have an unconscious psychological basis. Descriptive phenomenology makes no comment upon the unconscious mind. It depends upon the subject being able to describe internal experiences, i.e. conscious material. Descriptive psychopathology is not dependent upon brain localization but on clarifying the nature of the subjective phenomena in discussion with the patient; if links can then be shown between certain phenomena and specific brain lesions, that is, of course, highly advantageous in furthering psychiatric knowledge. Descriptive phenomenology can be a unifying factor between concepts of brain and mind; it does not depend on philosophical stance on the nature of mind or brain.

Disorders of perception

Perception is not restricted to the screening of physical signals by sense organs but implies the processing of these data to represent reality. Ideas from the philosophy of mind have influenced psychiatric concepts of perception and the constitution of reality. Recently the distinction between sensory screening and interpretation has been confirmed by neurocognitive research.

Hundert[3] used the philosophical idea contained in the Kantian distinction between *a priori* categories and *a posteriori* experiences as a framework for differentiating perception by the sense organs from the secondary evaluation process. Kant's emphasis on the interplay between 'distal' perception and 'proximal' conceptualization can be exemplified by the perception and recognition of faces, disturbed in the Capgras syndrome and to a lesser degree in schizophrenia. The processing of visual perception is organized on at least four levels of complexity: the retina, the lateral geniculate body, the occipital visual cortex, and the hippocampus. The occipital cortex, where we actually 'see', does not contain an image any more than do the preceding levels; rather, it holds a database composed of signals from specific neurones for edges, angles, curves, sudden movements, and so on. Compared with the perceptual screen of the retina, these signals are 'scrambled' but even so they form a notion of what we perceive as reality. Recognition of faces needs further processing, probably in the hippocampal area where associations from other cortical fields are integrated with the

visual information (e.g. the voice belonging to the face). In psychiatry we deal with heterogeneous aetiologies, and perceptual disturbances may originate from different levels of processing, usually from a more integrated level than in neurological disease, and further from the immediate screening of physical stimuli by the sense organs. Thus, psychiatric disorders of perception affect different stages of information processing—from disturbances in the sense organs to complex phenomena involving feelings and ideas.

Here we shall mainly focus on hallucinations and some related phenomena, which are relevant for psychiatric illnesses.

Definitions of perceptual disturbances

Cutting[4] defines **hallucination** as 'perception without an object or as the appearance of an individual thing in the world without any corresponding material event'. The problem with this definition is that although some hallucinating patients mistake a hallucinatory perception for a real one, others can differentiate them: as demonstrated experimentally by Zucker,[5] there is an 'as if' quality even when patients assert that they perceive real objects or events. Voices described in detail by hallucinating patients were imitated and presented to the patients without warning. They had no difficulty in discriminating these external voices from their hallucinations. For this reason Janzarik[6] defined hallucinations, without associating them with perception at all, as 'free running psychic contents' (using a concept similar to Jackson's disinhibition). In keeping with this idea, lack of perception may facilitate hallucinations as in sensory deprivation or in the oneiroid states of paraplegic patients.[7]

The perceptual quality of hallucinations differs from similarity to sensory experiences, as in delirium, to the bizarre apprehensions of some with schizophrenia. Also, the extent to which the person is affected varies from descriptions of hallucinations as film-like in amphetamine psychoses to the affectively overwhelming experiences of hallucinations associated with delusional mood.

The term **pseudohallucination**, sometimes, is used to describe a perception recognized as *unreal*. Jaspers[8] defined hallucination as corporeal and tangible; pseudohallucination lacks this quality. According to Jaspers, pseudohallucinations are not tangible and real as hallucinatory perceptions; they appear spontaneously; they are discernible from real perception; and, they are difficult, but not impossible, to overcome voluntarily. Kandinsky illustrated Jaspers' definition of pseudohallucination: spontaneously arising images of acquaintances arose when a patient kept his eyes closed. He was fully aware of the unrealistic character of this experience and could abandon it by opening his eyes. Thus, to Jaspers, pseudohallucinations are close to imagined images except that they arise spontaneously and are more vivid. Jaspers' definition is not used consistently; in some Anglo–American literature it has been sufficient for the definition of pseudohallucination that there be subjective awareness that the percept lacks a real external equivalent and arises from the subject.

Imagery describes vivid visual experiences, which can be produced and manipulated voluntarily. It occurs in trance states when the perceptions are produced voluntarily, but are more real and last longer than in a normal state.

Illusions differ from hallucinations in being based on a misinterpretation of a real object or event, often associated with a mood. Illusions have to be distinguished from delusional perceptions which are percepts based on real objects to which an incorrect meaning has been attached. In delusional perceptions this 'error' cannot be corrected by the patient; in illusions the patient can recognize the true meaning.

Kurt Schneider described *Gedankenlautwerden* (*écho de la pensée*, or thoughts heard aloud) as a transitional phenomenon between vivid imagination and auditory hallucination. The patient recognizes that the words he hears are his own thoughts, but he cannot voluntarily control them. *Gedankenlautwerden* can disturb concentration when talking to other people. It can be differentiated from thought insertion and from auditory hallucinations in that there is a lesser degree of alienation.

Klosterkötter[9] has described transitions from elementary unformed hallucinatory sensations, like a crack, bump, or hiss, through more meaningful perceptions which still can be localized 'inside' the head, to complex hallucinations which become part of a delusional cognitive structure. These transitions were related to increasingly affective involvement in the themes of the hallucination. Klosterkötter's observations support Janzarik's interpretation of hallucinations as 'free running psychic contents', as do experimental studies of model psychoses which show a regular sequence of three psychopathological states: vegetative arousal, affective change, and 'productive' phenomena-like hallucinations and delusions.

Some misperceptions, found mainly in schizophrenic patients, are less complex than hallucinations, appear to be more closely related to neuropsychological disturbances, and include less systematization. They include **optical distortions** of size, colour, distance, and perspective, which can resemble experiences reported by people taking cannabis or other psychoactive drugs. These fluctuating, circumscribed misperceptions exemplify the way in which a more complex phenomenon of psychopathology can be built upon something more basic. Krause *et al.*[10] videotaped the non-verbal behaviour of schizophrenic patients and their healthy partners in a conversation. Brief non-verbal cues play an important part in dialogue. Schizophrenic patients miss these non-verbal brief cues and are poor at judging the intentions of others; their own non-verbal communication is poorly co-ordinated. The ensuing dysfunction diminishes social competence. Schizophrenic painters, trained before the onset of their illness, have been shown to misperceive perspective.[11]

Sensory modalities

Hallucinations can affect every sense modality. The most common, in the idiopathic psychoses, are **auditory hallucinations**, usually in the form of voices, although other kinds of sound may be associated with delusional contents. Voices talking to each other about the patient, and voices commenting about the patient's ongoing acting or thinking, are considered to be typical of, but not specific to, schizophrenia.[12] Voices calling the patient's name or talking without comments to the patient are diagnostically non-specific.

Visual hallucinations are most frequently found in organic psychosis, particularly delirium, in which they may occur for only a couple of hours during the night if the syndrome is not full blown. Visual hallucinations, more often than those in other sensory modalities, depict animals and scenes with several persons. In alcoholic delirium in particular, optical hallucinations of fine structures (such as hairs, threads, or spider webs) occur, and are especially likely to appear if the patient stares at a white wall. A typical, although not specific, combination of hallucination and delusion in organic psychosis is the 'siege experience', in which

patients believe they are besieged by enemies and have to bar their doors and windows.

Bodily, tactile, or coenaesthetic hallucinations are associated more often with schizophrenia than with affective or organic psychoses. The phenomenology includes simple tactile sensations of the skin, sexual sensations, sensations of the contraction, expansion, or rotation of inner organs, or atypical pain. Usually these sensations are associated with delusional explanations. Tactile hallucinations localized in the skin can underlie the **delusion of parasitosis**. Elderly patients in the early stages of organic cerebral alterations are at highest risk.

Coenaesthesia is a bodily misperception, which may last for minutes to days. It fluctuates (sometimes in relation to stress), and is usually not attributed to external agents or explained by delusional ideas. Patients seldom report them spontaneously. Klosterkötter[9] suggests that when coenaesthesia is attributed strongly to external influences, it is likely to be followed by schizophrenia.

Hallucinations may be **gustatory** or **olfactory**, for example, a smell of gas (perhaps thought to emanate from neighbours trying to kill the patient). Blunting of gustatory sensations or misperception of food as oversalted or overspiced is occasionally reported by melancholic patients.

Aetiological theories of hallucination

Aetiological theories are of three kinds:

1 overstimulation affecting different levels of information processing;

2 failure of inhibition of mental functions;

3 distortion of the processing of sensory information at the interpretive level.

The work of Penfield and Perot[13] has suggested that **overstimulation** may be a pathogenic mechanism. They stimulated the temporal regions of 500 patients, of whom 8 per cent reported scenic hallucinations, some in several modalities. Stimulation of the visual occipital cortex led to simple hallucinations-like flashes, circles, stars, or lines. This phenomenon has been observed in drug-induced experimental psychosis. It is interesting that schizophrenic patients can usually distinguish drug-induced hallucinations from those arising from their disorder. Using neural network theories, Emrich[14] simulated hallucinations by using Hopfield networks; overloading the storage capacity of the network generated what appeared to be the equivalent of hallucinations.

Disinhibition theory originated with Hughlings Jackson, who considered that productive symptoms were caused by the disinhibition of controlling neural activities, while negative symptoms resulted from damage to the systems, which generate the productive symptoms. More recently, sensory deprivation research has yielded inconsistent results; hallucinations, narrowly defined, seldom occur after deprivation, which may be of greater relevance to vivid, usually visual, imaginative experiences. Disinhibition may also underlie the 'hypnagogic hallucinations' which can occur in healthy subjects shortly before they fall asleep.

The role in the production of hallucinations of post-sensory interpretation and evaluation of stimuli is uncertain. In these terms, hallucinations are a sort of deception, but this is not a sufficient description of their nature. Recent neurophysiological hypotheses and findings from neuroimaging studies have suggested that there is an 'inner censorship' involved in clarifying ambiguities of perception.[14]

Disorders of thinking

Types of thinking

Three types of thinking can be distinguished which represent a continuum, without sharp boundaries, and intertwined in everyday life, from low to high regard for external reality and goal-directness: fantasy thinking, imaginative thinking, and rational thinking.[15] Since each of these types can predominate under some conditions, this distinction is useful to understand certain abnormal phenomena.

Fantasy thinking (also called dereistic or autistic thinking) produces ideas, which have no external reality. This process can be completely non-goal-directed, even if the subject is to some extent aware of the mood, affect, or drive, which motivates it. In other cases fantasy serves to exclude reality, which may require material with which the subject does not want to engage. This type of fantasy thinking is directed. Its goal is not to solve a problem but to avoid it via neglect, denial, or distortion of reality. Normal subjects use fantasy thinking deliberately and sporadically. However, if its content becomes subjectively accepted as fact, it becomes abnormal. This pathological exclusion of reality can remain limited in extent (e.g. in hysterical conversion and dissociation, pseudologia phantastica, and some delusions) or it may be manifested as withdrawal from the real world.

Rational (conceptual) thinking attempts to resolve a problem through the use of logic, excluding fantasy. The accuracy of this endeavour depends on the person's intelligence, which can be affected by various disturbances of the different components involved in understanding and reasoning.

Imaginative thinking comes between fantasy thinking and rational thinking. It is a process of forming a representation of an object or a situation using fantasy but without going beyond the rational and possible. This thinking is goal-directed but frequently leads to more general plans than the solution of immediate problems. Imaginative thinking becomes pathological if the person attaches more weight to his representation of events than to other objectively equally possible interpretations. In overvalued ideas, the imagined interpretation surpasses other interpretations in strength; in delusions, all other possibilities are excluded.

Delusions

The term 'delusion' signifies a complex edifice of thinking in which 'delusional ideas' are linked with other ('normal') thoughts. Delusions are communicated to others in the form of judgement. In this context, the term 'delusional idea' customarily refers to pathologically false judgement for which three criteria have been proposed: the unrivalled conviction with which they are held, their lack of amenability to experiences or compelling counter-arguments, and the impossibility of their content.[16] The last criterion must be discarded for two reasons. Firstly, collective beliefs derived from the socio-cultural setting of a person can be considered, in other surroundings, as false or impossible. Taking this into account, delusion is often defined as a 'false unshakable belief, which is out of keeping with the patient's social and cultural background'.[15] Secondly, in certain delusions (e.g. delusional jealousy) the content

does not go beyond the possible. Thus delusions are best defined as overriding, rigid, convictions which create a self-evident, private, and isolating reality requiring no proof.[17]

(a) The genesis of delusions

Jaspers[18] introduced a distinction between primary and secondary delusions. He supposed that the first, called true *delusional ideas*, are characterized by their 'psychological irreducibility', whereas the second, called *delusion-like ideas*, emerge understandably from disturbing life experiences or from other morbid phenomena, such as pathological mood state or misperception. This led to the assumption that primary delusions are the direct expression of the underlying condition considered to be the basis of schizophrenia. Four types of primary delusion have been distinguished in this perspective.

1 **Delusional intuition** (autochthonous delusion), occurring spontaneously, 'out of the blue'.

2 **Delusional percept**, in which a normal perception acquires a delusional significance. Schneider[19] assumed that 'psychological irreducibility' was clearly evident in this process, and included *delusional percept* among his 'first-rank symptoms' of schizophrenia.

3 **Delusional memory** can be distorted or false memory coming spontaneously into the mind, like delusional intuition. In other cases they occur, like delusional percept, in two stages, which means that normal memories are interpreted with delusional meaning.

4 **Delusional atmosphere** refers to an ensemble of minuscule and almost unnoticed experiences, which impart a new and bewildering aspect to a situation. The world seems to have been subtly altered; something uncanny seems to be going on in which the subject feels personally involved, but without knowing how. From this uncertainty evolves first certainty of self-reference, and then the formation of fully structured and specific delusional meaning. The apparent change in the surrounding situation is accompanied by tension, depression, or suspicion, and by anxious or even exciting expectations, so that it is often called 'delusional mood'.

The primary–secondary distinction assumes that the delusional atmosphere is part of the process underlying all primary delusional phenomena. If this preliminary disturbance is not perceived clearly or is not communicated by the patient as a general change in the situation, delusion may be manifested only as delusional percept, intuition, or memory. When the initial change in atmosphere is experienced clearly, a subsequent alteration in the environment, or a fully formed delusional idea, can lead to release from the preceding perplexity. The origin of primary delusions is commonly attributed to a basic cognitive anomaly disturbing information-processing, which reduces the influence of past experience on current perception. This is considered to entail a heightened awareness of irrelevant stimuli and an ambiguous unstructured sensory input allowing the intrusion of unexpected and unintended material from long-term memory.[20]

(b) The content of delusions

The content of delusions is determined by the mood in which they emerge and evolve, by the patient's personality and socio-cultural background, and by previous life experiences. In principle, the content can embrace all kinds of presumptions in separate categories. The following six delusional themes are usually distinguished:

- **delusion of persecution** based on the assumption that the patient is pursued, spied upon, or harassed
- **delusional jealousy**
- **delusion of love** characterized by the patient's conviction that another person is in love with him or her
- **delusion of guilt**, unworthiness, and poverty which may sometimes reach the degree of 'nihilistic delusion', in which the patient believes the real world has disappeared completely
- **grandiose delusion** in which patients are convinced that they have great talents, are prominent in society, or possess supernatural powers
- **hypochondriacal delusion** founded on the conviction of having a serious disease.

The mood state when delusional ideas emerge favours certain themes. Delusion of guilt, or unworthiness, and hypochondriacal delusion are strongly linked with depression. Grandiose and erotic delusion generally occurs in excited or manic states. Delusions of persecution and jealousy emerge most frequently from suspicious mood states or a delusional atmosphere, but may occur in depressed subjects.

Some further specific contents of delusions are:

- **religious delusion**, which may occur with grandiose delusion or delusion of guilt
- **delusion of infestation**, a subtype of hypochondriacal delusion, and characterized by the conviction of infestation by small organisms
- **delusional misidentification** in which the patient believes, on the basis of a delusional percept, that a perceived person has been replaced by an imposter, or in which he is convinced that another person has been physically transformed into his own self
- **delusion of control** in which the patient experiences sensations, feelings, drives, volition, or thoughts as *made* or influenced by others (this schizophrenic delusion is believed to result from cognitive dysfunction consisting of a failure of the system which monitors willed intentions).[21]

(c) The structure of delusions

1 The alternatives, 'logical' or 'paralogical', indicate whether or not the connection of ideas is consistent with logical thinking.

2 The notions, 'organized' or 'unorganized', indicate whether or not the delusional idea is integrated into a formed concept. Highly organized, logical delusions are described as *systematized*.

3 The relationship between delusion and reality varies:
   - in **polarized delusion**, delusional reality is inextricably intermingled with actual fact
   - if the delusional belief and reality exist side by side without influencing each other, we speak of **juxtaposition**
   - in **autistic delusion** the patient takes no account of reality and lives in a delusional world.

Overvalued idea

An overvalued idea is an acceptable, comprehensible idea pursued beyond the bounds of reason.[22] Overvalued idea causes disturbed functioning or suffering to the person himself or others.

Overvalued ideas of prejudice (overvalued paranoid ideas) are characterized by an underlying self-referent interpretation of the behaviour or sayings of others; patients assume themselves to be overlooked, slighted, unfairly treated, provoked, or loved. Overvalued apprehension may become apparent as morbid jealousy, hypochondriacal phobia (e.g. parasitophobia), or dysmorphophobia, in which patients assume that they attract attention because of a real or presumed bodily defect. In anorexia nervosa subjects are preoccupied by the endeavour to remain thin, and in transsexualism by the desire to change gender because they feel that they belong to the opposite sex.

Overvalued ideas generally occur with abnormal personality under stressful situations. Those with paranoid personality traits may develop, on the basis of a presumed injustice, querulous, or litiginous overvalued idea. Sometimes ideas become overvalued only during abnormal mood states (of various origins) which set aside counterbalancing influences.

Thinking in mood disorders

The content of thought in mood disorders is coloured by affect. Negative thinking about self, the future, and the world prevails.[23] Mishaps and failures are attributed to personal faults; success is attributed to the action of other people. This depressive thinking spreads from the starting point of negative life events to more general events, and it tends to become long lasting. The fixed viewpoint that emerges is called 'cognitive schema'. After recovery from an acute episode this schema may become latent, but it can be reactivated by distressing life events. It can also prolong symptoms. Negative thinking started by minor misfortunes can become autonomous, driving down mood—which in turn intensifies negative thinking. The negative schema can prolong a depressive episode or precipitate a new one. It is probable that such schemas are activated by both cognitions and emotions. Guilty thoughts are closely connected with this type of thinking, and may reach the intensity of a delusion. To a degree, guilty thinking in depression is dependent on culture. In mania, the content of thought is related to the mood of elation, with diminished self-criticism and excessive self-importance. In phobic and other anxiety states, thinking centres on situations leading to anxiety. Typical contents of delusional thinking in depression concern guilt, religious failure, condemnation, personal insufficiency, impoverishment, hypochondriasis, and nihilistic ideas. In mania, delusional ideas may be feelings of spiritual or economic power. In contrast with schizophrenic delusions, affective delusions grow out of the underlying, excessive mood and do not appear as something new and alien to the personality.

Phobic and anankastic phenomena

Phobic and anankastic (obsessional) phenomena have in common that the patient experiences them as unwanted, but cannot suppress them. They often occur together.

(a) Phobia

Phobias are inappropriate, exaggerated fears which are not under voluntary control, cannot be reasoned away, and entail avoidance behaviour.[24] The fears are kindled by particular stimuli. These may either be perceived objects, such as animals (animal phobia) or pustules (in some illness phobias), or situations such as open places (agoraphobia) or confined rooms (claustrophobia).

Phobias initially triggered by a very specific stimulus can eventually generalize. Thus, an elevator phobia may become extended to all kinds of closed rooms. Some phobias are linked with broader circumstances from the beginning. In social phobia, for instance, patients avoid meeting people because they fear that they will be noticed. Identical types of fears can be triggered by different stimuli in different subjects. Thus, illness phobia is activated in some patients by observed body changes, but in others by situations involving the risk of infection.

Phobias are characterized by avoidance behaviour: patients avoid anxiety-provoking objects or situations. Because of stimulus generalization, this can lead to severe impairment; for instance, they cannot leave home.

(b) Anankastic symptoms

Anankastic phenomena occur as obsessions or compulsions:

1 Obsessions occur as repeated thoughts, memories, images, ruminations, or impulses that patients know to be their own but are unable to prevent. The content of these ideas is often unpleasant, terrifying, obscure, or aggressive.

2 Compulsions are actions, rituals, or behaviours that the patient recognizes as part of his own behaviour, but cannot resist.

(c) Combined syndromes

In phobic–anankastic syndromes patients attempt to reduce their phobic fears by certain actions, such as hand washing in the case of an infection phobia. If obsessional thoughts or impulses induce anxiety (e.g. obscene ideas during worship, or the impulse to lean too far over a balustrade) and entail the avoidance of the situations that provoke them, the term anankastic–phobic syndrome is used.

Phobias, obsessions, and compulsions result most frequently from neurotic conflicts, but they also occur with functional or organic mental disorders. Anankastic personalities, characterized by perfectionism, rigidity, sensitivity, and indecisiveness, are especially prone to develop obsessions and compulsions.

Disorder of the thinking process

Disturbance of thinking may be recognized by the patient himself or deduced by an observer from the subject's speech.

Impairments of thought production are conventionally named 'formal thought disorder' and contrast with abnormalities of the 'content of thought' observed in delusions. In the deviant reality-testing of deluded patients there is always a disturbance of the form of thinking.

(a) Disorders of the flow of thinking

Each remembered idea is linked with a number of other notions, related closely as well as distantly. In rational thinking, a 'determining tendency'[25] guides the flow of ideas in the chosen direction and excludes associations which do not conform with this goal. This procedure can be disturbed in various ways which are commonly grouped together under the heading of 'formal thought disorder'.

(i) Disturbances of the speed of thinking

In **acceleration** of thinking, associations are still formed normally but at grossly accelerated speed. The goal is not maintained for long and the intervention of new thoughts produces 'flight of ideas'.

Retardation refers to a slowing down of the thinking process, which hampers formation of associations and may prevent reaching the original goal of thoughts. This results in difficulties in concentration and decision-making.

Acceleration and retardation of thinking are due to a change of affect, and are characteristic of mood disorders.

(ii) Circumstantiality

In circumstantiality the determining tendency is maintained but the patient can reach the goal only after having exhaustively explored unnecessary associations arising in his mind. When answering a question, he relates many irrelevant details before returning to the point. This inability to exclude unimportant associations occurs in organic mental disorders and in mental retardation.

(iii) Perseveration

Perseveration is found in organic mental disorders and is defined as an inability to shift from one theme to another; a thought is retained long after it has become inappropriate in the given context. For example, a patient may give a correct answer to the first question, but repeats the same response to a subsequent, completely different inquiry.

(iv) Interruptions in the flow of thinking

Thought blocking is a sudden unintended cessation in the train of thought, experienced by the patient as 'snapping off'. After this break, which may occur in the middle of a sentence, the previous thought may be taken up again or replaced by another. Thought blocking occurs in organic states, in depression, and frequently in schizophrenia where it is described as part of negative thought disorder.

In **loosening of association** the flow of thinking is interrupted by deviation towards distant or unrelated thought, in contrast with flight of ideas in which there is only a speeding up of access to nearby associations. Loosening of association is a type of formal thought disorder. In **tangentiality** the ideas deviate towards an obliquely related theme. In **fusion**, different kinds of association evoked by an original thought are blended to produce a word or sentence. **Derailment** is characterized by the interpolation of ideas which neither the patient nor the observer can link with the previous stream of thought. **Muddling** designates an extreme degree of derailment and fusion.

In organic states, incoherent thinking, which is clinically similar to derailment, may be attributable to a primary intellectual impairment and not to an increased spread of associations.

(b) Overinclusive thinking

This kind of thought disorder is not based on an interruption of the flow of thought but on an inability to preserve conceptual boundaries; ideas only distantly related to the concept under consideration become incorporated within it,[26] for example, when asked to indicate the essential components of a *room*, *table* might be included as well as *ceiling*, *wall*, and *floor*.

(c) Concrete and abstract thinking

In organic mental disorders and mental retardation, inability to think abstractly may be attributed to a diminished capacity to structure a concept. There have been various theories used to explain the **concrete thinking** of schizophrenia, involving memory, conceptualization, and intrusion of delusions. The process may be enhanced by loosening of associations. The fact that schizophrenia sometimes manifests excessively **abstract thinking** may also be explained by a disturbance of working memory such that the concrete meaning of the initial thought is not retained.

(d) Disorder of control of thinking

In **obsessions** and **compulsions** the subject recognizes his thoughts as being produced by himself but is unable to control them.

In **passivity of thought**, the patient experiences his thoughts as manipulated by outside influences. The interpretation resulting from this feeling is described as 'thought withdrawal', 'thought insertion', or 'thought broadcasting' (which denotes the patient's conviction that his thoughts are diffused to other people). These 'delusions of the control of thought' were included by Schneider[27] among his 'first-rank symptoms' of schizophrenia.

A particular variation of thought insertion occurring in schizophrenia is **crowding of thoughts**. In this condition, the patient experiences an excessive increase in the amount of thoughts imposed from the outside and compressed in his mind.

Language and speech disorder

'Speech disorder' refers to defects in the ability to generate and articulate verbal statements, whereas 'language disorder' designates deficits in the use of language. The terms 'aphasia' and 'dysphasia' are often used interchangeably for speech disorders.

(a) Disturbed generation and articulation of words

Aphonia designates the inability to vocalize. Thus, whispering occurs in somatic illnesses (paralysis of cranial nerve IX or disease of the vocal cords) and hysteria. **Dysphonia** is a somatic impairment with hoarseness.

Dysarthria refers to disorders of articulation occurring in various malformations or diseases, which impair the mechanisms of phonation, in lesions of the brain stem, in schizophrenia, and in psychogenic disorders.

The causes of **stuttering and stammering** are unclear, but are sometimes considered to be of neurotic origin. **Logoclonia** (the spastic repetition of syllables) occurs in Parkinsonism.

(b) Disturbance in talking

'Disturbances in talking' was proposed by Scharfetter[28] as a generic term for disorders of speech or language not belonging to the preceding group of disturbances.

Changes in volume of sound and in intonation occur in affective and schizophrenic states, and refer to loud excited and quiet monotonous speech.

Bradyphasia (decelerated talking) and **tachyphasia** (accelerated talking) occur in mood disorders, schizophrenia, and organic dysphasias.

Logorrhea (verbosity) is observed in various disorders, especially in manic states.

Alogia (poverty of speech) is a decrease in spontaneous talking; it occurs in depression and schizophrenia.

In **poverty of content of speech**, the amount of speech is adequate but conveys little information. This is often related to schizophrenic disorganization of thinking.

Verbigeration is the monotonous repetition of syllables and words observed in organic language disorders, schizophrenia, and agitated depression.

Echolalia is the repetition of words or parts of sentences that are spoken by others. It can be observed in schizophrenia, organic states, and subnormality.

Sometimes patients give **approximate answers**: i.e. they avoid giving the correct answer to a question that they have understood, just missing being correct. This occurs in organic disorders, schizophrenia, and hysteria.

Paraphasia denotes the enunciation of an inappropriate sound instead of a word or phrase. This happens in organic speech disorders but may also have psychogenic causes.

Speech may be unintelligible for various reasons. **Paragrammatism** and **parasyntax** (loss of grammatical and syntactical coherence) occur in organic mental disorders and excited manic states, and in schizophrenia, when severe thought derailments become manifest as 'word salad'. **Private symbolism** can be observed in schizophrenia in three forms: use of existing words with a particular symbolic meaning, creation of 'neologisms' (new words with an idiosyncratic meaning), and production of a private incomprehensible language, which may be spoken (cryptolalia) or written (cryptographia).

Mutism (refraining from speech) may be found in various kinds of psychiatric disorder. It is a cardinal feature of stupor and also occurs as an 'hysterical' reaction to stress.

Pseudologia fantastica is characterized by fluent lying, which is developed into a fantastic construct. This 'mythomania' occurs in histrionic and asocial personality disorders.

(c) Organic language disorders

This refers to impairments of spontaneous language, naming, writing, and reading, occurring as a result of brain dysfunction. These disorders can be divided into 'sensory' (receptive), 'motor' (expressive) defects, or both combined, containing the following principal subcategories:

(i) Sensory language disorders

In **primary sensory dysphasia** the patient cannot understand the speech of others. His own speech remains fluent, but contains errors in the use of words, syntax, and grammar. Writing and reading are also impaired. If, in this condition, the patient's speech becomes unintelligible, the disturbance is called 'jargon aphasia'. If only the repetition of a message is disturbed, the disorder is named 'conduction dysphasia'.

In **pure word-deafness** speech, reading, and writing are fluent and correct. The patient hears words as sounds, but cannot recognize their meaning. In **pure word-blindness** (alexia) speech and writing are normal but the patient cannot read with understanding.

(ii) Motor language disorders

In **primary motor dysphasia** the verbal or written expression of words and the construction of sentences is disturbed, but the understanding of speech and writing are preserved.

In **pure word-dumbness** the disturbance is limited to an inability to produce and repeat words at will. **Pure agraphia** is an isolated inability to write. **Nominal dysphasia** is an inability to produce names and nouns.

Disorders of intellectual performance

(a) Conceptualization of intelligence

'Intelligence' refers to the capacity to solve problems, to cope with new situations, to acquire skills through learning and experience, to establish logical deductions, and to form abstract concepts. There has been a classical debate amongst psychologists as to whether intelligence represents different and specific abilities or a unitary, general factor of intelligence.

(b) Measurements of intelligence

Individual intellectual capacity is graded by reference to the intelligence quotient (**IQ**), which is defined as the ratio of a subject's intelligence to the average intelligence for his or her age. The assessment of intelligence is considered in Chapter 1.8.3.

In addition to the global assessment of intelligence, numerous tests have been developed to assess organic impairment, scholastic achievement, and aptitude.

(c) Mental retardation (learning disability)

If the development of intellectual performance does not reach an IQ level of 70, the condition is designated 'mental retardation'. This is subdivided according to severity, with four levels recognized in ICD-10:

- mild (IQ 50–69)
- moderate (IQ 35–49)
- severe (IQ 20–34)
- profound (IQ below 20).

The causes of mental retardation are considered in Section 10.

Disorders of later onset

In these disorders normally developed intellectual performance declines. This can occur as a result of organic brain disorders, and in psychotic and affective disorders.

Organic disorders may have toxic, traumatic, inflammatory, or hypoxic causes. If these conditions are treated successfully, the disturbance can be arrested or even reversed.

In dementia there is a progressive disintegration of intellectual function, which usually begins insidiously and is often first recognized through an impairment of memory.

In psychotic states the distorted testing and evaluation of reality can impair intellectual performance. In schizophrenia, formal thought disorder may contribute to this effect.

Severe affective disorder can impair perception, attention, and motivation, leading to poor intellectual performance. These disturbances are observed more often in depression, but can occur in manic mood.

Disorders of mood

This section outlines the psychopathological elements comprising mood disorders, in particular the different varieties of depression, mania, anxiety state, and depersonalization.

Mood is a state of mind, which is longer lasting than affect or feeling. Mood encompasses all mental processes; it is not influenced

by will, and is strongly related to values. Heidegger[29] has considered mood as the fundamental expression of an individual's being. Kierkegaard[30] emphasized the role of existential orientation in determining mood, especially general anxiety.

The extent and type of deviation of mood is important in affective disorders. Although there are no sharp boundaries between the normal variations and pathological states of mood, severe states are clearly abnormal and difficult to understand. Mood can be abnormal in several ways: sad or anxious in depressive disorders; euphoric in mania; irritated in mania or agitated depression; dysphoric in depression or in mixed manic—depressive disorders; morose in chronic-depressed states, often with a component of resentment; blunted (the feeling of 'having no feelings' or 'petrified' feelings) in prolonged, severe depressive disorder. Stanghellini[31] analysed depressed patients and described how morose affect may emerge when the patient struggles against declining abilities and experiences resistance. In such cases feelings of timidity and despair may contrast with an outward appearance of hostility.

Two types of **euphoria** should be differentiated: one shows elation and feelings of increased spiritual, intellectual, or physical power, and the other results from disinhibition in organic states and dementia. This second type, rather than elation, may show lack of interest and an attitude of negligence towards the patient's actual situation.

These abnormal moods are related to altered **bodily feelings** and thinking.

Abnormal **somatic** symptoms can be divided into physical symptoms, such as cardiovascular dysregulation, increased sweating, and feeling cold, and hypochondriacal symptoms, such as headache and feeling of tightness in the chest, heavy limbs, being choked, or difficulty in swallowing. These latter symptoms are related to feeling of loss of energy.

Lopez-Ibor[32] suggested the term 'depression-equivalent' for conditions in which somatic symptoms (e.g. headaches which vary on a diurnal pattern) dominate the clinical picture. Cross-cultural research has found higher rates of such somatic symptoms in depression in Africa[33] and South America,[34] and a lower rate of guilt compared with Western industrialized countries. However, the results are not wholly consistent and variation may reflect cultural differences or differing patterns of consultation with doctors, and what patients expect doctors to treat.

A feedback loop may develop between anxiety and physical **arousal**, e.g. palpitations, which accompanies it.[35,36] The prevalence of mitral valve prolapse is higher in anxiety disorder (37 per cent) than in the general population (5 per cent).[37] This finding is consistent with the idea that palpitation may lead to a conditioned anxiety response. The behaviour therapy technique of exposure aims to decondition this reflex. In social phobia and panic disorder anxiety is often complicated by anxiety-provoking situations which may lead to severe social disablement. Somatic symptoms of anxiety may be so prominent in some depressive states that patients are misdiagnosed as medically ill, with loss of weight, atypical pain, or sensory or motor disturbances. This type of depression has been called 'depressio sine depressione', or 'somatoform depression'.

Disturbances of diurnal rhythm can influence all the other symptoms of mood disorder.[38] There are changes associated with sleep in the electroencephalogram, with shorter REM latency (phase advance), and also changes in endocrine and cardiovascular circadian rhythms. In depression, sleep disturbance is characterized by early awakening, whereas falling asleep in the evening is often undisturbed. About 70 per cent of melancholic patients show diurnal distribution of mood, psychomotor activity, somatic symptoms, and slowed and impoverished thinking.

Psychomotor retardation or acceleration is one of the most prominent symptoms of mood disorder. Often the patient's appearance and expressive movements reveal more than words. The retarded patient's movements are slow, the limbs are rigid, the body is bent, and the expression is sad or anxious, and does not respond to the situation. The subjective feeling may be of emptiness, weakness, and tension. If the condition is severe, it can be difficult to discriminate between depressive and catatonic stupor; patients with depressive stupor seldom have increased muscular tension or rigidity. Increased psychomotor activity can appear in depression as agitation, i.e. restlessness without the ability to attain goals or organize behaviour. In mania, increased psychomotor activity is also seen in sexual excesses and extravagant spending.

Psychomotor retardation, and probably also acceleration, may be accompanied by a changed experience of time.[39] Depressed patients overemphasize the past, remembering guilt-connected events; manic patients feel that the future is immanent. Inability to distinguish wishes from reality results in poor decision-making in both depression and mania. Some depressives are unable even to decide how to dress in the morning. A manic patient's workroom can reflect the dissolution of his ability to give priority to important things, for example tools for immediate and frequent use and those seldom used. Extreme retardation is seen in depressive stupor when patients do not move, speak, eat, or drink. Extreme acceleration occurs in mania ('boiling over') and may be accompanied by a sense of confusion.

Retardation and acceleration are closely related to depressive and manic **thought disorder**. In depression the flow of associations is reduced and slowed, and short-term memory can appear impaired (pseudodementia). Depressed patients often ruminate about negative topics and have difficulty in terminating these thoughts. In mania, acceleration of thinking leads to a plethora of associations, 'flight of ideas', and pressure of speech. Unlike patients with schizophrenic thought disorder, depressed patients retain logical connections.

Depersonalization (see later) can occur alone or as part of a depressive state. In the latter, part of the body, the self, the mind, actions, or thinking are sensed as being alienated—not belonging to the self. In mood disorders, depersonalization does not usually reach the intensity of delusion, as it can in schizophrenia.

Although anxiety disorders and major depression have been defined by operational criteria in the diagnostic manuals, the clinical symptoms of mood states vary considerably. Attempts have been made to define a core syndrome by using factor analysis to identify latent trait symptom profiles derived from several assessment scales and from different samples of depressed patients. Cross-cultural comparisons of symptom profiles can also help to identify core symptoms. Among the latent traits, retardation was found most often, together with loss of interest and alteration of diurnal rhythm. Guilt, death wish, and affective reactivity occurred inconsistently.[40]

Disorders of self and body image

Disorders of self

These describe the abnormal inner experiences of I-ness and my-ness which occur in psychiatric disorders. Scharfetter has added the characteristic of awareness of being or ego vitality to the four formal characteristics previously described by Jaspers: feeling of awareness of activity, awareness of unity, awareness of identity, and awareness of the boundaries of self.[41,42]

(a) Disorder of the awareness of being

This is demonstrated by **nihilistic delusions**, which frequently occur in severe depressive illness and are a feature of the eponymous Cotard's syndrome.[43] Non-psychotic abnormality is exemplified by **depersonalization** in which the sufferer experiences his mental activity, body, or surroundings as changed in quality to become unreal, remote, or automatized.

(b) Disorder of awareness of activity

Disorder of the awareness of activity occurs with neurological lesions, such as some dyspraxias, and also in psychotic conditions in which the individual believes that no action has occurred when it has, or vice versa. This does not include action that the patient knows he has executed but with a belief it was under the influence of another. Non-psychotic disorder of activity occurs when an individual believes that he has no freedom of action and that his range of choice is limited by external circumstances, for instance a person with depressive symptoms who believes that he is inevitably incompetent.

(c) Disorder of awareness of singleness

In health, one assumes that 'I am one person'. Disorder occurs in the rare visual perceptual experience of **autoscopy**.[44] Non-psychotic examples of disorder of singleness include the double phenomenon, described by Jaspers,[45] and **multiple personality disorder,** which is the apparent existence of two or more distinct personalities within an individual, only one of them being evident at any time. The **double phenomenon** is much more frequent, and describes the self-experience of those who feel that there are two different parts of themselves in conflict with each other; they are fully aware of both at the same time.

(d) Disorder of awareness of identity

Disorder of identity occurs in **delusion of control** or **passivity experience**, in which the sufferer believes that he has been taken over by an alien, with the belief that there is a break in continuity from 'myself' who was there before. Non-psychotic disorder of awareness of identity is exemplified by **possession disorder**, in which there is a temporary loss of the sense of personal identity and the individual may act *as if* they have been taken over by another personality, spirit, or force.

(e) Disorder of the awareness of boundaries of self

Disorder of boundaries of self occurs in first-rank symptoms of schizophrenia such as thought withdrawal, control, and diffusion.[46] The patient believes that thoughts 'are being taken out of me, influenced by an outside source'. Non-psychotic disorder of the boundaries of self occurs in ecstasy states, characteristically described as an 'as if' experience. There is disturbance of boundaries of self in that the individual may feel that there is no limit between self and the outside world.

Depersonalization and derealization

Depersonalization is the experience of one's own feelings and experiences being detached, distant, not one's own, lost or altered. Derealization is the same range of subjectivity describing awareness of the outside world. The sufferer recognizes that this is a subjective change and is not imposed by outside forces. Because the sufferer finds it difficult to describe, this experience tends to be underdiagnosed, but the misery it causes and the disturbance in functioning is considerable; it is experienced as being so subjectively unpleasant that not uncommonly deliberate self-harm results.

Insight

The clinical assessment of a patient's capacity to understand the nature, significance, and severity of his or her own illness has been called insight. There is current interest in describing its characteristics and establishing how it correlates with other measures of illness.[47] The attitude of patients towards their illness has clear clinical implications, and the assessment of insight tries to investigate the patient's awareness concerning the impact their illness has, and their capacity to adapt to the changes brought about by illness. The patient's awareness of illness and the extent to which it is interfering with function affects compliance for prescribed treatment. David has proposed that insight implies the ability to relabel unusual mental events as *pathological*, the recognition that one has mental illness, and compliance with treatment. Some parallels have been drawn between the loss of insight in psychiatric patients and the denial of disease or loss of function that occurs in certain neurological conditions.

Because of its importance for clinical management, there have been many attempts over recent years to measure insight, all of which depend upon a precise operational definition of the concept. McEvoy *et al.*[48] developed a questionnaire to measure the patients' awareness of the pathological nature of their experiences and also their acceptance of the need for treatment. The measure constructed by David *et al.*[49] added the ability to relabel unusual mental events as 'pathological' to the recognition of mental illness and compliance with treatment.

The relationship between impairment of insight and the presence of other aspects of psychopathology is complicated; there is no clear association between impairment of insight and intellectual or neuropsychological deficit.[50] Not surprisingly, patients with unimpaired insight are found to be significantly less likely to require readmission to hospital, tend to be more compliant with treatment, and show an improved prognosis.[51] Surprisingly, and this shows how little is known about this subject, many patients are prepared to comply with treatment, even though they do not believe themselves to be ill, if the social milieu is conducive to receiving treatment.[48]

Insight is a multifaceted phenomenon with considerable clinical significance as it predicts the likelihood of patients complying with treatment. Most studies of insight have been concerned with patients suffering from schizophrenia, and it is important to extend work to other serious mental illnesses.

Disorders of awareness of the body

(a) Bodily complaint without organic cause

Such conditions create difficulties for psychopathological understanding.

1 Aetiology is often obscure, sometimes with doubt that there may be an unrevealed physical cause.
2 The descriptive terms used come from different theoretical backgrounds and have changed their meaning over the years.
3 There is often discrepancy between the meanings attached to the symptoms by the patient and by the doctor.

'Somatoform disorders', which include both somatization and hypochondriacal disorders[52] are, characteristically, repeated presentation of physical symptoms with persistent requests for medical investigation, despite negative findings, and reassurance by doctors that the symptoms have no physical basis. The patient with **somatization** as the prominent disorder complains of multiple recurrent, and often changing, physical symptoms in different bodily systems over a prolonged time. The patient with **hypochondriasis** has a persistent preoccupation with bodily function, the possibility of illness, and the seriousness with which symptoms should be treated. Not infrequently these two groups of symptoms overlap. Co-morbid anxiety and depression is quite frequent with both somatization and hypochondriasis. The content of hypochondriasis may take the form of delusion, overvalued ideas, hallucination, anxious or depressive rumination, or anxious preoccupation.

The term 'Dissociative (conversion) disorder' has replaced the confusing, but graphic, hysteria. **Conversion symptoms** can be categorized as motor, sensory (including pain), or psychological. Motor symptoms include weakness or paralysis of limbs or part of a limb and abnormality of gait; sensory symptoms include glove, and stocking anaesthesia. Amongst the psychological symptoms is a narrowing of the field of consciousness with selective amnesia such as may occur in fugue states. For conversion disorder, or hysteria, to be diagnosed, symptoms should appear to be psychogenic in nature, causation should be considered unconscious, symptoms may carry some sort of advantage to the patient, and they occur by the mediation of the processes of conversion or dissociation.

Artefactual illness includes two categories: *elaboration* of physical symptoms for psychological reasons, and intentional production or *feigning* of symptoms or disabilities, either physical or psychological. Conversion symptoms are believed to arise without the patient's conscious involvement, but artefactual illness implies that the illness, lesion, or complaint is ultimately the individual's own conscious production. **Malingering** implies feigning or producing symptoms expressly for the social advantages of being regarded as ill, while the broader category of artefactual illness includes other motivations and simply describes the behaviour.

Narcissism is an exaggerated concern with one's self-image, especially with personal appearance. This absorption with self is usually associated with feelings of insecurity and ambivalence concerning the self and feelings of threat to one's integrity.

Dislike of the body and distortion of body image are subjectively different experiences but often occur together, for example in anorexia nervosa or with gross obesity. In **dysmorphophobia** the primary symptom is the patient's belief that he or she is unattractive. Sufferers believe themselves to have a physical defect, such as the size of their nose or breasts, that is noticeable to other people, but objectively their appearance may lie within normal limits. The content disorder of dysmorphophobia is an overvalued idea in which the degree of concern and consequent distress is clearly out of proportion and comes to dominate the whole of life. The overvalued idea of dysmorphophobia may be associated with an underlying personality disorder of anankastic or dependent type, or with other psychiatric disorders.

Awareness of body size and **disturbance of eating** frequently occur together; alteration of body image is associated with eating disorder. Obesity in adolescence, in diet-conscious Western societies, frequently results in self-loathing, more frequently in girls than boys, with overestimation of body fatness. Disturbance of body image occurs in sufferers from anorexia nervosa, characteristically an overestimate of width with an accurate estimation of height or the width of inanimate objects. The more 'over-fat' an individual considers herself to be, the more dissatisfaction with herself she will experience.[53] Such disorders of self-image, with significant overestimation of size and discrepancy between perceived and desired size, also occur in bulimia nervosa, and may be associated with depression of mood and feelings of guilt and unworthiness.

(b) Organic changes in body image

Organic change may result from either damage to the conceptualized object (e.g. following amputation, with a phantom limb) or damage to the process of conceptualization (e.g. section of the corpus callosum). Hyperschemazia, pathological accentuation of body image, occurs when physical illness or neurological lesion causes enhancement of perception of an organ. Diminished or absent body image (hyposchemazia, aschemazia) may occur with loss of innervation, or with parietal lobe lesions. The diminution of body image may be simple (e.g. loss or neglect of a limb) or complex. There may also be distortions of the body image (paraschemazia), in which enhancement or diminution of parts of the body may occur.

(c) Disorder of gender and sexuality

Core gender identity is established very early in life and then retained; it is biologically influenced and socially reinforced. **Transsexualism** is a disorder of gender identity, much more common in biological males, in which there is discrepancy between anatomical sex and the gender that the person assigns to himself. The subjective belief is an overvalued idea. Other disorders of sexuality are considered elsewhere. (See Chapter 4.11.3)

(d) Pain as a psychopathological entity

Pain is a subjective experience, which is hard to describe and categorize; it is not well-charted phenomenologically. It appears to have more in common with mood than perception. Pain associated with psychiatric illness tends to be more diffuse and less well localized and to spread with non-anatomical distribution. It also tends to be complained of constantly, becoming even more severe at times but persisting without remission. It may clearly be seen to be associated with underlying disturbance of mood, which appears to be primary in time and causation. Psychogenic pain tends to progress in severity and extent over time. Persistent, severe, and distressing pain, which cannot be explained fully by a physiological process or physical disorder has been designated **persistent somatoform pain disorder**. (See Chapter 5.2.6.)

Motor symptoms and signs

Motor symptoms and signs may be due to a neurological disorder causing organic brain syndrome, such as rigidity in Parkinson's disease, or may be related to emotional states such as restlessness or tremor in anxiety. However, there is a further group of symptoms, which affect voluntary movements and often occur in functional psychoses. These symptoms are neither unequivocally neurological nor clearly psychogenic in origin and are termed **motility disorder** by some authors. Table 1.7.1 gives a glossary of disordered motility. Whether patients are unable or unwilling to move normally is still a matter of debate. The origin of motility symptoms may well be a functional (rather than a morphological) abnormality of basal ganglia.

A further classification of motility disorder distinguishes psychomotor hyperphenomena (e.g. tic disorder), hypophenomena (e.g. stupor), and paraphenomena (e.g. mannerism). **Tics** are rapid, irregular movements involving groups of facial or limb muscles. **Stupor** is a state in which a patient does not communicate, i.e. does not speak (mutism) or move (akinesia), although he or she is alert. **Mannerisms** are uncommon; they are conspicuous expressions by gesture, speech, or objects (e.g. dress) that seem to have a particular meaning, often delusional.

Catatonia is a psychopathological syndrome of disturbed motor behaviour. It is generally reversible, and it occurs with mood disorders, general medical conditions, toxic and psychotic states, and neurological disorders. Brain tumour, encephalitis, endocrine, and metabolic disorders may elicit catatonic symptoms. In Western countries catatonia is considered, nowadays, to be uncommon in general psychiatric practice, however, some catatonic symptoms have been found to occur in 5–10 per cent of acute psychiatric in-patients.[54]

Table 1.7.1 Symptoms and signs of motility disorder

Catalepsy (synonym; waxy flexibility, flexibilitas cerea)	Maintaining uncomfortable positions against resistance
Posturing	Maintaining uncomfortable positions that may have a delusional meaning
Stupor	Inability to communicate despite being awake
Akinesia	Inability to move
Mutism	Inability to speak
Echolatia	Repetition of another person's speech
Echopraxia	Repetition of another person's acts
Mannerism	Uncommon conspicuous expression by gestures, speech, or objects
Grimacing	Uncommon conspicuous facial expression
Stereotypy	Repetition of actions
Verbigeration	Repetition of speech
Tic	Rapid movements of facial or limb muscles
Akathisia	Inability to remain seated or standing
Psychomotor retardation	Slowing of mental and motor activity
Psychomotor agitation	Arousal of mental and motor activity (typically by anxiety)

Stupor, *mutism*, and *negativism* are the classical triad of symptoms demarcating the catatonia syndrome, and automatic obedience and stimulus-bound behaviour, stereotypy, and catalepsy contribute to the syndrome in manic patients.[55] Lesser symptoms may occur, and catatonia may take the form of hypomobility, with stupor only in extreme cases. Patients in stupor remain persistently unresponsive for hours, days, or even longer. They appear to be unaware of events around them and are mute.

Catatonic excitement presents as excessive motor activity. Such patients may talk incessantly, especially when in an 'exalted stage'.[56] There may be outbursts of talking, singing, dancing, and removing their clothes. Such states carry the risk of exhaustion, dehydration, and injury; it may be harmful and dangerous to the patient and to others.

In **negativism** the patient resists the examiner's manipulations with force equal to that applied by the examiner. In **catalepsy** (posturing), the patient maintains posture for long periods. These include facial postures, such as grimacing or *schnauzkrampf* (lips in a pucker); body postures, such as *psychological pillow* (lying on his back with head elevated as if on a pillow); lying in a 'jack-knife' position; and many other uncomfortable and bizarre postures maintained against gravity or attempts to rectify them. An examiner trying to move a cataleptic limb passively will notice **waxy flexibility**, in which initial resistance to an induced movement changes to gradually allowing the imposition of a posture, like bending a candle.

Stereotypy is non-goal directed, repetitive behaviour, the verbal form of which is called *verbigeration*, endless repetition of phrases and sentences. **Automatic obedience** occurs when, despite instructions to the contrary, the patient permits the examiner to move his limbs into a new posture. This may then be maintained against instructions to the contrary. In **ambitendency** the patient appears stuck in indecisiveness, resisting the examiner's non-verbal signals, but showing hesitancy in doing so.

Echo phenomena may occur when the patient is interacting with another person and present as *echolalia* (imitation of the speech of others) or *echopraxia* (imitation of the actions of others). **Mannerisms** are strange but purposeful movements characteristic of that person. They may be exaggerated caricatures of ordinary movements.

Disordered speech may also be regarded as a sign of disordered motility, as in mutism or verbigeration.

In **delirium**, tremor often occurs. Anxiety is accompanied by restlessness. In a particular motor pattern in delirium tremens (alcohol withdrawal delirium) the patient appears to be collecting objects or brushing away dust. Typically, the movements never seem to achieve what they are meant to and, of necessity therefore, are repetitive. Suggestibility in delirium may lead to movements, which are based on erroneous assumptions, such as trying to take hold of a proffered, but non-existent, thread. Patients may develop panic and try to flee. Speech may be hurried and indistinct. In some cases of delirium, such as that due to hepatic failure, patients may be hypoactive before becoming drowsy and comatose. Hepatic failure may also result in catatonic disorder.

Many conditions, such as brain tumour, encephalitis, and endocrine and metabolic disorders, may elicit catatonic symptoms. Patients with a variety of mental disorders may show abnormal movements that are of histrionic nature. They may throw themselves to the ground, seek and maintain bodily contact, or show psychomotor agitation. Alternatively, there may be psychogenic paresis.

In dementia there may be general disturbance of psychomotor functions leading to disturbed co-ordination and clumsiness. During the further progress of dementia, lethargy, and akinesia may occur.

Sequelae of encephalitis are known to include a number of motor symptoms apart from parkinsonism, as seen in the epidemic of encephalitis lethargica that occurred around 1920. **Tardive dyskinesia** is a side-effect of neuroleptic therapy. However, since signs of tardive dyskinesia such as perioral hyperkinesia and dystonias were described before the introduction of neuroleptics,[57] it is also a motor symptom of mental disorder in its own right.

Disorders of memory

The psychology of memory is discussed in Chapter 2.5.3.

Memory may be differentiated into short-term or recent memory and long-term or remote memory. Furthermore, ultra-short-term memory may be distinguished from short-term memory. Ultra-short-term memory encompasses immediate registration within the span of attention. Short-term memory reflects new learning. Long-term memory is usually associated with earlier data or other information that has been stored for months or years.

Additional terms describing memory functions are *declarative* and *procedural* memory. Declarative memory contains facts, which may be consciously recalled, whereas procedural memory contains skills and automatic activities. In dementia—both degenerative (Alzheimer type) and vascular (multi-infarct dementia)—recent memory is usually impaired earlier than remote memory.

Biographical memory is the recall of events in a person's past, which have an emotional loading, and therefore an impact on understanding depression.

Amnesia is a period of time, which cannot be recalled, and it may be global or partial. With regard to time it may be retrograde—an expression derived from the idea that one is looking backwards from an event (such as brain trauma or electroconvulsive therapy) to find the period that is deleted before the event. Correspondingly, anterograde amnesia means a period of deleted memory after an event. Although it is difficult to distinguish between types of amnesia, focal lesions in the hippocampus seem to affect remote memory less than recent memory, whereas diffuse brain disease often affects both. In psychogenic amnesia it is sometimes possible to recognize specific personal meaning in the events which cannot be recalled.[58] Amnestic disorders should strongly alert the examiner to the possibility of cerebral pathology.

Disorders of memory are closely connected with other disorders, such as disorders of consciousness; there is often amnesia for episodes of disturbed consciousness.

Some patients are aware of memory disorder and complain about it; others tend to neglect their memory deficits and manifest secondary signs such as confabulation. Confabulations are inventions, which substitute for missing contents in gaps of memory; the patient is not aware that they are not true memories.

A disorder of short-term memory, as in Korsakoff's syndrome or transient global amnesia, is often neglected by the patient. Behaviour appears normal, and it often seems that the personality is intact. Such a patient may be engaged in lively conversation or seemingly purposeful actions, and only after further investigation does it become obvious that these activities are not based on facts. This memory disorder can be assessed directly by examining the patient. Other forms become apparent retrospectively on taking the patient's history. In these cases the patient complains about periods of global or partial amnesia. Memory for certain events may have faded or become obscured by layers of other events (palimpsest); this is typical of repeated amnestic periods following bouts of drinking. In mood disorder there may be complaints about impaired memory, although no memory deficit is found in objective tests. Examples of false memory (paramnesia) are *déjà vu*, an erroneous feeling of familiarity with, for example, a person or a room, and jamais vu, a feeling of unfamiliarity for a well-known object. *Déjà vu* may occur in temporal lobe epilepsy, although it is not specific for that disorder. Delusional memories are also examples of paramnesia.

Disorders of consciousness

Consciousness is the sum of various mental functions—in the words of Jaspers[59] 'the whole of present mental life'. Lipowski,[60] who regards the concept of consciousness to be 'completely redundant', describes what is commonly meant by clouding of consciousness on the basis of a number of behavioural features (Table 1.7.2). In contrast with Lipowski, the concept of consciousness has recently elicited fresh interest in philosophy and clinical neurology. (See Chapter 2.1)

Consciousness is a mode of relatedness between mind and world. Disordered consciousness may occur on a dimension of severity, which ranges from lucidity via clouding and then towards unconsciousness. The latter represents a state of coma. In addition, consciousness may be assessed on a dimension of vigilance.[61] Ey[62] regards consciousness as an attribute of wakefulness. Indeed, sleepiness implies a reduction in consciousness; but consciousness may also be reduced despite normal vigilance. Likewise, consciousness is impaired by a disorder of memory, orientation, or coherence, as in the clouded consciousness of delirium.

When consciousness is impaired there is clouding of perception, ideas, and images. The intensity of perception is diminished and there is a disintegration of order in the perceptive field. Accordingly, patients become disoriented.

The term 'confusional state' is a synonym for delirium that emphasizes thought disorder and disorientation. **Disorientation** may concern time, place, or person. Temporal and geographical disorientation are common. Remote contents are better remembered than recent ones; name or date of birth is usually more available than age, or name of the hospital. It is useful, after a polite excuse, to ask direct questions concerning orientation, even if they sound trivial, since some patients are skilful in avoiding topics that show the degree of their disorientation.

Table 1.7.2 Behavioural features indicating clouding of consciousness

The person is awake but may be drowsy
Awareness of the self and the environment is reduced
Both immediate and recent memory are impaired
Thinking is disorganized, and may be dreamlike; for instance perception is faulty and misperceptions may occur
The ability to (learn new material is reduced) learn
The person is unable to overcome this state by deliberate effort

Another abnormality is described by the term **narrowing of consciousness**, which means that awareness of a person's environment is restricted, for example, owing to an abnormal affective or delusional state.

In epileptic aura or after taking certain drugs, consciousness may be experienced as heightened with increased intensity of awareness.

Twilight state is a well-defined interruption of the continuity of consciousness. Consciousness is clouded and sometimes narrowed. Despite the disorder of consciousness, the patient is able to perform certain actions, such as dressing, driving, or walking around. Subsequently, there is amnesia for this state. Twilight states may occur in epilepsy, alcoholism (*mania à potu* is a twilight state), brain trauma, general paresis, and dissociative disorder. *Mania à potu* describes the situation where a person reacts excessively by developing twilight state with small amounts of alcohol. Often these patients have an increased vulnerability due to pre-existing organic brain pathology. Twilight state occasionally leads to violent behaviour.

In an **oneiroid state** the patient experiences narrowing of consciousness together with multiple scenic hallucinations. Oneiroid states may occur in schizophrenia, but are also observed in patients who have to be totally passive and dependent on others. The atmosphere is perceived as strange and dreamlike. Accordingly patients may be aloof and behave like dreamers.[63] Unlike twilight states, the contents of oneiroid states are often remembered.

Disorders of attention and concentration

Attention and concentration imply the directing of mental activities towards a particular object. Attention is associated with present alertness, and concentration with longer lasting achievement and performance; there is a distinction between *selective* and *shared* attention. Attention and concentration may be impaired by clouded consciousness or individual aspects, such as sleepiness, incoherence, or memory deficit. However, there may be other reasons for inattention such as hallucination or mood disturbances. Attention deficit is a permanent feature in the childhood disorder, attention-deficit hyperactivity disorder.

Assessment of attention and concentration may consist of simple arithmetical tasks and include psychometric performance test in addition to the clinical examination. Psychometric performance tests are also valuable tools in assessing disorder of memory and consciousness.

Disorders of sleep are described in Chapter 4.14.

Disorder of personality

It is the expression of disordered personality which is the consideration of descriptive phenomenology, the observation of characteristic behaviour and the subject's self description. Schneider has defined personality as 'the unique quality of the individual, his feelings and personal goals'[64] *Abnormality of personality* is present when a characteristic or trait of clinical relevance is developed in the patient to a statistically abnormal extent, that is either deficient or excessive. *Personality disorder* is present when that abnormality causes suffering to the patient or to other people. A person with antisocial personality disorder not uncommonly causes discomfort to other people; with obsessive-compulsive personality disorder the abnormal characteristics may frequently cause distress to the individual himself.

Both ICD 10 and DSM-IV are derived from Schneider's description of personality types. The advantage of such a typological approach is that it does not imply any specific theory of causation. The accurate description of personality characteristics and type is valuable in clinical practice for diagnosis, prognosis and the rational planning of treatment. The skills of psychopathology are ideally suited to the observation of consistent personality traits, and forming an opinion unprejudiced by preconceived theoretical considerations. Descriptions of different personality types and disorders are developed elsewhere.

Acknowledgements

This revised chapter, prepared by Andrew Sims, is based on that in the first edition by Andrew Sims, Christoph Mundt, Peter Berner, and Arnd Barocka. The contributions of these authors to the original text is gratefully acknowledged.

Assessment

Contents

1.8.1. The principles of clinical assessment in general psychiatry

John E. Cooper and Margaret Oates

Introduction

This chapter is focused on the needs of the clinician in a service for general adult psychiatry, who has to carry-out the initial assessment of the patient and family, working either in the context of a multi-disciplinary team or independently. Within this quite wide remit, the discussion is limited to general principles that guide the practice of all types of psychiatry. The chapter does not include the special procedures and techniques also needed for assessment of children and adolescents, the elderly, persons with mental retardation, persons with forensic problems, and persons requiring assessment for suitability for special types of psychotherapy.

It is assumed that the reader has already had significant experience of clinical psychiatry and has completed the first stages of a postgraduate psychiatric training programme. Therefore details of the basic methods recommended in commonly used textbooks or manuals of instruction for obtaining and recording information on essentials such as the history, personal development, mental state, and behaviour of the patient are not included in this chapter.[1]

Three topics have been given special attention. These are assessment by means of a multi-disciplinary **team**, the trio of concepts **diseases, illness, and sickness**, and the development of **structured interviewing and rating schedules**. The first two have a special connection that justifies emphasis in view of the recent increase in multi-disciplinary styles of assessment. For instance, when different members of the team appear to be in disagreement about what should be done, it is usually a good idea to ask the question: 'What is being discussed—is it the patient's possible physical disease, the patient's personal experience of symptoms and distress, or the interference of these with social activities?' It will then often become apparent that the issues in question are legitimate differences in emphasis and priority of interest, rather than disagreements. The third topic is given prominence in order to illustrate some aspects of the background of the large number of such schedules (or 'instruments') that are now available. They are usually given the shortest possible mention in research reports, but since most advances in clinical methods and service developments come from studies in which an assessment instrument has been used, clinicians should know something about them.

The aim of the initial clinical assessment is to allow the clinician and team to arrive at a comprehensive plan for treatment and management that has both short-term and longer-term components. The achievement of this will be discussed under the following headings.

- Concepts underlying the procedures of assessment
- Contextual influences on assessment procedures
- Assessment as a multi-disciplinary activity
- Instruments for assessment
- The condensation and recording of information
- Making a prognosis
- Reviews
- Writing reports

Concepts underlying the procedures of assessment

The separation of form from content, and from effects on activities

In psychiatric practice more than in other medical disciplines, the key items of information that allow the identification of signs and symptoms of psychiatric disorders are often embedded in a mixture of complaints about disturbed personal and social relationships, together with descriptions of problems to do with work, housing, and money. These complaints and problems may be a contributing cause or a result of the symptoms of psychiatric disorders, or they may simply exist in parallel with the symptoms. A preliminary sorting out into overall categories of information is therefore essential.

The distinction between the form and the content of the symptoms is particularly important, together with the differentiation of both of these from their effects upon the functioning of the patient (function is used here in a general sense as applying to all activities, in contrast to the specific meaning given to it in the classification of disablements). This differentiation is discussed in Chapter 1.7, so only a brief mention is needed here.

The presenting complaint of the patient is often the interference with functions, but enquiry about the reasons for this should then reveal the contents of the patient's thoughts and feelings. The form of the symptoms (i.e. the technical term, such as phobia or delusion used to identify a recurring pattern of experience or behaviour known to be important) allows the identification of the psychiatric disorder. Knowledge of the effects on functions is essential for decisions about the management of patient and family, and is an important aspect of the severity of the disorder.

This sorting into different types of information often implies a conflict of priorities during the interview. The clinician must be seen to acknowledge the concerns and distress of the patient, but also must ask questions that will allow the identification of symptoms. Learning to balance this conflict of interest is an essential part of clinical training, and has been well recognized by previous generations of descriptive psychiatrists, including Jaspers. The separation of the social effects of a symptom from the symptom itself is also a necessary part of the assessment process. Further comments on this and related issues have been made by Post[2] and by McHugh and Slavney.[3]

Categories of information: subjective, objective, and scientific

Is there such a thing as a truly objective account of events? If 'objective' is intended to mean absolutely true and independent of all observers, the answer must be negative. Students and trainee psychiatrists often come to psychiatric clinical work from medical and surgical disciplines where they have been encouraged to 'search for the facts' with the implication that 'true' facts exist. They may need to be reminded that the supposed facts of all medical histories, even those of clearly physical illnesses, depend upon the perceptions, opinions, and memories of individuals who may give different versions of the same events at different times.

'Objective' has several shades of meaning in ordinary usage, but in clinical assessment it's most useful meaning is that an account of an event or behaviour is based on agreement between two or more persons or sources. In contrast, 'subjective' can be used to indicate that the account comes from only one person. Objective information is likely to be safer to act upon than subjective, so efforts should always be put into raising as much as possible of the information about a patient into the objective category. Nevertheless, many of the most important symptoms in psychiatry can only be subjective, since they refer to the inner experience of the one person who can describe them.

When assessing the reliability and usefulness of other types of information, such as the results of treatment or possible explanations of causes, a further useful distinction can be made between objective defined as above and 'scientific', taking this to mean that systematic efforts have been made to obtain evidence based upon comparisons (or 'controls') which demonstrate that one explanation can be preferred out of several possibilities that have been considered.

Simple definitions such as these are useful in clinical discussions, but it must be remembered that in the background are many complicated and unsolved problems of philosophy and semantics. Some of these suggestions on the status of information in clinical work are based upon the writings and clinical teaching of Kraupl Taylor.[4]

Disease, illness, and sickness

These concepts have existed in the medical and sociological literature for many years, and are best regarded as useful but inexact concepts that refer to different but related aspects of the person affected, namely pathology (disease), personal experience (illness), and social consequences (sickness), respectively.[5] They are useful as a trio because they serve as a reminder that all three levels should be considered in a clinical assessment, even though for different patients they will vary greatly in relative importance. There are no simple answers to questions about how they are best defined and how exactly they are related to each other, but time spent on these issues is not wasted because they reflect quite naturally some of the different interests and priorities of the different health professions (and are therefore often the basis of different viewpoints put forward by various members of a multi-disciplinary team).

Another reason for being familiar with these concepts is that in legal and administrative settings, simple and categorical pronouncements about the presence of mental illness or mental disease and their causes and effects may be required whatever the medical viewpoint might be about the complexity of these concepts.

Clinicians of any medical discipline know from everyday experience that the complete sequence of disease—illness—sickness does not apply to many patients. Although disease usually causes the patient to feel ill and the state of illness then usually interferes with many personal and social activities, in practice there are many exceptions. Potentially serious physical, biochemical, or physiological abnormalities (disease) may be discovered in surveys of apparently healthy persons before any symptoms, distress, or interference with personal activities (illness) have developed, and some patients may have either or both of illness and sickness (interference with social activities) without any detectable disease.

A number of sociologists, anthropologists, and philosophers have joined psychiatrists in trying to define mental illness and mental health, but without achieving much clarification. Aubrey

Lewis[6] and Barbara Wootton,[7] although writing from the different contexts of clinical psychiatry and sociology, both arrived at the conclusion that neither mental illness nor mental health could be given precise definitions, although they are useful terms in everyday language (and the same applies equally to physical health and physical illness).

More positive conclusions have resulted from attempts to define disease, in that Scadding (a general physician) has suggested that it should be defined as an abnormality of structure or function that results in 'a biological disadvantage'.[8,9] This seems reasonable if one is dealing only with conditions that have a clear physical basis, but if applied in psychiatry it implies that, for instance, behaviours such as homosexuality that reduce the likelihood of reproduction would have to be regarded as diseases alongside infections, carcinoma, and suchlike. This seems to be stretching a traditional concept too far, and different approaches clearly need to be explored.

One way forward is to accept that simple definitions and concepts encompassed by one word cannot cope with complicated ideas such as disease or health, and to take care to differentiate between definitions of these as concepts in their own right, and attempts to develop **models of medical practice**. The debate noted above refers to concepts of health, disease, and disorder, and it has been continued more recently with respect to psychiatry in two quite extensive reviews, in terms of the types of concepts,[10] and of their possible contents.[11] What follows below is better regarded as about *models of medical practice*, and two points are suggested as a basis for the discussion. First, more than one dimension or aspect of the person affected always needs to be included in descriptions of health status. Second, models of medical practice and thinking do not necessarily have to start with the assumption that physical abnormalities (diseases) are the basic concept from which all others are derived.

Regarding the first point (of more than one aspect or dimension), soon after the contribution of Susser and Watson[5] noted above, Eisenberg, a psychiatrist with social and anthropological interests,[12] made a plea for all doctors, but particularly psychiatrists, to recognize the importance of appropriate illness behaviours in addition to giving the necessary attention to the diagnoses and treatment of serious and dangerous disorders.[13] He gave special emphasis to the need to minimize problems that may arise from discrepancies between disease as it is conceptualized by the physician and illness as it is experienced by the patient: 'when physicians dismiss illness because ascertainable disease is absent, they fail to meet their socially assigned responsibilities'. A similar model with a more overtly three-dimensional structure usually referred to as 'bio-psychosocial' has also been described by Engel.[14] and also by Susser.[15] Historically, all these can be regarded as variations on and explicit developments of a theme that has been accepted implicitly by generations of psychiatrists influenced by the 'psychobiology' of Adolf Meyer and his many distinguished pupils, manifest in the importance given to the construction of the traditional clinical formulation.

The second point, to do with the disease level not being the best starting point for conceptual models of medical practice, is of more recent and specifically psychiatric origin. Both Kraupl Taylor[16] and, more recently, Fulford[17] give detailed arguments for the conclusion that the illness experience of the patient is the most satisfactory starting point from which to develop a model of medical practice. Taylor presents his case as a matter of logic, and Fulford works through lengthy philosophical and ethical justifications. This new viewpoint has the virtue of starting with the encounter between patient and doctor, which has the strength of being one of the few things that is common to all types of clinical practice. In Taylor's terms, by describing symptoms and distress the patient arouses 'therapeutic concern' in the doctor and so first establishes 'patienthood'. Whether or not a diagnosis is reached or a disease is later found to be present, and whether or not the social activities of the patient are also interfered with, are other issues of great importance, but they do not diminish the primary importance of the first interaction; in this, both patient and doctor play their appropriate roles according to their personal, social, cultural, and scientific backgrounds.

If medical training and practice are guided by this model, there is no interference with the essential obligation of the doctor to identify and treat any serious disease that may be present. However, a parallel obligation to satisfy the patient and family that the illness (comprising complaints and distress) and the sickness (interference with activities) have also been recognized and will be given attention, is equally clear.

How to answer questions by the patient and family about whether the patient has a mental illness or not, and what this implies, needs careful discussion. Within a multi-disciplinary team it is usually best for the team to reach early agreement on a particular way of describing the patient's illness so that conflicting statements will not be made inadvertently by different members if asked about it. This is because the patient or family may expect this type of statement, and not because distinctions between, for instance, mental illness and physical illness, or between nervous illness and emotional upset, are regarded as fundamental from a psychiatric viewpoint. This difficult issue will be made easier if something about the patient's ideas about the nature and implications of terms such as 'mental illness' and 'nervous breakdown' is always included as part of the initial assessment information. Similarly, all members of the team need to be familiar with the concept of illness behaviour and the way this is determined by cultural influences[18] (see Chapter 2.6.2).

The diagnostic process: disorders and diagnoses

Psychiatrists learn during their general medical training that the search for a diagnosis underlying the presenting symptoms is one of the central purposes of medical assessment. This is because if an underlying cause can be found, powerful and logically based treatments may be available. But even in general medicine, as Scadding pointed out 'the diagnostic process and the meaning of the diagnosis which emerges are subject to great variation . . . the diagnosis which is the end-point of the process may state no more than the resemblance of the symptoms and signs to a previously recognized pattern'.[8,9] In psychiatry, 'may' becomes 'usually', and this has been recognized by the compilers of both ICD-10 and DSM-IV, in that these are presented not as classifications of diagnoses, but of disorders. These classifications use similar definitions of a disorder; the key phrases in ICD-10 are 'the existence of a clinically recognizable set of symptoms or behaviour associated in most cases with distress and with interference with personal functions', and in DSM-IV 'a clinically significant behavioural or psychological syndrome or pattern that occurs in an individual and that is associated with present distress or disability . . . '.

The use of such broad definitions is necessary because of the present limited knowledge of the causes of most psychiatric disorders, and a similarly limited understanding of processes that underlie their constituent symptoms. To avoid overoptimistic assumptions, there is much to be said for psychiatrists avoiding the use of the term 'diagnosis' except for the comparatively small minority of instances in which it can be used in the strict sense of indicating knowledge of something underlying the symptoms. A consequence of this viewpoint is that the currently used 'diagnostic criteria' in both these classifications should be relabelled as 'criteria for the identification of disorders'.

In spite of this, it must be accepted that the patient and family are likely to expect statements to be made about the cause of their distress and symptoms. The members of all human groups expect their healers to discover the causes of their misfortunes (i.e. to make a diagnosis), and to provide remedies. This is so whether the group is a sophisticated and scientifically oriented modern society, or a non-industrialized society that relies on ethnic healers and folk remedies. The obvious relief of a patient or family on the pronouncement of an 'official' diagnosis is often evident in any type of healing activity, even though the diagnostic terms themselves mean very little. The pronouncement of an official diagnosis is taken to show that the doctor knows what is wrong, and therefore will be able to provide successful treatment or advice. If the diagnosis is expressed in terms that the patient can understand, it will have additional power as an explanatory force.

The readiness of ethnic healers and practitioners of complementary (or alternative) medicine to provide a diagnosis and treatment in terms that have a meaning and therefore a powerful appeal to their customers is probably one of the main reasons for their continued survival and popularity alongside scientifically based medicine. This is a separate issue from the question of whether or not the treatments of complementary practitioners are successful in the sense of having effects that could be demonstrated by means of a controlled clinical trial.

Within psychiatry and clinical psychology, the medical habit of searching for a diagnosis has at times been misunderstood as an unjustified preoccupation with the presence of physical disease as a cause of mental disorders. This was most marked in the United States during the 1950s and 1960s, expressed particularly in the writings of Menninger in which the diagnostic process and attempts to classify patients were dismissed as a waste of time.[19] This viewpoint ignores two points made here and by many others; first, the choice of a diagnostic term is only one part of the overall process of assessment that leads also to a personal formulation. Second, any assessment of a person, whether made as statements about psychodynamic processes, as statements about structural and biochemical abnormalities, or as statements about interference with activities, is unavoidably an act of classification of some sort.

More detailed discussions about the importance of diagnosis have been provided by Scadding[8] as a general physician, and by Kendell[20] and Cooper.[21] as psychiatrists.

Concepts of disablement

Disablement will be used here as an overall term to cover any type of interference with activities by illness. This is often of more concern to the patient than the symptoms of the illness itself, since the fear of long-term dependence upon others is usually present, even though not voiced in the early stages. The question arises whether to leave the description and assessment of disablement to different members of the team as it arises in various forms, or whether in addition to encourage reference to one of the systematic descriptive schemes that are now available. Even if not used as fully as their authors intend, these have the merit of serving as checklists or reminders for the whole team, to ensure that the many different effects of the illness have been considered.

Two widely used descriptive schema are the *International Classification of Functioning, Disability and Health* (*ICF*),[22] and a broadly similar framework described by Nagi[23] that is often used in the United States, particularly by neurologists. These are best regarded as descriptive conceptual frameworks rather than classifications, sharing a basic structure of several levels of concepts. For the ICIDH, these are **functioning**, **disability**, and the **contextual factors (both environmental and personal)** relevant to what is being assessed. These terms and concepts are defined in the manuals published by WHO Geneva. The ICF is published as both a short and a long version, and it is probably wise for interested users to start by examining the short version. As noted in Fig. 1.8.1.1, these three concepts can be put alongside the sequence of ideas that leads from complaints, through symptoms to the identification of disorders or diagnoses. This may represent a causal sequence in some individuals, and this is clearest in acute physically based illnesses. But for many patients encountered in psychiatric practice, whose illnesses often have prominent social components, causal relationships may be absent or even in the opposite direction. For instance, sudden bereavement, i.e. loss of a social relationship, may be the clear cause of interference with the ability to perform daily activities (disability), and also of uncontrolled weeping (an impairment of the normal control of emotions). Social handicaps can also be imposed unjustifiably by other persons, as when a patient who is partly or fully recovered from long-standing psychiatric illness and quite able to work is refused employment due to the prejudice of a potential employer.

Many mental health workers find that to use a scheme such as Fig. 1.8.1.1 or the ICF helps to clarify how different aspects of a patient's problems fit together. Similarly, the different members of the team may be able to see more clearly how their activities with the patient and family complement one another, since the different concepts in the framework correspond approximately with the interests of different health disciplines. Social workers will focus on assessment of work and social relationships, occupational therapists will have a special expertise in the assessment of daily activities, and clinical psychologists are skilled in the assessment of cognitive and other psychological functions. Researchers in the various health disciplines have naturally devised rating scales that reflect their own interests and ideas, independently of the ICF or other overall schema, but it is usually found that such scales correspond quite closely with one or other of the concepts just discussed. The reluctance of both researchers and clinicians to adopt a standard set of terms to cover the various levels or concepts continues to be a problem; the reader needs to be aware that the terms impairment, disability, and handicap are often used synonymously by different authors.

The description of social and interpersonal relationships is in principle included in comprehensive schemas such as the ICF and that of Nagi, but many separate instruments that cover relationships in great detail have been devised over the years by psychotherapists, family therapists, and others.[24–26]

The sequence of assessment: collection, analysis, synthesis, and review

As information accumulates and is discussed, several different but related aspects of the patient and the illness have to be kept in mind. Good psychiatric practice is a part of what is sometimes referred to as 'whole-person medicine' in which at different times the contrasting but complementary processes of both analysis and synthesis of the information available will be needed. The patient must be seen both as an individual with a variety of attributes, abilities, problems, and experiences, and as a member of a group that is subject to family, social, and cultural influences; at different stages in the process of assessment each of these aspects will need separate consideration.

Analysis is needed to identify those attributes, experiences, and problems of the patient and the family that might require specific interventions by different members of the team. This must then be followed by several types of synthesis (or bringing together of information) to enable attempts to understand both subjective and objective relationships between the patient and the illness. First, possible interventions must be placed in order of priority for action. Second, the whole programme needs to be reviewed at intervals so as to assess progress and decide about any additional interventions that are required. At these times of review, and particularly towards the end of the whole episode of illness, global statements about 'overall improvement', or changes in 'quality of life' may be additional useful ways of summarizing and evaluating what has been happening from the viewpoint of the patient.

From complaints to formulation

Figure 1.8.1.1 demonstrates how the information contained in the complaints presented by the patient needs to be sorted out into different conceptual categories so that it can form the basis of actions by the various members of the multi-disciplinary team.

The top box represents the complaints. Unpleasant symptoms are likely to head the list, but inability to do everyday activities or a description of problems with relationships may well come first. Symptoms that give a clue to disorders, diagnoses, and possible treatments may not be identified without close questioning by someone who knows what to ask about.

The second box indicates that the complaints need to be sorted out into symptoms and impairments (an impairment in this sense is interference with a normal physiological or psychological function, as explained below). Some complaints are both symptoms and impairments: symptoms because it is known that they can contribute towards the recognition of an underlying diagnosis or towards the identification of a disorder, and impairments because they indicate measurable interference with the function of a part of the body or of a particular organ. For instance, inability to remember the time of the day is a symptom (disorientation in time) that may contribute towards a diagnosis of some kind of dementia. It is also an impairment of cognitive functioning that is likely to interfere with the performance of everyday activities such as getting up and going to bed at the correct time, and organizing housework.

The left-hand side of Fig. 1.8.1.1 represents the progress towards the identification of a disorder and perhaps even an underlying diagnosis. These are important concepts because they may indicate useful treatments and likely eventual outcomes. The right-hand side shows the progression from impairment of functions of parts of the body or organs, through interference with personal and daily activities to interference with participation in social activities.

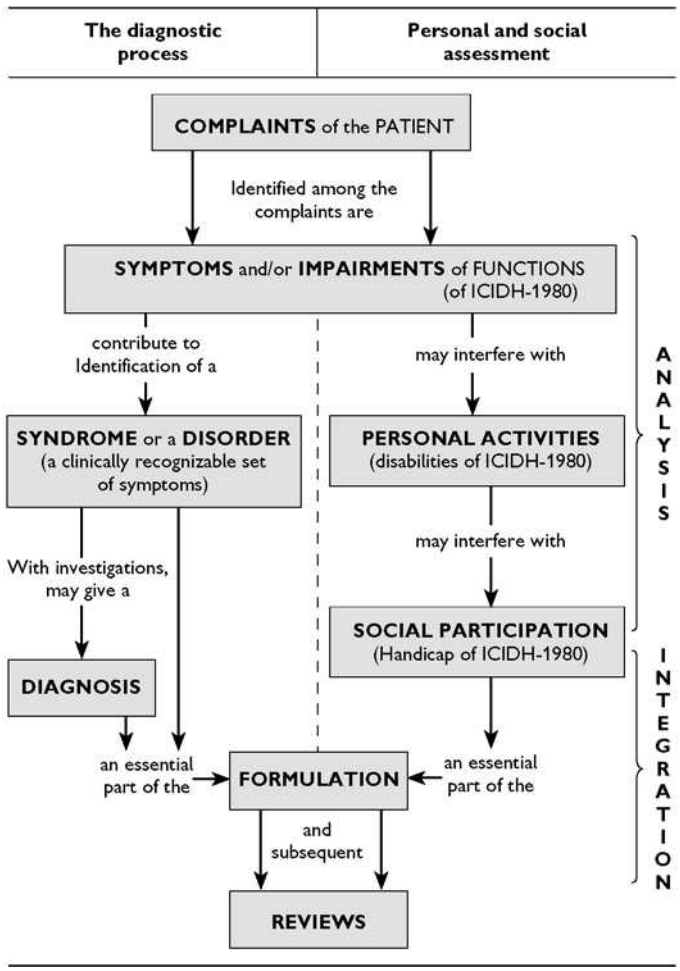

Fig. 1.8.1.1 Analysis and integration of information.

A clinical assessment is not complete until all the components of both sides of Fig. 1.8.1.1 have been considered. In doing this, the different components and the two pathways of concepts will need to be given widely varying emphasis for different patients, and also for the same patient at different times. For instance, if there is a physical cause for a disturbance of behaviour, an accurate diagnosis of this will lead to the best possible chance of rapid and successful treatment. In contrast, if a disturbance of social behaviour has its origin in personal relationships or has been imposed upon the patient by the social prejudices of others, the correct diagnostic category is unlikely to add much. An assessment of social networks and supportive relationships will be more relevant to deciding upon useful actions.

Life events and illness

For clarity, the right-hand side of Fig. 1.8.1.1 is given in a very compressed form, but in practice it is likely to need dividing into several components. The possibility of discovering relationships in time between life events and the onset of symptoms or interference with activities, particularly if repeated, should always be kept in mind, since this may be relevant to management plans and the

assessment of prognosis. The best guide to this will be a lifechart. The opinions of patients and families about the causes of illness must be listened to with respect, while bearing in mind that the attribution of illness to the effects of unpleasant experiences is a more or less universal human assumption that often has no logical justification. Clinicians have to arrive at their own conclusions about such relationships by means of experience, common sense, and some acquaintance with research findings. Researchers seeking robust evidence on this topic are faced with a very difficult task, since the assessment of vulnerability to life events is a surprisingly complicated and controversial issue. The leading method in this field is the Life Events and Difficulties Schedule developed by Brown and Harris; a bulky training manual has to be mastered during a special course, and this then serves as a guide to an interview which may last for several hours. The length and detail of these procedures illustrate well the technical and conceptual problems that have to be faced.[27–29]

Psychodynamics and the life story

'Psychodynamics' refers in a general sense to the interactions between discrete life events, personal relationships, and personality attributes, in addition to its use to cover internal psychological processes (such as defence mechanisms and coping strategies). All of these need to be examined when trying to understand which of several possible causes of an illness at a particular time is the most likely.

A mixture of knowledge about local social and cultural influences and more technical psychological issues is needed for this appraisal of the patient's life story, and suggestions about different components of the overall pattern may well come from different members of the team.

The internal psychodynamics of the patient often need to be considered in detail, and one way to do this would be to construct a subdivision of the right-hand side of Fig. 1.8.1.1 to show interpersonal relationships and psychodynamic processes. In some patients a major conclusion of the initial assessment will be that these aspects are paramount, indicating the need for referral to a specialist psychotherapy service. The assessment of suitability for specific forms of psychotherapy and cognitive behavioural approaches are dealt with in section 6.

Contextual influences on assessment procedures

The place of assessment should not be regarded as automatically fixed in the outpatient or other clinical premises. One or more assessment interviews at home should be considered,[30] since the patient and family may feel much more at ease and therefore likely to express themselves more freely in familiar surroundings, but with the proviso that privacy may be more difficult to achieve. The assessor will often be surprised how much useful information about the home and family circumstances is gained from an interview at home, even when there appeared to be no special reason for this at first. In addition, the behaviour of both the patient and family members in the clinic or hospital is often different from that observed in familiar home surroundings. There are also obvious advantages to both assessment and care at home for mothers who have psychiatric disorders in the puerperium.[31]

Interviews on primary care premises are also often appreciated by patients who dislike going to hospitals of any sort, and the ease of consultation with the general practitioner is an additional advantage. The adoption of regular visits by a consultant psychiatrist to primary care premises as a major element in cooperation between psychiatrists and general practitioners is a style of work that seems to be spreading, with advantages to all concerned.[32]

Privacy of interviewing and **confidentiality** of what is discussed needs careful consideration; there are few absolute rules, but the following points of procedure should be explained clearly to both patient and relatives from the start. First, the patient and any member of the family should know that if they wish they are entitled to speak to the doctor in private, and they must be able to feel that what they say will not be conveyed to any other member of the family unless they request this. Second, in addition to the usual rules of professional secrecy, the patient must agree not to question other family members about what they said to the doctor, and vice versa. These may seem to be elementary points to trained professionals, but they are often not appreciated by patients or relatives who may be in fear of each other, or at least apprehensive about the reaction of the other on learning that statements they might construe as critical have been made about them. These are all points by which trust is established and maintained between patient and doctor, and for the same reason any attempts by relatives to seek interviews on condition that the occasion is kept secret from the patient should be firmly resisted.

An interpreter should always be sought if the patient cannot speak fluently in the language of the interviewer. Mental health professionals who can also act as interpreters are increasingly available nowadays due to the presence of almost all communities of sizeable ethnic minorities. Because of the issues of confidentiality noted above, a professional of the same sex as the patient should always be preferred to family members when interpretation is needed.

Language barriers are usually, but not always, accompanied by a cultural difference. The interviewer must remember that the concept of a private interview between two strangers in which personal and often unpleasant events and experiences are discussed freely comes from 'middle-class western' culture, and is not necessarily shared by persons from other cultures. A discussion of this point before the interview with a mental health professional familiar with the patient's background will help the interviewer to determine what to aim at in terms of intimate or possibly distressing information.

Multiple sources of information are always an advantage for those topics (mainly events) for which objective accounts are possible. Clinical experience is the best guide as to which account to use when conflicts of information arise. Serious conflicts of information arising during the initial assessment that involve the patient's account of events are best resolved by trying to obtain more information. Confrontation of the patient with important conflicts of information should be avoided since it easily leads to misunderstandings. If done at all, confrontation should be reserved for later stages in the overall management when it forms part of a planned intervention with a special purpose.

Assessment as a multi-disciplinary activity

Multi-disciplinary teams can take many forms, varying from the tightly organized and necessarily hierarchical surgical theatre team in which the role of each member is clearly defined and unchanging, to loosely knit groups in other types of health service in which

only some of those attending meetings about patients regard what is taking place as a team event. For the purposes of discussion of the types of multi-disciplinary teamwork increasingly to be found in the mental health services, it is useful to differentiate between multi-disciplinary practice, familiar to many generations of mental health workers, and the more recently evolved multi-disciplinary teamwork. Both of these styles of work have many variations, but they both have some key features that need to be recognized by those involved.

In **multi-disciplinary practice** the consultant or most senior doctor present at clinical meetings or 'ward rounds' is accepted by all as the leader of the group, and listens to (and usually depends upon) the views of the senior nurses and other health professionals who may or may not be present. But the decisions about treatment and management are clearly acknowledged to be the responsibility of the doctors present. In most settings the only essential attendees at these meetings are the doctors and nurses; attendance of other health professionals is usually welcomed and valued, but they are not regarded as necessary members of the group.

Multi-disciplinary teamwork has probably developed in response to a marked increase in the number of social workers, occupational therapists, clinical psychologists, and others, in those medical services in which patients and families with multiple needs are the rule rather than the exception. Clinical skills and techniques that were not previously available are now available, and the health professionals offering these expect quite naturally to be given increased personal and professional recognition; this can usually be found as a member of a multi-disciplinary team of the sort described here. The most fully developed style of multi-disciplinary teamwork involves a very significant commitment of professional time by each member so that all the team meetings can be attended, in addition to the time spent directly with the patient and family.

Some sharing of responsibilities and blurring of roles is needed, but each member also must be seen as retaining the professional skills of their parent discipline. Role blurring is most obvious in the information-gathering and information-sharing phases of assessment, and in the team discussions that lead to agreement about the content of a programme of activities.

Leadership

The concept of a team implies that a team leader is recognized, but a leader does not have to be an obviously dominant speaker and decision maker. Many successful team leaders 'lead from behind' to great effect and to everyone's satisfaction. The main reasons for having an agreed leader are, first, to keep discussions acceptably brief and to a practical timetable; second, to facilitate decisions between reasonable alternatives; and third, to arbitrate when insoluble disagreements arise between team members.

There are a number of settings within the mental health services in which there may be no need for the leader for everyday purposes to be a doctor. This occurs most frequently in special crisis intervention and emergency units, in rehabilitation units, and in services for those with mental retardation. However, members of such teams have to acknowledge that decisions about the presence of physical illness, and the need for medication or laboratory investigations, can only be made by a medically qualified person. The team then has to accept the authority of the doctor on these occasions because of the unique ethical and legal responsibilities that accompany a medical qualification.

In teams running an inpatient unit such as an acute admission ward, there is a clear need for the whole team to accept that medical and nursing members have free access to all the patients for purposes of physical examination, laboratory investigations, the administration of medication, and a variety of nursing procedures.

Key workers and the planning of care

The allocation of a team member as key worker (or case manager) for each patient being assessed is the usual method of work in teams of this sort. Which member becomes key worker for which patient depends upon the ability of the team to match the needs of each patient with the skills available amongst the team members, according to their training. Although all patients are discussed in detail at team meetings, and any team member can contribute suggestions and viewpoints, it is usually accepted that once a programme of activities is identified and agreed upon, most if not all of the contacts with the patient and family will be made by the key worker. The key worker also has the responsibility of reporting back to the team about progress, and about problems encountered which might require new major decisions or changes in the programme.

In the United Kingdom, due to yet another recent reorganization of primary care and hospital services, the situation with respect to urgent assessments and psychiatric emergencies has recently become complicated. Fundamental structural changes are taking place as a result of administrative and financial pressures rather than because of evidence from studies of the previous pattern of services. There is, however, now an element common to all areas in that the provision of a written plan for the care proposed is now a statutory responsibility for all patients. Further changes seem likely, and it is beyond the remit of the general principles of assessment described here to try to describe the present situation in the United Kingdom in detail. Reviews by Burns[33] and others[34] are very helpful guides through the complexities and terms used to cover some of these developments in the United Kingdom.

In addition to the specific medical responsibilities noted above, psychiatrists as members of a multi-disciplinary team have other important areas of expertise that should be recognized by the other members. Experienced psychiatrists are likely to have special skills in the assessment of dangerousness and risks of various sorts, and psychiatrists at any stage in their training should be able to show that they are specially trained to summarize information by the production of an overall *formulation* that reflects the agreed policies of the team.

To be an efficient and accepted long-term member of a multi-disciplinary team of this type requires personal characteristics not necessarily possessed by all mental health professionals. Tolerance of the different viewpoints of other team members is essential, in addition to the professional skills needed to carry-out the work required.

The frequency of team meetings is determined by the size and nature of the workload. Special meetings to discuss topics not directly related to the patients are also usually found to be necessary, so as to deal with issues such as team policies, recruitment and appointments, relationships with outside agencies (for instance about too few, too many, or inappropriate referrals), interpersonal problems between team members, and work-related stress in the team members. This last problem is particularly important in teams dealing with crisis intervention and psychiatric emergencies

because of the need to maintain a rapid turnover of patients and families who are seen over only a limited period of time.

A different type of problem that may need sensitive handling by the team leader and others in authority outside the team itself is the relationship between the team members and their immediate superiors (or 'line managers') in the hierarchy of their own discipline. Each team member has to strike a balance between personal needs for professional supervision and training, and the ability to make decisions within the team because of special skills not possessed by other team members. This type of problem will be minimized if team members are comparatively senior and experienced within their parent discipline. Student health workers are not appropriate as team members, but they can benefit greatly if attached to the team as observers. They will have the opportunity to learn something about how other disciplines operate, which is an aspect of training usually absent from the rest of their training.

Disagreements often arise within a team about the best time for patients to be discharged from care, or about the precise time for referral when it is in the patient's interests to be assessed by another service. In countries where outpatient services and inpatient services are staffed by different teams under different organizations, there will be many such breaks in care, and multi-disciplinary teamwork can become frustrating. But where continuity of care between different parts of the general psychiatric services is the norm, the most frequent changes of care result from the need for the patient to be assessed for more specialized treatment such as rehabilitation, cognitive behavioural therapy, or intensive psychotherapy. The team needs to develop agreed policies for these occasions, and these will depend largely upon the structure of the local services available.

Although no systematic information is available, there is little doubt that the style of multi-disciplinary teamwork just described has become accepted in the mental health services in many countries. Its popularity and success are probably due to the recognition of multiple rather than single needs in a large proportion of psychiatric patients and families, plus an increased job satisfaction experienced by the non-medical team members. Multi-disciplinary styles of working are especially important in emergency psychiatric services and crisis intervention units.[35,36]

Instruments for assessment

Reasons for the development of structured interviewing and rating instruments

The training of all mental health professionals includes instruction in some system of information-gathering and recording based upon a conceptual structure that helps them to organize the large amount of information they usually need to collect. With training, the list of headings under which this information is collected becomes incorporated in the professional's mind as an automatically available guide to the conduct of assessment interviews. For research purposes, however, it is necessary to demonstrate overtly that the essential topics have been covered in a comprehensive and systematic manner. In many types of research not only the headings covered but the detailed items also need to be recorded so that others studying the results of the research can be confident that nothing was missed, and that the information obtained was not a biased selection of the total that might have been available. It has also been generally recognized since the 1950s that for purposes of communication between researchers in different centres, conclusions must be based upon information that has been shown to have a satisfactory inter-rater reliability.

With these aims in mind, detailed and comprehensive structured interviewing and rating schedules for recording many varieties of information have been developed (nowadays these are usually called 'instruments'; for brevity this term will be used to cover any sort of published interviewing and rating schedule). The most common types cover the present mental state and behaviour. Most of these instruments are not appropriate for use in everyday clinical work because they have been designed for research studies, but nevertheless it is useful for clinicians to know something about how they originated.[37]

Since the first appearance of partly or fully structured psychiatric rating instruments in the 1950s, there has been a steady increase in their number, type, and complexity. In the discussion that follows, some of the most widely used instruments are commented upon as examples but many others are available that are not mentioned. Comprehensive lists of such instruments can be found in catalogues of instruments and reviews by the WHO and others.[38–42]

A word of warning is needed about the use of these instruments in ordinary clinical work. Any of them can be used as useful checklists by clinicians to improve the range of information collected. But this does not mean that the quality of information recorded will necessarily be high. Most instruments were originally designed for use in research studies in which they were used by researchers specially trained in their use, and occasional use by untrained staff will not produce information of the same quality and usefulness.

Instruments for the assessment of mental state and behaviour

The instruments now available can be grouped according to the main purposes for which they were designed.

Screening instruments such as the General Health Questionnaire[43] are needed for the identification of likely cases or high-risk individuals amongst large populations. These tend to be short and economical in use, since they have to be administered to large numbers of subjects. They are designed to generate a simple score that indicates the status of the subject in relation to the populations upon which the instrument was developed and validated. This is essential for screening and for epidemiological studies, but this single score does not convey much about the details of the subject's feelings or behaviour, and so is of limited interest to the clinician.

Screening instruments are often questionnaires, defining this to mean that they are simply a means of recording the answers to a set of questions, without any further questions or enquiry about the extent to which the subject understands the question or wishes to qualify answers given. Questionnaires are usually filled in by the subject as a 'paper-and-pencil' exercise, as in the General Health Questionnaire, but one widely used questionnaire that has a very detailed content (the *Composite International Diagnostic Interview*[44,45]) is completed by an interviewer.

Detailed instruments may contain the following:

1 Symptoms of only one type, as in Hamilton's rating scale for depression,[46] or the Scale for Assessment of Negative Symptoms.[47]

2 A selection of symptoms for the study of the relationships between two closely related types, such as depressive and schizophrenic symptoms in the Schedule for Affective Disorders and Schizophrenia.[48]

3 A limited number of items covering different symptoms and behaviour selected as being of special importance, as in the recently developed Health of the Nation Scales of the United Kingdom.[49]

4 A more or less comprehensive array of symptoms that allows the study of the relative distribution of symptoms of many different types, such as Schedules for Clinical Assessment in Neuropsychiatry[50] and the Composite International Diagnostic Interview.[44,45] Other widely used but less tightly structured instruments with a comprehensive content are the Brief Psychiatric Rating Scale[51] and the Comprehensive Psychopathological Rating Scale,[52] aimed at measuring change.

The source and method for collection of information is usually specified by the designers of an instrument. These can include interviews with patients, relatives, and carers, observation of the patient, extracts from other documents, and any combination of these.

The more detailed instruments usually depend upon an interview, and the style of interviewing recommended and the training needed to achieve this depend upon both the quality of the information required and the type of research interviewer for whom the instrument is designed. These vary widely; for instance, Schedules for Clinical Assessment in Neuropsychiatry require a clinical professional training plus a special course for the instrument itself; the Comprehensive Psychopathological Rating scale, the Brief Psychiatric Rating scale, and the *Structured Clinical Interview for DSM*[53] assume a clinical professional training only. The Composite International Diagnostic Interview requires experience in interviewing such as market research plus a special course for the instrument itself, but no clinical professional training.

The time period covered varies from a cross-sectional picture of the present mental state and behaviour ('present' usually being taken to mean the immediately recent period of 2 or 4 weeks), to longer periods of follow-up, personal history, and development, and lifetime histories of psychiatric disorders. The more complicated and lengthy instruments that cover these longer periods are usually designed for particular studies, so are rarely suitable for general use.

Developments since the 1950s

A historical approach is helpful in trying to understand how and why the many instruments now available have developed. Hamilton's Rating Scale for Depression, published in 1959, is a good example of the first generation of instruments, most of which are comparatively short and simple.[46] Its contents can easily be printed on one page, and comprise the following:

1 the names of the symptoms to be rated

2 a rating scale, the same for all the symptoms, by which the presence or absence and the severity of each symptom is recorded

3 a box in which the rating of each symptom is placed

No special recommendations about length and style of interview are given, and no explanations or definitions of the symptoms are given other than what is provided on the rating sheet itself. In other words, the interpretation of the ratings is based on the assumption that the raters have sufficient experience and training to know what most of their contemporaries also mean by the named symptoms. Data analysis is left to the user, other than recommendations about the likely meaning of the sum of the ratings with respect to severity of illness and 'caseness'. This and other early instruments were not tied to the use of any particular set of diagnostic categories, probably because the diagnostic classifications that were available in the 1950s and 1960s were not widely used.

The first generation of instruments made it much easier for researchers to communicate the detailed results of their clinical studies to others, mainly by facilitating the study of changes in symptoms over comparatively short periods of time. The need for this was no doubt connected with the increasing numbers of psychotropic medicines that became available around that time. Measurement of change in symptoms is more immediately useful for the study of response to treatment than reliance upon statements about overall improvement or waiting for a change in diagnosis. But in the absence of guidance about how the symptoms are defined, problems still remain in the interpretation of the results.

Improvements in more recent instruments leading to better quality and meaning of the data they collect have been of two main types, in that the structure and the associated procedures of the instruments have become more elaborate as time has passed. First, the input has been improved by the provision of written descriptions and definitions of symptoms, and by recommending particular styles of interviewing. This implies that researchers using the instrument should carry-out preliminary training work so that satisfactory levels of inter-rater reliability are achieved before starting the main study. Second, the output has been improved by the use of computers to organize and summarize the symptom ratings, allied with the development of widely used psychiatric classifications.

Computer programs based upon decision trees (algorithms) first appeared in the 1970s, and are now commonplace. They allow the specification of sets of symptoms that identify disorders or indicate diagnoses, so that the resulting statements about symptom profiles or the presence of disorders or diagnoses are free from errors of human judgement such as carelessness, simple forgetting, and personal variations from one occasion to the next. But the biases and assumptions built into the programs by their authors still remain, and these may be a problem to others with different opinions.

Programs can also be written to assign disorders and diagnoses according to a selected classification, such as ICD-10 or DSM-IV, and some of the most recently developed instruments such as Schedules for Clinical Assessment in Neuropsychiatry and the Comprehensive International Diagnostic Interview are of this type. When used as intended, the data output from these more recent structured instruments is versatile and of high reliability, but to obtain these benefits the researcher has to pay the penalty of working hard to achieve and to maintain inter-rater reliability.

There are, of course, still plenty of uses for the simpler types of instruments; it is up to those designing and carrying out a study to decide what type of information they need and why, and to select their instruments accordingly. For the sake of those who will be interested in trying to interpret the results, a justification of the

quality of the information obtained should always be included in the description of the findings.

Once an instrument (or often a related group of instruments) has demonstrated its usefulness it is likely to stay in use for many years, while at the same time being subject to extensions and improvements. Families of instruments and traditions of interviewing style therefore develop and persist in the major research centres and groups, and it is possible to identify some of these and follow them over the years.

Three such traditions of instrument development are selected for mention so as to illustrate the continuity and close relationships that sometimes exist between different instruments; these relationships may not be apparent from reports of studies in which they have been used. Three research centres that have produced particularly prominent sets of instruments are the Medical Research Council Social Psychiatry Unit at the Institute of Psychiatry in London, Biometrics Research at the New York State Psychiatric Institute at Columbia University, New York, and the Department of Psychiatry at Washington University, St Louis, Missouri. The instruments mentioned below are only a small proportion of the many in the literature, but they are well known because of their association with some large collaborative international research studies and with widely used classifications of psychiatric disorders such as ICD-8, ICD-9, and ICD-10, and DSM-III, DSM-IIIR, and DSM-IV.

At approximately the same time in the early 1960s, but independently, research groups headed by John Wing, at the Institute of Psychiatry of the University of London (at the Maudsley Hospital), and by Robert Spitzer, at the Biometrics Research Unit at the New York State Psychiatric Institute at Columbia University, began to produce structured interviewing and rating schedules that provided extensive coverage of symptoms and were accompanied by recommendations for training procedures.

The present state examination

The present state examination (**PSE**)[54] is a semi-structured procedure, based upon an interview schedule containing items that are rated as the interview proceeds. The content of the PSE has always been more or less comprehensive and it contains a number of symptoms, such as worry, muscular tension, restlessness, etc. that are not associated with particular diagnoses. These symptoms are included because they are often clinically obvious and also important to the patient (see comments below on 'bottom-up' and 'top-down' organization of interview schedules).

The ratings made by the interviewer do not depend entirely upon the immediate reply of the subject, but represent the interviewer's clinical judgement as to whether or not the subject has the symptoms as described in the glossary of definitions learned during the interview training. Questions are provided for all the symptoms and items and are used whenever possible in the order provided, but the order may be varied if the interviewer thinks fit. The interviewer is also encouraged to ask any other questions that seem relevant to determine the timing, frequency, and severity of the symptoms, as in an ordinary clinical interview. In other words, the interviewer aims to conduct a clinical interview that has been structured as much as possible so as to allow symptoms to be rated with high inter-rater reliability, but without seeming to be unpleasantly rigid to either the subject or the interviewer. Much practice and training are required before these aims can be achieved, but there is no doubt that it is possible.

The PSE was not developed with any particular diagnostic classification in mind. It was intended from the start simply to be a means of arriving at a comprehensive and defined set of symptoms described in a reliable manner, with the user being left to decide whether and how to condense the symptoms into groups and what to do with the results. This is sometimes referred to as a 'bottom-up' style of instrument organization. Versions 7 and 8 of the PSE were first used on a large scale in two studies that involved international collaboration and comparisons, namely the United States–United Kingdom Diagnostic Project between London and New York,[55,56] and the International Pilot Study of Schizophrenia coordinated by the WHO, Geneva.[57] Since then its content has been revised and extended as versions 9 and 10, but the techniques of interviewing and rating remain the same. PSE-10 is one of the main components of Schedules for Clinical Assessment in Neuropsychiatry.

Schedule for affective disorders and schizophrenia, and the structured clinical interview for DSM

The series of instruments developed by Spitzer and his colleagues at Biometrics of the New York State Psychiatric Institute have been of several different kinds and, in the early years at least, had a much more rigid structure than the PSE. Users of the Mental Status Schedule and the longer Psychiatric Status Schedule were instructed to follow the order of the questions as printed in the schedule, the only deviation from this being a repetition of the same questions if thought necessary by the interviewer. However, later instruments such as the Schedule for Affective Disorders and Schizophrenia[48] and, more recently, the Structured Clinical Interview for DSM-III and DSM-IV[53] allow more flexibility for the interviewer in both interview style and the choice of a little or a lot of training (despite its length, the Structured Clinical Interview for DSM is recommended for clinical use as well as for research). There has also been an increasing tendency for instruments from the New York group to be dedicated to a particular purpose. For instance, the content of the Schedule for Affective Disorders and Schizophrenia is keyed towards the study of relationships between schizophrenia and affective disorders, and the Structured Clinical Interview for DSM contains only those items that are necessary for identifying disorders present in the corresponding DSM. Like the Diagnostic Interview Schedule mentioned in the next section, the Schedule for Affective Disorders and Schizophrenia and the Structured Clinical Interview for DSM have a 'top-down' structure, meaning that their content is determined from the start by an already existing set of criteria or symptoms.

The instruments produced by these two centres in the 1960s and 1970s have been used widely in many countries, and their success led to the production of many similar instruments by other researchers. The adoption of the PSE for use by the WHO in a number of international collaborative studies also led to its being translated into more than 25 languages, with varying but never extensive degrees of adaptation to fit the different cultures and social settings involved.

The diagnostic interview schedule

The third major research group is based at Washington University, St Louis, Missouri, and is well known as the originator of the first widely used sets of *Diagnostic Criteria for Research*.[58] Following the publication of DSM-III in 1980, there was considerable interest

in discovering how the disorders it contained were distributed in the American population. Supported by the National Institute of Mental Health, Lee Robins and her colleagues designed the Diagnostic Interview Schedule (**DIS**)[59] for this purpose. This is composed of questions covering the symptoms required to identify what were considered to be the 15 most important disorders in DSM-III. The Epidemiological Catchment Area study of the National Institute of Mental Health, the very large study in which the DIS was first used, included a population sample of more than 18 000 subjects in five largely urban areas.[60]

So as to avoid the costs and other problems involved in employing trained psychiatrists or psychologists as interviewers, the DIS was designed as a highly structured questionnaire administered as an interview by lay interviewers. The interviewers, usually already experienced in interviewing for market research, had to undergo a week-long intensive training course on the DIS. The DIS questions must be given in the order printed in the schedule. Possible symptoms are not rated as present if in the opinion of the subject they may be due to physical disorders, but there is no free questioning about timing, severity, and other details of the symptoms. Questions may be repeated, but only questions provided in the schedule may be asked of the subject. This is a very different concept from that of the PSE technique, and it is based upon the assumption made by the designers of the DIS that by controlling the interviewer in this way, the DIS would 'enable the interviewer to obtain psychiatric diagnoses comparable to those a psychiatrist would obtain'.[60] Put in another way, this is an assumption that expressed complaints can be used as near equivalents of inferred symptoms for the purposes of identifying psychiatric disorders.

Schedules of clinical assessment for neuropsychiatry and the composite international diagnostic interview

Although originating from different groups with different traditions and purposes, the PSE and the DIS have now given rise to direct descendants, namely the Schedules of Clinical Assessment for Neuropsychiatry (**SCAN**) and the Composite International Diagnostic Interview (**CIDI**), that are closely connected. During the early 1980s, a collaborative programme of work between WHO and the National Institute of Mental Health of the United States (known as the Joint Project) resulted in the transformation of DIS into CIDI[61] by increasing its contents by adding large parts of first DSM-IIIR and then of the drafts of ICD-10 and DSM-IV. This was matched by the evolution of PSE-9 into PSE-10, the centrepiece of SCAN,[50] whose content similarly covers almost all of both ICD-10 and DSM-IV. The only sections of ICD-10 and DSM-IV not now covered by SCAN and CIDI are those dealing with disorders of adult personality, disorders of childhood and adolescence, and mental retardation.

The coordination by WHO of the development of the final stages of SCAN and CIDI has been aimed at the production of two instruments with different but complementary uses in epidemiological studies. CIDI can be administered to comparatively large numbers of subjects in the community since the use of lay interviewers keeps costs to a minimum. SCAN is more suitable for the professional (and therefore more expensive) assessment of subjects with obvious or severe disorders, whether these have been selected from a larger population by means of CIDI or other screening instruments, or whether they are being studied clinically for other reasons. The latest development in this long-term programme has been the establishment of WHO-sponsored training centres in a number of countries. Psychiatrists and other mental health professionals can now obtain the necessary training for both SCAN and CIDI in English, French, German, Spanish, Chinese, Japanese, and Arabic.[61]

These and other instruments will no doubt be developed further, but every new instrument and every change to an existing one carries with it problems of data interpretation. Even though the content of changed or new instruments may seem to be the same as their predecessors, quite small changes in the method or the sequence of questions may have important effects, particularly for highly structured instruments in which the ratings are not filtered through the clinical judgement of a trained mental health professional. For instance, a recent report from the United States[62] discusses the possibility that the differences in prevalence rates for some disorders found between the Epidemiological Catchment Area study[60] and the more recent Co-morbidity Study[63] are due at least in part to changes in the 'stem questions' that introduce other specific questions rather than being due to real differences in the community subjects.

There are also unsolved problems in the study of individuals in the community, who have not sought professional help, by means of instruments originally designed for the study of psychiatric patients already in contact with services. To fulfil the criteria for a psychiatric disorder does not necessarily indicate a need for treatment, since the assessment of 'caseness' requires more than a simple count of symptoms. The debate about this problem has now stretched over 20 years, but needs to continue,[64,65] together with further examination of the closely related topic of clinical validity.[66]

Other selected issues

The importance of **negative symptoms** in the assessment of individuals with schizophrenic syndromes has led to the development of instruments devoted to these symptoms; the Scale for the Assessment of Negative Symptoms[47] is one of the most widely used, particularly in the United States. The Psychological Impairments Rating Scale (WHO/PIRS)[67] has been found to be acceptable in a variety of cultural settings, and has been used in several large international collaborative studies coordinated by the WHO. Both these instruments and a variety of others are useful as checklists for ordinary clinical purposes.[68] However, because of the nature of the symptoms being assessed, most of them are still beset with significant problems about inter-rater reliability and the exact meaning of their constituent items.

The **assessment of personality** poses special problems because to obtain a satisfactory account of a individual's personality, however the concept is defined, requires much more than the views of that individual; additional accounts of personal development and relationships from relatives or close friends are needed for comparison. Current concepts of personality disorders as listed in ICD-10 and DSM-IV also have serious limitations; the problems are well illustrated by a recent large international collaborative study coordinated by the WHO, using the International Personality Disorder Examination (IPDE).[61] Several hours of skilled interviewing are required, with at least two informants, to cover the content of the items that are needed to identify the disorders of adult personality contained in both the above classifications.

This study and others with similar aims have found that if an individual fulfils the criteria for one disorder of personality, they are quite likely to fulfil the criteria for at least one more. This implies that the present categories reflect only parts of the overall personality; this may be quite useful, but a fairly drastic overhaul of the currently used categories is clearly needed.

Clinically, it is useful to assess three aspects of personality, according to the salience of personal characteristics and problems arising from them. First, one or more of the personality disorders described in ICD-10 or DSM-IV should be used only if there are quite clear accounts of repeated problems and behaviours as specified, and they are not due to symptoms of any other disorders that may be present. Second, for less severe but repeated problems and behaviours, the concept of 'accentuated personality type' is often useful, described simply by a short list of ordinary adjectives. These indicate recurring behaviours and attitudes likely to cause a variety of mild interpersonal or social problems, again not attributable to symptoms of other disorders. Finally, even though neither of these first two types of personality disturbance is present, it is always worthwhile describing the usual characteristics of the patient by means of a few adjectives (such as 'a worrier', somewhat shy and socially inhibited, definitely gregarious, etc.). Vaguely optimistic terms commonly offered by friends and relatives, such as 'happy-go-lucky', should be avoided.

Multiaxial descriptive systems (often optimistically called classifications) have been available for many years,[69] and now apply to both ICD-10 and DSM-IV. Multiaxial systems describe several aspects of the person in addition to the disorder, and can be regarded as providing a systematized formulation that facilitates the coded recording of several aspects of the person concerned. Most of them have been designed more for research than for everyday clinical use, but they can all serve as very useful checklists when preparing for clinical reviews. DSM-IV, like DSM-III, is presented as a multiaxial scheme covering five aspects of the subject (Axis I, clinical disorders; Axis II, personality disorders and mental retardation; Axis III, General Medical Conditions; Axis IV, Psychosocial and Environmental Problems; Axis V, Global Assessment of Functioning). Similar instruments are now available for ICD-10,[70] covering general adult psychiatry and the psychiatry of childhood and adolescence (see Chapter 1.9 and 9.1.1).

Quality of life has come to the fore in recent years, but in the same way as for multiaxial assessment, to use this term does no more than make explicit something that has always been implicit in a good clinical assessment. Examination of the content of the many assessment instruments that are now available with this title shows that they contain various mixtures of almost every possible attribute of the person, the illness, and the environment. There is no point in using a new term when the information collected refers only to already familiar problems such as symptoms, disablements, how the patient's time is occupied, and contacts with medical services. There is even a considerable literature on the 'quality of life' of whole communities and countries, in which indices are calculated from national or regional statistics about, for instance, standards of housing, education, transport, and consumption of material resources. Such indices are of value to economists and demographers, but are far removed from clinical assessments. There is much to be said for using the term in clinical work only when it indicates 'higher-level' value-judgements and concepts such as personal satisfaction, self-fulfilment, and freedom from distress. Most of these are subjective and difficult to measure, but in many ways they reflect the ultimate aims of all medical care. An excellent recent review of this topic from the viewpoint of psychiatry is available,[71] which illustrates well the wide range of subjects now covered by the term.

Service research into the closely related **needs assessment** has resulted in the production of some detailed instruments that, again, are of interest to clinicians largely as potential checklists. A good example from the United Kingdom is the MRC Needs for Care Assessment.[72]

Administrative pressure to provide some sort of **quantification of clinical outcome** has resulted in several comparatively brief instruments designed for clinical use. Two widely used examples are the Global Assessment of Functioning (**GAF**) scale (Axis V of DSM-IV) and, in the United Kingdom, the recently developed Health of the Nation Outcome Scale (**HONOS**).[49]

In both of these, the assessor uses whatever information is available about the patient to make judgements about the presence and severity of symptoms and troublesome behaviour, and the extent to which these interfere with activities, relationships, and social performance. In the GAF scale this is expressed as a single overall score. In HONOS, 12 separate ratings are made which can be used independently, or added together to give an overall score if required. This type of instrument is likely to become increasingly important as the demand for 'evidence-based medicine' spreads, since they are designed for use by virtually any health professional in almost any setting. So long as precautions are always taken to ensure that the ratings made are as reliable and as valid as the setting permits, and likely sources of bias and error are kept in mind, their use can be a valuable aid to many forms of clinical assessment.

One further example of a **comprehensive assessment instrument** should be mentioned because it was designed for both research and clinical purposes, and it has been at times widely used in a number of European countries. The ADMP (an acronym in both German and English for the Association of Methodology and Documentation in Psychiatry) exists in English, German, French, Spanish, and Japanese versions, covering virtually all the information needed for a comprehensive assessment by means of lists of items to be coded as present or absent. It is up to the user to decide the meaning of each item, and how much to train with fellow raters (or not) so as to improve inter-rater reliability.[73]

The condensation and recording of information

Summary and formulation

The skills required to produce summaries and formulations should be acquired early on in professional training, since they are central to the process of getting the information about the patient into a form which facilitates the making of decisions and the allocation of priorities for actions. Useful preliminaries to the writing of both summary and formulation are the preparation of a problem list and a lifechart; how to prepare these should also be covered in the early stages of training. The summary for an individual patient should be more or less the same whoever prepares it, since it should be a simple record of what is known, arranged under conventional headings. A 'telegram' style of writing is acceptable for the sake of brevity. In contrast, a formulation should be written as a grammatically correct narrative, and there is no necessary expectation

that two different clinicians using the same summary about a patient would arrive at exactly the same conclusions in their formulations. This is because a formulation is an attempt by the writer to understand, and therefore to some extent to interpret, what has been influencing (and perhaps causing) the feelings and behaviour of the patient, and what relationships might exist between life events, illness, and contact with medical services.

Like the rest of the written medical records, the summary, formulation, and problem lists should be regarded as being as much for future readers as for the present carers. A clearly written summary and a well-argued formulation recorded in the case records will ensure that the reasons for treatments and decisions to do with the present illness are clear, and will be of great help to others if the patient has to be assessed in subsequent episodes of illness.

Summaries and formulations written by psychiatric members of a multi-disciplinary team should be freely available to all the team, so that they can be discussed before the meetings at which a diagnosis is agreed and care programmes are set-up. But it is not usually appropriate to send summaries and formulations made for hospital and team purposes to general practitioners or to consultants in other specialties. Specially written and shorter letters are best for this, taking into account the possibility that the patient or family may gain sight of, or even be shown, documents about them sent to other medical professionals.

Differential, main, subsidiary, and alternative diagnoses

A differential diagnosis should be placed in the case records in a prominent place, with a clear indication of who made it ('diagnosis' will be used in this section because of current conventions, but the difference between identifying a disorder and inferring an underlying diagnosis already noted must be kept in mind). When the patient suffers from more than one disorder it is usually possible to select one as the main diagnosis and specify the other(s) as additional or subsidiary diagnoses. The main diagnosis will usually be the one that is leading to immediate action, but the choice may depend upon the purposes for which the diagnoses are being recorded. Usually it reflects the reason for the current contact with services or admission but there are patients and occasions when, for instance, it makes more sense to record a lifetime diagnosis (such as schizophrenia or bipolar disorder) as the main diagnosis, even though something else such as anxiety or a phobic disorder is the reason for the current episode of care.

When one main diagnosis clearly applies yet does not account for some symptoms which, although a significant part of the clinical picture, still fall short of fulfilling the criteria for another disorder, it is useful to record these simply as 'additional symptoms' (for instance, depressive disorder with some obsessional symptoms; agoraphobia with some depressive symptoms, etc.). Neither ICD-10 nor DSM-IV mention this way of recording symptoms 'leftover' after the main disorder has been accounted for, even though it is a useful clinical custom familiar to many generations of clinicians in a variety of countries. However, omission from formal classifications should not be allowed to inhibit clinicians from following clinical habits they find useful.

When there is reasonable debate about what is the best diagnosis out of two or more possibilities, one must be chosen provisionally as the main diagnosis as a basis for action but the other should be recorded as an alternative diagnosis. It is also good practice in quite early stages of the assessment process to record provisional diagnoses, which can then be changed as more information becomes available. About a third of psychiatric patients fulfil the criteria for more than one disorder as defined in current classifications, but as already noted, this does not carry the same implications about underlying morbid physiological, psychological, or anatomical processes as would a statement about the presence of the same number of medical or surgical diagnoses.

Making a prognosis

The final statement in the formulation should be the prognosis. This attempt to predict what will happen to the patient in the future should be expressed as clear statements about likely outcomes, avoiding vague comments such as 'the prognosis is guarded' (found all too often in case records). The patient and family usually hope to be told about the prospects for recovery and the likelihood of relapse. Efforts should be made to do this, but with due care to emphasize that a prognosis is only an estimate that may be proved wrong by events. A prognostic statement should contain predictions of such things as:

1 immediate response to treatment, assuming compliance
2 duration of this episode of illness and/or stay in hospital
3 degree of recovery from this illness (i.e. partial or complete) in terms of both symptoms and return to previous activities
4 risk of recurrence, stated as the likely position at specific points in time, depending upon the circumstances of the case (6 months, 1 year, and 2 years from the present are often appropriate)

However difficult it may seem, attempts should be made to record a prognosis in these terms, and to sign it. To do this will fulfil the legitimate expectations of the patient and family, and the clinician will make possible a uniquely valuable learning experience when faced in the future with such statements about those patients seen in further episodes of care.

Reviews

The initial assessment should produce a list of agreed actions to be carried out in a stated order of priority by the various members of the team. Division into immediate and medium-term actions will help the whole process, and also indicate the timescale of reviews to assess progress. One of the main functions of the acknowledged team leader is to keep an eye on the progress of all the patients in the care of the team, discussing with each key worker both outside and within team meetings the best timing of the next review. Review meetings should be recorded as such in the case documents, with conclusions about progress made and any changes in plans or objectives. It is particularly important, again for future readers of the records, to write down clearly whether there was any response treatment (it is very frustrating to read in a case record of treatments given in the past, and then to find no indication of the result.)

Writing reports

Consultant psychiatrists are often asked by external agencies to provide written reports on patients for whom they have a current

clinical responsibility, and requests may also be received for a report on a patient they have not seen previously. The purpose of these external reports is usually different to that of the usual clinical communications undertaken in the ordinary clinical care of the patient, in that the request is usually for an opinion about one specific issue. These requests frequently involve an opinion on the risk posed to others by the patient's inability to perform certain skills, or by the positive adverse effect of the patient's problems on others. An opinion on the capacity of the patient to understand and competently agree about important issues is also frequently requested.

The purposes of reports

Reports requested by individuals or agencies (both judicial and non-judicial) will usually fall into one of four broad groups:

1 Protection of the public or an institution:
   (a) life assurance and mortgage companies who are interested in the risk of suicide, or loss of earnings due to future illnesses;
   (b) licensing authorities and transport companies who are concerned with fitness to drive or risks due to the public, due to impairment of skills and judgement consequent upon psychiatric illness;
   (c) employment and benefit agencies who are concerned with fitness to work;
   (d) employers or occupational health physicians who are concerned about the risk posed by the patient's psychiatric disorder to an institution's clients, or about the likelihood of periods of absence because of sick leave.
2 Protection of the patient:
   (a) solicitors or courts may require reports on the competence of individual patients to conduct their financial affairs, to protect themselves from exploitation, and to engage in civil contracts;
   (b) bodies concerned with the Mental Health Act (in the United Kingdom the Mental Health Act Commission and Mental Health Review Tribunals) may require reports on the competence of individuals to give informed consent to non-voluntary psychiatric treatment or inpatient care, and the risk to the safety and well-being of the individual patient posed by such treatment.
3 Child protection:
   (a) Social Services Child Care Departments and others involved in the welfare of children may request reports of the supervising psychiatrist for Child Protection Case Conferences on the contribution of a psychiatric disorder to the childcare problem, and on the likely impact of the psychiatric disorder on the future parenting of the patient;
   (b) solicitors acting for all parties in childcare proceedings (the child, the Social Services Department, and the patient) may ask for a psychiatric report on a mentally ill parent about the likely risk to the child of suffering significant physical, developmental, or emotional harm from the patient in question.
4 Medico-legal and compensation proceedings: lawyers acting for either the patient or an agency being sued may ask for a report on the impact of the event on the mental health of the patient, together with the nature of the psychiatric disorder and its prognosis. Such reports may be requested of the supervising consultant, or of another psychiatrist as an independent expert.

Reports for forensic or criminal proceedings are dealt with in Chapter 11.15.

Guiding principles

The general principles noted below apply to all reports, whether the psychiatrist knows the patient because of current or previous clinical responsibility, or whether the report is on a patient whom the psychiatrist has not seen before (this latter is known as providing an 'expert opinion').

(a) Confidentiality

In most situations written consent must be obtained from the patient before personal information can be given to an outside agency. In almost all situations involving the writing of a report on an individual to an outside agency, that individual will gain sight of the report or will be entitled to do so. It is therefore good clinical practice for the patient to be aware of the content of the report, and particularly of any opinions or recommendations it may contain. Nevertheless, there are certain situations where the duty of care to the public or to a child overrides the duty of confidentiality, and in such circumstances the psychiatrist may write the report even without the patient's consent.

(b) Partiality

The opinion of the psychiatrist is being sought as an expert professional. The report should not be biased in favour of one side or another and should not be influenced unduly by the interests of the commissioning agency or the psychiatrist's view of the best interests of their patient. This may cause difficulties if the patient is in the personal care of the psychiatrist because in most clinical situations psychiatrists try to be non-critical, non-judgemental, and supportive, tending to encourage rather than to prevent. But the best interests of the patient will not be served by being put in a situation where the likely outcomes are failure to do what is expected or to function at a suboptimal level.

Structure of reports

All reports should have three main sections. First, the report should begin with the patient's personal details and the reasons for which the report has been requested, together with the identity of the commissioning agency. It should also specify the relationship between the writer and the patient. If the patient is or was in the clinical care of the writer the duration of the care should be noted, and the date of the last occasion the patient was seen should be given. If a special interview had to be arranged with a patient not previously known, the duration and date of the interview should be stated. The sources of information other than the patient used to prepare the report should then be detailed, plus any other documents that have been read. Reports for civil, judicial, and child protection proceedings will also require a short paragraph on the current employment and status of the author of the report, and a note of any special experience of relevance.

The second section should describe in appropriate detail the patient's personal, social, medical, and psychiatric history, the mental

state and behaviour at examination, the diagnosis and differential diagnosis, and comments upon aetiology, management, and prognosis. In almost all reports, the prognosis is the primary concern, so this should be given special attention. It is important to remember that one of the most reliable predictors of the recurrence of behaviours or episodes of illness in the future is the frequency of their occurrence in the past. Similarly, the vulnerability of the patient in the past (that is, any enduring predisposing factors and patterns of past precipitants) will tend to predict future vulnerability and the likelihood of further episodes of illness. Some mention of the past will therefore always be necessary, but in many instances this can be brief and reduced to a commentary of a few lines. But in other situations, particularly those involving civil court actions or childcare proceedings, a more detailed account of the past will be necessary.

Certain aspects of the patient's past history and previous levels of functioning will need to be highlighted depending upon the purposes of the report and the nature of the questions asked of the psychiatrist. For example, if the report has been requested by an occupational physician about the fitness of a patient to return to work, then attention will need to be paid in the report to the duration of illnesses in the past and the amount of sick leave that has been taken. Detail will need to be given about the impact, if any, that the patient's ill health has had on the past to his or her capacity to work. If the report has been requested in relation to the safety of the patient to care for a child, then information will need to be given in the past history of the patient about the previous impact of the patient's illness on his or her capacity to care for children or any risks that the patient posed to a child in the past. Life assurance and mortgage companies are likely to be particularly interested in suicidal behaviour.

The last section should contain the opinion of the psychiatrist about the specific questions posed by the commissioning agent. These questions may be unrealistically simple or there may be requests for categorical assertions of outcome that are simply not possible. The writer must avoid falling into the trap of complying with unreasonable requests about certainties. One way of avoiding this is to give opinions about risks or outcomes by stating criteria that would indicate different outcomes with different likelihoods, expressed by words such as possible, probable, and definite.

In situations where one of the variables involved in the patient's prognosis is the response of helping agencies and the availability of resources, great care must be exercised on the part of the report writer to ensure that this contingency is made clear. If possible, suggestions should be made as to how the availability of the required resources can be assured. When considering the likely impact of a future breakdown in the mental health of a patient on some other person, such as a child, consideration should be given not only to the direct impact of the illness but also to the indirect consequences and the presence or absence of other protective factors. For example, if a woman with schizophrenia lives with her parents who can safely take over the care of her child, then the impact of a further episode on that child may be much less than if she is living alone and the child needs to be removed into the care of the local authority.

An opinion is often requested on whether an accident or an act of omission such as medical negligence caused the current psychiatric disorder or disabilities of the patient. If the psychiatrist concludes that the accident or omission was definitely a contributing cause but not in itself sufficient to cause all aspects of the existing disorder and disability, then further comments will be expected on other possible contributing influences, such as predisposing personal traits, or special vulnerability to current adversities. In such circumstances, there should be an attempt to weigh the contributing factors in order of their aetiological importance.

The last section of the report is usually the best place to list the sources of information used for the report, making clear distinctions between personal observations and information obtained by the writer, opinions and observations made by other team members, and written information obtained from other documents. There should always be a clear distinction between opinions based upon objective information and direct examination, and suppositions based upon interpretations, speculation, and past clinical experience. If opinions based upon research conducted by others are given, then the sources of this information should be acknowledged and referenced in the usual manner.

The language of the report should be appropriate to the commissioning agency. If the report has been requested by an occupational physician or medical officer working for a company, then it is appropriate to use accepted medical and psychiatric terminology. If the report has been requested by a civil or judicial authority, non-technical language should be used wherever possible and any medical or psychiatric terms used should be defined. At all times when writing psychiatric reports it is important to use psychiatric terms in an appropriate fashion according to a stated international classification, and to avoid idiosyncrasies.

1.8.2 Assessment of personality

C. Robert Cloninger

Introduction

The assessment of personality provides the context needed to understand someone as a whole person with particular goals and values that they pursue with a unique emotional style. A person's way of adapting to life experience can tell an experienced clinician much about his level of well-being and his vulnerability to various forms of psychopathology. Knowing a person's personality well can allow a psychiatrist to predict what other mental and physical disorders are likely to occur in the same person or in the same family. For example, individuals with antisocial personality are more likely to have substance abuse and less likely to have Parkinson's disease than others.[1] On the other hand, if you learn someone has substance abuse, then you can reasonably suspect that they may be impulsive or novelty seeking. Recognition of the many associations between personality and psychopathology can greatly enhance clinical assessment and differential diagnosis in general.

Assessment of personality also helps to establish a therapeutic alliance and mutual respect, because it involves the sharing of unique personal and social information that distinguishes one person's style of life from others. Patients feel understood and appreciated when their psychiatrist understands their motivation and can predict their reactions to different situations and people. On the other hand, no one likes to be reduced to a 'case' or a 'label'. Everyone is unique, and yet it is possible to explore the mystery of each person's uniqueness in a systematic way. Consequently, effective clinical assessment of personality is designed to understand a person's emotions, goals and values, strengths and weaknesses in the context of the narrative of his life.

Understanding personality also helps in treatment planning because people differ markedly in the types of treatments to which they respond and with which they will comply. For example, personality traits predict much of the variability in response to antidepressants, whereas the symptoms of depression or other psychopathology do not.[2,3]

Fortunately, personality can be well assessed clinically without psychometric testing in ways that are simple and brief as part of routine history taking and mental status examination. The clinical assessment of personality requires little extra time if the clinician is alert to non-verbal cues in a person's general appearance, expressions, and behavior, as well as to the significance of what is said and how it is said. Only brief questions to clarify complaints and their context may be needed.

Personality develops over time in response to a changing internal and external environment. As a result, the longitudinal course of a person's development of personality and psychopathology is a key element in the clinical assessment of personality. Specifically, it is highly informative to know what a patient's personality was like as a child when assessing him in the presence of additional psychopathology, like a depression or anxiety state that modifies his emotions, thoughts, and behaviour. However, personality traits are not fixed and completely stable. Rather, each of us has a range of thoughts, feelings, and behaviours at any given point in time. As a result, our personality traits frequently vary within that range and occasionally change by moving beyond the previous range in response to particular internal and external events. Understanding the course of a person's development during his life is what allows the psychiatrist to understand him as a unique person.

In this chapter, I will try to explain the basic constructs and methods of personality assessment, so that a clinician can apply this knowledge in a flexible and practical manner. If you have to ask standardized questions that are not tailored to opportunities that arise in the course of an interview, then you don't understand the basic constructs adequately. On the other hand, some clinical features about personality traits are sufficiently high in yield and diagnostic value, that they should be assessed in a final review if they haven't been come up more spontaneously during the interview.

What is personality?

In order to assess something it is crucial to have a good understanding of what it is and what it is not. People differ markedly from one another in their outlook on life, in the way they interpret their experiences, and in their emotional and behavioral responses to those experiences. These differences in outlook, thoughts, emotions, and are what actions characterize an individual's personality. More generally, personality can be defined as the dynamic organization within the individual of the psychobiological systems that modulate his or her unique adaptations to a changing internal and external environment.[4] Each part of this definition is important for a clinician to appreciate. Personality is 'dynamic', meaning, it is constantly changing and adapting in response to experience, rather than being a set of fixed traits. Inflexibility of personality is actually an indicator of personality disorder. Personality is regulated by 'psychobiological' systems, meaning, personality is influenced by both biological and psychological variables. Consequently, treatment of personality disorders requires growth in psychological self-understanding and not just treatment with medications, although these can be helpful adjuncts to therapy.[5,6] These systems involve interactions among many internal processes, so that each person's pattern of adjustment is 'unique' to them, even though they follow general rules and principles of development as complex adaptive systems.[7] Finally, to understand personality and its development, we must pay attention to both the 'internal' and 'external' processes by which an individual interacts with and adapts to his own internal milieu and external situation. For example, when a person is under stress, he is likely to think and feel differently about himself and other people. On the other hand, when he is calm and encouraged, he may act more maturely and happily. Everyone has personal sensitivities or 'rough spots' that surface when they are under stress. Everyone has 'good days' and 'bad days', and this pattern of variability over time is what characterizes a person's unique personality configuration.

An individual's personality can only be adequately characterized in terms of interactions among different internal and external forces that influence a person's emotions, thoughts, and behaviour. A person may feel and act differently on a date, at work, with trusted friends, at school, or in church. His personality doesn't change, rather his personality can only be adequately assessed when the psychosocial context is specified. Some traits are strong and pervasive regardless of the situation, but other aspects of personality may be markedly affected by the situation. Furthermore, the internal processes may modify a person's outlook, as when his outlook is influenced by prior or anticipated events, or when his goals and values allow him to change his outlook in ways that are not predictable by what he has previously done. Human beings have an amazing ability to change their outlook for the better or the worse in ways that are unpredicted by their past or present circumstances. Personality traits can be described in ways that are moderately stable over time and situations, but a prudent clinician must never mistake average probabilities with predictive certainty.

Five major types of situations are useful to distinguish for human beings: Sexual situations involving reproduction and sexuality; Material situations involving the quest for material possessions and power; Emotional situations involving emotions and social attachments; Intellectual situations involving communication and culture; Spiritual situations involving the quest for what is beyond individual human existence. The average person is concerned with material situations most of the time—obtaining food, clothing, shelter, transportation, and striving for power and wealth. However, to understand a person fully it is essential to recognize his feelings, thoughts, and intuitions in other types of situations ranging from the sexual to the spiritual. The way a person adapts to these five different types of situations correspond to layers of an individual's personality. The treatment of psychopathology can be viewed as a working-through of problems and blind spots in these five layers of everyone's personality, enabling the development of self-awareness in the full range of life situations.[8]

Personality involves much more than the description of a fixed set of traits that allow the prediction of a person's behavior. Personality involves the interaction of internal and external forces that influence the development of a person's behavior, but nevertheless allow for the potential of a person to grow in self-awareness and thereby change in ways that cannot be predicted from his past behavior.[9]

How can personality be described quantitatively?

Personality refers to the motivational systems *within* a person, not between individuals. In other words, to understand what motivates a person we need to recognize empathically what he is thinking and feeling within his own being. We need a model of the dynamic psychobiological processes within a human being. Unfortunately, the people who have developed most personality tests often treat each person as a black box that emits self-reports. As a result, most personality psychologists have failed to understand the internal dynamics underlying the thoughts and feelings of the people they assess. However, it is possible to describe a person's internal processes, which interact with his or her external situations. In order to account for both the internal and the external influences on personality, it is essential to distinguish the dimensions of a person's temperament and those of his character.[4]

The temperament traits are biases in emotional responses that are fully developed early in life and relatively stable thereafter. On the other hand, character involves higher cognitive processes that develop in a stepwise manner over the life course to enable a person to regulate his emotions, achieve certain goals, and maintain particular values and virtues. Initially, it was thought that character was less heritable than temperament, but empirical studies have shown that both are moderately heritable. The key difference is the difference in the pattern of learning and memory: the procedural learning of habits and skills influences the conditioning of temperament, whereas propositional learning of goals and values influences the development of character. Both procedural and propositional learning interact with one another in self-aware consciousness so that a person can maintain a personal sense of continuity throughout many episodes of experience as the story of his life unfolds.

Temperament can be assessed in terms of four quantifiable dimensions, as measured by the Temperament and Character Inventory.[4] These are described in Table 1.8.2.1, which shows that each trait is manifested in slightly different ways depending on the situation. A situation necessarily depends on both the person's outlook and the external circumstances themselves. For example, a person is described as high in Harm Avoidance if he is easily fatigued, fearful, shy, pessimistic, and inhibited. On the other hand, a person is described as low in Harm Avoidance if he is vigorous, risk-taking, beguiling, optimistic, and uninhibited.

Table 1.8.2.1 Descriptions of temperaments according to emotional responses elicited by particular external situations and internal outlooks

Temperament	Sexual situations	Material situations	Emotional situations	Intellectual situations	Spiritual situations
Harm Avoidance	Fatigable vs Vigorous	Fearful vs Risk-taking	Shy vs Beguiling	Pessimistic vs Optimistic	Inhibited vs Uninhibited
Novelty Seeking	Craving vs Reserved	Extravagant vs Frugal	Irritable vs Stoical	Impulsive vs Rigid	Exploratory vs Immobile
Reward Dependence	Insecure vs Independent	Sympathetic vs Aloof	Sociable vs Distant	Sentimental vs Indifferent	Attached vs Detached
Persistence	Ambitious vs Apathetic	Overachieving vs Underachieving	Loyal vs Fickle	Determined vs Ambivalent	Perfectionistic vs Pragmatic

However, the level of Harm Avoidance varies moderately between situations. For example, some people who are shy are not easily fatigued, and some people who are shy meeting strangers are risk-takers when driving an automobile. The components of Harm Avoidance that are manifested in different situations are moderately correlated, and so it is useful to consider all these as part of a higher order trait that is moderately heritable and moderately stable across time and situations. Likewise, Novelty Seeking, Reward Dependence, Persistence are also moderately heritable and stable dimensions of temperament.

Likewise, there are three dimensions of character, which quantify the nature of a person's goals and values (Table 1.8.2.2). Each of these character traits is comprised of components that are expressed in different situations. The character dimensions also correspond to key functions of a person's mental self-government. As a result, character traits provide a rich description of key features of the mental status examination, including insight and judgment.

Insight refers to the depth of a person's ability to recognize and understand the inner nature of things, rather than basing opinions on superficial appearances. Insight is quantifiable as the character trait of Self-transcendence. A person with deep insight is respectful, mindful, and holistic in perspective, whereas one with little insight is unrealistic, shallow, and fragmented in perspective.

Judgment refers to a person's legislative ability to cooperate and get along with others in ways that are appropriate and flexible, and can be quantified as the character trait of Cooperativeness. A person with good judgment is cooperative and principled, whereas a person who has poor judgment is uncooperative and opportunistic.

Foresight refers to a person's executive ability to anticipate what will be satisfying in the long-term or in the future. This executive function allows a person to follow a life path that maintains well-being. A person who is far-sighted is responsible, purposeful, resilient, and resourceful, whereas one who learns from hindsight only is irresponsible, aimless, fragile, and inadequate. In addition, foresight leads to cheerfulness and spontaneity, whereas reliance on hindsight is associated with moodiness and conventionality. Accordingly, the degree of a person's foresight provides important clinical information about a person's ability to appreciate what is real, meaningful, and satisfying. As a result, a person's self-directedness is an important indicator of reality testing, maturity, and vulnerability to mood disturbance. Self-directedness is high

Table 1.8.2.2 Descriptions of the three dimensions of character according to the five layers of everyone's personality, which are defined by the predominant focus of the person's internal perspective on the external situation. Within each layer of personality, maturation and integration involves increasing each of the three character dimensions, which describe the functions of insight, judgment, and foresight. Integration of the whole person requires working through these functions in each of the layers of personality

Cognitive function (Character dimension)	Characteristics of the sexual layer	Characteristics of the material layer	Characteristics of the emotional layer	Characteristics of the intellectual layer	Characteristics of the spiritual layer
Insight (Self-Transcendence)	Trustful vs Alienated (prelogical categorizing)	Free-Flowing vs Compulsive (concrete-vivid logic)	Identifying vs Avoiding (emotive imagery)	Creative vs Imitative (abstract symbols)	Intuitive vs Conventional (preverbal schemas)
Judgment (Cooperativeness)	Tolerant vs Prejudiced	Forgiving vs Revengeful	Empathic vs Inconsiderate	Helpful vs Unhelpful	Principled vs Opportunistic
Foresight (Self-Directedness)	Responsible vs Irresponsible	Purposeful vs Aimless	Resilient vs Moody	Resourceful vs Inadequate	Spontaneous vs Predetermined

in people who are mature and happy, whereas it is low in people with personality disorders and in those vulnerable to psychoses and mood disorders.

Psychometric testing of personality traits

A wide variety of psychometric tests can be used to describe personality traits, so it is useful for a clinician to understand the relationships among alternative measures. The number and content of traits describing personality vary but there is actually extensive overlap among the traits measured. Hans Eysenck popularized tests that measured three factors called Neuroticism, Extraversion, and Psychoticism.[10] The Eysenck Personality Questionnaire also includes validity measure called 'Lie'. Nearly all tests subsequently developed include factors corresponding closely to Neuroticism and Extraversion at least. Later, Jeffrey Gray showed that individual differences in rates of learning corresponded to weighted combinations of Neuroticism and Extraversion.[11] In other words, people who are most prone to anxiety and respond most sensitively to punishment are neurotic introverts (that is, they are high in Neuroticism and low in Extraversion). On the other hand, people who are most impulsive and respond most sensitively to rewards are stable extraverts (that is, they are low in Neuroticism and high in Extraversion). As a result, both Zuckerman and Cloninger developed tests that correspond to these individual differences in learning and vulnerability to psychopathology, as summarized in Table 1.8.2.3. Essentially, people who are most prone to anxiety are those who are described as neurotic introverts by Eysenck, neurotic or anxiety-prone by Zuckerman and Gray, and harm-avoidant by Cloninger. On the other hand, people who are most prone to impulsivity, anger, and substance abuse are called stable extraverts by Eysenck, impulsive sensation-seekers by Zuckerman and Gray, and Novelty seekers by Cloninger.

Later, Cloninger and others showed that all seven of the dimensions of his Temperament and Character Inventory had unique genetic determinants and unique brain processes, suggesting that a seven dimensional model is needed to account for the dynamic processes within each individual that regulates his personality. Nevertheless, five factor models like Zuckerman and Kuhlman's Personality Qeustionnaire or Costa and McCrae's NEO personality inventory can capture most of the information about personality in a statistical sense, even though they ignore the non-linear structure of personality resulting from its complex evolutionary history. Tables 1.8.2.3 and 1.8.2.4 and 4 show the correlations between measures of Cloninger's seven factor model and alternative five factor models (Zuckerman's ZKPQ in Table 1.8.2.3, Costa's NEO-PI in Table 1.8.2.4). As in Eysenck's Neuroticism factor, Neuroticism in five factor models is a composite of anxiety-proneness (as measured by high Harm Avoidance) and personality disorder (as measured by low Self-directedness). Extraversion is a composite of intrapsychic processes involving risk-taking (as measured by low Harm Avoidance), impulsivity (as measured by high Novelty Seeking), and sociability (as measured by high Reward Dependence), and personality maturity (as measured by high Self-directedness).[12] Essentially, Neuroticism and Extraversion are composites of traits leading to maladaptive and adaptive emotional styles. Five factor models now also distinguish traits related to agreeability and sociability (as measured by TCI Reward Dependence and Cooperativeness, low ZKPQ hostility, and high NEO agreeability). There is also consistent recognition of a trait variously identified as conscientiousness, persistence, and vigorous activity, which has been identified by a specific resistance to extinction of intermittently reinforced behaviour regulated by specific brain circuitry in rodents and humans.[13]

Beyond these four personality traits (anxiety-proneness, impulsive anger-proneness, social attachment, and persistence), alternative models of personality vary according to how the remaining features of personality are measured. Five factor models like the ZKPQ and NEO do not measure the personality trait underlying self-awareness, which leads to insight, creativity, and spirituality; however, this trait is measured as Self-transcendence in the TCI. Individual differences in serotonergic receptor function has been found to be strongly related to Self-transcendence.[14]

No consensus is possible to choose among alternative structures derived from factor analysis because an infinity of alternative rotations are statistically equivalent. Information beyond statistics is needed to choose among alternative models, as has been done by Gray, Zuckerman, and Cloninger. Such information includes brain imaging, genetics, development, or utility for developing insight

Table 1.8.2.3 Correlations (r x 100) between the Temperament and Character Inventory (TCI) scales and those of the Eysenck Personality Questionnaire (EPQ-revised) and the Zuckerman-Kuhlman Personality Questionnaire (correlations over 0.4 in bold, significant correlations only shown, n = 207. into intrapsychic processes, as described in more detail elsewhere.[7] Fortunately, familiarity with the strong relationships among alternative measures will allow the clinician to interpret flexibly whatever information is available.

The assessment of personality can also be based upon abnormal traits indicative of personality disorder, as has been done by Livesley and others.[15] Whether the starting point is normal or abnormal personality traits, the same structure of personality is observed.[11,16] This shows that personality disorders are particular configurations of traits that vary quantitatively in the general population, not qualitatively in discrete disorders.

Clinical assessment of personality

Personality can be well assessed by allowing the patient to tell his life story and conducting a standard mental status examination. A checklist of signs and symptoms is not adequate for the assessment of personality because narratives only provide an account of a person's continuity of self-awareness over his lifespan. Within the life story, the key elements on which temperament ratings are made are the narrative account of emotional style, particularly in childhood, and general appearance and behaviour on mental status examination. The key elements on which character ratings are based are the range of a person's thoughts, the nature of his interpersonal relationships, and his insight and judgment. The clinician must consider not only the words of the patient, which may involve little or no cognitive insight or self-awareness, but also recognize the significance of non-verbal signs from body posture, facial expression, and gestures to understand his way of perceiving and relating to others.

The level of a person's foresight reflects all of these other sources of information. Lack of foresight is the cardinal feature of personality disorder. Other consistent features of personality disorders are summarized in Table 1.8.2.5.

Temperament involves emotional biases that can be directly observed and felt by an experienced clinician. The tendency of a person to elicit strong emotions from others or 'to get under the skin' of another is a sign of extreme temperament traits or personality disorder. For example, the person with extreme temperament may elicit an urge to be rescued or hostility in the examiner. His general appearance and behavior may be ingratiating or negativistic. Specific features of temperament that distinguish subtypes of personality disorders are summarized in Table 1.8.2.6.

Character traits are assessed partly on intuitive recognition and partly on history. A person who frequently blames others or elicits strong emotional responses in the examiner should be suspected of having a personality disorder. The ratings of character are more precisely based on observations of key functions of self-awareness obtained in the life narrative and the mental status examination. The most informative finding concerns the level of a person's self-awareness, as described in Table 1.8.2.7. The presence of personality disorder means essentially that a person is usually not self-aware (stage 0 in Table 1.8.2.7). Most adults are in the first stage of self-awareness most of the time: they are responsible, have initiative, and are able to delay gratification if they want, but are egocentric. As previously mentioned, they are preoccupied with material concerns. Such individuals may have problems with jealousy or pride, but are sufficiently self-aware so that they are not considered personality disordered. Elsewhere, a simple exercise to evaluate level of self-awareness is described as the Silence of the Mind meditation.[7] It can also be used to help a person improve his level of self-awareness, so it is useful for both assessment and treatment. The ability to reach the second or third stage of self-awareness is the key to improvement in psychotherapy, as described in detail elsewhere.[3] Such growth in self-awareness or

Table 1.8.2.5 Qualitative description of personality disorders

Discriminating features
A maladaptive pattern of responses to personal and social stress that is
stable and enduring since teens
inflexible and pervasive
causing subjective distress
and/or impaired work and/or social relations
Consistent features
lack of foresight (that is, the ability to anticipate what will be satisfying in the long run)
strong emotional reactions elicited from others
(like anger or urge to rescue)
efforts to blame and change others, rather than oneself
Variable features
odd, eccentric
erratic, impulsive
anxious, fearful

Table 1.8.2.6 Qualitative clusters and subtypes of personality disorders according to the American Psychiatric Association (DSM-IV, 1994)

Cluster	Subtype	Discriminating features
Odd/Eccentric	(Low Reward Dependence)	
	Schizoid	socially indifferent
	Paranoid	suspicious
	Schizotypal	eccentric
Erratic/Impulsive	(High Novelty Seeking)	
	Antisocial	disagreeable
	Borderline	unstable
	Histrionic	attention-seeking
	Narcissistic	self-centered
Anxious/Fearful	(High Harm Avoidance)	
	Avoidant	inhibited
	Dependent	submissive
	Obsessive	perfectionistic
Not otherwise specified		
	Passive-Aggressive	negativistic
	Depressive	pessimistic

character traits corresponds closely to the stages of cognitive and character development as described by Piaget, Freud, and Erikson (Table 1.8.2.8). For example, the first stage of self-awareness corresponds to the presence of initiative in Erikson's terms. The second stage involves the presence of generativity. More fine-grained ways to quantify the range of a person's thoughts and human relationships are also described elsewhere.[3] Such refined ratings are important for treatment but not for initial diagnosis.

Table 1.8.2.7 Three stages of self-awareness on the path to well-being (Reproduced from Cloniger, C.R. (2004). *Feeling Good: The Science of Well Being*, with permission of Oxford University Press, New York)

Stage	Description	Psychological characteristics
0	unaware	irresponsible, seeking immediate gratification ('child-like' ego-state)
1	average adult cognition	purposeful but egocentric able to delay gratification, but has frequent negative emotions (anxiety, anger, disgust) ('adult' ego-state)
2	meta-cognition	resourceful and allocentric aware of own subconscious thinking calm and patient, so able to supervise conflicts and relationships ('parental' ego-state,'mindfulness')
3	contemplation	creative and holistic perspective wise, spontaneous, and loving able to access what was previously unconscious as needed without effort or distress able to anticipate what will be satisfying in future ('state of well-being','foresight')

Insight and judgment are also important for assessing character because they are really simply alternative terms for describing the character traits of Self-transcendence and Cooperativeness, as previously discussed. The person's history about his family of rearing, education, marriage, and work history provide the key information for evaluating character. It is important to inquire about a person's goals and his hobbies and recreational activities, whether someone has secure friends, particularly anyone they fully trust and can confide in now or in the past, is important to know as a measure of capacity for intimacy and as a predictor of capacity for forming a therapeutic alliance. Relationships with prior counselors, as well as history of disability claims and law-suits provide important information about personality.

Remember that it is often important with psychiatric patients to assess their personality when they were children or adolescents. In other words, it is as important to evaluate their personality retrospectively as well as in practical, particularly at an age before the onset of other psychopathology, like substance abuse or depression. Current anxiety or depression is expected to inflate Harm Avoidance ratings. Stress or intoxication tends to release temperaments from higher cortical control by character. Likewise, chronic substance abuse, depression, or psychosis arrest character development while active, so early onset of mental disorders is often associated with character deficits. It is usually easy for a patient to provide meaningful information about his childhood personality if the clinician simply asks about the child's early relationships with parents, siblings, schoolmates, and other childhood friends.

Remember also that the single most important dimension of personality to assess in rating a person's level of maturity is his degree of foresight, measured as his Self-directedness. Is the person responsible, or does he tend to blame his problems on other people on unfortunate circumstances? Is the person purposeful, or does he lack clear goals in his life? Is he resourceful, or does he feel inadequate himself and depends on others to solve his problems for him? Assessment of Self-directedness alone is sufficient to determine if a person has a personality disorder of at least moderate severity.[2,4] In contrast, the finding of high Neuroticism is not the same as finding of low Self-directedness, even though they are strongly correlated: a person with anxiety or mood disorder and no personality disorder may be high in Neuroticism but not low in Self-directedness.

Some mild personality disorders also require consideration of the person's capacity to get along with others, as measured by his Cooperativeness. In addition, high functioning individuals who do not merit a diagnosis of personality disorder may nevertheless have specific blind spots in their insight and judgment that leads to severe problems. For example, a competent physician may usually be self-aware but lacks a capacity for intimacy or a sense of fairness in business. Such specific deficits may have severe impairment, even if a person is self-aware in other situations. As a result, it is important to consider the overall profile of a person's life in all five types of situations mentioned earlier. Simply deciding whether or not a person has a personality disorder is insufficient for an assessment of his personality and risk for psychopathology. An adequate initial assessment of a person's personality should allow ratings of all four dimensions of temperament and three dimensions of character, which in turn provide a basis for understanding a person's capacity for well-being and vulnerability to psychopathology.

Table 1.8.2.8 Comparison of different descriptions of character development

Stage of character development	Stage of Piaget	Stage of Freud	Stage of Erikson	Judgment (Cooperative)	Insight (Self-Transcendent)	Foresight (Self-directed)
0	Reflexive					
1	Enactive			Tolerance		
2		Oral	Trust		Trust	
3						Responsible
4	Intuitive	Anal	Autonomy	Forgiving		
5		Phallic	Initiative		Free-Flowing Productivity	
6	Concrete Operations	Latency	Industry			Purposeful
7		Early Genital		Empathic		
8					Transpersonal Identification	
9	Abstract Operations		Identity			Resilient
10		Later Genital	Intimacy	Helpful		
11			Keeper of Meaning		Creativity	
12						Resourceful
13			Integrity	Principled		
14					Holistic Intuition	
15						Spontaneous

Clinical value of psychometric testing

Most experienced clinicians should be able to make valid personality assessments without psychometric testing. However, psychometric testing may still be useful for at least three reasons. First, it helps the clinician to refine his or her clinical assessments by asking more questions with comparisons to normative data than is usually practical during a clinical session. Second, it provides the patient written feedback that can be studied and reflected upon, which does not depend on the clinicians' subjective biases—it reflects back to the patient what was said and provides a language that can be used for accurate communication between the patient and the doctor. Third, it provides a standard for comparison to later assessments as a means of measuring growth. As a result, it is often useful to supplement clinical impression with documentation that allows the patient to describe himself or herself without reliance on the judgment of anyone else. The patient's effort to describe himself or herself often has the therapeutic value of stimulating the patient to begin to understand the motives underlying the pattern of his behaviour. In addition, comparison of psychometric test scores with clinical impression is a helpful way for the clinicians to train themselves in the art of personality assessment.

1.8.3 Cognitive assessment

Graham E. Powell

Principles of assessment

Assessment, testing, or measurement is the evaluation of the individual in numerical or categorical terms, adhering to a range of statistical and psychometric principles. Examples of measurement are, assigning people or behaviour to categories, using scales to obtain self-ratings or self-reports, using tests of ability and performance, or collecting psychophysiological readings. Even diagnosis is a form of measurement and should have various psychometric properties such as satisfactory reliability and validity. In this chapter we concentrate on cognitive or neuropsychological assessment, which typically employs standardized psychometric tests, but it is axiomatic that the basic principles are applicable to all forms of measurement without exception. For example, stating that a patient does or does not have a symptom is potentially just as much of a measurement as stating his or her IQ. It should be noted that this account is of English language tests, and readers elsewhere should note the principles but ask local psychologists what tests they use.

Psychometric tests aim to measure a real quantity—the degree to which an individual possesses or does not possess some feature or trait, such as social anxiety or spelling ability or spatial memory. This real quantity is known in classical test theory as the **true score** *t*, and the score that is actually obtained on the given test is the **observed score** *x*. It is assumed that the observed score is a function of two values, the true score plus a certain amount of **error** *e*, because no test is perfect. Therefore we have the most basic equation in psychometrics: $x = t + e$. The statistical aim of psychometric measurement is to keep the error term to an absolute minimum so that the observed score is equal to the true score, which happens when the error term is reduced to zero. Of course, this is never achieved, but the error term can be reduced to the minimum by making the test as reliable as possible, where reliability is simply the notion that the test gives the same answer twice.

In practice, of course, if a test were repeated many times, each occasion would give a slightly different result, depending on how the person felt, the precise way questions were asked, the details of how answers were scored, or whether there has been any lucky guessing. In other words, observed scores would cluster around the true score. Like the distribution of any variable, the distribution of observed scores would have a mean and a standard deviation. The mean is obviously the true score, and this standard deviation is called the **standard error of measurement (SEM)**. The aim of a good test is to keep the SEM as near as possible to zero, and test manuals should state the actual SEM.

There is a relationship between SEM and the reliability of the test:

$$SEM = SD\sqrt{(1 - r_{11})}$$

where SD is the standard deviation of the test and r_{11} is the test–retest reliability of the test (expressed as a correlation coefficient ranging from −1 to +1). If the reliability of the test is perfect (+1), as can be seen the SEM will be zero:

$$SEM = SD\sqrt{(1-1)} = SD\sqrt{0} = 0.$$

Thus a test should be as reliable as possible because then the observed score will be the true score and the standard error of measurement will be zero.

An unreliable test is always useless, but if reliability can be achieved then it is worth considering the test score and, more specifically, what it measures. The degree to which a test measures what it is supposed to measure is known as **validity**. There may be various threats to validity. For example, a test of numeracy may be so stressful that scores are highly dependent upon the patient's anxiety level rather than on his or her ability, or a test of social comprehension may have questions which are culturally biased and so scores may depend in part upon the person's ethnic background.

In practice, there are various types of reliability and validity, and these are summarized in Tables 1.8.3.1 and 1.8.3.2. Further discussion can be found in Kline.[1]

Having used a reliable and valid test, the next issue is how the numbers are analysed and expressed. It has to be noted first that there are three types of scale of measurement. A **nominal** scale is when numbers are assigned to various categories simply to label the categories in a manner suitable for entry onto a computer database—the categories actually bear no logical numerical relationship to each other. Examples would be marital test status or ethnic background or whether one's parents were divorced or not. Nominal scales are used to split people into groups and all statistics

Table 1.8.3.1 Types of reliability

Scorer or rater reliability	The probability that two judges will (i) give the same score to a given answer, (ii) rate a given behaviour in the same way, or (iii) add up the score properly. Scorer reliability should be near perfect.
Test–retest reliability	The degree to which a test will give the same result on two different occasions separated in time, normally expressed as a correlation coefficient. A reliability of less than 0.8 is dubious.
Parallel-form reliability	The degree to which two equivalent versions of a test give the same result (usually used when a test cannot be exactly repeated because, say, of large practice effects).
Split-half reliability	If a test cannot be repeated and there are no parallel forms, a test can be notionally split in two and the two halves correlated with each other (e.g. odd items versus even items). There is also a mathematical formula for computing the mean of all possible split halves (the Kuder–Richardson method).
Internal consistency	The degree to which one test item correlates with all other test items, i.e. an 'intraclass correlation' such as the a coefficient, which should not drop below 0.7.

Table 1.8.3.2 Types of validity

Face validity	Whether a test seems sensible to the person completing it; i.e. does it appear to measure what it is meant to be measuring? This is in fact not a statistical concept, but without reasonable face validity, a patient may see little point in co-operating with a test that seems stupid.
Content validity	The degree to which the test measures all the aspects of the quality that is being assessed. Again, this is not a statistical concept but more a question of expert judgement.
Concurrent validity	Whether scores on a test discriminate between people who are differentiated on some criterion (e.g. are scores on a test of neuroticism higher in those people with a neurotic disorder than in those without such a disorder!). Also, whether scores on a test correlate with scores on a test known to measure the same or similar quality.
Predictive validity	The degree to which a test predicts whether some criterion is achieved in the future (e.g. whether a child's IQ test predicts adult occupational success; whether a test of psychological coping predicts later psychiatric breakdown). For obvious reasons, these last two types of validity are often jointly referred to as *criterion-reiated validity.*
Construct validity	Whether a test measures some specified hypothetical construct, i.e. the 'meaning' of test scores. For example, if a test is measuring one construct, there should not be clusters of items that seem to measure different things; the test should correlate with other measures of the construct (*convergent validity*); it should not correlate with measures that are irrelevant to the construct (*divergent validity*).
Factorial validity	If a test breaks down into various subfactors, then the number and nature of these factors should remain stable across time and different subject populations.
Incremental validity	Whether the test result improves decision-making (e.g. whether knowledge of neuropsychological test results improves the detection of brain injury).

are based on the frequency of people in each group. The relationship or association between groups can be examined using χ^2 statistics, for example to test whether there is a relationship between being divorced and having parents who divorced. Next there is an **ordinal** scale, in which larger numbers indicate greater possession of the property in question. Rather like the order of winning a race, no assumptions are made about the magnitude of the difference between any two scale points; it does not matter whether the race is won by an inch or a mile. Ordinal scales allow people to be rank ordered and numerical scales can be subjected to non-parametric statistical analysis (which is that branch of statistics which makes minimal assumptions about intervals and distributions), including the comparison of means and distributions and the computation of certain correlation coefficients. Finally comes the **interval** scale in which each scale point is a fixed interval from the previous one, like height or speed. The types of test described in this chapter for the most part aspire to be interval scales, allowing use of the full range of parametric statistics (which assume equal intervals and normally distributed variables).

Having obtained a test score for someone, that score then has to be interpreted in the light of how the general population or various patient groups generally perform on that test. There are two general characteristics of a scale that have to be remembered. The first is the measure of central tendency. Typically one would consider the mean (the arithmetic average), but it is also sometimes useful to consider the median (the middle score) and the mode (the most frequently obtained score). This will be the first hint as to whether the score is normal or whether it is more typical of one group than another. However, in order to gauge precisely how typical a given score is, it is necessary to take into account the **standard deviation (SD)** of the test (other measures relating to the dispersion of test scores, such as the range or skew, can be considered but are not of such immediate relevance).

As long as the mean and SD of the test are known, it is possible to work out exactly what percentage of people obtain up to the observed score x. This is done by converting the observed score into a **standard score** z and converting the z-score to a **percentile**. A standard score is simply the number of SDs away from the mean m, and it will have both negative and positive values (because an observed score can be either below or above the mean, respectively). In other words, $z = (x - m)/\text{SD}$. For reference, Table 1.8.3.3 gives some of the main values of z and what percentage of people score up to those values. It is this percentage that is known as the percentile and it is obtained from statistical tables. For example, a score at the 25th percentile means that 25 per cent of people score lower than that specific score. Obviously, the 50th percentile is the mean of the test. For illustration, the equivalent IQ scores (IQ scores have a mean of 100 and SD of 15) and broad verbal descriptors are also given in Table 1.8.3.3.

A knowledge of percentile scores can help to decide to which category a patient may belong. For example, if a patient completes a token test of dysphasia and scores at the 5th percentile for normal controls and the 63rd percentile for a group of dysphasics, the score is clearly more typical of the dysphasic group.

However, in clinical practice it is often not just a comparison with others that is needed, but a comparison between two of the patient's own scores. For example, verbal IQ might seem depressed

Table 1.8.3.3 z-scores, percentiles, IQ scores, and descriptions

z-score	Percentile	IQ	Description
−2.00	2.5th	70	Scores below the 2.5th percentile are *deficient* or in the *mentally retarded* range
−1.67	5th	75	
−1.33	10th	80	Scores between the 2.5th and 10th percentile are *borderline*
−1.00	16th	85	
−0.67	25th	90	Scores between the 10th and 25th percentile are low average
−0.33	37th	95	
0.00	50th	100	The mean score
+0.33	63rd	105	
+0.67	75th	110	Scores between the 25th and 75th percentile are in the *average* range
+1.00	84th	115	
1.33	90th	120	Scores between the 75th and 90th percentile are high average
		120+	Scores over the 90th percentile are *superior*

in comparison with spatial IQ, or the patient's memory quotient might seem too low for his or her IQ. These are known as **difference scores**, and their analysis is a crucial part of the statistical analysis of a patient's profile. There are two key concepts: the **reliability of difference scores** and the **abnormality of difference scores**. Failure to distinguish between these two leads to all manner of erroneous conclusions. In brief, a reliable difference is one that is unlikely to be due to chance factors, so that if the person were to be retested then the difference would again be found. If the test is very reliable (see the previous discussion of reliability), even a small difference score, may be reliable. As a concrete example, the manual of the Wechsler Adult Intelligence Scale—Third Edition (**WAIS-III**)[1] indicates that a difference of about nine points between verbal IQ and performance IQ is statistically reliable at the 95 per cent level of certainty.

However, although a difference of this size would be reliable, this does not necessarily mean that it is abnormal and therefore indicative of pathology. The abnormality of a difference score is the percentage of the general population that has a difference score of this size or greater. Published tables,[2] show that 18 per cent of adults have a discrepancy of at least 10 points between verbal and performance IQ, so a difference of 10 points is not at all unusual. In fact, to obtain an abnormal difference between verbal and performance IQ the discrepancy has to be of the order of 22 points for adults and 26 points for children (i.e. less than 5 per cent of adults or children have discrepancy scores of this size).

Having introduced the basic concepts of psychometric assessment, this is an appropriate point, prior to the description of specific tests, at which to summarize the information that can (or should) be found in a typical test manual, and this is set out in Table 1.8.3.4.

Table 1.8.3.4 What to expect in a good test manual

Theory	The history of the development of the concept and earlier versions of the test The nature of the construct and the purpose of measuring it
Standardization	Characteristics of the standardization sample, how the sampling was carried out. and how well these characteristics match those of the general population Similar data on any criterion groups Similar data for each age range if the test is for children
Administration	How to administer the test in a standard fashion so as to minimize variability of administration as a factor in the error term
Scoring	How to score the test, and criteria for awarding different scores, so as to minimize scorer error
Statistical properties	Means and standard deviations of all groups Reliability coefficients and how they were obtained Validity measures and how they were derived Standard error of measurement Reliability of difference scores Abnormality of difference scores Other data on the scatter of subtest scores Scores of criterion groups
Special considerations	Groups for whom the test is not suitable or less suitable, i.e. the range of convenience of the tests Ceiling effects: at what point does the test begin to fail to discriminate between high scorers? Floor effects: at what point does the test begin to fail to discriminate between low scorers?

Tests of cognitive and neuropsychological functioning

General ability and intelligence

A very useful broad screening test, especially when it is suspected that mental functions are severely compromised, is the Mini-Mental State Examination.[3,4] It is brief, to the point, and can be repeated over time to gauge change. It measures general orientation in time and place, basic naming, language and memory functions, and basic non-verbal skills, and has good norms for a middle age range, especially the elderly, with appropriate adjustment for age. The maximum score is 30, and a score of 24 or less raises the possibility of dementia in older persons, especially if they have had nine or more years of education (a score of 24 is at about the 10th percentile for people aged 65 and older).

However, the Mini-Mental State Examination is only a screening test and the presence or nature of cognitive impairment cannot be diagnosed on the basis of this test alone. A detailed cognitive assessment is provided by the Wechsler scales, i.e. the Wechsler Adult Intelligence Scale—Third Edition UK Version (**WAIS-III^{UK}**),[1] the Wechsler Intelligence Scale for Children—IV UK Version (**WISC-IV^{UK}**),[5] or the Wechsler Preschool and Primary Scale of Intelligence—Revised (**WPPSI-III**).[6] Outlines of the WAIS-III^{UK} and WISC-IV^{UK} are given in Table 1.8.3.5.

IQ scores themselves are very broad measures, drawing upon a wide range of functions. This does not only mean that the scores are very stable (reliable), but also that the IQ score is relatively insensitive to anything except quite gross brain damage. Rather, a careful analysis of subtest scores is needed, always bearing in mind the concepts of reliability and abnormality of difference scores. For example, it takes a subtest range of 11 to 12 points to be considered abnormal (i.e. found in less than 5 per cent of people) on the WAIS-III^{UK} and the WISC-IV^{UK}.

Sometimes the patient may have a language disorder or English may not be his or her first language. In such circumstances Raven's Progressive Matrices Test,[7] which is a non-verbal test of inductive reasoning (non-verbal in the sense that it requires no verbal instructions and no verbal or written answers), can be used. The present author avoids the new norms because they were not collected in the normal fashion (i.e. not in a formal test session under the direct supervision of a psychologist), but the old norms are good. The Matrices Test has the additional advantage of having an advanced version for people in the highest range of ability.[8] No non-English versions of the WAIS-III^{UK} or the WISC-IV^{UK} are available, but the non-verbal scores can be used with caution as there may be unexpected cross-cultural effects.

Speed of processing

Reasoning is not just about solving difficult problems, but also about solving them quickly; the difference between power and speed. IQ tests as above do have timed subtests sensitive to speed, but it can be useful to administer specific tests that are not quite so confounded with intellectual ability.

One example, particularly sensitive to even quite mild concussion, is the Paced Auditory Serial Addition Test (**PASAT**).[9,10] Here, the

Table 1.8.3.5 Outline of the WAIS-III^{UK} and WISC-IV^{UK}

	WAIS-III^{UK}	WISC-IV^{UK}
Age range	16–89 years	6.0–16.11 years
Verbal subtests	Vocabulary Similarities Arithmetic Digit span Information Comprehension Letter-number sequencing	Similarities Digit span Vocabulary Letter-number sequencing Comprehension Information Arithmetic Word reasoning
Non-verbal or spatial subtests	Picture completion Digit symbol Block design Matrix reasoning Picture arrangement Symbol search Object assembly	Block design Picture concepts Coding Matrix reasoning Symbol search Picture completion Cancellation
IQ score	Verbal IQ (VIQ) Performance IQ (PIQ) Full scale IQ (FSIQ)	Full scale IQ (FSIQ)
Index scores	Verbal comprehension Perceptual organization Working memory Processing speed	Verbal comprehension Perceptual reasoning Freedom from distractibility Processing speed
Mean IQ or index scores	100 (SD of 15)	100 (SD of 15)
Mean subtest scores	10 (SD of 3)	10 (SD of 3)
Test–retest reliability of IQ	0.98 for Full scale IQ	0.97 for Full scale IQ
Standard error of measurement of FSIQ	About 2.5, so all scores are about ±5 points[a]	About 2.68, so all scores are about ±5 points
Reliable differences (p <.05)	About 9 points between VIQ and PIQ	About 11 points between VCI and PRI
Abnormal differences (p <.05)	About 22 points between VIQ and PIQ	About 26 points between VCI and PRI
Validity	Highly related to other tests of ability and to criteria related to ability	Highly related to other tests of ability and to criterion groups

[a]95% of the time, true scores are the observed score ±1.96 SEM. In other words, the likely true score is within the range defined by about 2 SEMs either side of the score obtained.

client is read a list of numbers, and as each one is read out so it has to be added to the previous number and the answer spoken aloud (Table 1.8.3.6). This has to be done quickly or the next number will come along. There are several trials in which the numbers are delivered at a faster and faster pace, from one number every 2.4 s down to every 1.2 s. It sounds easy but in actuality is very demanding; even at the slowest speed the average score is only about 70 per cent correct, and this falls away to only about 40 per cent at the fastest speed. Indeed, if a patient has any significant mental slowing, they often cannot do the test at all. Obviously the test cannot be used if the patient has a stammer, or is dysarthric or innumerate.

A less stressful test of mental speed is the Speed of Comprehension Test,[11] in which the person indicates as fast as possible whether simple sentences are true or false (e.g. tomato soup is a liquid, grapes are people). The test can be given orally for patients who cannot read.

Two visual tests of mental speed are Map Search (looking for target symbols on a map as fast as possible) and Telephone Search (looking for various symbols on a page from a telephone directory).[12]

One test that tries to disentangle the relative contribution of slowed motor speed versus slowed mental speed, often a crucial issue in patients with motor deficits, is the Adult Memory and Information Processing Battery,[13] which has two useful timed tests of cancelling target digits.

Attention and concentration

There are various aspects of attention and concentration: the ability to focus resources, the ability to focus on the right aspect, the ability to sustain this attention, the ability to ignore extraneous

Table 1.8.3.6 Sample from PASAT

Number on tape	(Mental process)	Patient says
7		
5	(5+7)	12
1	(1+5)	6
4	(4+1)	5
9	(9+4)	13

information or distracting events, and the ability to divide attention between different tasks. The tests on speed listed above are of course also measures of attention, because highly focused and selective attention has to be sustained for the duration of a pressured task. Digit span on the WAIS-III^{UK} is also a test of attention, as any lapse in attending to the incoming digits will necessarily result in a wrong answer.

However, in addition to these tests, a battery may be used, such as the Test of Everyday Attention[12] which has eight different subtests. Test–retest reliability is quite good, over 0.83 for Map Search and Telephone Search, for example. In terms of validity, the tests are very sensitive to the effects of head injury and stroke.

Memory

Memory is a complex set of processes whereby the person registers, stores, and retrieves information within different modalities (e.g. verbal memory versus spatial memory) and across different time periods (e.g. primary or shorter-term memory versus secondary or longer-term memory or learning). Therefore, as with intelligence, various batteries have evolved with subtests that tap these various aspects. Two examples of batteries are the Wechsler Memory Scale—Third Edition[14] for adults and the Children's Memory Scale,[15] which are both summarized in Table 1.8.3.7. Another battery, which makes a special effort to reflect real-life tasks, is the Rivermead Behavioural Memory Test,[16] which also has a child's version.[17]

Sometimes time constraints make it difficult to give complete memory batteries. Often, just a few key subtests are selected, or other individual tests may be given. For example, to gauge verbal learning the Rey Auditory-Verbal Learning Test is well researched,[18] a test of visual memory is the Rey–Osterrieth Complex Figure Test[19]; and a forced choice recognition tests for words and faces is the Recognition Memory Test.[20] If the ability of the patient to recall details of his or her past life is an issue, the Autobiographical Memory Interview can be used.[21]

Language

Commonly used batteries for the assessment of language deficits are the Boston Diagnostic Aphasia Examination[22] and the closely related Western Aphasia Battery.[23] The Boston Examination covers auditory comprehension, oral expression, understanding written language, and writing. These tests can take a long time to give and so brief screening tests are often used, such as the Boston Naming Test[24] or the Graded Naming Test,[25] which both assess word finding, or the Token Test,[26] which assesses verbal comprehension. Finally, a good test to gauge reading and spelling ability is the Wechsler Objective Reading Dimensions Test[27] which will produce reading and spelling ages, and give the abnormality of difference scores between IQ and reading or spelling scores.

Frontal and executive functions

The term executive function derives from the theory that there is a supervisory system exerting executive control of attention. Deficits of this system cause broad patterns of cognitive and behavioural change called the dysexecutive syndrome,[28] which includes changes in volition, poor planning, a disruption of purposive action, and reduced efficacy of performance. One of the most frequent causes of this syndrome is damage to the frontal lobes (frontal-lobe syndrome is a dysexecutive syndrome) but it may also be caused by other patterns of lesion. Table 1.8.3.8 lists some of the features of the dysexecutive syndrome, and examples of tests that are sensitive to them.

Table 1.8.3.7 Summary of two memory batteries

	Wechsler memory Scale-III	Children's memory scale
Age range	16–89 years	5–16 years
Subtests	Information and orientation Logical memory[a] Faces[a] Verbal paired associates[a] Family pictures[a] Word lists[a] Visual reproduction[a] Letter—number sequencing Spatial span Mental control Digit span (Means typically 10, SDs typically 3)	Dot locations[a] Stories[a] Faces[a] Word pairs[a] Family pictures[a] Word lists[a] Numbers Sequences Picture locations (Means of 10, SDs of 3)
Index Scores	Auditory immediate Visual immediate Immediate memory Auditory delayed Visual delayed Auditory recognition delayed General memory Working memory (Means of 100, SDs of 15)	Verbal immediate Verbal delayed Verbal delayed recognition Learning Visual immediate Visual delayed Attention/concentration General memory (Means of 100, SDs of 15)
Reliability	0.60–0.87 for the index scores (i.e. rather low, and note a practice effect of up to 15 points across 5 weeks)	0.76–0.91 for the index scores (note a large practice effect of about 10–15 points across a 2-month interval)
Standard error of measurement	3.88–7.40 (so true scores are at best ±8 points from the observed score)	4.5–7.4 (so true scores are at best ±9 points from the observed score)
Validity	See manual for content, criterion-related, construct, and other types of validity	See manual for content, construct, and criterion-related validity

[a]Also delayed trial.

Some clinical issues

Sources of tests and test data

A good summary of the principles of test theory is given by Halligan *et al.*[36] Information about tests and where to order them from can be found in Lezak's *Neuropsychological Assessment*,[37] Strauss's *Compendium of Neuropsychological Tests*[2] and Mitrushina's[38] *Handbook of Normative Data*.

Understanding tests

The onus is upon the test user to be sufficiently knowledgeable about test theory to gauge the strengths and limitations of tests. Common problems with tests are small standardization sample sizes, unknown or unstable factor structure, poor or no theoretical adequacy, poor or no use of criterion groups, vague scoring

Table 1.8.3.8 Features and tests of the dysexecutive syndrome

Features	Tests
Behavioural change	The Dysexecutive Questionnaire (DEX), both self-report and other report[29]
Planning and impulsivity	Mazes subtest of the WISC-IV[UK][7]
Fluency	Of generating words and designs, the DKEFS[30]
Concept formations and ability to shift mental set	Modified Card Sorting Test[31] Rule Shift Cards Test[33]
Estimation	Of various amounts, the Cognitive Estimates Test[32,33] Temporal Judgement Test of time estimation[29]
Alternating plans	Switching between plans based on numbers or letters, the Trail Making Test, see DKEFS[30]
Screening out distracting information	The Stroop Test,[34] e.g. reading the word 'BLUE' when it is printed in red ink
Suppression of competing responses	The Hayling Test[35] which requires patients to choose connected or unconnected words to finish a sentence
Rule attainment	Brixton Test, requiring the patient to learn the rule whereby a pattern changes[35]
Planning	Action Program Test, to use given materials to achieve a given end[29] Zoo Map Test of organizing a route[29] Modified Six Elements Test of planning the order of tasks according to rules[29]

criteria, and poor or no information on difference scores within or between tests.

Even a well-normed and proven test may not actually be applicable to the particular patient at hand; tests only have a certain range of convenience. Tests have to be very carefully chosen when confounding factors are present, such as when English is not the patient's first language or when there is a sensory or motor deficit.

Indeed, there are a range of potentially confounding variables even in those patients who are within the range of convenience of the test. These include effects of medication, fatigue as the testing progresses, motivation, mental state, disturbed behaviour, cultural background and beliefs, and educational background. Test manuals may provide information on such potentially confounding variables, but often it is necessary to know the primary research on the test and its sensitivity to such factors.

Assessing children

Special issues arise in the assessment of children because the neuropsychology theory and conceptual framework are different, the effects of specified lesions change with age, the pattern of recovery of function varies with age, extensive developmental norms, covering the age range, are needed, and children may be more stressed by tests or may find it harder to cooperate with test procedures. These and other issues are fully discussed in texts on developmental neuropsychology,[39] paediatric neuropsychology,[40] and head injury in children.[41] Several children's tests have already been cited by name in preceding sections, and many of the adult tests cited have also been standardized on children, often in subsequent research studies not necessarily carried out by the original test author. Examples of tests with children's norms are word fluency, design fluency, auditory verbal learning, the original Wechsler Memory Scale, the Stroop Test, the Token Test, the Trail-making Test, Wisconsin Card Sorting, the Paced Serial Addition Test, and the Progressive Matrices Test.

Assessing premorbid ability

In order to understand the effects of a brain injury, to gauge intellectual loss, to plan rehabilitation, and to advise on issues relating to personal injury compensation, it is necessary to estimate premorbid intelligence. A summary of strategies for estimating premorbid IQ is given in Table 1.8.3.9.

Capacity

Within the context of intellectual and cognitive functioning, a person is incapable of managing his or her own affairs if two

Table 1.8.3.9 Strategies for estimating premorbid IQ

Strategy	Test and/or comment
Assume highest subtest score on the WAIS-III represents original level	Normal individuals have a profile of abilities and show quite a wide range of subtest scores. It makes no sense at all to say that a person's best score is his or her 'real' potential. Anyone using this method will grossly over-estimate IQ loss
Consider scores on subtests thought to be relatively insensitive to the effects of brain injury	Vocabulary is highly correlated with IQ and is also such a deeply ingrained ability that it is relatively insensitive to the affects of brain injury. Therefore, scores on the Vocabulary subtest can indeed be a guide to premorbid IQ
Gauge IQ from educational record	This is reasonable as long as the person had (i) full access to education, and (ii) the motivation to take and pass exams. Gauging ability band is made easier now that national statistics on examination pass rates are published annually in the UK
Gauge IQ from occupational record	Again this is reasonable as a broad approximation, but cultural and sociological constraints on choice of work or progress in work have to be taken into account
Tests of overlearned skills such as reading	Reading ability is highly correlated with IQ, and is a very overlearned skill, not easily affected by brain injury. This is the best and safest method, as long as the patient had no history of dyslexia and is not currently dysphasic. Tests include the Wechsler Test of Adult Reading[42] and the Spot the Word Test[11]
Genetic endowment	If the patient was damaged at birth, or if the damage caused gross physical deficits adversely affecting educational and occupational potential, then the ability and educational and occupational record of natural parents and siblings may be considered

criteria are met. First, they must have an objective deficit likely to impair problem-solving and decision-making. Second, they must be incapable of sensibly delegating or of appropriately seeking advice. Cognitive assessment obviously bears upon both of these issues. In the first instance assessment can help gauge whether there is a deficit at all, and if so its severity and precise nature. For example, most people would be able to manage their own lives despite some mild reduction in intellectual efficiency or some mild memory problem—after all, this is in any case the course of natural ageing but it is much more difficult to cope with a severe memory deficit. In the second instance, cognitive assessment can point to deficits which make it unlikely that the person can appropriately delegate certain responsibilities. For example, those with dysexecutive syndrome may be gullible or impulsive over whom to approach for advice, or may be reluctant to accept advice, may delegate only inconsistently, or may say they accept certain advice but then do the opposite. In short, they cannot plan to delegate, or if they do make such plans, the plans are poorly monitored and inconsistently implemented.

Malingering

There is no single test of malingering (i.e. consciously motivated deliberate underperformance on tests). Rather, a pattern builds up which gradually raises the suspicion of malingering.[2] Features of test performance which raise the issue are as follows:

1 a degree of deficit that is disproportionate to the severity of the injury;

2 bizarre errors not typically seen in patients with genuine deficits;

3 patterns of test performance that do not make sense;

4 not showing expected patterns;

5 inconsistencies between test performance and behaviour in real life;

6 inexplicable claims of remote memory loss even for important life events like weddings;

7 random responding on forced-choice tests;

8 below random responding on forced-driven tests;

9 poor performance on effort tests that look hard but are in fact easy;

10 the absence of severe anxiety or profoundly low mood such as might cause a collapse in performance;

11 after head injury, the absence of any improvement or indeed a worsening of performance over time;

12 failure to report deficits following a brain injury when in retrospect those deficits are claimed to have been severe;

13 relative absence of a history of somatization or related disorders.

Typical clinical neuropsychological assessment

Having set out the theory, tests, and issues, we can build up a picture of a typical clinical neuropsychological assessment, as given in Table 1.8.3.10.

Table 1.8.3.10 Typical protocol for a clinical neuropsychological assessment and report

Aims	The purpose of the assessment, e.g. to describe deficits. monitor improvement, inform rehabilitation planning, address certain specific issues
Background of patient	Information relevant to the interpretation of test findings, e.g. language, handedness, age, educational history, occupational history, medical and psychiatric history
Nature of the brain injury	For example, time since injury, age at injury, mechanisms of injury, retrograde amnesia, loss of consciousness, post-traumatic amnesia, results of neurological examination, results of scans
Behaviour and mental state	Motivation, co-operation with procedures, anxiety, mood, any aspect that threatens reliability or validity, a clear statement as to whether or not reliability has been compromised
Intelligence	Verbal, non-verbal, skills profile
Speed	Verbal, non-verbal, motor
Attention and concentration	Verbal/spatial tasks General behaviour and lapses on tests
Memory	Verbal/non-verbal Immediate/delayed recall Learning
Language	Reading Screening tests for dysphasia Aphasia battery if needed
Construction skills	Refer to performance subtests Copying a complex figure
Sensory deficits	Note gross deficits and subjective account Record problems noted on tests Refer to neurological examination Tests of spatial neglect Tests of visual agnosia
Motor deficits	Note gross problems and subjective accounts Record problems noted on tests Refer to neurological examination Tests of apraxia
Executive functions	Fluency Planning Estimation Personality/behaviour Record dysexecutive problems noted on other tests
Life situation	Way of life, typical day, leisure activities Nature and amount of any support Impact of deficits upon everyday living
Interview with other informant	An observer's account of deficits, changes, coping, etc.
Formulation	A coherent account of the injury and its repercussions, taking all information into account, focusing on the aims of the assessment

Generalizability theory and ecological validity

There is a broad issue how to generalize from an observation made in one context to what might be observed in other contexts. Traditional divisions between reliability and validity become blurred because they are both expressions of the degree to which a score can be generalized. This sweeps away the notion of a true score, to be replaced by the notion of a universe score, which is the mean of all possible observations under all possible conditions. Classical test theory is replaced by generalizability theory, in which variance in a test score is apportioned to various factors. However, in practice generalizability theory informs test construction rather than replacing classical test theory.[15]

There is one very important aspect of generalizability, and this is ecological validity or the degree to which a test score predicts real-life functioning. Some of the various threats to ecological validity are listed in Table 1.8.3.11 (see Long[43] for a fuller discussion), but the recent trend is to make neuropsychological tests increasingly a distillation of real-life tasks so as to lessen this generalizability problem.[12,16,29]

Table 1.8.3.11 Threats to the ecological validity of test results

The assessment session	Data are collected in a quiet sterile focused environment, whereas real life is noisy and full of distractions
Type of test	Cognitive tests are often constructed to measure a single pure aspect of processing, whereas real-life tasks are multidimensional
Type of interaction	The behaviour of the patient is constrained by the nature of the examiner-patient relationship, and is unlike spontaneous behaviour
Content of tests	The limited number and content of tests that can be given may not tap the real-life problems that are complained of (e.g. reduced sense of humour)
Confounding factors	Test anxiety Motivation to co-operate with the assessment or to perform in a certain way Short test sessions to avoid fatigue whereas most problems are reported when the patient *is* fatigued
Over-reliance on test data	Blinkered adherence to numbers to the exclusion of background information, general observation, information from others, and common sense
Failure to consider ecological validity	Lack of understanding of the issue Failure to follow up patients in such a way as to obtain feedback on the ecological validity of the original assessment, which is necessary to shape ecologically valid assessment procedures
Solutions	Use tests of concentration and distraction Develop new tests or new versions of tests reflecting real-life tasks Find sources of information about real-life behaviour Continue to widen the range of tests available, focusing test development on clinical need Estimate effects of confounding factors Treat numbers as only one form of data Specifically address ecological issues in the final report

Cognitive assessment of psychiatric disorders

It is possible to give only a summary of findings from the cognitive assessment of psychiatric and neuropsychiatric disorders. A fuller account is given by Grant and Adams[44] and McCaffrey.[45]

Epilepsy

There is no single cognitive profile of people with epilepsy. The relationship between epilepsy and the presence of mental retardation (learning disability) will mainly be mediated by the original brain damage causing both the epilepsy and the mental retardation. However, some patients do deteriorate intellectually if seizures are frequent or uncontrolled or if there are lapses into status epilepticus. In terms of partial seizures, the most common pattern is disturbance of verbal memory if there is a left temporal (dominant) focus and of non-verbal memory if there is a right focus. Anticonvulsants themselves may mildly impair performance on a wide variety of intellectual, cognitive, and speeded tasks.

Parkinsonism

The pattern of deficits in patients without overt dementia is memory disturbance and dysexecutive syndrome (e.g. reduced fluency, concept formation, ability to shift set). If there is an overt (subcortical) dementia, aphasia, agnosia, and severe amnesia are relatively uncommon, but mood change is frequent.

Dementia

The most common early sign of Alzheimer's disease is poor performance on delayed verbal memory, possibly with dysexecutive signs, eventually joined by a deterioration in the meaningfulness of speech with a breakdown in semantic relationships and understanding; speech becomes empty of content and frontal dysexecutive deficits emerge.

Depression

In younger neurologically intact persons, depression affects attention and memory. After head injury, the presence of anxiety or depression can make a significant to test scores, including IQ, mental speed, and verbal and spatial memory.

Alcohol

There is a typical neurocognitive profile found in chronic detoxified alcoholics after 2 to 4 weeks abstinence: intact IQ and verbal skills, but impairment of novel problem-solving, abstract reasoning, learning and memory, visual spatial analysis, and complex perceptual–motor integration. If severe thiamine deficiency arises, Wernicke–Korsakoff syndrome may ensue, with profound anterograde amnesia.

Other drugs[37]

Findings regarding the long-term neuropsychological effects of marijuana are equivocal, but if there are long-term changes they probably involve attention. Long-term cocaine use may also affect attention and memory. There are conflicting reports about the long-term use of opiates, but there may be a diffuse effect upon visuospatial and visuomotor activities. Chronic solvent abuse

leads to cerebellar ataxia and also some impairment of IQ and memory.

Schizophrenia

There is a growing awareness of dysexecutive deficits in the aetiology of schizophrenic symptoms, relating to disorders of willed action for example. Patients with schizophrenia score poorly on the Behavioural Assessment of the Dysexecutive Syndrome and show other dysexecutive features.

Summary, conclusion, and future directions

Psychometric methods based on classical test theory have permitted the development of reliable and valid tests assessing a wide range of intellectual and cognitive functions. Test results assist in formulation and diagnosis, guide rehabilitation and management, provide baseline measures to detect change, and generally assist clinical decision-making regarding such issues as capacity. Tests and assessment procedures are being further developed so as to improve their ecological validity, enabling better prediction of real-life behaviour and functioning.

1.8.4 Questionnaire, rating, and behavioural methods of assessment

John N. Hall

The earliest forms of psychiatric assessment were based on direct interviews with patients, on reported observations by those who knew the patient, and on direct observations by attendants—later nurses—in the care setting. Attempts to codify these forms of assessment had begun over 90 years ago, as illustrated by the 'Behavior Chart' of Kempf.[1] The present range of structured psychiatric assessment methods grew from the 1950s in association with the introduction of neuroleptic medication and the development of psychiatric rehabilitation programmes. The two most frequently used types of systematic and structured assessment used in both clinical practice and research continue to be questionnaires and ratings. Their value lies in the systematic coverage of relevant content, and the potential for comparing scores across individuals and groups and over time.

This section covers assessment methods that are appropriate for both self-report by patients and others—questionnaires—and observations and judgements made by others about the patient and their immediate circumstances—rating methods. This section will also briefly describe behavioural approaches to assessment of clinical relevance.

Questionnaires offer the respondent a preset range of written questions covering the area of clinical interest, such as depression. The questions are usually completed by marking one of a set of provided response categories (**forced-choice** questions), but may be completed by the patient writing their own response in free text.

Self-report and 'self-monitoring' methods are similar to the latter form of questionnaire, in that the patient completes a diary or premarked sheets. These are more open-ended, and any associated thoughts of the patient may be included. Self-report measures are used widely in cognitive behavioural interventions.

Ratings are judgements about the quality or characteristics of a defined attribute or behaviour, completed subjectively, or on the basis of direct observation of the behaviour in question. While questionnaires are usually self-completed, ratings may be completed by one person with respect to another person. In psychiatric practice, ratings include those made by professional staff, often a nurse or care worker, or by a family member or informal carer, about a patient.

Ratings and behavioural measures have a special use in the assessment of disturbed or bizarre behaviour, where the patient may have little insight or knowledge of the nature or degree of their disturbance, which may pose a major ongoing management problem, or a barrier to their placement in the community. An example of such a measure is the Aberrant Behavior Checklist.[2] This is a 58-item behavioural rating scale completed by an informant, with the content covering five subscales: irritability, agitation, and crying; social withdrawal and lethargy; stereotyped behaviour; hyperactivity and non-compliance; and inappropriate speech.

The purpose of questionnaire, rating, and behavioural assessments

Scales may be used for a number of purposes:

- for the initial assessment of a patient as part of a clinical formulation
- for ongoing monitoring during the course of treatment
- as outcome measures
- for assigning patients from a larger population to a particular therapeutic regime
- for service planning

Normally an assessment will focus on the presented or referred patient. However, it may be helpful to either focus on a family member or on a formal or informal direct carer of the patient. Another potential focus is the patient's environment. The range of behaviour a patient can display is limited by the physical nature of their environment, by the range of equipment or materials available to the patient, and by the social rules of the setting (such as rules against smoking). A rating of environmental restrictiveness would then survey both environmental constraints and the range of formal institutional regulations and informal rules followed by care staff.

Most measures simply describe the current functioning of the patient, without offering a framework for translating the obtained scores into clinical priorities for treatment. An important development in rating methodology has been the 'needs assessment' approach that incorporates the views of patients and carers when taking into account the extent to which their needs have been met, or remain unmet. The Camberwell Assessment of Need (CAN) family of measures[3] has adopted a consistent set of content domains, which has been applied to separate need assessment schedules which can now be applied to adults, older adults, people with learning disabilities, and in forensic settings.

Scale content

A questionnaire or rating is defined by both **overall content** and **item format**. The content of a measure should logically be determined by its purpose. One model of assessment[4] suggests that there are four main content areas for assessment, including cognition, affect (including verbal-subjective components of behaviour), physiological activity, and overt behaviour. The content should cover all the domains of clinical relevance, including current and past behaviour, and psychopathology. While most rating scales cover a relatively limited number of functional areas, and are often designed for use with a specific client group or clinical population, some measures are designed for wider use.

The format of each item typically consists of an **item stem**, or question, followed by a set of **response options**. The item stem and responses should be grammatically complementary, and the total set of response options for each item should together cover all logically possible response options. Responses should use exact frequencies (such as 'twice a day' or 'at least every hour') rather than vague terms such as 'often' or 'frequently'. Response options may be set out verbally, or may have a numerical value attached. Usually the responses for each item will be laid out in sequence to form a graded series of increasing or decreasing severity or quality of response. These items may be set out in **unipolar** (where one end is 'zero' or nil occurrence) or **bipolar** (with the mid-point being neutral or 'normal') form. In general, if an item has more than five response options there is a risk of poor reliability. Figure 1.8.4.1 illustrates the most common individual item formats.

Most items in questionnaires and rating scales are designed to produce ordinal scores—that is, the score simply gives the relative order of items, without implying any mathematical equality of the differences between scores. This limits the statistical methods that can be used with the scores arising from these measures.

Criteria for evaluating questionnaires and rating scales

There are a number of technical and practical factors to bear in mind in appraising and selecting a measure. Anyone using a published questionnaire or rating scale should examine the technical qualities of the measure, which should be included in the original publication or on a scale manual. This is both to critically assess whether or not a specific measure is suitable for the intended purpose, and also to understand how best to use the scale in practice—including any training requirements.

Direct frequency count

How many cigarettes a day do you smoke? ....

Dichotomous or binary item (used in checklists)

Have you ever smoked a cigarette? Yes ☐ No ☐

Three or more response options

a. Nominal scaling: please describe your marital status

Single ☐ Married ☐ Separated/divorced ☐ Widowed ☐

b. Ordinal Unipolar: how often do you feel constipated?

Never ☐ Between 1 and 3 times a week ☐ 4 or more times a week ☐

c. Ordinal Bipolar: how good are you as a car driver?

Above average ☐ average ☐ below average ☐

Linear or **Visual analogue** scale (the line is usually 10 cm long)

What quality of care have you received?

Very poor ——— Very good

Fig. 1.8.4.1 Examples of item formats.

Psychometric adequacy

Psychometric criteria are the most important technical ways to evaluate the quality of a measure. Chapter 1.8.3 outlines those minimum psychometric principles and properties that are applicable to all psychological measures, including the classical approaches to scaling, reliability, validity, and sensitivity to change, as well as generalizability approaches. The most widely known psychometric requirements of any scale are validity and reliability: neither of these are inherent properties of a scale. Scales are valid for specific purposes, which should be clearly described in the original published article about a scale.

The form of reliability most characteristic of rating scales, and of other behavioural measures, is inter-rater or inter-observer reliability, which examines the similarity of scores when two or more different raters administer a scale. Ideally the manual for a scale should describe a rater training procedure. If not, it is always sensible to carry out some basic rater training, carrying out some assessments prior to the main study, analyzing score discrepancies, and ensuring that raters have discussed these differences and why they arose.

Typically, ratings may be completed after an observation period varying from a few minutes or hours, to a few days. For those ratings based on observation periods of more than a day, there is then a variable delay between the relevant observations and the completion of the rating, and also any one observer will only have been present or on duty for a proportion of the observation period. Unless the observer against whom reliability is being assessed is observing for exactly the same period, the periods of observation will not be coincident. Under these circumstances a double rating may not be strictly a reliability check, but more of a check of the stability of the behaviour. Patel *et al.*[5] discuss how the use of a simple checklist of the occurrence of key events can substantially improve the reliability of this type of scale.

A further technical issue for observer-based scales is that of reactivity, which is the change in behaviour due to the patient's awareness of the presence of an observer. *Any* live observer will induce some reactivity effects, and this issue is often ignored. Reactivity factors may be reduced by making the observation procedure as minimally intrusive as possible by, for example, careful siting of the observer.

Practical factors and an example

Because of their apparent simplicity, the limitations of questionnaires are not always considered. Bowling[6] has reviewed the main sources of variation in data quality between four modes of administering questionnaires, comparing face-to-face interviews, telephone interviews, self-administration, and electronic procedures. The quality of data was defined in terms of overall response rates, item response rates, response accuracy, and social desirability response bias. These different ways of administering questionnaires have differing cognitive demands on respondents,

so that face-to-face interviews tend to yield higher quality data. Regier *et al.*[7] point out the need to standardize measures for both clinical and epidemiological work, given the 'drift' or 'mutations' that can occur with repeated use of even the most carefully designed measures, with major consequences, for example, for public health and policy if prevalence estimates cannot be made reliably.

Practically, scales should be written at the level of vocabulary simple enough for the lowest level of educational attainment likely to be found among scale users. Usually one type of item format is used throughout the scale: sometimes the wish to have one format means that some items are then not easy to understand because that one format is not suited to the content of every item. Shorter scales are usually preferred to longer ones. Some scales are in the public domain. Others are copyright and payments should then be made each time a copy of the scale is used.

There are several steps involved in creating a questionnaire or rating scale. The creation of the original item pool is the first step in designing a new measure, and often existing measures provide some of the items, as well as those identified from any other surveys or studies. Individual items must be selected from this pool, implying, making judgements about the most important topics to cover, and about the bandwidth of the possible range of response options from 'normal' to the most extreme likely to be found.

McGuire *et al.*[8] give a very clear description of the construction of a new rating scale to assess the quality of the clinician–patient therapeutic relationship in community care. They describe the four stages in the creation of the scale:

- generating an item pool
  - conducting semi-structured interviews with clinicians and patients
  - reviewing the content of existing scales covering the same phenomena
- identifying factors and items in the new scale
  - original pool of items rated by clinicians and patients
  - rating scores subjected to principal components factor analysis
- conducting a test–retest reliability study of the new scale
- testing the factorial structure of the revised new scale in a new sample of clinicians and patients

Multiple measures

In both clinical practice and research, the concurrent use of several different measures may be helpful, addressing different categories of functioning and behaviour, with care taken to consider the overall assessment load on any one staff member in the light of their other clinical commitments. Rutter,[9] in reviewing changes in child psychiatry, pays particular attention to the importance of sound measurement by contrasting standardized interviews and checklists, and points out that multiple measures involving different informants, which are repeated over time, are necessary to reduce error and minimize rater bias. Self-completed questionnaires may supplement observer-completed ratings or checklists in the assessment of specific behavioural problems. Deale *et al.*[10] in evaluating the outcome of a treatment trial for chronic fatigue, used 10 outcome measures, namely: three functional impairment measures; two fatigue measures; two psychological distress questionnaires or inventories; and three other variables, including a global self-rating and a self-written statement of illness attributions.

Behavioural and observational assessment methods

A number of existing simple observational methods were refined alongside the clinical introduction of behaviour therapy procedures in the 1960s, and these continue to be associated with contemporary cognitive behavioural interventions (see Fig. 1.8.4.2).

These methods focus on current overt behaviour, and are used for the immediate recording of events, for example counting the number of times an event occurs (leading to frequency counts), or coding observed event by using a set of prescribed behavioural categories that exhaustively and mutually exclusively cover all anticipated possibilities. Direct observation methods can be used in a standardized manner for a group of patients. But they also lend themselves to flexible modification, so that the frequency and the duration of observation periods, and coding systems, can be chosen to suit the requirements of the behavioural difficulties of an individual.

Functional analysis

The term 'functional analysis' generally refers to attempts to discern the variables controlling or maintaining a phenomenon. It usually describes the observation of an individual's behaviour of clinical significance, linked to the observation of those events in the immediate environment that directly preceded, were concurrently associated with, and followed, the target behaviour. This sequence of **antecedent** environmental events, target **behaviour** and concurrent events, and **consequent** environmental events, is often called an **ABC** analysis. For example, incidents of aggression by a particular client in a day-setting may be a function of who is near them or talking to them, so that a record of their presence or absence would be important.

Sampling

A key issue with both rating and direct observational methods is the spread of observation periods over the waking day. Since many behaviours vary in their natural frequency during the waking day, many events should, theoretically, be observed continuously throughout the day. However, since the time needed for continual observation is usually unavailable, a representative sample of the whole day should be observed. Ideally, a random sample of time

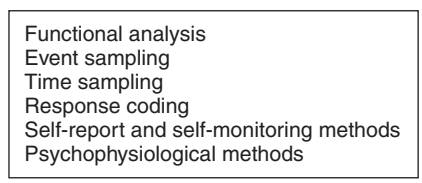

Fig. 1.8.4.2. Categories of behavioural and observational assessment methods.

periods throughout the day should be observed. When events of clinical interest are very complex, it may take too long to code each event fully, so then only, say, every fifth or tenth event is coded in detail—this is termed as **event sampling**. When events are happening very rapidly, or if they tend to happen at about the same rate during the day, it is time-wasting to observe all the time, so observations may then be made only every 15 or 30 min—this is termed as **time sampling**.

Response coding

A set of qualitative coding categories should cover all the most likely events, using clear and unambiguous language, coding categories should be simple enough to be entered quickly. When continuous observation is used, especially for high rates of behaviour, the observer must be allowed regular rest periods.

Psychophysiological methods

These methods typically involve the use of surface sensors to measure changes in, for example, skin electrical conductivity (as in measuring changes in sweating), in light transmission (as in measuring changes in finger blood flow), and in volume (as in plethysmography). These sensors are now always electronic, so the electrical signals from them are calibrated with the associated physical change, which is taken as a proxy measure for the assumed underlying change in physiological arousal. The small size, low weight, and the sophistication and reliability of electronic recording equipment, including hand-held electronic event recorders, now allows the immediate and unobtrusive recording of events, with concurrent data analysis.

Standard or individualized measures?

There are many standard ratings and questionnaires already in existence covering most areas of clinical interest. However, the fact that a scale is well used does not necessarily mean that it is psychometrically sound, or that the content covered is appropriate for a given clinical or research purpose. Rating scales may continue to be used widely when they are no longer the best scales technically, but because the volume of published research in which they have been used permits comparisons with other studies.

Solutions to this dilemma are either to create a totally new measure, making sure it *is* better than its predecessor, or to improve systematically the properties of an existing measure. Parker *et al.*[11] describe a modification of the well-established parental bonding instrument to include abusive parenting, which was omitted in the original version. Their article demonstrates both how to modify an original measure to improve item wording, and at the same time incorporate additional material to increase the value of the measure. An unsound solution is to change the measure in an *ad hoc* way—scale vandalization!—with no awareness of the principles of sound scale and item construction. This only results in an instrument that will then be of poor or unknown reliability or validity.

Conclusions

The value of rating and questionnaire methods is that they can be used by a variety of assessors who do not need to be qualified mental health professionals—although the need for at least some training in rating methods should not be overlooked. They can be presented in very short versions therefore making minimal demands on both assessors and patients, and so can lead to high levels of compliance. Since they can be used by patients, they can themselves be tools to increase engagement and to give patients direct feedback about their own current state. Behavioural and observational assessment measures constitute a clinically useful subgroup of methods, which potentially have high validity with respect to day-to-day functioning. However, the apparent simplicity of all of these methods masks the need for care in their construction, the importance of training in their use, and caution in over-sophisticated interpretation of data arising from their use.

Further information

There are a number of helpful core texts, describing general technical issues in questionnaire and rating scale design (see Streiner & Norman[a] and McDowell[b]). Similarly Haynes & O'Brien[c] and Hersen[d] cover the general principles of behavioural assessment. Andrews *et al.*[e] give an excellent review of outcome measures in mental health, covering many of the most commonly used rating scales. McDowell[b] and Bowling[f] include extensive lists of the most commonly used scales in health and social care, including those covering mental health issues.

Diagnosis and classification

Michael B. First, and Harold Alan Pincus

In Psychiatry, as in all of medicine, diagnosis is a key function and central to developing a plan of treatment for patients. Psychiatry, however, faces special challenges. The etiopathogenesis of most psychiatric disorders is not known. For the most part, a clinician must rely on reports from, and direct observation of patients to gather the necessary information to determine a diagnosis. Until very recently, laboratory tests had little relevance. Even diagnostic information found in medical records may not be useful, since the clinician cannot ascertain whether the historically recorded diagnoses of previous clinicians were based on reliable observations, the application of similar diagnostic approaches, or even the same system of classification. These special challenges faced by the field have ensured that diagnosis and classification in psychiatry has a long and rich history.

Definitions

The term 'diagnosis' can mean both the name of a particular disease as well as the process of determining or 'making' a diagnosis. In medicine, generally, various terms are used to describe a pathological entity. When there is the presence of objective pathology or the presumed understanding of aetiology, the term 'disease' is generally used, e.g., pancreatic cancer, strep throat, Alzheimer's disease. In instances of unknown aetiology or when the disease process is not apparent, the term 'disorder' is usually applied with a syndromic characterization, i.e., definition based on symptom presentation, history, and sometimes, associated laboratory findings. Other terms are also used in common parlance, such as 'illness' for an individual's subjective awareness of distress and 'sickness' for the inability to perform usual social roles. For the most part, in psychiatry, the term 'disorder' is used.

Classification represents the process of placing diagnostic entities into various groupings in a systematic way, based on a set of principles with regard to the similarities and differences among these categories. Depending upon the principles and conceptual framework underlying the categorization process, classifications can be very different.

Goals of the classification

In some ways, the most important question may be 'whose needs is the classification primarily intended to address?' Clinicians want a classification that can categorize as many people that come in for help as possible. They want the classification to facilitate the identification and treatment of patients and provide guidance on prognosis and cause. Researchers want to have groupings that are highly homogeneous in order to test the efficacy of specific treatments and to better understand the aetiology of specific disorders. Educators want a classification system to offer a structure for teaching about psychopathology and differential diagnosis. Public health administrators want to track epidemiology, health utilization, and costs over time. Some argue that psychiatric diagnosis is a reductionistic labelling of individual differences or social deviance and exposes individuals to potential stigma. At a minimum, they would like a psychiatric diagnostic system to be less prone to misuse. Ultimately, most classifications attempt to balance among those competing priorities, not always successfully. In some cases, e.g., the ICD-10, different products are developed for different target groups, i.e., research diagnostic criteria for investigators, a simpler, more aggregated classification for primary care providers, etc.

Conceptual issues

A range of conceptual issues and their resolution determines the principles and rules governing a system of classification. It is important to note, however, that classification systems do not necessarily apply these rules in a consistent manner. Some of the issues noted below may not be resolved in an absolute manner, but in a way that employs compromises among multiple priorities, e.g. balancing the needs of clinicians, researchers, educators, and public health administrators or having some diagnostic groupings based on a descriptive approach and others on a theory-based approach.

Descriptive v. theory-based: Do the classification principles emanate from a theory regarding the aetiology or mechanisms of psychopathology (e.g. psychodynamics, behavioural, neurobiological) or does the classification attempt to provide a theoretical heuristic framework for describing syndromic entities?

Pathology v. normalcy: What assumptions underlie distinguishing what constitutes a 'mental disorder' or 'caseness' from normative behavior?

Categorical v. dimensional: Does the classification assume discrete categories with sharp boundaries or does it assume that psychopathology lies on a continuum across a range of dimensions (and if so, what dimensions and how were they chosen?)

Lumping v. splitting: Does the classifications system establish a smaller number of broad, relatively heterogeneous categories or numerous homogeneous categories?

Multiple v. single diagnosis: Is there a hierarchy where certain diagnoses have priority and 'trump' other diagnoses if an individual fits into more than one category or are multiple simultaneous diagnoses (i.e. comorbidity) encouraged to communicate more complete diagnostic information?

The development of modern classifications

The first international classification of diseases in 1855 was concerned with a nomenclature of causes of death.[1] After many revisions this list was adopted by the World Health Organization (WHO) in 1948 and the so-called *Sixth Revision of the International Statistical Classification of Diseases, Injuries and Causes of Death* (ICD-6) was produced.[2] The sixth edition of the ICD included for the first time a classification of mental disorders, containing 10 categories of psychoses, nine categories of psychoneurosis, and seven categories of character, behaviour, and intelligence. A number of problems with this classification (e.g., many important categories such as the dementias, many personality disorders, and adjustment disorders were not included) rendered it unsatisfactory for use in most countries; only five countries, including the United Kingdom, adopted it officially. The first edition of the American Psychiatric Association's Diagnostic and Statistical Manual of Mental Disorders (DSM-I)[3] was published in the United States as an alternative to ICD-6. For the first time in an official classification, glossary definitions of the various disorders were included in addition to the names of the disorders.

Work on ICD-8 began in 1959 with the goal of developing a classification system that would be acceptable to all of its member nations. The resulting system, ICD-8, went into effect in 1968, and in 1974 added a glossary which was largely based on British views about diagnostic concepts.[4] Coincident with the development of ICD-8, the American Psychiatric Association prepared a second edition of its DSM based on ICD-8, defining each disorder for use in the United States.[5]

The early 1970s saw the introduction of explicit operationalized diagnostic criteria that were developed for research purposes. Although the glossary definitions of disorders in DSM-II and ICD-8 were an improvement over just having a list of diagnostic categories, these brief descriptions were too vague to be useful in identifying diagnostically homogeneous populations for study. Researchers responded to this need by developing their own operationalized criteria. The first set of diagnostic criteria that covered a wide range of disorders was developed by Robins and Guze at Washington University in St. Louis[6] with the stated purpose of 'provid[ing] common ground for different research groups so that diagnostic definitions can be emended constructively as further studies are completed'. (p. 57). They were known as the 'Feighner criteria' after the first author of the paper that presented them. Criteria sets for 16 disorders were presented and listed those features required for each diagnosis (known as 'inclusion criteria') as well as features whose presence would rule out the disorder (known as 'exclusion criteria'). The Feighner criteria proved to be enormously useful to the research community as illustrated by the large number of times they were cited in other papers (i.e. 1650 citations from 1972 to 1982 as compared to the typical average of 2.1 citations per paper). Several years later, an expanded set of research criteria based on the Feighner criteria was developed to meet the needs of a National Institute of Mental Health-sponsored collaborative project on the psychobiology of depression.[7] These criteria, known as the Research Diagnostic Criteria (RDC) subsequently became very popular among researchers and were heavily used, especially in research on mood and psychotic disorders.

To develop the mental disorders section for ICD-9, WHO initiated an intensive program to identify problems encountered by psychiatrists in different countries in the use of the mental disorders section of ICD-8 and to formulate recommendations for their solution. A series of eight international seminars were held annually from 1965 to 1972, each of which focussed on a recognized problem in psychiatric diagnosis. The outcome of the seminars formed the basis for the recommendations made for ICD-9,[8] which was ultimately published in 1978.

As work progressed on the development of ICD-9, the American Psychiatric Association decided to develop a third edition of its diagnostic manual, DSM-III.[9] This decision was made both because of identified inadequacies of the ICD-9 for research and clinical use, and because the ICD-9 did not include important innovations that had already been demonstrated by researchers to be both technically feasible and useful, like operationalized diagnostic criteria. Under the leadership of Robert L. Spitzer, successive drafts of DSM-III were prepared by 14 advisory committees, with the drafts being distributed among both American and international psychiatrists for comments and review. Many of the DSM-III criteria sets were based on the RDC criteria, with the rest developed based on expert consensus.

The improvement in reliability over DSM-II (which provided only glossary definitions) was demonstrated by a large NIMH-supported field trial in which clinicians were asked to independently evaluate patients using drafts of the DSM-III criteria.[10] The explicit diagnostic criteria provided for each of the disorders in the classification were based on the symptomatic presentation of the disorder rather than on theories about the underlying cause. Even though the DSM-III was a product of the American Psychiatric Association, its adoption of this 'descriptive approach' resulted in its widespread acceptance by all mental health professionals in the United States, regardless of their theoretical orientation. For example, clinicians from different orientations might have very different understandings of what causes panic attacks; a cognitively-oriented clinician might attribute a panic attack to the person's tendency to catastrophize in response to normal physical sensations like increased heart rate; a neurobiologically-oriented clinician might consider panic attacks to be due to overactivity of brain circuitry involved in fight-or-flight responses, and a psychodynamically-oriented clinician might see panic as a consequence of the breakdown of the defense organization at various levels. Despite these divergent hypotheses, however, all of these clinicians can agree on how a panic attack presents (i.e. a discrete period of apprehension or fear with at least four symptoms such as shortness of breath, palpitations, chest pain, choking, dizziness, etc), thus facilitating communication among them.

DSM-III also introduced the use of a multiaxial system for recording the diagnostic evaluation. The multiaxial system facilitated the use of a biopsychosocial model of evaluation by separating (and thereby calling attention to) developmental and personality disorders (Axis II), physical conditions (Axis III), stressors (Axis IV),

and degree of adaptive functioning (Axis V) from the usually more florid presenting diagnoses (Axis I).

Despite initial opposition among some psychiatrists (most especially those with a psychoanalytic orientation), DSM-III proved to be a great success, becoming the common language of mental health clinicians and researchers for communicating about mental disorders. Although it was intended primarily for use in the United States, it was translated into 13 languages and was widely used by the international research community.

Experience with DSM-III in the few years after its publication in 1980, revealed a number of inconsistencies and lack of clarity in the diagnostic criteria sets. Furthermore, research conducted in the early 1980's demonstrated errors in some of the assumptions that went into the construction of the DSM-III criteria sets. For example, the DSM-III prohibition against giving an additional diagnosis of Panic Disorder to individuals with both Major Depressive Disorder and panic attacks was shown to be incorrect based on data demonstrating that relatives of individuals with both Major Depressive Disorder and Panic Attacks can have either Major Depressive or Panic Disorder.[11] For these reasons, work began on a revision of the DSM-III, which was published as DSM-III-R in 1987.[12]

Initial work began on the development of the psychiatric section of the *10th Revision of the International Classification of Diseases* (ICD-10), in 1982 under the chairmanship of Norman Sartorius. After a meeting of WHO representatives and consultants together with representatives of the American Drug and Mental Health Administration in Copenhagen in 1982, several further meetings took place (e.g. in Djakarta and in Geneva in 1984) in which a provisional psychiatric classification was designed. It was decided that the ICD-10 classification of mental disorders would be produced in several versions. The first of these is to be used, as are other parts of the International Classification of Diseases, mainly for statistical purposes, and included a short glossary definition for each category.[13] This is the version that was officially approved by the World Health Assembly and thus, is the version for which international compatibility is mandated by treaty agreements. The second version, Clinical Descriptions and Diagnostic Guidelines is for the use of the practicing clinician.[14] Each category in this version has a detailed definition specifying the main features of the disorder followed by diagnostic guidelines. The third version, the Diagnostic Criteria for Research is primarily intended for research and contains diagnostic criteria which are stricter in form than those in the clinical diagnostic guidelines from which they were derived.[15] For example, while the guidelines may indicate that a particular disorder 'usually starts in early childhood', the diagnostic criteria for research would specify that the diagnosis 'should not be made if the onset is after the age of 30', The decision to separate the criteria for research from the clinical guidelines was made because clinicians in their daily work do not observe overly strict rules when making diagnoses, which are of cardinal importance for research.[16] Finally, a version of the mental disorders section was produced for use in primary care settings.[17] It contains a much smaller number of categories (i.e. those that are frequently encountered in every day general practice) as well as treatment guidelines corresponding to these categories.

By 1986, a first draft of the psychiatric chapter, including details of the categories, code numbers, diagnostic guidelines, and precise diagnostic criteria for research had been written, and by June 1987, the clinical diagnostic guidelines were being circulated by WHO's division of mental health for field trials in 194 different centers in 55 different countries.[18] In 1989, the International Revision Conference, attended by representatives of the health ministries of a majority of WHO member states gave formal approval to the basic categories and text. A draft of the diagnostic criteria for research was produced in 1990 and field trials to evaluate inter-rater agreement, confidence in diagnosis, and ease of use began later in the year.[19] Finally, in 1990, the World Health Assembly formally approved its introduction in member states starting in January 1, 1993.

The American Psychiatric Association started work on the development of DSM-IV in 1988, shortly after the publication of DSM-III-R, spurred on by the need to coordinate its development with the already ongoing development of ICD-10. DSM-IV continued the descriptive atheoretical approach advanced by both DSM-III and DSM-III-R, but this time also incorporated a meta-analytic data-based revision process to guide changes.[20,21] This was in contrast to both DSM-III and DSM-III-R which by necessity, given the paucity of available empirical data, relied almost exclusively on expert consensus. The DSM-IV workgroups began their deliberations by identifying a series of diagnostic questions to be considered and problems to be addressed and employed a three-stage empirical review process to address, these questions. The first stage involved a systematic comprehensive review of the published literature guided by literature searches using rules established at a DSM-IV methods conference. The second stage involved supplementing the literature reviews with a data reanalysis project funded by the MacArthur foundation in which existing data sets collected for other studies were combined and analyzed using meta-analytic methods. These data reanalyses were useful in answering a number of diagnostic questions (e.g. determining the minimum number of panic attacks required in order to justify a diagnosis of panic disorder) but were unfortunately limited by incompatibilities in the data sets and the fact that the data needed to answer specific diagnostic questions often had not been collected. Proposed criteria sets formulated based on the literature reviews and data reanalyses were then tested in 15 NIMH-funded multi-site field trials. The entire empirical review process and the reasons underlying the decisions made by the DSM-IV workgroups have been documented in the four volume DSM-IV Sourcebook.[22–25]

In order to increase compatibility between ICD-10 and DSM-IV, a collaborative relationship was established between the DSM-IV workgroups and the developers of ICD-10. Two meetings were convened in which the respective workgroups joined forces with the goal of minimizing the differences between diagnostic definitions in the two systems. Unfortunately, the potential to make the two systems identical was seriously constrained by differences in the timelines between the two revision processes. By the time the DSM-IV workgroups were first convened in 1989, the categories and basic text of the ICD-10 had already been settled by the International Revision Conference.[26] Thus, although final DSM-IV and ICD-10 systems were much more similar than were DSM-III and ICD-9, a number of mostly small differences in criteria sets persist. While some of the discrepancies are the result of genuine differences in diagnostic outlook (e.g., the one month duration of ICD-10 schizophrenia vs. 6 month duration of DSM-IV schizophrenia), the overwhelming majority appear not to have any justification.[27]

One of the most important uses of the DSM-IV has been as an educational tool. This is especially true of the descriptive text that accompanies the criteria sets for the DSM-IV disorders. Given that the interval between DSM-IV and DSM-V was being extended from seven years between DSM-III and DSM-III-R, and between DSM-III-R and DSM-IV to at least 12 years, concerns were raised that the information in the text would become increasingly out-of-date over time. Therefore, in order to bridge the span between DSM-IV and DSM-V, a revision of the DSM-IV text was undertaken.[28] The primary goal of the DSM-IV-TR was to maintain the currency of the DSM-IV text, which reflected the empirical literature up to 1992. Thus, most of the major changes in DSM-IV-TR were confined to the descriptive text. Changes were made to a handful of criteria sets in order to correct errors identified in DSM-IV. In addition, some of the diagnostic codes were changed to reflect updates to the ICD-9-CM coding system adopted by the U.S. Government.

Differences between DSM-IV and ICD-10

A fundamental difference between the ICD-10 and the DSM-IV reflects the different purposes of the two systems, i.e., that ICD-10 is set up as a classification system whereas DSM-IV is a diagnostic nomenclature. The primary goal of the ICD is to facilitate the collection of statistics about those individuals who present themselves to a health care professional. Thus, the ICD has been designed to provide the coder with an unambiguous choice of diagnostic category given a particular case. The main rule for deciding whether to include a diagnostic category in the ICD is its common international usage. Inclusion of a category in the ICD carries with it no implication of diagnostic validity—in fact, a number of categories included in ICD-10 were considered for inclusion in DSM-IV—but were not added because of concerns about their validity (e.g., mixed anxiety depression). In contrast, inclusion of a category in the DSM implies that the category has been officially sanctioned by the American Psychiatric Association as appropriate for clinical and research usage, i.e., the category has both clinical utility and is backed up by an empirical data base. It should be noted, however, that the empirical data base is not equivalent for all of the categories—to minimize disruption, diagnostic categories, that were included in earlier editions of the DSM have been 'grandfathered' in. Starting with DSM-IV, new categories were only added if they met these higher standards.

Another important difference between the DSM and ICD approach is the role of impairment in the definition of a disorder. With only a few exceptions (e.g., dementia, phobias), mental disorders in ICD-10 are defined exclusively by the symptomatic presentations—there is no requirement that the symptoms cause any impairment in the individual's level of functioning. Impairment in functioning caused by the symptoms is indicated in ICD-10 by using an orthogonal scale, the International Classification of Functioning.[29] In contrast, most of the DSM-IV criteria sets include a criterion (known as the 'clinical significance criterion') requiring that the disturbance causes clinically significant distress or impairment in social, occupational, or other important areas of functioning. According to the introduction of the DSM-IV, this criterion has been included to help establish 'the threshold for the diagnosis of a disorder in those situations in which the symptomatic presentation by itself (particularly in its milder forms) is not inherently pathological and may be encountered in individuals for whom a diagnosis of 'mental disorder' would be inappropriate'. (p. 8). Accordingly, the only diagnoses that do not include this criterion are those whose symptomatic presentations are considered to be inherently indicative of psychopathology (e.g., the psychotic disorders).

The diagnostic implications of this difference can be illustrated in the different ways that specific phobia is defined in DSM-IV and ICD-10. In DSM-IV, a phobia is diagnosed only if 'the avoidance, anxious anticipation, or distress in the feared situation interferes significantly with the person's normal routine, occupational (or academic) functioning or social activities or relationships, or there is marked distress about having the phobia'. (p. 449, DSM-IV-TR). ICD-10 has no such requirement; the phobia is diagnosed so long as there is a marked fear or avoidance of a specific object or situation. Thus, an individual residing in New York City who has a snake phobia but who never has any occasion to encounter a snake would not be diagnosed as having a mental disorder in DSM-IV-TR because the phobia does not have any impact on the person's functioning whereas in ICD-10 such an individual would be diagnosed as having a snake phobia because the person would react with fear or avoidance if he or she had the occasion to be confronted with a snake.

Separating symptoms from the functional impairment that results from them certainly makes conceptual sense. In other areas of medicine, the diagnosis of a disorder is based solely on the presence of pathology and not on the effect that the pathology exerts on a person's life (e.g., a patient is diagnosed with pneumococcal pneumonia if the patient's lungs are infected with the pneumococcus bacillus regardless of the impact of the pneumonia on the patient's level of functioning). The problem with diagnosing mental disorders in this way is that it is not currently possible to define the presence of a mental disorder based on the identification of its underlying pathology. The descriptive symptoms that make up the definitions of mental disorders in the DSM-IV and ICD-10 are not specific to mental disorders but can and do occur in individuals without any mental disorder. Thus, defining disorders exclusively in terms of presenting symptomatology, much of which can occur in normal individuals, can lead to false positive diagnoses. For this reason, in order to avoid false positive diagnoses in the absence of objective evidence of disease, DSM relies on functional impairment or distress to help set the diagnostic threshold between normality and disorder.

The structure of ICD-10, (Chapter V)

The psychiatric classification is part of the general medical classification. There are 21 chapters, each designated by a Roman numeral. The psychiatric disorders are included in Chapter V which is also identified by the letter F. The letter F is followed by Arabic numbers, the so-called second digit for the larger diagnostic groups and the third digit for more special groups. Thus the use of three digits allows a choice of 100 diagnostic possibilities. Proceeding further with a fourth digit, 1000 possible diagnoses are available, of which about one-third are used at present. This system is thus designed to allow the addition of new diagnoses in future without having to change substantial parts of the classification.

Furthermore, it is possible to code the course over time or characteristic features of a disorder by using a fifth or sixth digit. By using codes from other chapters of ICD-10, such as X, Y, and Z, additional

circumstances (e.g. suicide) or special symptoms (e.g. nausea) as well as psychosocial factors can be coded. Somatic comorbidity is coded from the related chapters, for example diseases of ear, nose, and throat from Chapter VIII headed by the letter H (e.g. tinnitus H93.1) or diseases of the gastrointestinal system from Chapter XI headed by the letter K (e.g. alcohol gastritis K29.2). The specific challenges encountered in diagnosing psychiatric disorders reliably over the years has led WHO to include short definitions plus inclusion and exclusion terms for all psychiatric disorders in Chapter V (F). In all other chapters, diagnoses are named without further explanation.

As described earlier in this chapter, Chapter V of ICD-10 is not just a catalogue of disorders for statistical purposes, but is also a clinical manual, a textbook of diagnoses, and an instrument for research for different users. Therefore, a group of texts had to be produced to serve the various purposes—the so-called 'ICD-10 family of documents'

The *Short Glossary of ICD-10, Chapter V (F)* is part of the basic work known as the *International Statistical Classification of Diseases and Related Health Problems* The Short Glossary is part of the first of three volumes, the general systematic classification, and gives short definitions which are useful not only for medical personnel but also for statisticians, health insurance clerks, and others who are not in medical or related professions.

The *Clinical Descriptions and Diagnostic Guidelines (CDDG Version)*, known as the Blue Book because of the colour of its cover, was developed first and can be regarded as the central part of the psychiatric classification[14] intended for use by psychiatric clinicians in their daily practice. The *Diagnostic Criteria for Research* (DCR), known as the Green Book, has been developed for scientific use[15] and is intended to be used together with the diagnostic guidelines. Compared with the Blue Book, the symptom criteria are more clearly defined, the time criteria are stricter, and the inclusion and exclusion criteria are more precise in the Green Book. Thus, many unclear cases which are unsuitable for research are excluded. However, despite its title, this book is also useful for diagnosticians in clinical practice.

The *multiaxial version* of the ICD-10 classification of mental disorders allows different aspects of the patient's health and social situation to be assessed. Introduced by Rutter and colleagues,[30] multiaxial diagnosis has been employed for many years in child and adolescent psychiatry. It contains clinical syndromes, problems of development, intelligence, somatic disorders, and psychosocial problems. To a considerable degree, the multiaxial version of ICD-10 is comparable with that of DSM-IV. However, in DSM-IV, axis I is for psychiatric clinical disorders, axis II is for personality disorders and intellectual disability, and axis III is for general medical conditions. In ICD-10, axis I includes all disorders. Thus, psychiatric disorders (F1–F5), personality disorders (F6) and intellectual disability (F7), and the chapters on somatic comorbidity all use one axis.

Axis II of ICD-10 is for disability. To facilitate its use, WHO developed an instrument, the short disability assessment schedule (WHO DAS-S), which helps to describe and assess the consequences of axis I disorders.[31] Axis II corresponds to the widely used DSM-IV axis V, Global Assessment of Functioning (GAF). In connection with the disability axis, the International Classification of Functioning created by WHO for the whole of rehabilitative medicine, of which psychiatry is only a part, should be mentioned.[29] Axis III of ICD-10 covers psychosocial and other problems, and corresponds to DSM-IV axis IV (psychosocial and environmental problems).

The *primary health care* (PHC) version of the ICD-10 classification of mental disorders was developed because of the great importance of psychiatric disorders in general practice, for example the high prevalence of depressions, anxiety disorders, and dependence on alcohol and psychotropic drugs.[17] There are 24 syndromes, including dementia, delirium, depression, etc. Each disorder is understood in a rather broad sense, and not subdivided, and the descriptions are simpler than those in the main classification. A flipcard containing symptoms, diagnostic criteria, differential diagnoses, and counselling and treatment of the patient and the family is provided for every syndrome.

At first glance, the structure of ICD-10, Chapter V (F), follows that of ICD-8 or ICD-9 (See Appendix 1). The classification begins with the 'organic disorders', followed by disorders due to the abuse of psychoactive substances. The next section of the classification contains schizophrenia and other psychotic disorders. This is followed by affective disorders and then neurotic and personality disorders. The chapter ends with intellectual disability and disorders of childhood and adolescence. Closer examination of the classification reveals that the traditional dualistic principle—psychoses on the one hand (in ICD-9: codes 290–299) and neuroses on the other (in ICD-9: codes 300–310)—has been abandoned. The diagnostic terms now used take a more phenomenological descriptive approach. According to the authors of ICD-10, the same psychiatric disorder may show both psychotic and non-psychotic symptoms. 'Psychotic' is defined as the manifestation of productive symptoms. The term 'neurosis' did not appear in the first drafts of ICD-10 because it is used in different and contradictory ways and is supposedly based on theories of intrapsychic processes which many of the WHO experts regarded as not generally accepted. However, after protests and objections by many clinicians worldwide, it was concluded that 'psychotic' and 'neurotic' should be used, although only as descriptive terms and not as diagnostic rubrics. Thus the term 'neurotic disorders' follows the traditional use of the word but does not imply an etiological theory.

(a) Organic, including symptomatic, mental disorders

Disorders of organic aetiology are grouped in this subchapter, independent of whether they contain psychotic or non-psychotic symptoms. However, the use of the term 'organic' does not imply that conditions elsewhere in the classification are non-organic in the sense of having no cerebral substrate.

(b) Mental and behavioural disorders due to psychoactive substance use

An improvement over ICD-9 is the compilation of all mental and behavioural disorders due to psychoactive substances within a single subchapter. The third digit indicates which substance or class of substances (e.g. F10 Alcohol) is responsible for the disorder, which is coded as a fourth digit (e.g. F10.3 Alcohol withdrawal state) or a fifth digit (e.g. F10.31 Alcohol withdrawal state with convulsions). It is possible to differentiate acute intoxication, harmful use, dependence syndrome, withdrawal state with or without delirium, different psychotic disorders, amnesic syndrome, and a number of other disorders. Thus, the psychopathological syndrome can be described and related to the dominant substance class.

(c) Schizophrenia, schizotypal, and delusional disorders

This subchapter covers schizophrenia, acute psychotic disorders, schizoaffective disorders, delusional disorders, and schizotypal

disorders. Before schizophrenia can be diagnosed the symptoms have to be observed for at least one month, unlike DSM-IV where symptoms should be observed for six months before using this diagnosis. Special care is taken with the description of short-lasting psychoses, since acute and transient psychotic disorders are of particular interest to psychiatrists from developing countries where short-lasting acute psychoses with a good prognosis are observed quite frequently.

(d) Mood (affective) disorders

All mood disorders are combined in this subchapter, which represents a considerable change compared with ICD-9. The disorders previously known as endogenous and neurotic depressions are coded in this subchapter; the differentiation between these categories has been abandoned. The ICD-9 category of neurotic depression (300.4) is no longer found in ICD-10; most of these cases are now coded as dysthymia (F34.1). Single manic episodes are coded as F30, while recurrent manic episodes are now coded as bipolar affective disorder (F31), regardless of whether or not there has been a previous depressive episode.

(e) Neurotic, stress-related, and somatoform disorders

The disorders in this subchapter are divided into a large number of categories. For instance, dissociative disorders are divided into seven subcategories, some of which represent rather rare disorders. The term hysteria is no longer used. In this subchapter, reactions to severe stress and adjustment disorders are enumerated according to time criteria and severity. Here, aetiology is generally accepted to mean exceptional mental stress or special life events. A new group of disorders in this classification are the somatoform disorders, which are of particular importance in developing countries. The traditional term neurasthenia is still maintained for a special category, in contrast with DSM-IV.

(f) Behavioural syndromes associated with physiological disturbances and physical factors

This subchapter brings together eating disorders, non-organic sleep disorders, sexual dysfunction, mental and behavioural disorders associated with the puerperium, and abuse of non-dependence-producing substances. In ICD-9, all sexual disorders were contained in one subchapter. In ICD-10, only disorders of sexual dysfunction are in F5; disorders of gender identity and sexual preference have been assigned to two different sections in subchapter F6 on personality disorders. The special code F54, psychological and behavioural factors associated with disorders or diseases classified elsewhere, allows classification of psychosomatic disorders by coding an additional somatic diagnosis.

(g) Disorders of adult personality and behaviour

Specific personality disorders are coded in this subchapter. Cyclothymic personality is not included, but an equivalent appears in F3 as cyclothymia. Also, schizotypal disorders could have been assigned to this subchapter but appear instead in F2 (as F21). The emotionally unstable personality disorder is found in this subchapter, where it is subdivided into an impulsive type (F60.30) and a borderline type (F60.31). A new entity is the factitious disorder, i.e. the intentional production or feigning of symptoms or disabilities, either physical or psychological (F68.1). If desired, narcissistic personality disorder and passive–aggressive personality disorder may be coded by using the criteria in Annex 1 of the Diagnostic Criteria for Research.

An important aspect of this subchapter is the inclusion of enduring personality changes after catastrophic experience (F62.0) or after psychiatric illness (F62.1). Personality changes after surviving a concentration camp or torture are coded under the first of these.

(h) Remaining subchapters

F7 intellectual disability, F8 Disorders of psychological development, and F9 Behavioural and emotional disorders with onset during childhood and adolescence are

The structure of DSM-IV-TR

The 'DSM-IV-TR Classification of Mental Disorders' refers to the comprehensive listing of the official diagnostic codes, categories, subtypes, and specifiers (see Appendix 2). It is divided into various 'diagnostic classes' which group disorders together based on common presenting symptoms (e.g., mood disorders, anxiety disorders), typical age-at-onset (e.g., disorders usually first diagnosed in infancy, childhood, and adolescence), and aetiology (e.g., substance-related disorders, mental disorders due to a general medical condition).

Disorders usually first diagnosed in infancy, childhood, or adolescence

The DSM-IV-TR classification begins with disorders usually first diagnosed in infancy, childhood, or adolescence. The inclusion of a separate 'childhood disorders' section in DSM-IV-TR is only for convenience—some of these conditions are sometimes diagnosed for the first time in adulthood (e.g., attention-deficit/hyperactivity disorder) and many disorders included in the rest of DSM-IV-TR can start in childhood (e.g., major depressive disorder, schizophrenia). Thus, a psychiatrist doing a diagnostic assessment of a child or adolescent should not only focus on those disorders listed in this section but also consider disorders from throughout the DSM-IV-TR. Similarly, when evaluating an adult, the psychiatrist should also consider the disorders in this section since many of them persist into adulthood (e.g., stuttering, learning disorders, tic disorders).

While the first set of disorders included in this section (i.e., intellectual disability learning and motor skills disorders, and communication disorders) are not, strictly speaking, regarded as mental disorders they are included in the DSM-IV-TR to facilitate differential diagnosis. Autism and other pervasive developmental disorders are characterized by gross qualitative impairment in social relatedness, in language, and in repertoire of interests and activities and include autistic disorder, Asperger's disorder, Rett's disorder, and childhood disintegrative disorder. The Disruptive Behaviour Disorders (i.e. Attention-deficit/hyperactivity disorder, conduct disorder, and oppositional-defiant disorder) are grouped together because they are all characterized (at least in their childhood presentations) by disruptive behavior. The Feeding Disorders of Infancy and Early Childhood include the DSM-IV-TR categories of pica, rumination disorder, and feeding disorder of infancy and early childhood (also known as failure to thrive). Tic disorders, elimination disorders, and other disorders of infancy and early childhood (which include separation anxiety disorder, selective mutism, reactive attachment disorder, and stereotypic movement disorder) round out the childhood section.

Delirium, dementia, amnestic disorder, and other cognitive disorders

In DSM-III-R, delirium, dementia, amnestic disorder, and other cognitive disorders, along with substance-induced mental disorders and mental disorder due to a general medical condition, were included in a section called 'organic mental disorders', which contained all disorders that were due to either a general medical condition or substance use. In DSM-IV, the term 'organic' was completely eliminated from the classification because of the misleading implication that disorders not included in that section (e.g., schizophrenia, bipolar disorder) did not have an organic component[32]. In fact, virtually all mental disorders have both psychological and biological components, and to designate some disorders as 'organic' and the remaining disorders in the DSM-IV as 'non-organic' reflected a reductionistic mind-body dualism.

As a result of the elimination of the Organic Mental Disorder diagnostic grouping, those disorders originally included in that section had to be redistributed throughout DSM-IV into other diagnostic classes. Delirium, dementia, and amnestic disorder were thus grouped together into a major diagnostic class because of their central roles in the differential diagnosis of cognitive impairment. Although both delirium and dementia are characterized by multiple cognitive impairments, delirium is distinguished by the presence of clouding of consciousness which is manifested by an inability to appropriately maintain or shift attention. Three types of delirium are included in DSM-IV based on causative factors: delirium due to a general medical condition, substance-induced delirium, and delirium due to multiple etiologies.

Dementia is defined by clinically significant memory impairment accompanied by impairment in one or more other areas of cognitive functioning (e.g. language, executive functioning). DSM-IV-TR includes several types of dementia based on aetiology, including dementia of the Alzheimer's type, vascular dementia, a variety of dementia due to general medical and neurological conditions (e.g., HIV, Parkinson's disease), substance-induced persisting dementia, and dementia due to multiple etiologies. In contrast to dementia, amnestic disorder is characterized by memory impairment occurring in the absence of other cognitive impairments. Two types are included in DSM-IV: amnestic disorder due to a general medical condition and substance-induced persisting amnestic disorder.

Mental disorders due to a general medical condition not elsewhere classified

In DSM-IV-TR, most of the mental disorders due to a general medical condition have been distributed alongside their 'non-organic' counterparts in the classification (e.g. mood disorder due to a general medical condition and substance-induced mood disorder was included in the mood disorders section). Two specific types of mental disorders due to a general medical condition (i.e. catatonic disorder due to a general medical condition and personality change due to a general medical condition) do not fit into any of the other diagnostic classes and therefore, are included here in this diagnostic class.

Substance-related disorders

In DSM-IV, substance-related disorders include psychiatric disturbances that result from medication side effects and the consequences of toxin exposure, in addition to those that arise due to drug and alcohol abuse. Two types of substance-related disorders are included in DSM-IV: substance use disorders (dependence and abuse), which focus on the maladaptive nature of the pattern of substance use; and substance-induced disorders, which cover psychopathological processes caused by the direct effects of substances (including toxins and medications) on the central nervous system.

Schizophrenia and other psychotic disorders

Included in this grouping are those disorders in which psychosis is the primary characteristic symptom (i.e. schizophrenia, schizophreniform disorder, schizoaffective disorder, delusional disorder, shared psychotic disorder and brief psychotic disorder). It should be noted that other disorders that may have psychotic features are not included in this grouping (e.g. mood disorders with psychotic features, delirium).

Mood disorders

This diagnostic class includes disorders in which the predominant disturbance is in the individual's mood. Although the term 'mood' is generally considered to include emotions such as depression, euphoria, anger, and anxiety, DSM-IV includes in this section only disorders characterized by depressed, elevated, or irritable mood. This diagnostic class is further divided into depressive and bipolar disorders. The term 'bipolar' is misleading because the name implies the presence of both 'down' and 'up' moods. In fact, bipolar disorder is defined by the presence of one or more manic or hypomanic episodes. Thus, patients with multiple manic episodes (i.e. unipolar mania) are considered to be bipolar despite the lack of the second 'pole'.

Anxiety disorders

The common thread tying together disorders in this section is the fact that the clinical presentation of these disorders is typically characterized by significant anxiety. The rationale for this grouping has been criticized because of evidence suggesting that at least some of the disorders are likely to be etiologically distinct from the others. For example, it has been argued that obsessive-compulsive disorder is most likely part of an obsessive-compulsive spectrum that might include tic disorders, hypochondriasis, body dysmorphic disorder, and perhaps trichotillomania.[33]

Somatoform disorders

Somatoform disorders are characterized by their presentation in general medical settings by individuals who do not consider themselves to be suffering from a mental disorder. Individuals with somatoform disorders present with somatic complaints or bodily concerns that are not adequately explained by an underlying general medical condition. Conceptually, the somatoform disorders can be divided into three general types: 1) those in which the individual's focus is on the physical symptoms themselves (somatization disorder, undifferentiated somatoform disorder, pain disorder, and conversion disorder); 2) those who are preoccupied by the belief that one has a serious physical illness despite medical reassurance (hypochondriasis); and 3) those who are preoccupied by the belief that a part or parts of their body are physically defective (body dysmorphic disorder).

Factitious disorders

Individuals with a factitious disorder intentionally produce or feign a physical or psychological symptom, motivated by the psychological need to assume the sick role and be taken care of. This is in contrast to malingering (which is not considered to be a mental disorder) in which the person is motivated by secondary gain (e.g. to evade criminal responsibility, to receive disability benefits).

Dissociative disorders

Dissociation is the core element of this group of disorders, which is defined as a disruption in the usually integrated functions of consciousness, memory, identity, and perception. Four specific disorders are included (dissociative amnesia, dissociative fugue, dissociative identity disorder, and depersonalization disorder).

Sexual and gender identity disorders

This diagnostic class groups together disorders involving three relatively distinct aspects of human sexuality: sexual dysfunctions, which involve disturbances in sexual desire or functioning, paraphilias which involve unusual sexual preferences that interfere with functioning (or in the case of preferences that involve harm to others like paedophilia, merely acting on those preferences), and gender identity disorder that entail one's internal identity of maleness and femaleness (gender identity) being at odds with one's anatomical sexual characteristics.

Eating disorders

Disorders in this section involve abnormal eating behavior; either the refusal to maintain adequate body weight (anorexia nervosa) or discrete episodes of uncontrolled eating accompanied by excessive effects to counteract the effects of these binges (bulimia nervosa).

Sleep disorders

Sleep disorders are subdivided into four groups based on presumed aetiology (primary, related to another mental disorder, due to a general medical condition, and substance induced). Two types of primary sleep disorders have been included: dyssomnias (problems in regulation of amount and quality of sleep) and parasomnias (events that occur during sleep). The dyssomnias include primary insomnia, primary hypersomnia, circadian rhythm sleep disorder, narcolepsy, and breathing-related sleep disorder, whereas the parasomnias include nightmare disorder, sleep terror disorder, and sleepwalking disorder.

Impulse control disorders not elsewhere classified

Many disorders in the DSM-IV-TR are characterized by problems with impulse control (e.g. borderline personality disorder, substance dependence, attention-deficit/hyperactivity disorder). This diagnostic grouping is for those impulse-control disorders not included in other sections of the DSM-IV-TR. Included are problems controlling angry impulses (intermittent explosive disorder), problems controlling impulses to steal (kleptomania) or set fires (pyromania), problems controlling impulses to pull out one's hair (trichotillomania) and problems controlling impulses to gamble (pathological gambling).

Adjustment disorders

This diagnostic class is for presentations that do not meet criteria for specific disorders (i.e. subthreshold presentations) that represent a maladaptive response to a stressor. For example, if depression occurring after a job loss is severe enough to meet full symptomatic criteria for a major depressive episode, then major depressive disorder would be diagnosed. If the job-loss-related depression falls symptomatically short of this diagnostic threshold, then adjustment disorder with depressed mood is diagnosed.

Personality disorders

Each of us has a personality, that is our characteristic way of experiencing and processing the world and ourselves. When an individual's characteristic patterns of relating, feeling, and thinking are so inflexible and maladaptive that they interfere with his or her functioning, then that person is considered to have a personality disorder. 10 specific personality disorders are included in DSM-IV-TR: paranoid personality disorder (pervasive distrust and suspiciousness of others), schizoid personality disorder (lack of desire for social relationships and a restricted expression of emotions), schizotypal personality disorder (acute discomfort with close relationships, odd beliefs, perceptual distortions, and eccentricities of behaviour), antisocial personality disorder (disregard for the rights of others), borderline personality disorder (instability of personal relationships and self-image, fears of abandonment, and marked impulsivity), histrionic personality disorder (extensive emotionality and attention seeking), narcissistic personality disorder (grandiosity, need for admiration, and lack of empathy), avoidant personality disorder (social inhibition, and hypersensitivity to negative evaluation), dependent personality disorder (excessive need to be taken care of), and obsessive-compulsive personality disorder (preoccupation with orderliness, perfectionism, stubbornness).

Research planning for DSM-V and ICD-11

It is currently anticipated that the DSM-V will be published in 2012 and that the ICD-11, although likely to be in a final draft form around the same time, will be officially published a few years later after approval by the WHO Assembly. When the last major revision of the DSM, DSM-IV, was published in 1994, the American Psychiatric Association decided to hold off on starting work on the next revision of the DSM until at least 2010, at least partly in response to the criticism that the seven year interval between prior versions of the DSM was too short.[34] Similarly, resistance to the implementation of ICD-10 by many countries (including the United States) ensured that the next revision of the ICD would also be put off for a number of years. The American Psychiatric Association decided to take advantage of this delay in the diagnostic revision process by partnering with the National Institute of Mental Health and the World Health Organization in order to initiate a research planning process with the aim of stimulating potentially informative research prior to the formal beginning of the DSM-V and ICD-11 revision processes.

Part of the impetus for encouraging research in advance of the next diagnostic revision is the general frustration felt by both researchers and clinicians with the superficially descriptive approach taken by DSM-IV and ICD-10. Although the operationalized criteria in DSM-III were developed based largely on expert consensus, there was a general understanding that the categories would continually be revised and improved in future editions of the DSM, ultimately culminating in the identification of the underlying disease processes.

Unfortunately, in the more than 25 years since the publication of DSM-III, the goal of validating these syndromes and discovering the underlying pathophysiology has remained elusive. Despite many proposed candidates, not one laboratory marker has been found to be diagnostically useful for any DSM category.[35] Epidemiological and clinical studies have shown extremely high rates of comorbidities among the disorders, undermining the hypotheses that these syndromes represent distinct etiologies. Regarding treatment, lack of treatment specificity is the rule: SSRI's effective for treating disorders across the diagnostic spectrum (e.g. depression, panic, generalized anxiety disorder, posttraumatic stress disorder, social anxiety, body dysmorphic disorder, obsessive-compulsive disorder, pathological gambling, trichotillomania, borderline personality disorder, etc.). Results of twin studies have also contradicted DSM-IV's assumptions that separate syndromes have a distinct underlying genetic basis (e.g. major depressive disorder and generalized anxiety disorder have the same genetic risk factors).

The considerable limitations of the DSM paradigm have fueled the desire that DSM-V and ICD-11 would be etiologically-based rather just descriptive. The main barrier to making DSM-V and ICD-11 more etiological is, of course, the enormous gaps in our understanding of the pathophysiology of mental disorders. Therefore, in order to help move the field forward towards the goal of a primarily etiological classification, a series of 'white papers' was commissioned under joint sponsorship of the American Psychiatric Association, the National Institute of Mental Health (NIMH), National Institute for Alcoholism and Alcohol Abuse (NIAAA), and the National Institute for Drug Abuse (NIDA). Research planning workgroups responsible for the development of these white papers were constituted for two primary reasons: 1) to stimulate research that will enrich the empirical data base prior to the start of the DSM-V revision process; and 2) to devise a research and analytic agenda that would facilitate the integration of findings from animal studies, genetics, neuroscience, epidemiology, clinical research, cross-cultural research, and clinical services research, which will lead to the eventual development of an etiologically-based, scientifically-sound classification system. In order to encourage thinking beyond the current DSM-IV framework, most of the workgroup members had not been closely involved in the DSM-IV development process. Furthermore, rather than organizing the white paper workgroups around the traditional diagnostic categories, the workgroups focused instead on cross-cutting issues, which included 1) a basic nomenclature workgroup, focusing on a variety of issues that had to do with the way disorders are classified in the DSM; 2) a neuroscience and genetics workgroup whose focus was to develop a basic and clinical neuroscience and genetics research agenda to guide the development of a future pathophysiologically-based classification; 3) a developmental science workgroup which outlined a research agenda to inform developmental aspects of the diagnostic classification; 4) a workgroup focusing on two major gaps in the DSM-IV, namely inadequacies in the classification of personality disorders and of relational disorders; 5) a mental disorders and disability workgroup which focused on disentangling the concepts of symptom severity and disability; and 6) a culture and psychiatric diagnosis workgroup which considered cross-cultural issues in diagnosis and classification. It should be noted that given the breakthrough nature of the suggested research and the relatively short time frame leading up to the anticipated publication of DSM-V and ICD-11, it was understood that most of the proposed research agenda was unlikely to bear fruit until DSM-VI/ICD-12 or later.

The six white papers were published by American Psychiatric Publishing, Inc. in 2002 in a monograph entitled 'A Research Agenda for DSM-V'.[36] Three additional white papers, one focusing on gender issues, one focusing on diagnostic issues in the geriatric population, and one focusing on mental disorders in infants and young children were commissioned subsequently and appear in a second volume of the research agenda.[37]

The second phase of the DSM-V Research Planning Process consisted of 11 research planning conferences (plus a methods conference) that occurred from 2004 to 2007. These conferences were being organized with the assistance and support of the World Health Organization and are co-funded by APA, NIMH, NIAAA, and NIDA. Unlike the white papers in the first phase which focused on general cross-cutting issues, these conferences for the most part focussed on specific diagnostic topics. The primary goals of these conferences were to stimulate the empirical research necessary to allow informed decision-making regarding crucial diagnostic deficiencies identified in DSM-IV and ICD-10, and to promote international collaboration in order to increase the likelihood of developing a future unified DSM/ICD (i.e. each conference had two co-chairs, one from the United States and the other outside the US, each conference included an equal number of the US and international participants, and half the conferences took place outside the US). Conference topics were selected after consultation with the US and international experts. Finite resources necessitated that the number of conferences be limited to a total of 11 (and the number of participants to 25); thus a number of potentially important topics could not be included. The 11 diagnostic-topic focused conferences covered Dimensional Approaches Personality Disorders (December 2004, Arlington, VA);[38] Substance-Related Disorders (February 2005, Rockville, MD);[39] Stress-Induced and Fear Circuitry Disorders (June 2005, Arlington, VA); Dementia (September 2005, Geneva, Switzerland),[40] Deconstructing Psychosis (February 2006, Arlington, VA);[41] Obsessive-Compulsive Spectrum Disorders (June 2006, Arlington, VA);[33] Dimensional Approaches to Diagnosis (July 2006, Bethesda, MD);[42] Somatic Presentations (September 2006, Beijing, China); Externalizing Disorders of Childhood (February 2007, Mexico City); Comorbidity of Anxiety and Depression (June 2007, London, UK), and Public Health Implications (September 2007, Geneva, Switzerland). An additional conference on Autism spectrum disorders was also convened in Sacramento, CA in February 2008. Summaries of the conferences are available on the DSM-V website: www.dsm5.org.

The future

Despite the ubiquitous desire to move from a descriptive classification system to an etiologically-based classification system defined

by objective laboratory findings, results of the research planning process indicate that disorders in DSM-V and ICD-11 will continue to be defined based on descriptive symptomatology. Despite the advances in neuroimaging, genetics, and biological markers over the past 10 years, it is unlikely that any objective laboratory findings will be part of the definition of any DSM-V or ICD-11 disorder, with the one exception being polysomnography findings to define sleep disorders given that such findings are already part of the diagnostic definitions of sleep disorders in the International Classification of Sleep Disorders – 2nd Edition (ICSD-2).[43] Although research studies have reliably demonstrated differences in a wide variety of objective measures between groups of affected individuals and controls (for example, brain ventricular size in individuals with schizophrenia as compared to unaffected controls),[44] when it comes down to applying the findings to a particular individual for the purpose of making a diagnosis, none of these findings have been shown to be sufficiently sensitive or specific.

A central question being raised as part of the DSM-V/ICD-11 revision process is whether psychiatric diagnosis would be better served by a dimensional approach rather than the current categorical approach. This topic was the exclusive focus of one of the 11 research planning conferences being held in advance of the DSM-V/ICD-11 revision (i.e. 'Dimensional Approaches in Diagnostic Classification: A Critical Appraisal', held in Arlington VA, July 27–28, 2006)[42], was the main focus of the Personality Disorders Research Planning conference which proposed a research agenda for adopting a dimensional approach to personality disorders[45] and was a important component of the other diagnostic-related conferences (e.g. 'Should there be both categorical and dimensional criteria for the substance use disorders in DSM-V'.[46]) Much of the impetus for moving toward a dimensional approach comes from dissatisfaction with categorical diagnoses expressed by the research community.[47–58] There are a number of persuasive arguments for the superiority of a dimensional approach over a categorical one, including, 1) the lack of evidence for discrete breaks or demarcations in distributions of symptoms; 2) evidence of a superior fit of empirical data to latent structuring models that correspond to dimensional vs. categorical approaches; 3) higher levels of diagnostic reliability and stability over time; and 4) elimination of the problematic artifacts of the categorical system, like excessive diagnostic comorbidity and arbitrary diagnostic thresholds.[59] On the other hand, a categorical approach to diagnosis remains critically important because of its clinical and administrative utility. Clinicians typically must make dichotomous decisions in everyday practice (i.e. whether to treat or not treat, to hospitalize or not hospitalize, to refer or not refer, etc.) and need to assign diagnostic categories to their patients for the purposes of reimbursement.[60] Categorical labels also facilitate clinical communication by providing a convenient shorthand when discussing a patient's diagnosis (e.g. it is more efficient for a clinician to use a single diagnostic term when talking about a patient who has a borderline personality disorder rather than having to describe all the dimensions that went into that summary judgment). Given the relative advantages of each approach, DSM-V and ICD-11 will most likely adopt some sort of hybrid approach, retaining the categorical diagnoses for communication and decision-making purposes but also providing accompanying dimensions.

Finally, there is a strong push for DSM-V and ICD-11 to become more developmentally focused. ICD-10 and DSM-IV provide definitions of mental disorders that, as far as possible, are applicable across age groups. Given that most disorders can occur at any time during an individual's lifespan, for the most part, the definitions of disorder ignore developmental variations in presentation. It should be noted that DSM-IV does include some age-appropriate modifications in the diagnostic definitions (e.g. in PTSD, criterion B(1), 'recurrent and intrusive distressing recollections of the event, including images, thoughts, or perceptions' is supplemented by 'in young children, repetitive play may occur in which themes or aspects of the trauma are expressed'), these modifications are the exceptions. It is anticipated that DSM-IV and ICD-11 will pay considerably more attention to these issues, reviewing longitudinal studies that track the evolution of disorders across the lifespan and also consider whether definitions should be modified to take into account developmental context.

Appendix 1

International classification of diseases, 10th revision

F00–F09 Organic, including symptomatic, mental disorders

F00 Dementia in Alzheimer's disease

F00.0 Dementia in Alzheimer's disease with early onset
F00.1 Dementia in Alzheimer's disease with late onset
F00.2 Dementia in Alzheimer's disease, atypical or mixed type
F00.9 Dementia in Alzheimer's disease, unspecified

F01 Vascular dementia

F01.0 Vascular dementia of acute onset
F01.1 Multi-infarct dementia
F01.2 Subcortical vascular dementia
F01.3 Mixed cortical and subcortical vascular dementia
F01.8 Other vascular dementia
F01.9 Vascular dementia, unspecified

F02 Dementia in other diseases classified elsewhere

F02.0 Dementia in Pick's disease
F02.1 Dementia in Creutzfeldt–Jakob disease
F02.2 Dementia in Huntington's disease
F02.3 Dementia in Parkinson's disease
F02.4 Dementia in human immunodeficiency virus (HIV) disease
F02.8 Dementia in other specified diseases classified elsewhere

F03 Unspecified dementia

A fifth character may be added to specify dementia in F00–F03, as follows:

.*x*0 Without additional symptoms
.*x*l Other symptoms, predominantly delusional
.*x*2 Other symptoms, predominantly hallucinatory
.*x*3 Other symptoms, predominantly depressive
.*x*4 Other mixed symptoms

F04 Organic amnesic syndrome, not induced by alcohol and other psychoactive substances

F05 Delirium, not induced by alcohol and other psychoactive substances

F05.0 Delirium, not superimposed on dementia, so described
F05.1 Delirium, superimposed on dementia
F05.8 Other delirium
F05.9 Delirium, unspecified

F06 Other mental disorders due to brain damage and dysfunction and to physical disease

F06.0 Organic hallucinosis
F06.1 Organic catatonic disorder
F06.2 Organic delusional (schizophrenia-like) disorder
F06.3 Organic mood (affective) disorders
.30 Organic manic disorder
.31 Organic bipolar disorder
.32 Organic depressive disorder
.33 Organic mixed affective disorder
F06.4 Organic anxiety disorder
F06.5 Organic dissociative disorder
F06.6 Organic emotionally labile (asthenic) disorder
F06.7 Mild cognitive disorder
F06.8 Other specified mental disorders due to brain damage and dysfunction and to physical disease
F06.9 Unspecified mental disorder due to brain damage and dysfunction and to physical disease

F09 Unspecified organic or symptomatic mental disorder

F07 Personality and behavioural disorders due to brain disease, damage and dysfunction

F07.0 Organic personality disorder
F07.1 Postencephalitic syndrome
F07.2 Postconcussional syndrome
F07.8 Other organic personality and behavioural disorders due to brain disease, damage, and dysfunction
F07.9 Unspecified organic personality and behavioural disorder due to brain disease, damage, and dysfunction

F10–F19 Mental and behavioural disorders due to psychoactive substance use

F10 Mental and behavioural disorders due to use of alcohol
F11 Mental and behavioural disorders due to use of opioids
F12 Mental and behavioural disorders due to use of cannabinoids
F13 Mental and behavioural disorders due to use of sedatives or hypnotics
F14 Mental and behavioural disorders due to use of cocaine
F15 Mental and behavioural disorders due to use of other stimulants, including caffeine
F16 Mental and behavioural disorders due to use of hallucinogens
F17 Mental and behavioural disorders due to use of tobacco
F18 Mental and behavioural disorders due to use of volatile solvents
F19 Mental and behavioural disorders due to multiple drug use and use of other psychoactive substances

Four- and five-character categories may be used to specify the clinical conditions, as follows

F1*x*.0 Acute intoxication
.00 Uncomplicated
.01 With trauma or other bodily injury
.02 With other medical complications
.03 With delirium
.04 With perceptual distortions
.05 With coma
.06 With convulsions
.07 Pathological intoxication
F1*x*.1 Harmful use
F1*x*.2 Dependence syndrome
.20 Currently abstinent
.21 Currently abstinent, but in a protected environment
.22 Currently on a clinically supervised maintenance or replacement regime (controlled dependence)
.23 Currently abstinent, but receiving treatment with aversive or blocking drugs
.24 Currently using the substance (active dependence)
.25 Continuous use
.26 Episodic use (dipsomania)
F1*x*.3 Withdrawal state
.30 Uncomplicated
.31 Convulsions
F1*x*.4 Withdrawal state with delirium
.40 Without convulsions
.41 With convulsions
F1*x*.5 Psychotic disorder
.50 Schizophrenia-like
.51 Predominantly delusional
.52 Predominantly hallucinatory
.53 Predominantly polymorphic
.54 Predominantly depressive symptoms
.55 Predominantly manic symptoms
.56 Mixed
F1*x*.6 Amnesic syndrome
F1*x*.7 Residual and late-onset psychotic disorder
.70 Flashbacks
.71 Personality or behaviour disorder
.72 Residual affective disorder
.73 Dementia
.74 Other persisting cognitive impairment
.75 Late-onset psychotic disorder
F1*x*.8 Other mental and behavioural disorders
F1*x*.9 Unspecified mental and behavioural disorder

F20–F29 Schizophrenia, schizotypal, and delusional disorders

F20 Schizophrenia

F20.0 Paranoid schizophrenia
F20.1 Hebephrenic schizophrenia
F20.2 Catatonic schizophrenia
F20.3 Undifferentiated schizophrenia
F20.4 Post-schizophrenic depression
F20.5 Residual schizophrenia
F20.6 Simple schizophrenia
F20.8 Other schizophrenia
F20.9 Schizophrenia, unspecified

A fifth character may be used to classify course
*x*0 Continuous
.*x*1 Episodic with progressive deficit
.*x*2 Episodic with stable deficit
.*x*3 Episodic remittent
.*x*4 Incomplete remission
.*x*5 Complete remission
.*x*8 Other
.*x*9 Period of observation less than one year

F21 Schizotypal disorder

F22 Persistent delusional disorders

F22.0 Delusional disorder
F22.8 Other persistent delusional disorders
F22.9 Persistent delusional disorder, unspecified

F23 Acute and transient psychotic disorders

F23.0 Acute polymorphic psychotic disorder without symptoms of schizophrenia
F23.1 Acute polymorphic psychotic disorder with symptoms of schizophrenia
F23.2 Acute schizophrenia-like psychotic disorder
F23.3 Other acute predominantly delusional psychotic disorders
F23.8 Other acute and transient psychotic disorders
F23.9 Acute and transient psychotic disorders unspecified

A fifth character may be used to identify the presence or absence of associated acute stress

.*x*0 Without associated acute stress
.*x*1 With associated acute stress

F24 Induced delusional disorder

F25 Schizoaffective disorders

F25.0 Schizoaffective disorder, manic type
F25.1 Schizoaffective disorder, depressive type
F25.2 Schizoaffective disorder, mixed type
F25.8 Other schizoaffective disorders
F25.9 Schizoaffective disorder, unspecified

F28 Other non-organic psychotic disorders

F29 Unspecified non-organic psychosis

F30–F39 Mood (affective) disorders

F30 Manic episode
F30.0 Hypomania
F30.1 Mania without psychotic symptoms
F30.2 Mania with psychotic symptoms
F30.8 Other manic episodes
F30.9 Manic episode, unspecified

F31 Bipolar affective disorder

F31.0 Bipolar affective disorder, current episode hypomanic
F31.1 Bipolar affective disorder, current episode manic without psychotic symptoms
F31.2 Bipolar affective disorder, current episode manic with psychotic symptoms
F31.3 Bipolar affective disorder, current episode mild or moderate depression
.30 Without somatic symptoms
.31 With somatic symptoms
F31.4 Bipolar affective disorder, current episode severe depression without psychotic symptoms
F31.5 Bipolar affective disorder, current episode severe depression with psychotic symptoms
F31.6 Bipolar affective disorder, current episode mixed
F31.7 Bipolar affective disorder, currently in remission
F31.8 Other bipolar affective disorders
F31.9 Bipolar affective disorder, unspecified

F32 Depressive episode

F32.0 Mild depressive episode
.00 Without somatic symptoms
.01 With somatic symptoms
F32.1 Moderate depressive episode
.10 Without somatic symptoms
.11 With somatic symptoms
F32.2 Severe depressive episode without psychotic symptoms
F32.3 Severe depressive episode with psychotic symptoms
F32.8 Other depressive episodes
F32.9 Depressive episode, unspecified

F33 Recurrent depressive disorder

F33.0 Recurrent depressive disorder, current episode mild
.00 Without somatic symptoms
.01 With somatic symptoms
F33.1 Recurrent depressive disorder, current episode moderate
.10 Without somatic symptoms
.11 With somatic symptoms
F33.2 Recurrent depressive disorder, current episode severe without psychotic symptoms
F33.3 Recurrent depressive disorder, current episode severe with psychotic symptoms
F33.4 Recurrent depressive disorder, currently in remission
F33.8 Other recurrent depressive disorders
F33.9 Recurrent depressive disorder, unspecified

F34 Persistent mood (affective) disorders

F34.0 Cyclothymia
F34.1 Dysthymia
F34.8 Other persistent mood (affective) disorders
F34.9 Persistent mood (affective) disorder, unspecified

F38 Other mood (affective) disorders

F38.0 Other single mood (affective) disorders
.00 Mixed affective episode
F38.1 Other recurrent mood (affective) disorders
.10 Recurrent brief depressive disorder
F38.8 Other specified mood (affective) disorders

F39 Unspecified mood (affective) disorder

F40–F48 Neurotic, stress-related, and somatoform disorders

F40 Phobic anxiety disorders
F40.0 Agoraphobia
.00 Without panic disorder
.01 With panic disorder
F40.1 Social phobias
F40.2 Specific (isolated) phobias
F40.8 Other phobic anxiety disorders
F40.9 Phobic anxiety disorder, unspecified

F41 Other anxiety disorders

F41.0 Panic disorder (episodic paroxysmal anxiety)
F41.1 Generalized anxiety disorder
F41.2 Mixed anxiety and depressive disorder
F41.3 Other mixed anxiety disorders
F41.8 Other specified anxiety disorders
F41.9 Anxiety disorder, unspecified

F42 Obsessive-compulsive disorder

F42.0 Predominantly obsessional thoughts or ruminations
F42.1 Predominantly compulsive acts (obsessional rituals)
F42.2 Mixed obsessional thoughts and acts
F42.8 Other obsessive-compulsive disorders
F42.9 Obsessive-compulsive disorder, unspecified

F43 Reaction to severe stress, and adjustment disorders

F43.0 Acute stress reaction
F43.1 Post-traumatic stress disorder
F43.2 Adjustment disorders
.20 Brief depressive reaction

.21 Prolonged depressive reaction
.22 Mixed anxiety and depressive reaction
.23 With predominant disturbance of other emotions
.24 With predominant disturbance of conduct
.25 With mixed disturbance of emotions and conduct
.28 With other specified predominant symptoms
F43.8 Other reactions to severe stress
F43.9 Reaction to severe stress, unspecified

F44 Dissociative (conversion) disorders

F44.0 Dissociative amnesia
F44.1 Dissociative fugue
F44.2 Dissociative stupor
F44.3 Trance and possession disorders
F44.4 Dissociative motor disorders
F44.5 Dissociative convulsions
F44.6 Dissociative anaesthesia and sensory loss
F44.7 Mixed dissociative (conversion) disorders
F44.8 Other dissociative (conversion) disorders
.80 Ganser's syndrome
.81 Multiple personality disorder
.82 Transient dissociate (conversion) disorders occurring in childhood and adolescence
.88 Other specified dissociative (conversion) disorders
F44.9 Dissociative (conversion) disorder, unspecified

F45 Somatoform disorders

F45.0 Somatization disorder
F45.1 Undifferentiated somatoform disorder
F45.2 Hypochondriacal disorder
F45.3 Somatoform autonomic dysfunction
.30 Heart and cardiovascular system
.31 Upper gastrointestinal tract
.32 Lower gastrointestinal tract
.33 Respiratory system
.34 Genitourinary system
.38 Other organ or system
F45.4 Persistent somatoform pain disorder
F45.8 Other somatoform disorders
F45.9 Somatoform disorder, unspecified

F48 Other neurotic disorders

F48.0 Neurasthenia
F48.1 Depersonalization-derealization syndrome
F48.8 Other specified neurotic disorders
F48.9 Neurotic disorder, unspecified

F50–F59 Behavioural syndromes associated with physiological disturbances and physical factors

F50 Eating disorders

F50.0 Anorexia nervosa
F50.1 Atypical anorexia nervosa
F50.2 Bulimia nervosa
F50.3 Atypical bulimia nervosa
F50.4 Overeating associated with other psychological disturbances
F50.5 Vomiting associated with other psychological disturbances
F50.8 Other eating disorders
F50.9 Eating disorder, unspecified

F51 Non-organic sleep disorders

F51.0 Non-organic insomnia
F51.1 Non-organic hypersomnia
F51.2 Non-organic disorder of the sleep-wake schedule
F51.3 Sleepwalking (somnambulism)
F51.4 Sleep terrors (night terrors)
F51.5 Nightmares
F51.8 Other non-organic sleep disorders
F51.9 Non-organic sleep disorder, unspecified

F52 Sexual dysfunction, not caused by organic disorder or disease

F52.0 Lack or loss of sexual desire
F52.1 Sexual aversion and lack of sexual enjoyment
.10 Sexual aversion
.11 Lack of sexual enjoyment
F52.2 Failure of genital response
F52.3 Orgasmic dysfunction
F52.4 Premature ejaculation
F52.5 Non-organic vaginismus
F52.6 Non-organic dyspareunia
F52.7 Excessive sexual drive
F52.8 Other sexual dysfunction, not caused by organic disorders or disease
F52.9 Unspecified sexual dysfunction, not caused by organic disorder or disease

F53 Mental and behavioural disorders associated with the puerperium, not elsewhere classified

F53.0 Mild mental and behavioural disorders associated with the puerperium, not elsewhere classified
F53.1 Severe mental and behavioural disorders associated with the puerperium, not elsewhere classified
F53.8 Other mental and behavioural disorders associated with the puerperium, not elsewhere classified
F53.9 Puerperal mental disorder, unspecified

F54 Psychological and behavioural factors associated with disorders or diseases classified elsewhere

F55 Abuse of non-dependence-producing substances

F55.0 Antidepressants
F55.1 Laxatives
F55.2 Analgesics
F55.3 Antacids
F55.4 Vitamins
F55.5 Steroids or hormones
F55.6 Specific herbal or folk remedies
F55.8 Other substances that do not produce dependence
F55.9 Unspecified

F59 Unspecified behavioural syndromes associated with physiological disturbances and physical factors

F60–F69 Disorders of adult personality and behaviour

F60 Specific personality disorders
F60.0 Paranoid personality disorder
F60.1 Schizoid personality disorder
F60.2 Dissocial personality disorder
F60.3 Emotionally unstable personality disorder
.30 Impulsive type
.31 Borderline type
F60.4 Histrionic personality disorder
F60.5 Anankastic personality disorder

F60.6 Anxious (avoidant) personality disorder
F60.7 Dependent personality disorder
F60.8 Other specific personality disorders
F60.9 Personality disorder, unspecified

F61 Mixed and other personality disorders

F61.0 Mixed personality disorders
F61.1 Troublesome personality changes

F62 Enduring personality changes, not attributable to brain damage and disease

F62.0 Enduring personality change after catastrophic experience
F62.1 Enduring personality change after psychiatric illness
F62.8 Other enduring personality changes
F62.9 Enduring personality change, unspecified

F63 Habit and impulse disorders

F63.0 Pathological gambling
F63.1 Pathological fire-setting (pyromania)
F63.2 Pathological stealing (kleptomania)
F63.3 Trichotillomania
F63.8 Other habit and impulse disorders
F63.9 Habit and impulse disorder, unspecified

F64 Gender identity disorders

F64.0 Transsexualism
F64.1 Dual-role transvestism
F64.2 Gender identity disorder of childhood
F64.8 Other gender identity disorders
F64.9 Gender identity disorder, unspecified

F65 Disorders of sexual preference

F65.0 Fetishism
F65.1 Fetishistic transvestism
F65.2 Exhibitionism
F65.3 Voyeurism
F65.4 Paedophilia
F65.5 Sadomasochism
F65.6 Multiple disorders of sexual preference
F65.8 Other disorders of sexual preference
F65.9 Disorder of sexual preference, unspecified

F66 Psychological and behavioural disorders associated with sexual development and orientation

F66.0 Sexual maturation disorder
F66.1 Egodystonic sexual orientation
F66.2 Sexual relationship disorder
F66.8 Other psychosexual development disorders
F66.9 Psychosexual development disorder, unspecified

A fifth character may be used to indicate association with:

.*x*0 Heterosexuality
.*x*l Homosexuality
.*x*2 Bisexuality
.*x*8 Other, including prepubertal

F68 Other disorders of adult personality and behaviour

F68.0 Elaboration of physical symptoms for psychological reasons
F68.1 Intentional production or feigning of symptoms or disabilities, either physical or psychological (factitious disorder)
F68.8 Other specified disorders of adult personality and behaviour
F69 Unspecified disorder of adult personality and behaviour

F70–F79 Mental retardation (intellectual disability)

F70 Mild mental retardation (intellectual disability)

F71 Moderate mental retardation (intellectual disability)

F72 Severe mental retardation (intellectual disability)

F73 Profound mental retardation (intellectual disability)

F78 Other mental retardation (intellectual disability)

F79 Unspecified mental retardation (intellectual disability)

A fourth character may be used to specify the extent of associated behavioural impairment:

F7x.0 No, or minimal, impairment of behaviour
F7x.1 Significant impairment of behaviour requiring attention or treatment
F7x.8 Other impairments of behaviour
F7x.9 Without mention of impairment of behaviour

F80–F89 Disorders of psychological development

F80 specific developmental disorders of speech and language

F80.0 Specific speech articulation disorder
F80.1 Expressive language disorder
F80.2 Receptive language disorder
F80.3 Acquired aphasia with epilepsy (Landau-Kleffner syndrome)
F80.8 Other developmental disorders of speech and language
F80.9 Developmental disorder of speech and language, unspecified

F81 Specific developmental disorders of scholastic skills

F81.0 Specific reading disorder
F81.1 Specific spelling disorder
F81.2 Specific disorder of arithmetical skills
F81.3 Mixed disorder of scholastic skills
F81.8 Other developmental disorders of scholastic skills
F81.9 Developmental disorder of scholastic skills, unspecified

F82 Specific developmental disorder of motor function

F83 Mixed specific developmental disorders

F84 Pervasive developmental disorders

F84.0 Childhood autism
F84.1 Atypical autism
F84.2 Rett's syndrome
F84.3 Other childhood disintegrative disorder
F84.4 Overactive disorder associated with mental retardation and stereotyped movements
F84.5 Asperger's syndrome
F84.8 Other pervasive developmental disorders
F84.9 Pervasive developmental disorder, unspecified

F88 Other disorders of psychological development

F89 Unspecified disorder of psychological development

F90–F98 Behavioural and emotional disorders with onset usually occurring in childhood and adolescence

F90 Hyperkinetic disorders

F90.0 Disturbance of activity and attention
F90.1 Hyperkinetic conduct disorder
F90.8 Other hyperkinetic disorders
F90.9 Hyperkinetic disorder, unspecified

F91 Conduct disorders

F91.0 Conduct disorder confined to the family context
F91.1 Unsocialized conduct disorder

F91.2 Socialized conduct disorder
F91.3 Oppositional defiant disorder
F91.8 Other conduct disorders
F91.9 Conduct disorder, unspecified

F92 Mixed disorders of conduct and emotions

F92.0 Depressive conduct disorder
F92.8 Other mixed disorders of conduct and emotions
F92.9 Mixed disorder of conduct and emotions, unspecified

F93 Emotional disorders with onset specific to childhood

F93.0 Separation anxiety disorder of childhood
F93.1 Phobic anxiety disorder of childhood
F93.2 Social anxiety disorder of childhood
F93.3 Sibling rivalry disorder
F93.8 Other childhood emotional disorders
F93.9 Childhood emotional disorder, unspecified

F94 Disorders of social functioning with onset specific to childhood and adolescence

F94.0 Elective mutism
F94.1 Reactive attachment disorder of childhood
F94.2 Disinhibited attachment disorder of childhood
F94.8 Other childhood disorders of social functioning
F94.9 Childhood disorders of social functioning, unspecified

F95 Tic disorders

F95.0 Transient tic disorder
F95.1 Chronic motor or vocal tic disorder
F95.2 Combined vocal and multiple motor tic disorder (de la Tourette's syndrome)
F95.8 Other tic disorders
F95.9 Tic disorder, unspecified

F98 Other behavioural and emotional disorders with onset usually occurring in childhood and adolescence

F98.0 Non-organic enuresis
F98.1 Non-organic encopresis
F98.2 Feeding disorder of infancy and childhood
F98.3 Pica of infancy and childhood
F98.4 Stereotyped movement disorders
F98.5 Stuttering (stammering)
F98.6 Cluttering
F98.8 Other specified behavioural and emotional disorders with onset usually occurring in childhood and adolescence
F98.9 Unspecified behavioural and emotional disorders with onset usually occurring in childhood and adolescence

F99 Unspecified mental disorder

F99 Mental disorder, not otherwise specified

Appendix 2

Diagnostic and Statistical Manual of Mental Disorders (4th edition)

NOS = Not Otherwise Specified.

An x appearing in a diagnostic code indicates that a specific code number is required.

An ellipsis (. . .) is used in the names of certain disorders to indicate that the name of a specific mental disorder or general medical condition should be inserted when recording the name (e.g., 293.0 Delirium Due to Hypothyroidism).

If criteria are currently met, one of the following severity specifiers may be noted after the diagnosis

Mild
Moderate
Severe

If criteria are no longer met, one of the following specifiers may be noted

In Partial Remission
In Full Remission
Prior History

Disorders usually first diagnosed in infancy, childhood, or adolescence

Mental retardation

Note: *These are coded on Axis II.*

317 Mild Mental Retardation
318.0 Moderate Mental Retardation
318.1 Severe Mental Retardation
318.2 Profound Mental Retardation
319 Mental Retardation, Severity Unspecified

Learning disorders

315.00 Reading Disorder
315.1 Mathematics Disorder
315.2 Disorder of Written Expression
315.9 Learning Disorder NOS

Motor skills disorder

315.4 Developmental Coordination Disorder

Communication disorders

315.31 Expressive Language Disorder
315.32 Mixed Receptive–Expressive Language Disorder
315.39 Phonological Disorder
307.0 Stuttering
307.9 Communication Disorder NOS

Pervasive Developmental disorders

299.00 Autistic Disorder
299.80 Rett's Disorder
299.10 Childhood Disintegrative Disorder
299.80 Asperger's Disorder
299.80 Pervasive Developmental Disorder NOS

Attention-deficit and disruptive behaviour disorders

314.xx Attention-Deficit/Hyperactivity Disorder
.01 Combined Type
.00 Predominantly Inattentive Type
.01 Predominantly Hyperactive-Impulsive Type
314.9 Attention-Deficit/Hyperactivity Disorder NOS
312.xx Conduct Disorder
.81 Childhood-Onset Type
.82 Adolescent-Onset Type
.89 Unspecified Onset

313.81 Oppositional-Defiant Disorder
312.9 Disruptive Behaviour Disorder NOS

Feeding and eating disorders of infancy or early childhood

307.52 Pica
307.53 Rumination Disorder
307.59 Feeding Disorder of Infancy or Early Childhood

Tic disorders

307.23 Tourette's Disorder
307.22 Chronic Motor or Vocal Tic Disorder
307.21 Transient Tic Disorder
Specify if: Single Episode/Recurrent
307.20 Tic Disorder NOS

Elimination disorders

—.— Encopresis
787.6 With Constipation and Overflow Incontinence
307.7 Without Constipation and Overflow Incontinence
307.6 Enuresis (Not Due to a General Medical Condition)
Specify type: Nocturnal Only/Diurnal Only/Nocturnal and Diurnal

Other disorders of infancy, childhood, or adolescence

309.21 Separation Anxiety Disorder
Specify if: Early Onset
313.23 Selective Mutism
313.89 Reactive Attachment Disorder of Infancy or Early Childhood
Specify type: Inhibited Type/Disinhibited Type
307.3 Stereotypic Movement Disorder
Specify if: With Self-Injurious Behaviuor
313.9 Disorder of Infancy, Childhood, or Adolescence NOS

Delirium, dementia and amnestic and other cognitive disorders

Delirium

293.0 Delirium Due to . . . [Indicate the General Medical Condition]
—.— Substance Intoxication Delirium (refer to Substance-Related Disorders for substance-specific codes)
—.— Substance Withdrawal Delirium (refer to Substance-Related Disorders for substance-specific codes)
—.— Delirium Due to Multiple Etiologies (code each of the specific etiologies)
780.09 Delirium NOS

Dementia

294.xx Dementia of the Alzheimer's Type, With Early Onset (also code 331.0 Alzheimer's disease on Axis III)
.10 Without Behavioural Disturbance
.11 With Behavioural Disturbance
294.xx Dementia of the Alzheimer's Type, With Late Onset (also code 331.0 Alzheimer's disease on Axis III)
.10 Without Behavioural Disturbance
.11 With Behavioural Disturbance
290.xx Vascular Dementia
.40 Uncomplicated
.41 With Delirium
.42 With Delusions
.43 With Depressed Mood
Specify if: *With Behavioural Disturbance*

Code presence or absence of a behavioural disturbance in the fifth digit for Dementia Due to a General Medical Condition:
294.10 = Without Behavioural Disturbance
294.11 = With Behavioural Disturbance
294.1x Dementia Due to HIV Disease (*also code 042 HIV on Axis III*)
294.1x Dementia Due to Head Trauma (*also code 854.00 head injury on Axis III*)
294.1x Dementia Due to Parkinson's Disease (*also code 331.82 Dementia with Lewy Bodies on Axis III*)
294.1x Dementia Due to Huntington's Disease (*also code 333.4 Huntington's disease on Axis III*)
294.1x Dementia Due to Pick's Disease (*also code 331.11 Pick's disease on Axis III*)
294.1x Dementia Due to Creutzfeldt–Jakob Disease (*also code 046.1 Creutzfeldt–Jakob disease on Axis III*)
294.1x Dementia Due to . . . [*Indicate the General Medical Condition not listed above*] (*also code the general medical condition on Axis III*)
—.— Substance-Induced Persisting Dementia (*refer to Substance-Related Disorders for substance-specific codes*)
—.— Dementia Due to Multiple Etiologies (*code each of the specific etiologies*)
294.8 Dementia NOS

Amnestic disorders

294.0 Amnestic Disorder Due to . . . [*Indicate the General Medical Condition*]
Specify if: Transient/Chronic
—.— Substance-Induced Persisting Amnestic Disorder (*refer to Substance-Related Disorders for substance-specific codes*)
294.8 Amnestic Disorder NOS

Other cognitive disorder

294.9 Cognitive Disorder NOS

Mental disorders due to a general medical condition not elsewhere classified

293.89 Catatonic Disorder Due to . . . [*Indicate the General Medical Condition*]
310.1 Personality Change Due to . . . [*Indicate the General Medical Condition*]
Specify type: Labile Type/Disinhibited Type/Aggressive Type/Apathetic Type/Paranoid Type/Other Type/Combined Type/Unspecified Type
293.9 Mental Disorder NOS Due to . . . [*Indicate the General Medical Condition*]

Substance-related disorders

The following specifiers apply to Substance Dependence as noted:
[a]With Physiological Dependence/Without Physiological Dependence

[b]Early Full Remission/Early Partial Remission Sustained Full Remission/Sustained Partial Remission
[c]In a Controlled Environment
[d]On Agonist Therapy/
The following specifiers apply to Substance-Induced Disorders as noted:
[I]With Onset During Intoxication/[W]With Onset During Withdrawal

Alcohol-related disorders

Alcohol use disorders

303.90 Alcohol Dependencea,b,c
305.00 Alcohol Abuse

Alcohol-induced disorders

303.00 Alcohol Intoxication
291.81 Alcohol Withdrawal
Specify if: With Perceptual Disturbances
291.0 Alcohol Intoxication Delirium
291.0 Alcohol Withdrawal Delirium
291.2 Alcohol-Induced Persisting Dementia
291.1 Alcohol-Induced Persisting Amnestic Disorder
291.x Alcohol-Induced Psychotic Disorder
.5 With Delusions[I,W]
.3 With Hallucinations[I,W]
291.89 Alcohol-Induced Mood Disorder[I,W]
291.89 Alcohol-Induced Anxiety Disorder[I,W]
291.89 Alcohol-Induced Sexual Dysfunction[I]
291.82 Alcohol-Induced Sleep Disorder[I,W]
291.9 Alcohol-Related Disorder NOS

Amphetamine (or Amphetamine-like)-related disorders

Amphetamine use disorders

304.40 Amphetamine Dependence[a,b,c]
305.70 Amphetamine Abuse

Amphetamine-Induced Disorders

292.89 Amphetamine Intoxication
Specify if: With Perceptual Disturbances
292.0 Amphetamine Withdrawal
292.81 Amphetamine Intoxication Delirium
292.xx Amphetamine-Induced Psychotic Disorder
.11 With Delusions[I]
.12 With Hallucinations[I]
292.84 Amphetamine-Induced Mood Disorder[I,W]
292.89 Amphetamine-Induced Anxiety Disorder[I]
292.89 Amphetamine-Induced Sexual Dysfunction[I]
292.85 Amphetamine-Induced Sleep Disorder[I,W]
292.9 Amphetamine-Related Disorder NOS

Caffeine-related disorders

Caffeine-induced disorders

305.90 Caffeine Intoxication
292.89 Caffeine-Induced Anxiety Disorder[I]
292.85 Caffeine-Induced Sleep Disorder[I]
292.9 Caffeine-Related Disorder NOS

Cannabis-related disorders

Cannabis use disorders

304.30 Cannabis Dependence[a,b,c]
305.20 Cannabis Abuse

Cannabis-induced disorders

292.89 Cannabis Intoxication
Specify if: With Perceptual Disturbances
292.81 Cannabis Intoxication Delirium
292.xx Cannabis-Induced Psychotic Disorder
.11 With Delusions[I]
.12 With Hallucinations[I]
292.89 Cannabis-Induced Anxiety Disorder[I]
292.9 Cannabis-Related Disorder NOS

Cocaine-related disorders

Cocaine use disorders

304.20 Cocaine Dependencea,b,c
305.60 Cocaine Abuse

Cocaine-induced disorders

292.89 Cocaine Intoxication
Specify if: With Perceptual Disturbances
292.0 Cocaine Withdrawal
292.81 Cocaine Intoxication Delirium
292.xx Cocaine-Induced Psychotic Disorder
.11 With Delusions[I]
.12 With Hallucinations[I]
292.84 Cocaine-Induced Mood Disorder[I,W]
292.89 Cocaine-Induced Anxiety Disorder[I,W]
292.89 Cocaine-Induced Sexual Dysfunction[I]
292.85 Cocaine-Induced Sleep Disorder[I,W]
292.9 Cocaine-Related Disorder NOS

Hallucinogen-related disorders

Hallucinogen use disorders

304.50 Hallucinogen Dependence[b,c]
305.30 Hallucinogen Abuse

Hallucinogen-induced disorders

292.89 Hallucinogen Intoxication
292.89 Hallucinogen Persisting Perception Disorder (Flashbacks)
292.81 Hallucinogen Intoxication Delirium
292.xx Hallucinogen-Induced Psychotic Disorder
.11 With Delusions[I]
.12 With Hallucinations[I]
292.84 Hallucinogen-Induced Mood Disorder[I]
292.89 Hallucinogen-Induced Anxiety Disorder[I]
292.9 Hallucinogen-Related Disorder NOS

Inhalant-related disorders

Inhalant use disorders

304.60 Inhalant Dependence[b,c]
305.90 Inhalant Abuse

Inhalant-induced disorders

292.89 Inhalant Intoxication
292.81 Inhalant Intoxication Delirium
292.82 Inhalant-Induced Persisting Dementia

292.xx Inhalant-Induced Psychotic Disorder
.11 With Delusions[I]
.12 With Hallucinations[I]
292.84 Inhalant-Induced Mood Disorder[I]
292.89 Inhalant-Induced Anxiety Disorder[I]
292.9 Inhalant-Related Disorder NOS

Nicotine-related disorders

Nicotine use disorder

305.1 Nicotine Dependence[a,b]

Nicotine-induced disorders

292.0 Nicotine Withdrawal
292.9 Nicotine-Related Disorder NOS

Opioid-related disorders

Opioid use disorders

304.00 Opioid Dependence[a,b,c,d]
305.50 Opioid Abuse

Opioid-induced disorders

292.89 Opioid Intoxication
Specify if: With Perceptual Disturbances
292.0 Opioid Withdrawal
292.81 Opioid Intoxication Delirium
292.xx Opioid-Induced Psychotic Disorder
.11 With Delusions[I]
.12 With Hallucinations[I]
292.84 Opioid-Induced Mood Disorder[I]
292.89 Opioid-Induced Sexual Dysfunction[I]
292.85 Opioid-Induced Sleep Disorder[I,W]
292.9 Opioid-Related Disorder NOS

Phencyclidine (or Phencyclidine-like)-related disorders

Phencyclidine use disorders

304.60 Phencyclidine Dependence[b,c]
305.90 Phencyclidine Abuse

Phencyclidine-induced disorders

292.89 Phencyclidine Intoxication
Specify if: With Perceptual Disturbances
292.81 Phencyclidine Intoxication Delirium
292.xx Phencyclidine-Induced Psychotic Disorder
.11 With Delusions[I]
.12 With Hallucinations[I]
292.84 Phencyclidine-Induced Mood Disorder[I]
292.89 Phencyclidine-Induced Anxiety Disorder[I]
292.9 Phencyclidine-Related Disorder NOS

Sedative-, Hypnotic-, Oranxiolytic-related disorders

Sedative, Hypnotic, or Anxiolytic use disorders

304.10 Sedative, Hypnotic, or Anxiolytic Dependence[a,b,c]
305.40 Sedative, Hypnotic, or Anxiolytic Abuse

Sedative-, Hypnotic-, or Anxiolytic-induced disorders

292.89 Sedative, Hypnotic, or Anxiolytic Intoxication
292.0 Sedative, Hypnotic, or Anxiolytic Withdrawal
Specify it: With Perceptual Disturbances
292.81 Sedative, Hypnotic, or Anxiolytic Intoxication Delirium
292.81 Sedative, Hypnotic, or Anxiolytic Withdrawal Delirium
292.82 Sedative-, Hypnotic-, or Anxiolytic-Induced Persisting Dementia
292.83 Sedative-, Hypnotic-, or Anxiolytic-Induced Persisting Amnestic Disorder
292.xx Sedative-, Hypnotic-, or Anxiolytic-Induced Psychotic Disorder
.11 With Delusions[I,W]
.12 With Hallucinations[I,W]
292.84 Sedative-, Hypnotic-, or Anxiolytic-Induced Mood Disorder[I,W]
292.89 Sedative-, Hypnotic-, or Anxiolytic-Induced Anxiety Disorder[W]
292.89 Sedative-, Hypnotic-, or Anxiolytic-Induced Sexual Dysfunction[1]
292.85 Sedative-, Hypnotic-, or Anxiolytic-Induced Sleep Disorder[I,W]
292.9 Sedative-, Hypnotic-, or Anxiolytic-Related Disorder NOS

Polysubstance-related disorder

304.80 Polysubstance Dependence[a,b,c,d]

Other (or Unknown) substance-related disorders

Other (or Unknown) substance use disorders

304.90 Other (or Unknown) Substance Dependence[a,b,c,d]
305.90 Other (or Unknown) Substance Abuse

Other (or Unknown) substance-induced disorders

292.89 Other (or Unknown) Substance Intoxication
Specify it: With Perceptual Disturbances
292.0 Other (or Unknown) Substance Withdrawal
Specify it: With Perceptual Disturbances
292.81 Other (or Unknown) Substance-Induced Delirium
292.82 Other (or Unknown) Substance-Induced Persisting Dementia
292.83 Other (or Unknown) Substance-Induced Persisting Amnestic Disorder
292.xx Other (or Unknown) Substance-Induced Psychotic Disorder
.11 With Delusions[I,W]
.12 With Hallucinations[I,W]
292.84 Other (or Unknown) Substance-Induced Mood Disorder[I,W]
292.89 Other (or Unknown) Substance-Induced Anxiety Disorder[I,W]
292.89 Other (or Unknown) Substance-Induced Sexual Dysfunction[1]
292.85 Other (or Unknown) Substance-Induced Sleep Disorder[I,W]
292.9 Other (or Unknown) Substance-Related Disorder NOS

Schizophrenia and other psychotic disorders

295.xx Schizophrenia
The following Classification of Longitudinal Course applies to all subtypes of Schizophrenia.

Episodic With Interepisode Residual Symptoms (*specify if*: With Prominent Negative Symptoms)/Episodic With No Interepisode Residual Symptoms/Continuous (*specify if*: With Prominent Negative Symptoms)

Single Episode In Partial Remission (*specify if*: With Prominent Negative Symptoms)/Single Episode In Full Remission
Other or Unspecified Pattern
.30 Paranoid Type
.10 Disorganized Type
.20 Catatonic Type
.90 Undifferentiated Type
.60 Residual Type
295.40 Schizophreniform Disorder
Specify it: Without Good Prognostic Features/With Good Prognostic Features
295.70 Schizoaffective Disorder
Specify type: Bipolar Type/Depressive Type
297.1 Delusional Disorder
Specify type: Erotomanic Type/Grandiose Type/Jealous Type/Persecutory Type/Somatic Type/Mixed Type/Unspecified Type
298.8 Brief Psychotic Disorder
Specify it: With Marked Stressor(s)/Without Marked Stressor(s)/With Postpartum Onset
297.3 Shared Psychotic Disorder
293.xx Psychotic Disorder Due to . . . [Indicate the General Medical Condition]
.81 With Delusions
.82 With Hallucinations
—.— Substance-Induced Psychotic Disorder (refer to Substance-Related Disorders for substance-specific codes)
Specify it: With Onset During Intoxication/With Onset During Withdrawal
298.9 Psychotic Disorder NOS

Mood disorders

Code current state of Major Depressive Disorder or Bipolar I Disorder in fifth digit:
1 = Mild
2 = Moderate
3 = Severe Without Psychotic Features
4 = Severe With Psychotic Features
Specify: Mood-Congruent Psychotic Features/Mood-Incongruent Psychotic Features
5 = In Partial Remission
6 = In Full Remission
0 = Unspecified
The following specifiers apply (for current or most recent episode) to Mood Disorders as noted
[a]Severity/Psychotic/Remission Specifiers/[b]Chronic/[c]With Catatonic Features/[d]With Melancholic Features/[e]With Atypical Features/[f]With Postpartum Onset
The following specifiers apply to Mood Disorders as noted:
[g]With or Without Full Interepisode Recovery/[h]With Seasonal Pattern/[i]With Rapid Cycling

Depressive disorders

296.xx Major Depressive Disorder,
.2x Single Episode[a,b,c,d,e,f]
.3x Recurrent[a,b,c,d,e,f,g,h]
300.4 Dysthymic Disorder
Specify it: Early Onset/Late Onset
Specify: With Atypical Features
311 Depressive Disorder NOS

Bipolar disorders

296.xx Bipolar I Disorder,
.0x Single Manic Episode[a,c,f]
Specify if: Mixed
.40 Most Recent Episode Hypomanic[g,h,i]
.4x Most Recent Episode Manic[a,c,f,g,h,i]
.6x Most Recent Episode Mixed[a,c,f,g,h,i]
.5x Most Recent Episode Depressed[a,b,c,d,e,f,g,h,i]
.7 Most Recent Episode Unspecified[g,h,i]
296.89 Bipolar II Disorder[a,b,c,d,e,f,g,h,i]
Specify (current or most recent episode): Hypomanic/Depressed
301.13 Cyclothymic Disorder
296.80 Bipolar Disorder NOS
293.83 Mood Disorder Due to . . . [*Indicate the General Medical Condition*]
Specify type: With Depressive Features/With Major Depressive-like Episode/With Manic Features/With Mixed Features
—.— Substance-Induced Mood Disorder (*refer to Substance-Related Disorders for substance-specific codes*)
Specify type: With Depressive Features/With Manic Features/With Mixed Features
Specify if: With Onset During Intoxication/With Onset During Withdrawal
296.90 Mood Disorder NOS

Anxiety Disorders

300.01 Panic Disorder Without Agoraphobia
300.21 Panic Disorder With Agoraphobia
300.22 Agoraphobia Without History of Panic Disorder
300.29 Specific Phobia
Specify type: Animal Type/Natural Environment Type/Blood-Injection-Injury Type/Situational Type/Other Type
300.23 Social Phobia
Specify if: Generalized
300.3 Obsessive–Compulsive Disorder
Specify if: With Poor Insight
309.81 Posttraumatic Stress Disorder
Specify if: Acute/Chronic
Specify if: With Delayed Onset
308.3 Acute Stress Disorder
300.02 Generalized Anxiety Disorder
293.89 Anxiety Disorder Due to . . . [*Indicate the General Medical Condition*]
Specify if: With Generalized Anxiety/ With Panic Attacks/With Obsessive–Compulsive Symptoms
—.— Substance-Induced Anxiety Disorder (*refer to Substance-Related Disorders for substance-specific codes*)
Specify if: With Generalized Anxiety/ With Panic Attacks/With Obsessive–Compulsive Symptoms/With Phobic Symptoms
Specify if: With Onset During Intoxication/With Onset During Withdrawal
300.00 Anxiety Disorder NOS

Somatoform disorders

300.81 Somatization Disorder

300.82 Undifferentiated Somatoform Disorder
300.11 Conversion Disorder
Specify type: With Motor Symptom or Deficit/With Sensory Symptom or Deficit/With Seizures or Convulsions/With Mixed Presentation
307.xx Pain Disorder
.80 Associated With Psychological Factors
.89 Associated With Both Psychological Factors and a General Medical Condition
Specify if: Acute/Chronic
300.7 Hypochondriasis
Specify if: With Poor Insight
300.7 Body Dysmorphic Disorder
300.82 Somatoform Disorder NOS

Factitious disorders

300.xx Factitious Disorder
.16 With Predominantly Psychological signs and Symptoms
.19 With Predominantly Physical Signs and Symptoms
.19 With Combined Psychological and Physical Signs and Symptoms
300.19 Factitious Disorder NOS

Dissociative disorders

300.12 Dissociative Amnesia
300.13 Dissociative Fugue
300.14 Dissociative Identity Disorder
300.6 Depersonalization Disorder
300.15 Dissociative Disorder NOS

Sexual and gender identity disorders

Sexual dysfunctions

The following specifiers apply to all primary Sexual Dysfunctions:
Lifelong Type/Acquired Type Generalized Type/Situational Type Due to Psychological Factors/Due to Combined Factors

Sexual desire disorders

302.71 Hypoactive Sexual Desire Disorder
302.79 Sexual Aversion Disorder

Sexual arousal disorders

302.72 Female Sexual Arousal Disorder
302.72 Male Erectile Disorder

Orgasmic disorders

302.73 Female Orgasmic Disorder
302.74 Male Orgasmic Disorder
302.75 Premature Ejaculation

Sexual pain disorders

302.76 Dyspareunia (Not Due to a General Medical Condition)
306.51 Vaginismus (Not Due to a General Medical Condition)

Sexual dysfunction due to a general medical condition

625.8 Female Hypoactive Sexual Desire Disorder Due to . . . [*Indicate the General Medical Condition*]
608.89 Male Hypoactive Sexual Desire Disorder Due to . . . [*Indicate the General Medical Condition*]
607.84 Male Erectile Disorder Due to . . . [*Indicate the General Medical Condition*]
625.0 Female Dyspareunia Due to . . . [*Indicate the General Medical Condition*]
608.89 Male Dyspareunia Due to . . . [*Indicate the General Medical Condition*]
625.8 Other Female Sexual Dysfunction Due to . . . [*Indicate the General Medical Condition*]
608.89 Other Male Sexual Dysfunction Due to . . . *Indicate the General Medical Condition*]
—.— Substance-Induced Sexual Dysfunction (*refer to Substance-Related Disorders for substance-specific codes*)
Specify if: With Impaired Desire/With Impaired Arousal/With Impaired Orgasm/With Sexual Pain
Specify if: With Onset During Intoxication
302.70 Sexual Dysfunction NOS

Paraphilias

302.4 Exhibitionism
302.81 Fetishism
302.89 Frotteurism
302.2 Pedophilia
Specify if: Sexually Attracted to Males/Sexually Attracted to Females/Sexually Attracted to Both
Specify if: Limited to Incest
Specify type: Exclusive Type/Nonexclusive Type
302.83 Sexual Masochism
302.84 Sexual Sadism
302.3 Transvestic Fetishism
Specify if: With Gender Dysphoria
302.82 Voyeurism
302.9 Paraphilia NOS

Gender identity disorders

302.xx Gender Identity Disorder
.6 in Children
.85 in Adolescents or Adults
Specify if: Sexually Attracted to Males/Sexually Attracted to Females/Sexually Attracted to Both/Sexually Attracted to Neither
302.6 Gender Identity Disorder NOS
302.9 Sexual Disorder NOS

Eating disorders

307.1 Anorexia Nervosa
Specify type: Restricting Type; Binge-Eating/Purging Type
307.51 Bulimia Nervosa
Specify type: Purging Type/Nonpurging Type
307.50 Eating Disorder NOS

Sleep disorders

Primary sleep disorders

Dyssomnias

307.42 Primary Insomnia
307.44 Primary Hypersomnia
Specify if: Recurrent

347.00 Narcolepsy
780.57 Breathing-Related Sleep Disorder
327.3X Circadian Rhythm Sleep Disorders
.31 Delayed Sleep Phase Type
.35 Jet Lag Type
.36 Shift Work Type
.30 Unspecified Type
Type/Unspecified Type
307.47 Dyssomnia NOS

Parasomnias

307.47 Nightmare Disorder
307.46 Sleep Terror Disorder
307.46 Sleepwalking Disorder
307.47 Parasomnia NOS

Sleep disorders related to another mental disorder

327.02 Insomnia Related to . . . [*Indicate the Axis I or Axis II Disorder*]
327.15 Hypersomnia Related to . . . [*Indicate the Axis I or Axis II Disorder*]

Other sleep disorders

780.xx Sleep Disorder Due to . . . [*Indicate the General Medical Condition*]
.52 Insomnia Type
.54 Hypersomnia Type
.59 Parasomnia Type
.59 Mixed Type
—.— Substance-Induced Sleep Disorder (*refer to Substance-Related Disorders for substance-specific codes*)
Specify type: Insomnia Type/Hypersomnia Type/Parasomnia Type/ Mixed Type
Specify if: With Onset During Intoxication/With Onset During Withdrawal

Impulse control disorders not elsewhere classified

312.34 Intermittent Explosive Disorder
312.32 Kleptomania
312.33 Pyromania
312.31 Pathological Gambling
312.39 Trichotillomania
312.30 Impulse-Control Disorder NOS

Adjustment disorders

309.xx Adjustment Disorder
.0 With Depressed Mood
.24 With Anxiety
.28 With Mixed Anxiety and Depressed Mood
.3 With Disturbance of Conduct
.4 With Mixed Disturbance of Emotions and Conduct
.9 Unspecified
Specify if: Acute/Chronic

Personality disorders

Note: *These are coded on Axis II*

301.0 Paranoid Personality Disorder
301.20 Schizoid Personality Disorder
301.22 Schizotypal Personality Disorder
301.7 Antisocial Personality Disorder
301.83 Borderline Personality Disorder
301.50 Histrionic Personality Disorder
301.81 Narcissistic Personality Disorder
301.82 Avoidant Personality Disorder
301.6 Dependent Personality Disorder
301.4 Obsessive–Compulsive Personality Disorder
301.9 Personality Disorder NOS

Other conditions that may be a focus of clinical attention

Psychological factors affecting medical condition

316 . . . [*Specified Psychological Factor*]
Affecting . . . [*Indicate the General Medical Condition*]
Choose name based on nature of factors:
Mental Disorder Affecting Medical Condition
Psychological Symptoms Affecting Medical Condition
Personality Traits or Coping Style Affecting Medical Condition
Maladaptive Health Behaviours Affecting Medical Condition
Stress-Related Physiological Response Affecting Medical Condition
Other or Unspecified Psychological Factors Affecting Medical Condition

Medication-induced movement disorders

332.1 Neuroleptic-Induced Parkinsonism
333.92 Neuroleptic Malignant Syndrome
333.7 Neuroleptic-Induced Acute Dystonia
333.99 Neuroleptic-Induced Acute Akathisia
333.82 Neuroleptic-Induced Tardive Dyskinesia
333.1 Medication-Induced Postural Tremor
333.90 Medication-Induced Movement Disorder NOS

Other medication-induced disorder

995.2 Adverse Effects of Medication NOS

Relational problems

V61.9 Relational Problem Related to a Mental Disorder or General Medical Condition
V61.20 Parent–Child Relational Problem
V61.10 Partner Relational Problem
V61.8 Sibling Relational Problem
V62.81 Relational Problem NOS

Problems related to abuse or neglect

V61.21 Physical Abuse of Child (*code 995.54 if focus of attention is on victim*)
V61.21 Sexual Abuse of Child (*code 995.53 if focus of attention is on victim*)
V61.21 Neglect of Child (*code 995.52 if focus of attention is on victim*)
—.— Physical Abuse of Adult
V61.12 (if by partner)
V62.83 (if by person other than partner) (*code 995.83 if focus of attention is on victim*)

—.— Sexual Abuse of Adult
V61.12 (if by partner)
V62.83 (if by person other than partner) (*code 995.83 if focus of attention is on victim*)

Additional conditions that may be a focus of clinical attention

V15.81 Noncompliance With Treatment
V65.2 Malingering
V71.01 Adult Antisocial Behaviour
V71.02 Child or Adolescent Antisocial Behaviour
V62.89 Borderline Intellectual Functioning

Note: *This is coded on Axis II*

780.93 Age-Related Cognitive Decline
V62.82 Bereavement
V62.3 Academic Problem
V62.2 Occupational Problem
313.82 Identity Problem
V62.89 Religious or Spiritual Problem
V62.4 Acculturation Problem
V62.89 Phase of Life Problem

Additional codes

300.9 Unspecified Mental Disorder (nonpsychotic)
V71.09 No Diagnosis or Condition on Axis I
799.9 Diagnosis or Condition Deferred on Axis I
V71.09 No Diagnosis on Axis II
799.9 Diagnosis Deferred on Axis II

From science to practice

John R. Geddes

The difficulties in keeping up to date

Clinicians need accurate and up-to-date information about emerging knowledge on assessment and treatment as well as other developments in practice. The presentation of this knowledge needs to be timely, accurate, and unbiased. In an ideal world, every psychiatrist would have instantaneuous access to the original scientific articles. As this is not feasible because clinicians are busy and the skills needed for an adequate systematic search, critical appraisal, and interpretation of research articles are not routinely available. Further, the volume of research articles is staggering: about 2 million papers are published in 20 000 biomedical journals every year,[1] and even if a psychiatrist restricted her reading to those clinical psychiatry journals it would be necessary to read about 5500 papers each year—equivalent to 15 papers every day.[2] Clearly, a strategy is required for efficient and timely identification of research that is both methodologically sound and clinically relevant.

Traditionally, clinicians have used a number of methods of keeping up to date with research, including consulting colleagues and reading textbooks and journals. Smith[3] reviewed the research on the information needs of doctors and rated sources of information on several dimensions: their relevance to clinical practice, their scientific validity, how easy they were to use, and an overall estimate of their usefulness. Most of the sources that scored highly on all dimensions (such as regularly updated evidence-based textbooks) were of limited availability. Traditional methods of obtaining information (such as conventional textbooks and lecture-based continuing medical education) were more widely available, but of limited validity.

The difficulty in accessing reliable information means that many clinical decisions are made with a greater degree of uncertainty than is necessary. The gap between research and clinical practice is often filled by an unsystematic combination of beliefs, opinions, and clinical experience, which inevitably leads to unnecessary variations in clinical practice. These have been widely documented in psychiatry and include variations in the use of electroconvulsive therapy,[4,5] the use of antipsychotics,[6,7] and the treatment of depression.[8–10] The existence of these variations can only mean that some patients are not receiving the optimum treatment.

Methods of improving use of best available evidence

A coherent set of strategies designed as a clinical tool to link the best available evidence directly to the care of individual patients was first formulated at McMaster University in Canada—an approach called **evidence-based medicine**.[11] Evidence-based medicine is problem-based and splits the process of linking research to practice into five stages (Fig. 1.10.1) plus the identification of clinical questions in need of more research.

To make evidence-based practice feasible in real-life clinical practice, a number of problems need to be solved at each stage of the process.

Formulating a structured clinical question

When uncertainty arises in clinical practice, the clinician needs to formulate a structured clinical question. This step is fundamental to the process of evidence-based medicine because it allows the

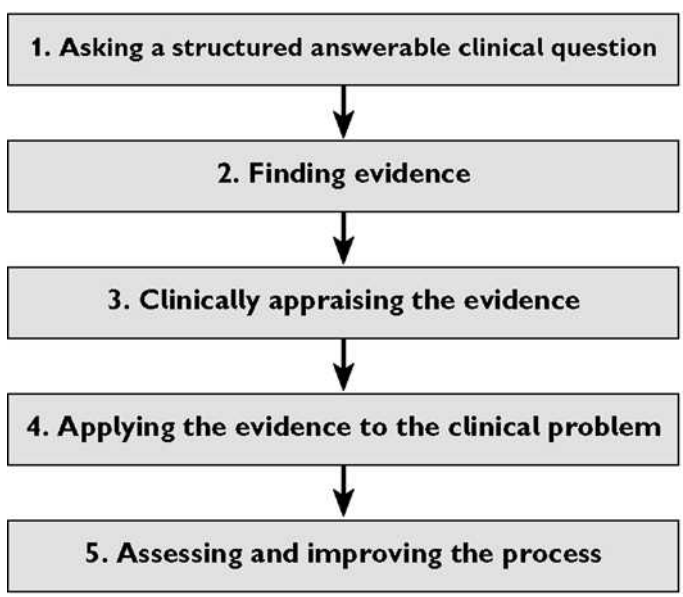

Fig. 1.10.1 The five stages of evidence-based medicine.

clinician first to classify the question, second to identify the research architecture that is most likely to yield a reliable result, and finally to determine the most efficient way of looking for the most reliable research.

(a) Example

Consider a patient who has suffered from two episodes of major depressive disorder both of which have caused substantial functional impairment. On each occasion his symptoms have responded to treatment with a selective serotonin reuptake inhibitor. Following remission of symptoms, the patient has been advised to continue treatment for 6 months before gradually discontinuing the drugs. His psychiatrist is now considering whether or not to advise long-term treatment with antidepressant medication to reduce the risk of relapse. The patient wants to know the risk of relapse without treatment and how much this would be reduced by continuing the drugs. The process of rapidly finding the best answer begins by formulating a clinical question:

1 in patients with major depressive disorder who have responded to drug treatment (the **problem**)

2 how effective are antidepressants (the **intervention**)

3 compared with alternative treatments (including none) (the **comparison intervention**)

4 in preventing relapse (the **outcome**)?

The next step is to classify the question. This example clearly concerns a question about therapy. Most of the questions that arise in clinical practice concern therapy, diagnosis, prognosis, or aetiology. Once the question has been formulated and classified, this suggests the most reliable research architecture (Table 1.10.1)

Finding evidence and advances in the organization of clinical knowledge

Identification of the nature of the clinical question and the most reliable study design enables the clinician to do a focused and efficient literature search. One of the main advances of evidence-based medicine has been the development of methods of research synthesis, or the process of identifying, appraising, and summarizing primary research studies into clinically usable knowledge. There are two main approaches to research synthesis—systematic reviews and clinical practice guidelines. Both these approaches are based on an explicit methodology that begins with the construction of a hierarchy of evidence in which certain forms of research architecture are considered to be reliable than others. The methodology is most clearly developed for questions about therapy and these will be the focus here.

(b) Levels of evidence

A commonly used hierarchy of evidence for studies of treatments is as follows:

Ia Evidence from a systematic review of randomized controlled trials,

Ib Evidence from at least one randomized controlled trial,

IIa Evidence from at least one controlled study without randomization,

IIb Evidence from at least one other type of quasi-experimental study,

Table 1.10.1 Types of clinical question and most reliable study architecture

Type of question	Form of the question	Most reliable study architecture
Diagnosis	How likely is a patient who has a particular symptom, sign, or diagnostic test result to have a specific disorder?	A cross-sectional study of patients suspected of having the disorder comparing the proportion of the patients who really have the disorder who have a positive test result with the proportion of patients who do not have the disorder who have a positive test result.
Treatment	Is the treatment of interest more effective in producing a desired outcome than an alternative treatment (including no treatment)?	Randomized evidence in which the patients are randomly allocated to receive either the treatment of interest or the alternative: this is usually a systematic review of RCTs or a single high-quality RCT.
Prognosis	What is the probability of a specific outcome in this patient?	A study in which an inception cohort (patients at a common stage in the development of the illness—especially first onset) are followed up for an adequate length of time.
Aetiology	What has caused the disorder?	A study comparing the frequency of an exposure in a group of persons with the disease (cases) of interest with a group of persons without the disease (controls)—this may be an RCT, a case-control study. or a cohort study.

RCT, randomized controlled trial.

III Evidence from non-experimental descriptive studies, such as comparative studies, correlation studies, and case-control studies,

IV Evidence from expert committee reports or opinions and/or clinical experience of respected authorities.

In this hierarchy, randomized evidence is considered, on average, to be more reliable thsan non-randomized evidence, and a systematic review of randomized evidence is considered to be the best defence against systematic bias.

Hierarchies of evidence have also been formulated for non-therapeutic studies, such as studies of aetiology, diagnosis, and prognosis. Again, the fundamental feature of these hierarchies is that the study architectures with the least susceptibility to bias are considered most reliable. The study design considered most reliable for each type of clinical question is shown in Table 1.10.1.

(c) Systematic reviews

The need for systematic reviews and the methodology used are described in Chapter 6.1.1.2. The recognition of the need for systematic reviews of randomized controlled trials, and the development of the scientific methodology of reviews, has been one of the most striking advances in health services research over the last decade. One key development was the founding of the Cochrane Collaboration, an international organization with the objective of

producing regularly updated systematic reviews of the effectiveness of all health care interventions.[12]

(d) Clinical practice guidelines

In some areas of health care there is sufficient evidence, coexisting with substantial clinical uncertainty, that it is worth developing clinical practice guidelines. Clinical practice guidelines have been defined as 'systematically developed statements to assist practitioner decisions about appropriate health care for specific clinical circumstances'.[13] Guidelines have been developed for several years, but there have been recent advances in the methodology of producing explicitly evidence-based guidelines. Evidence-based clinical practice guidelines are developed by a guideline development group consisting of key stakeholders who decide on the precise clinical questions to be answered. The evidence is then systematically reviewed and classified according to a hierarchy of evidence (see above) and presented to the guideline development group. The group then makes recommendations as appropriate. The degree to which the recommendations are directly based on the evidence is described using a second level of classification[14]:

1 directly based on category I evidence;

2 directly based on category II evidence or extrapolated recommendation from category I evidence;

3 directly based on category III evidence or extrapolated recommendation from category I or II evidence;

4 directly based on category IV evidence or extrapolated recommendation from category I, II, or III evidence.

Clinical practice guidelines are usually developed at a national level and need tailoring to suit local circumstances. Professional and scientific bodies such as the American Psychiatric Association and the British Association for Psychopharmacology often take the lead in developing national guidelines. Increasingly, health care providing organizations are developing clinical practice guidelines as a way of assuring quality, increasing standardization of care and controlling costs. For example, in the United Kingdom, the National Institute for Health and Clinical Excellence (NICE) is now the main body producing guidelines across all disease areas. These guidelines are extremely rigorous in terms of methodology and also routinely include economic analyses of the cost-effectiveness of health care technologies. At their best, these guidelines produce the most accurate syntheses of current knowledge available. NICE also produces Health Technology Appraisals (HTAs) of single interventions to determine the cost-effectiveness of new technologies (mainly medicines) prior to their introduction into the taxpayer-funded National Health Service. Cost-effectiveness analysis requires the translation of disease-specific estimates of clinical effectiveness into the common metric of Quality Adjusted Life Years (QALYs) using sophisticated modelling techniques. Decisions about whether to allow reimbursement of the treatment depends on the cost per QALY (incremental cost-effectiveness ratio, ICER): a treatment with an ICER of more than £30 000 is unlikely to be approved. NICEs HTA decisions are particularly likely to be controversial when there is some evidence that the treatment works, but that the ICER is found to be too high—for example, in the case of acetylcholinesterase inhibitors in Alzheimer's disease.

There are several limitations to clinical practice guidelines. Firstly, evidence-based clinical practice guidelines are expensive and time consuming to produce and rapidly become out of date. Secondly, to influence practice, evidence-based clinical practice guidelines need to be actively disseminated and implemented. Guidelines that are developed nationally and passively sent out to doctors are often not used.[15] A number of active approaches are effective in helping change clinicians' behaviour:[16]

- outreach visits (also known as academic detailing)
- local opinion leaders
- patient-mediated interventions (including patient education)
- multifaceted interventions involving a range of techniques.

There is some evidence that guidelines can improve patient outcomes by their effect on clinical practice, especially when they are made relevant to local circumstances.[15] In one study in the United States, 217 patients with depressive disorders were randomly assigned to usual care or a multifaceted intervention designed to achieve the Agency for Health Care Policy and Research guidelines on management of depression.[17] Patients in the intervention group were much more likely to be treated in accordance with the guidelines, and this led to improved outcomes in patients with major depressive disorder (more than 50 per cent reduction on the Symptom Checklist-90 Depressive Symptom Scale at 4 months in 74 per cent of experimental patients compared with 44 per cent of control patients).

Understandably, clinicians also seek guidance in important clinical questions that are poorly served by high-quality, especially randomized, evidence. To assist in these clinical decisions, Frances and his colleagues have developed an innovative method of guideline development based on a systematic survey of the views of clinical experts.[18,19]

(e) Use of electronic communication and the Internet

The development of the Internet—or World Wide Web—during the 1990s facilitated the development of evidence-based practice. The Internet has now become a vast information resource for doctors and patients. Improved access to information afforded to patients means that they are often very well informed about their condition. This is one of the factors contributing to the need for doctors to improve their own access to information. The Internet has several drawbacks including the disorganization of the information and the lack of quality control.[20,21] Web portals have been developed that provide organized and indexed access to critically appraised websites (e.g. www.nelh.nhs.uk). The Web has now become the main medium for transmitting and storing knowledge.

(f) Improving current awareness

Another area of improvement has been the development of tools to assist doctors to maintain their current awareness of advances in research. The idea of review and abstracting journals is not new, but there has been a recognition that such journals also need a methodology to allow them to identify the most reliable and clinically important research studies.

A number of new journals have been produced with the aim of improving the availability of high-quality evidence to clinicians. The first of these was *ACP Journal Club* (targeted primarily at general physicians), followed by *Evidence-Based Medicine* (targeted primarily at family doctors) and, more recently, Evidence-Based Mental Health (aimed at mental health clinicians of all disciplines).

Evidence-Based Mental Health scans over 200 journals regularly and selects only those articles that both meet explicit methodological criteria (see Box 1.10.1) and are clinically important. The articles are then summarized in structured abstracts and published on one page with an accompanying commentary by a clinical expert.

A systematic approach to searching for the best available evidence

The developments in the organization of clinical knowledge make it possible for a clinician to search rapidly and efficiently for current best evidence using a standard approach (Fig. 1.10.2). This approach will change as new methods of organizing knowledge are developed.

(a) Example (continued)

Although a recent clinical guideline has been produced by NICE, it does not include sufficient quantitative information to answer the patient's question.

Box 1.10.1 Examples of the criteria for selection and review of articles for abstracting in Evidence-Based Mental Health

Articles are considered for abstracting if they meet the following criteria

Basic criteria

- Original or review articles
- In English
- About humans
- About topics that are important to the practice of clinicians in the broad field of mental health

Studies of prevention or treatment must meet these additional criteria

- Random allocation of participants to comparison groups
- Follow-up (endpoint assessment) of at least 80% of those entering the investigation
- Outcome measure of known or probable clinical importance
- Analysis consistent with study design

Studies of diagnosis must meet these additional criteria

- Clearly identified comparison groups, at least one of which is free of the disorder or derangement of interest
- Interpretation of diagnostic standard without knowledge of test results
- Interpretation of test without knowledge of diagnostic standard result
- Diagnostic(gold) standard(e.g. diagnosis according to DSM-IV or ICD-10 criteria after assessment by clinically qualified interviewer) preferably with documentation of reproducible criteria for subjectively interpreted diagnostic standard(e.g. report of statistically significant measure of agreement among observers)
- Analysis consistent with study design.

Studies of prognosis must meet additional criteria

- Inception cohort (first onset or assembled at a uniform point in the development of the disease) of individuals, all initially free of the outcome of the interest
- Follow-up of at least 80% of patients until the occurrence of a major study endpoint
- Or to the end of the study
- Analysis consistent with study design.

Studies of causation must meet these additional criteria

- Clearly identified comparison group for those at risk of, or having, the outcome of interest (i.e. randomized controlled trial quasi-randomized controlled trial, non-randomized controlled trial, cohort analytical study with case by-case matching, or statistical adjustment to create comparable groups, case-control study)
- Masking of observers of outcomes to exposures (this criterion is assumed to be met if the outcome is objective), observers of exposures masked to outcomes for case-control studies, or masking of subjects to exposure for all other study designs
- Analysis consistent with study design.

Geddes, J.R., Carney, S.M., Davies, C., Furukawa, T.A., Kupfer, D.J., Frank, E., Goodwin. G.M. Relapse prevention with antidepressant drug treatment in depressive disorders. *Lancet* 2003, **361:** 653–61.[22]

This is a systematic review of randomized controlled trials comparing a number of antidepressants (including tricyclics, selective serotonin reuptake inhibitors, monoamine oxidase inhibitors, and low-dose antipsychotics) with placebo in the prevention of relapse in depressive disorder.

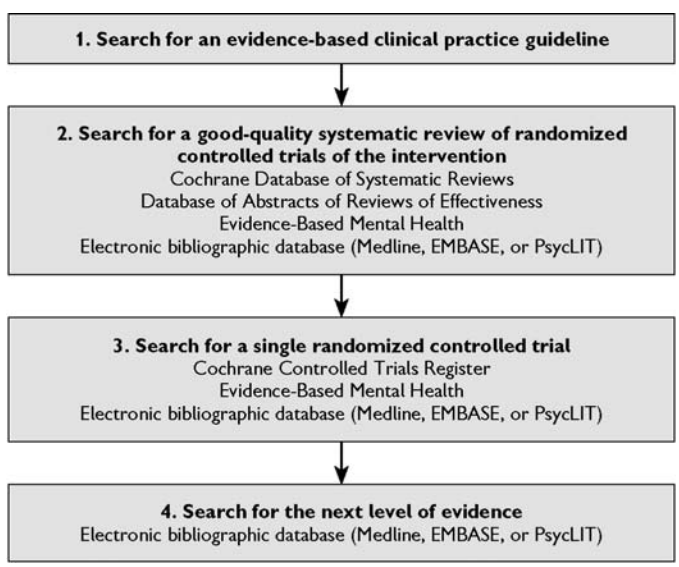

Fig. 1.10.2 A systematic approach to identifying the best evidence about a therapy.

Critical appraisal of research articles

Once the evidence has been found, it needs to be critically appraised for its reliability and usefulness. Psychiatrists need to be able to assess the scientific value and clinical importance of a study. This requires a range of epidemiological and biostatistical skills that have not traditionally been considered to be key skills for psychiatrists. In the United Kingdom, the Royal College of Psychiatrists introduced in 1999 a new part of the main professional examination that is designed to test these skills, recognizing their fundamental importance for clinical psychiatrists.[23]

Structured critical appraisal is an active process that involves a systematic assessment of the key methodological aspects of the paper. In particular, critical appraisal focuses systematically on those aspects of the study methodology that are most likely to lead to unreliability of results. A number of checklists, designed to make the appraisal quicker and more systematic, have been produced for different research study designs.[24] For example, the critical appraisal of a systematic review involves an assessment of those aspects of methodology described in Chapter 6.1.1.2. A commonly used checklist for systematic reviews is shown in Table 1.10.2.

(a) Example (continued)

Using the checklist, the review can be quickly critically appraised. It is a review of the efficacy of antidepressant drugs in preventing recurrence of depression in patients who responded to acute phase therapy with antidepressants and so appears relevant to the clinical question. The authors have only included randomized controlled trials, and this will make systematic error less likely and improve the reliability of the review. The literature search strategy is clearly documented and included electronic databases (Medline, Psyclit, Embase, Lilacs, and the Cochrane Library), hand searching of journals, and correspondence with researchers active in the field and drug companies. The quality of the randomized controlled trials was rated both from the description of the allocation of treatment and by assessing other methodological issues such as whether the primary analysis was done as an intention-to-treat analysis and the degree of blinding of the clinician and patient. It can be concluded that the reviewers have made a reasonable effort to identify the primary studies, although it is possible that other studies, perhaps with negative results, have not been published (publication bias, see Chapter 6.1.1.2).

The results of the primary studies are shown graphically as odds ratios (see Glossary) in Fig. 1.10.3. Odds ratios falling to the left of the vertical line indicate that the outcome (relapse of depressive symptoms) occurred less frequently in patients who continued treatment with an antidepressant. The smaller the odd ratio, the larger the treatment effect found in that particular study. For each study, the central diamond represents the most likely value of the relative risk and the box around the relative risk shows the 95 per cent confidence interval (**CI**). The larger studies (e.g. **Rouillon *et al.*[25]) have narrower confidence intervals because they are larger and therefore have less random error and greater precision.

From the figure, it can be seen that, the odds ratio of the all the studies included fall on the left-hand side of the line and therefore found the same direction of treatment effect. There is considerable overlap in the confidence intervals from study to study and, although there is some statistically significant heterogeneity between them (see Chapter 6.1.1.2), this appears to be in the size—rather than the nature—of the positive treatment effect. At the bottom of the figure is the estimate of the combined treatment effect of the trials. This is expressed as a pooled odds ratio. Combining the study results produces a more precise estimate of the drug's relative effectiveness, with tighter confidence intervals. The overall pooled odds ratio of relapse for patients taking antidepressants compared with placebo is 0.30 (95 per cent CI (see Glossary), 0.22–0.38).

Table 1.10.2 Checklist to assist the critical appraisal of a systematic review

Validity
1. Did the review address a clearly focused clinical question? Did the review describe: the population studied? the intervention given? the outcomes considered?
2. Did the authors select the right sort of studies for the review? The right studies would: address the review's question have an adequate study design (e.g. for a question re therapy, an RCT)
3. Were the important relevant studies included in the review? Which bibliographic databases were used? Personal contact with experts Search for unpublished as well as published studies Search for non-English language studies
4. Did the review's authors assess the quality of the included studies? Did they use: description of randomization? a rating scale?
Results
5. Were the results similar from study to study? Are the results of all the included studies clearly displayed? Are the results from different studies similar? If not, are the reasons for variations between studies discussed?
6. What is the overall result of the review? Is there a clear clinical conclusion (a clinical bottom-line)? What is it? What is the numerical result?
7. How precise are the results? Is there a confidence interval?
Clinical relevance of the results
8. Can I apply the results to my patient? Is this patient so different from those in the trial that the results do not apply?
9. Should I apply the results to my patient? How great would the benefit of therapy be for this particular patient? Is the intervention consistent with my patient's values and preferences? Were all the clinically important outcomes considered? Are the benefits worth the harms and costs?

RCT, randomized controlled trial.

Methods of using research findings at the level of individual patients

After the study has been critically appraised for its validity, the clinician needs to determine what the results are, and their importance for the patient. Patients in research studies are always different from those in real-life clinical practice in ways that may be difficult to determine even only if because they–or at least the

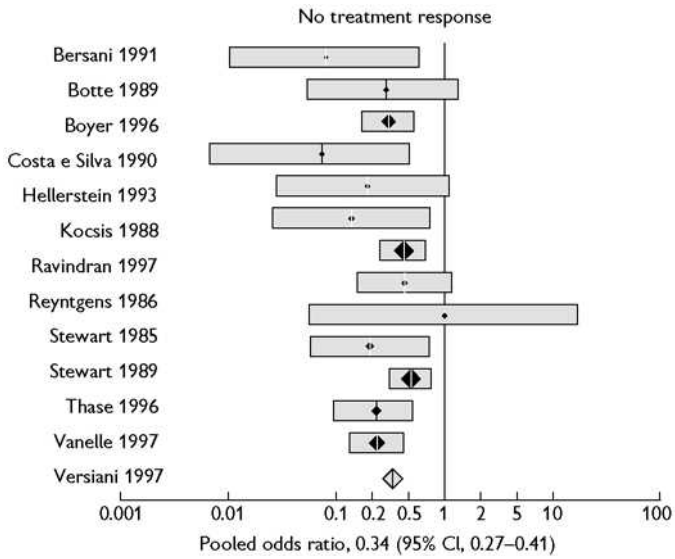

Fig. 1.10.3 Antidepressant versus placebo for the prevention of relapse in depressive disorder. (Reprinted from the *Lancet*, **361**, Geddes, J.R., Carney, S.M., Davies, C., *et al.* (2003), Relapse prevention with antidepressant drug treatment in depressive disorders, 653–61 Copyright 2003, with permission from Elsevier).[22]

episode of illness–was in the past rather than the present. Therefore, the use of results from research studies in clinical practice should be cautious and always requires a degree of extrapolation. The contribution of clinical epidemiology is in developing methods of applying research results to individual patients that are biologically and statistically robust and are explicit about any assumptions made. One of the most useful questions to ask when applying the results of a research study is: 'Is my patient so different from those in the study that the results cannot be used'? The next step is to try to interpret the study results for a particular patient, in terms of his or her clinical characteristics and treatment preferences.

An alternative measure of treatment effect which many find more clinically useful than the relative risk or odds ratio is the number needed to treat (**NNT**).[26,27] The NNT is an estimate of the number of patients that would need to be treated with the intervention of interest, compared with the alternative, in order to achieve one good outcome or to avoid one harmful outcome. The NNT is calculated by taking the reciprocal of the difference between the rates of the outcome of interest in the experimental and control groups.

(a) Example (continued)

Although the review supports the general conclusion that continued therapy with the same antidepressant that was effective in acute phase therapy is very much likely to decrease the risk of relapse, a clinician may wish to check the evidence for a specific drug. For example, how strong is the evidence for reboxetine? The systematic review identifies one trial that directly answers this question[28]. This was a multicentre trial performed in centres in Europe and South America. The trial recruited 358 outpatients who met DSM-IIIR criteria for an acute recurrence of major depressive disorder to open-label reboxetine and randomized the 285 patients who achieved >50 per cent reduction in baseline depressive symptoms on the Hamilton Depression Rating Scale to either continued reboxetine or placebo (mean age reboxetine 43.4 years, placebo 42.3 years, women 79.3 per cent reboxetine: 67.4 per cent men). One group of 145 patients were allocated to reboxetine, 4 mg b.d. and 141 patients were allocated to placebo. Treatment was continued for a further 46 weeks and the primary outcome was relapse (increase in the Hamilton Depression Rating Scale of 50 per cent or more and/or a total score of ≥18 points).

(i) Appraising the validity of a randomized controlled trial

The appraisal of an individual randomized controlled trial also addresses issues of internal and external validity. The main difference compared with the appraisal of a systematic review is that the reader can appraise the trial directly, rather than relying on the author of the review to have made an adequate assessment of the quality of the studies included. The most important questions to answer during the appraisal of the article are those relating to methodological issues that have been randomly shown to affect the reliability of the results (Table 1.10.3).

This study[28] was a **randomized controlled trial**. The method of randomization is not stated and no details are provided about the **concealment of treatment allocation**. Concealment of allocation is one of the most important features to appraise in a randomized controlled trial, and refers to how well the treatment allocation of the next patient was concealed from the participating clinician.[29] If a clinician has definite knowledge of, or can reasonably predict, the next allocation, he may decide not to enter a patient if he favours either treatment in that specific case. This would obviously lead to a subversion of randomization and biased results. This is why methods of quasi-randomization, such as alternate allocation, are often unsatisfactory. The most satisfactory methods of random allocation are when allocation is performed by a third party following entry of the patient into the study, for example using a centralized telephone service. Concealment of allocation should be distinguished from **blinding** of treatment allocation. Blinding refers to whether the patient (**single blind**), or both the patient and the clinician (**double blind**), are kept unaware of which arm of the study the patient has been allocated to *following* randomization. Blinding protects against bias in the treatment during the trial and in the assessment of subjective outcomes, but can be difficult to maintain when the experimental treatment has characteristic side-effects (e.g. antidepressants). This study was reported to be double blind; however, it is difficult to tell how effective the blinding was and whether this affected the treatment that the patients received or the ratings of outcome.

Of the patients who were randomized, 79/145 (54 per cent) of those allocated to reboxetine and 65/141 (46 per cent) of those allocated to placebo completed the trial. The reasons for drop-out are clearly stated and all the patients who entered the study are accounted for. Patients who drop out of a study may be different from those who complete it—this is a particular problem if there

Table 1.10.3 Questions that must be answered during the appraisal of an article

1. Was the assignment of the patients randomized?
2. Was the randomization list concealed?
3. Were all the subjects who entered the trial accounted for at its conclusion?
4. Were they analysed in the groups to which they were randomized?
5. Were subjects and clinicians 'blind' to which treatment was being received?
6. Other than the experimental treatment, were the groups treated equally?
7. Were the groups similar at the start of the trial?

is **differential drop-out** between the arms of the study. For this reason, the most statistically reliable and clinically useful method of analysis is to include all patients who were randomized in the analysis. This is called an **intention-to-treat analysis (ITT)**. In the reboxetine trial[28] the primary analysis was done on an ITT basis (although three patients who dropped out before the first follow-up assessment were excluded from the primary analysis—these were included in the systematic review), and the patients were analysed in the groups to which they were randomized. Lastly, although randomization will avoid bias in treatment allocation, it is possible that, by chance, the groups will be unbalanced on some key prognostic factors such as age, sex, duration, and severity of illness. Therefore it is important to assess the baseline characteristics of the patients to identify any obvious differences. In Versiani *et al.*[28] the patients were reasonably similar on baseline characteristics at entry into the trial, although the proportion of females was a little higher in the reboxetine group.

(ii) Are the results relevant for your patient?

To determine the relevance of the study to real-life patients, it is important to examine the inclusion and exclusion criteria of the trial. The main inclusion criteria are discussed above. Patients excluded from the trial were those with coexisting psychotic features or chronic depression, those with a first episode at the time of screening and patients with a history of seizures, serious brain injury, clinically significant haemopoietic or cardiovascular disease, urinary retention, or glaucoma. The user of the study results will have to take these inclusion and exclusion criteria into account, and the clinician needs to judge the relevance of the results for the individual patient.

(iii) What are the results?

Of the 145 patients treated with reboxetine, 29 relapsed, giving an experimental event rate (**EER**), of 20 per cent or a probability of relapse of 0.2. In the placebo-treated group 73 of 141 patients relapsed giving a control event rate (**CER**) of 52 per cent. Therefore the absolute difference between the rates was

$$\text{EER} - \text{CER} = 32 \text{ per cent}$$

and the difference between the probabilities is 0.32. This means that for every 100 patients treated with reboxetine, compared with placebo, 32 fewer relapsed. Therefore, to prevent one relapse over 46 weeks, 100/32, or about three patients, would need to be treated (NNT) with reboxetine.

(b) Interpretation of numbers needed to treat

The clinical interpretation of NNT depends on the seriousness of the outcome and the nature (and cost) of the intervention.

For example, if the number needed to treat with aspirin following acute stroke to avoid one death in the short-term is 100, this seems a very useful intervention because death is such a serious outcome that it is worth treating a lot of patients to save a few from dying—especially as aspirin is very cheap. Some examples of NNTs are given in Table 1.10.4.

Table 1.10.4 Examples of numbers needed to treat for interventions in psychiatry assessment and report

Intervention	Outcome	NNT	95% CI	Reference
Cognitive therapy in bulimia nervosa	Long-term remission	2		30
Antidepressants in dysthymic disorder	Clinical response	5	3–10	31
Family therapy in schizophrenia	Relapse at 1 year	**7**	4–14	32
SSRIs compared with TCAs in depressive disorder	Remain in treatment at 6 weeks	39	20–426	28

SSRI, selective serotonin reuptake inhibitor, TCA tricyclic antidepressant.

Critical appraisal of other research designs

The approach taken to the appraisal of research designs applied to other clinical questions is similar to that outlined above. Rather than passively reading the article or abstract, the clinician actively searches out the most important methodological features to determine the reliability of the study. By applying the methods developed by clinical epidemiologists, the results presented in the paper can be used to calculate more clinically meaningful measures. These can, in turn, be tailored to suit the characteristics of the individual patient. The clinician needs to develop a practical knowledge of the tools to allow him to use them routinely and quickly in clinical practice and also to develop sufficient familiarity to be able describe the results of studies to colleagues and patients.

Glossary

- **Absolute risk reduction (risk difference)** is the absolute arithmetic difference in the risk of the adverse outcome between control group (CER) and experimental group (EER). When an intervention increases the probability of a beneficial outcome it is known as the absolute benefit increase (ABI).
- **Confidence interval (CI)** is the range within which the true value of a statistical measure can be expected to lie. The CI is usually accompanied by a percentage value (usually 95 per cent) which shows the level of confidence that the true value lies within this range.
- **Event rate** is the proportion of patients in a group in whom the event is observed. In control patients, this is called the control event rate (CER) and in experimental patients it is called the experimental event rate (EER). The patient expected event rate (PEER) refers to the rate of events that would be expected in a patient who received no treatment or conventional treatment.
- **Number needed to treat (NNT)** is the reciprocal of the absolute risk reduction and is the number of patients that need to be treated to prevent one bad outcome or to achieve one beneficial outcome.
- **Odds ratio** is the odds of the outcome in the experimental group divided by the odds of the outcome in the control group. The odds ratio is often reported in meta-analyses because of its useful statistical properties.
- **Relative risk** is the risk of the outcome in the experimental group divide by the risk of the outcome in the control group. The risk ratio is increasingly reported in meta-analyses because it is easier to interpret clinically than the odds ratio.

2.1

Brain and mind

Martin Davies

History of the mind–brain relation

The thesis that the brain, rather than the heart, is the seat of the mind was already widely accepted by the ancient Greeks; but it was not universally accepted—Aristotle was an exception. Many issues in psychiatry resonate with the ancient debates over the roles of the heart and the brain. But a brief review of modern thinking about the mind–brain relation can begin two millennia later with René Descartes, who held that minds are real things of a fundamentally different kind from material bodies.(1)

Dualism: Descartes

Descartes's world-view included bodies or material things, whose essence is to be extended in space, and minds, which are immaterial things whose essence is thinking. According to **Cartesian dualism**, the mind is not literally housed within the body, because spatial properties belong to matter and not to mind. But, when he talked about the way we experience the states of our own body, Descartes sometimes spoke of the mind being 'mixed up with' the body.

Early theories of the brain as the seat of the mind assigned an important role to the ventricles. On Descartes's view, mechanical operations involving the release of animal spirits in the ventricles were adequate to explain animal behaviour but intelligent human action required something more. He postulated that the immaterial mind could modulate processes in the material brain by way of a causal interaction operating through the pineal gland.

The motion of bodies and the completeness of physics

Dualist interactionism is challenged by theories about the motion of bodies. According to Descartes's own theory, quantity of motion (defined as mass times speed) is conserved. Because motion is not a directional notion, this conservation law allowed that the immaterial mind could bend the trajectory of a physical particle in the pineal gland. But Gottfried Leibniz's superior theory, with conservation laws for momentum (a directional notion) and kinetic energy, had the consequence that only impacts with other bodies could cause changes in the direction or speed of physical particles. This left no room for immaterial causes of material changes and, while Leibniz was a dualist, he was not an interactionist dualist but believed, instead, in a **pre-established harmony** between the material and immaterial worlds.

By departing from the idea that impact was the only force on bodies, and allowing action at a distance, Isaac Newton reopened the possibility of distinctively mental forces affecting the trajectory of bodies. These forces were not even ruled out by the law of conservation of energy, which was widely accepted by the middle of the nineteenth century, but advances in biochemistry and neurophysiology during the first half of the twentieth century made appeal to vital and mental forces seem increasingly unmotivated. Since around 1950, the dominant theories of the mind–brain relation have been compatible with a broadly physicalist world-view and with the completeness of physics: physical effects have wholly physical causes.(2)

Behaviourism: Ryle

From the 1920s to the 1950s, particularly in the United States, behaviourism was a dominant approach within psychology. This was not just methodological behaviourism, which is a restriction on the kinds of evidence that can be used, but a radical reconception of psychology as the science of behaviour rather than the science of the mind. In philosophy, **analytical behaviourism** was a doctrine about the meaning of our mental discourse. The idea was to analyse or translate our mental talk into talk about patterns of behaviour.

Gilbert Ryle promoted behaviourism as a response to what he called 'Descartes's myth' of 'the ghost in the machine'.(3) A dualist would regard talk about being in love, or wanting to visit Paris, as talk about an immaterial mind whose states lie hidden behind observable bodily behaviour. Ryle proposed to analyse this mental talk as being about the observable behaviour itself. He did not, however, aim to replace all mental terms by terms appropriate to the science of material bodies moving through space. He analysed believing that the ice is thin as, in part, being 'prone to skate warily' and it was enough, for his purposes, that skating warily is an observable and recognizable kind of behaviour, even if it is not readily defined in terms of the trajectories of body parts.

Because action is explained in terms of what the agent believes and what the agent wants, analytical behaviourism faces a major objection of principle. There is no pattern of behaviour associated with a belief, by itself. Someone who believes that the ice is thin but has an unusual desire to be immersed in ice-cold water may not skate warily. So there is no prospect of analysing any belief in terms

of behaviour. We might elevate this point into a general requirement on the description of any creature as having beliefs. Attributions of beliefs are not warranted if they merely summarize the creature's dispositions to exhibit patterns of behaviour. A belief is a mental state that can figure in the explanation of indefinitely many different actions in pursuit of different goals.

The identity theory: Place and Smart

Ryle's behaviourism involved a clear rejection of Descartes's duality of material and immaterial substances, but **central state materialism** (also known as the **identity theory**) encapsulated a more thoroughgoing commitment to the physicalist world-view. If the physical effects of our experiences, thoughts, and volitions have wholly physical causes then there is no causal work left for distinct mental items to do. To avoid epiphenomenalism, mental states, processes and events were to be identified with physical states, processes and events, and mental properties with physical properties. Place advanced a precursor of the identity theory, restricted to the case of conscious experiences,[4] and this was generalized by Smart, who identified beliefs and desires, intentions and hopes, as well as sensations and experiences, with brain states or processes.[5]

The identity theory defends the idea of **mental causation** by identifying each mental state with a physical state that is a locus of causal powers. But, taken literally, the identity theory is bound to seem chauvinistic. No being with a physical constitution radically different from ours could be described as feeling anything, or thinking anything, or wanting anything.

Functionalism: Putnam and Lewis

The functionalist response to the identity theory is that what a system does is more important than what it is made from. Physically different computing machines can run the same software and one version of the functionalist theory of the mind–brain relation is that the mind is the software of the brain.[6]

In an early version of **functionalism**, Hilary Putnam proposed that mental states are functional states like the states of an abstractly defined Turing machine rather than physical states like the states of a human brain.[7] This **machine functionalism** had the advantage of not tying mental states to a particular physical substrate but also a disadvantage. Since a Turing machine is in only one state at a time, machine states are not analogous to mental states like being in love or wanting to visit Paris.

The dominant version of contemporary functionalism, attributable to David Lewis, is **analytical functionalism**.[8] The leading idea is that commonsense specifications of the interconnected causal roles of mental states can be taken as interlocking analyses of mental state terms. For any physical being with a mind, there will be physical states playing each of the mental state causal roles but different physical states may play the same causal role in physically different minded beings—in human beings and Martians, for example.

Functionalism thus avoids the apparent chauvinism of the identity theory by allowing that a human being may be in the same mental state as a being with a very different physical constitution. But functionalism faces the opposite problem of apparently being too liberal. It seems to be possible to make up examples in which physical states play the causal roles that are supposed to define mental states, yet where, intuitively, there is no intelligence and no mental life.[9]

Challenges to functionalism

The dominant contemporary theories of the mind–brain relation are compatible with a broadly physicalist world-view and analytical functionalism, in particular, is consistent with a version of physicalism, **a priori physicalism**, that is both ontologically and conceptually **reductionist**.[10]

Ontologically, analytical functionalism is like the identity theory in its commitment to types of physical state that *realize* mental states. Functionalism does not quite say that being in pain is to be identified with having C-fibres firing (the standard example for the identity theory); but it does say that the causal role of the mental state of being in pain is played, in human beings, by the physical state of having C-fibres firing.

Despite this ontological similarity to the identity theory, analytical functionalism is *conceptually* more like analytical behaviourism in being a thesis about the meanings of our mental terms. According to behaviourism, it is a matter of meaning, or **conceptual analysis**, that being in a mental state is being disposed to produce particular patterns of behaviour. According to functionalism, it is equally a matter of meaning that being in a mental state is being in a state that plays a particular causal role. Consequently, analytical functionalism is *conceptually reductionist*. The mental facts, as conceived by the functionalist, are *entailed a priori* by the physical facts.

As we shall now see, both the ontological and the conceptual commitments of analytical functionalism face challenges.

Rylean behaviourism revisited

A theorist of the mind–brain relation who was sympathetic to Rylean behaviourism might challenge the *ontological* commitments that are shared by functionalism and the identity theory. The neo-behaviourist might accept the idea that if a system has a disposition to exhibit a particular pattern of behaviour then there must be a basis for this disposition in the system's inner constitution. But he might argue that identifying individual mental states with physical states, or insisting that mental states are individually realized by physical states, goes beyond what is required by this idea.

Dispositions do not float free of inner constitution and the behavioural dispositions of human beings are, presumably, underpinned by states and processes of the brain. But it is not obviously required that there must be a single brain state that underpins precisely the dispositions that are associated with the attribution of a single mental state. This neo-behaviourism may draw support from remarks made by Wittgenstein.[11]

Neo-behaviourism will be open to objection so long as it retains the unattainable commitment to an analysis of belief attributions in behavioural terms. But there is an alternative view that abandons those analytical ambitions. The **interpretationist** says that mentalistic interpretation is answerable to a creature's behaviour in various actual and hypothetical circumstances, but that this answerability is a matter of 'making sense' of the creature and cannot be codified mental state by mental state.[12] Rather, the interpreter casts a net of psychological description—'X is in pain; X is in love; X wants to visit Paris; X believes that the ice is thin; …'—over a writhing mass of behaviour. Tracts of human behaviour normally support this interpretive project and, presumably, the behaviour is susceptible of causal explanation. But we should not assume that the physical causes of behaviour must have an articulation that matches the structure of the interpreter's description.[13]

Interpretationism is compatible with a broadly physicalist worldview but it involves some departure from apparently plausible claims about mental reality and mental causation. The interpretationist is not committed to the claim that there are individual mental states—for example, individual beliefs such as my belief that there is a bottle of white wine in the refrigerator, or that I have an appointment at 9 a.m.—that are bearers of causal powers.

Consciousness and the explanatory gap

The *conceptual* commitments of analytical functionalism are challenged by our conception of **conscious mental states**.

According to functionalism, all mental states are realized by physical, specifically neural, states and the phenomenal properties of conscious mental states are physical properties of those neural states. We can ask what makes the difference between conscious mental states and unconscious mental states. Is there, for example, something distinctive about the neural underpinnings of conscious mental states? If we had a plausible answer to that question, there would be the further question *why* mental states with that distinctive neural nature are *conscious* mental states. This question is apt to seem puzzling and even unanswerable. But, according to analytical functionalism, there would be no puzzling 'why?' question about consciousness. All the mental facts, including the facts about consciousness and phenomenology, are entailed a priori by the physical facts.

A powerful intuition thus speaks against the conceptual commitments of analytical functionalism. For it seems that even the full physical story about the world would not settle a priori the question whether a creature was in a conscious mental state. It seems to be conceivable (not ruled out a priori) that there could be a creature physically just like one of us yet lacking consciousness—a *zombie*—or even a complete physical duplicate of our world from which consciousness was totally absent—a *zombie world*.[14] Between the physical sciences and the facts of consciousness there seems to be an **explanatory gap**.[15]

Thomas Nagel has drawn attention to a difference between two kinds of conception. Conceptions of conscious mental states are **subjective**; they are accessible from some, but not all, points of view. The conscious mental states that we can *conceive* are limited to relatively modest imaginative extensions from the conscious mental states that we ourselves *undergo*. In contrast, the conceptions deployed in grasping theories in the physical sciences are **objective**; they are accessible from many different points of view. The physical theories that we can grasp are limited, not by our sensory experience, but by our intellectual powers.[16] Many contemporary philosophers of consciousness argue that the explanatory gap is a product of this duality of conceptions. There is no a priori entailment from the physical and functional facts *objectively conceived* to the phenomenal facts *subjectively conceived*.

The majority of these philosophers maintain that a duality of conceptions does not require an ontological dualism of substances, states, or properties and that the explanatory gap is consistent with physicalism as an ontological doctrine. But there is an important minority view that acceptance of an explanatory gap must lead to a rejection of physicalism. David Chalmers, beginning from the intuition of an explanatory gap, recommends a return to some form of dualism.[17] Others argue in the opposite direction, embracing physicalism, denying that there is an explanatory gap, and accepting the counterintuitive conceptual reductionism of analytical functionalism.

Personal and subpersonal levels of description and explanation

The mind–brain relation is an aspect of a more encompassing relationship between persons and the physical systems of which they are constituted, including systems of neural information processing.

Our conception of persons as such is a conception of subjects and agents. At the personal level of description and explanation, we describe what people feel, think, want and do, and we explain what people do in terms of their sensations, beliefs, and desires. As the case of conscious mental states illustrates, our personal-level *descriptions* are not always entailed a priori by physical and functional descriptions of the systems that constitute us. Personal-level descriptions involve subjective and normative concepts that are different from the objective and descriptive concepts that figure in the physical sciences.

Our personal-level *explanatory practices* seem to be different in kind from our scientific practices of explaining the operation of mechanical systems. McDowell describes personal-level explanations as 'explanations in which things are made intelligible by being revealed to be, or to approximate to being, as they rationally ought to be'.[18] In a similar spirit, Dennett describes them as 'non-mechanistic'. A mechanistic account of what happens when a person feels, thinks, wants, and acts would belong at a quite different level of description and explanation, not the 'level of people and their sensations and activities', but 'the *subpersonal* level of brains and events in the nervous system'.[19]

One extreme view of the relationship between the personal and subpersonal levels highlights what is distinctive about the personal level and regards it as substantially independent from the subpersonal level. This view might encourage the interpretationist account of personal-level psychological descriptions, minimizing the ontological and causal commitments of personal-level discourse to avoid constraints on that discourse from the subpersonal level of neuroscience.

The opposite extreme view is the conceptually reductionist view of analytical functionalism. The personal level is the level of mental states whose causal roles are revealed by conceptual analysis while the subpersonal level is the level of neural states that play those roles. There are no explanatory gaps. All that is true at the personal level is entailed a priori by physical truths at the subpersonal level.

According to an attractive view that is intermediate between these two extremes, the relationship between the personal and subpersonal levels is one of *interaction without reduction*.[20] As against the first extreme view, the personal level is not independent of the subpersonal level but constrained by it, because our personal-level descriptions—cast in terms of experience, thought, planning, and agency—carry commitments about causal structure in the brain. But, as against the second extreme view, there are also explanatory gaps that reveal themselves when we try to construct illuminating accounts of those personal-level notions using only the subpersonal-level resources of neuroscience.

Conclusion

Descartes's ontological dualism of mind and body made it difficult for him to describe the phenomenology of embodiment, the way we experience our own body. Contemporary theories of the mind–brain relation are predominantly physicalist, rather than dualist, in their ontology. But the duality of objective and subjective conceptions

still presents a challenge for the sciences of the mind. Persons understood as such, partly from the first-person perspective—persons conceived as subjects and agents, with their experiences, thoughts, plans and actions—will not be visible in a purely objective, scientific story of the physical world.

2.2

Statistics and the design of experiments and surveys

Graham Dunn

Introduction

Research into mental illness uses a much wider variety of statistical methods than those familiar to a typical medical statistician. In many ways there is more similarity to the statistical toolbox of the sociologist or educationalist. It would be a pointless exercise to try to describe this variety here but, instead, we shall cover a few areas that are especially characteristic of psychiatry. The first and perhaps the most obvious is the problem of measurement. Measurement reliability and its estimation are discussed in the next section. Misclassification errors are a concern of the third section, a major part of which is concerned with the estimation of prevalence through the use of fallible screening questionnaires. This is followed by a discussion of both measurement error and misclassification error in the context of modelling patterns of risk.

Another major concern is the presence of missing data. Although this is common to all areas of medical research, it is of particular interest to the psychiatric epidemiologist because there is a long tradition (since the early 1970s) of introducing missing data by design. Here we are thinking of two-phase or double sampling (often confusingly called two-stage sampling by psychiatrists and other clinical research workers). In this design a first-phase sample are all given a screen questionnaire. They are then stratified on the basis of the results of the screen (usually, but not necessarily, using two strata—likely cases and likely non-cases) and subsampled for a second-phase diagnostic interview. This is the major topic of the third section.

If we are interested in modelling patterns of risk, however, we are not usually merely interested in describing patterns of association. Typically we want to know if genetic or environmental exposures have a causal effect on the development of illness. Similarly, a clinician is concerned with answers to the question 'What is the causal effect of treatment on outcome?' How do we define a causal effect? How do we measure or estimate it? How do we design studies in order that we can get a valid estimate of a causal effect of treatment? Here we are concerned with the design and analysis of randomized controlled trials (RCTs). This is the focus of the fourth section of the present chapter.

Finally, at the end of this chapter pointers are given to where the interested reader might find other relevant and useful material on psychiatric statistics.

Reliability of instruments

In this section we consider two questions:

- What is meant by 'reliability'?
- How do we estimate reliabilities?

Models and definitions

Most clinicians have an intuitive idea of what the concept of reliability means, and that being able to demonstrate that one's measuring instruments have high reliability is a good thing. Reliability concerns the consistency of repeated measurements, where the repetitions might be repeated interviews by the same interviewer, alternative ratings of the same interview (as a video recording) by different raters, alternative forms or repeated administration of a questionnaire, or even different subscales of a single questionnaire, and so on. One learns from elementary texts that reliability is estimated by a correlation coefficient (in the case of a quantitative rating) or a kappa (κ) or weighted κ statistic (in the case of a qualitative judgement such as a diagnosis). Rarely are clinicians aware of either the formal definition of reliability or of its estimation through the use of various forms of intraclass correlation coefficient rho (ρ).

First consider a quantitative measurement X. We start with the assumption that it is fallible and that it is the sum of two components: the 'truth' T and 'error' E. If T and E are statistically independent (uncorrelated), then it can be shown that

$$\mathrm{Var}(X) = \mathrm{Var}(T) + \mathrm{Var}(E) \tag{2.2.1}$$

where $\mathrm{Var}(X)$ is the variance of X (i.e. the square of its standard deviation), and so on. The reliability ρ_x of X is defined as the proportion of the total variability of X (i.e. $\mathrm{Var}(X)$) that is explained by the variability of the true scores (i.e. $\mathrm{Var}(T)$):

$$\rho_x = \frac{\mathrm{Var}(T)}{\mathrm{Var}(X)} = \frac{\mathrm{Var}(T)}{\mathrm{Var}(T) + \mathrm{Var}(E)} \tag{2.2.2}$$

This ratio will approach zero as the variability of the measurement errors increases compared with that of the truth. Alternatively, it will approach one as the variability of the errors decreases. The standard deviation of the measurement errors (i.e. the square root of $\mathrm{Var}(E)$) is usually known as the instrument's standard error of measurement. Note that reliability is not a fixed characteristic of

an instrument, even when its standard error of measurement (i.e. its precision) is fixed. When the instrument is used on a population that is relatively homogeneous (low values of Var(T)), it will have a relatively low reliability. However, as Var(T) increases then so does the instrument's reliability. In many ways the standard error of measurement is a much more useful summary of an instrument's performance, but one should always bear in mind that it too might vary from one population to another—a possibility that must be carefully checked by both the developers and users of the instrument.

Now let us complicate matters slightly. Suppose that a rating depends not only on the subject's so-called true score T and random measurement error E, but also on the identity R, say, of the interviewer or rater R. That is, each rater has his or her own characteristic bias (constant from assessment to another) and the biases can be thought of as varying randomly from one rater to another. Again, assuming statistical independence, we can show that, if $X = T + R + E$, then

$$\text{Var}(X) = \text{Var}(T) + \text{Var}(R) + \text{Var}(E) \tag{2.2.3}$$

But what is the instrument's reliability? It depends. If subjects in a survey or experiment, for example, are each going to be assessed by a rater randomly selected from a large pool of possible raters, then

$$\rho_{xa} = \frac{\text{Var}(T)}{\text{Var}(X)} = \frac{\text{Var}(T)}{\text{Var}(T) + \text{Var}(R) + \text{Var}(E)} \tag{2.2.4}$$

However, if only a single rater is to be used for all subjects in the proposed study, there will be no variation due to the rater and the reliability now becomes

$$\rho_{xb} = \frac{\text{Var}(T)}{\text{Var}(T) + \text{Var}(E)} \tag{2.2.5}$$

Of course, $\rho_{xb} > \rho_{xa}$. Again, the value of the instrument's reliability depends on the context of its use. This is the essence of generalizability theory.[1] The three versions of ρ given above are all intraclass correlation coefficients and are also examples of what generalizability theorists refer to as generalizability coefficients.

Designs

Now consider two simple designs for reliability (generalizability) studies. The first involves each subject of the study being independently assessed by two (or more) raters but that the raters for any given subject have been randomly selected from a very large pool of potential raters. The second design again involves each subject of the study being independently assessed by two (or more) raters, but in this case the raters are the same for all subjects. Equations (2.2.1) and (2.2.2) are relevant to the analysis of data arising from the first design, whilst eqns (2.2.3–2.2.5) are relevant to the analysis of data from the second design.

Estimation of ρ and κ from ANOVA tables

When we come to analyse the data it is usually appropriate to carry out an analysis of variance (ANOVA). For the first design we carry out a one-way ANOVA (X by subject) and for the second we perform a two-way ANOVA (X by rater and subject). In the latter case we assume that there is no subject by rater interaction and accordingly constrain the corresponding sum of squares to be zero. We assume that readers are reasonably familiar with an analysis of variance table. Each subject has been assessed by, say, k raters. The one-way ANOVA yields a mean square for between-subjects variation (**BMS**) and a mean square for within-subjects variation (**WMS**). WMS is an estimate of Var(E) in eqn. (2.2.1). Therefore, the square root of WMS provides an estimate of the instrument's standard error of measurement. The corresponding estimate of ρ_x is given by

$$r_x = \frac{\text{BMS} - \text{WMS}}{\text{BMS} + (k-1)\text{WMS}} \tag{2.2.6}$$

where r_x is used to represent the estimate of ρ_x rather than the true, but unknown, value. In the case of $k = 2$, r_x becomes

$$r_x = \frac{\text{BMS} - \text{WMS}}{\text{BMS} + \text{WMS}} \tag{2.2.7}$$

In the slightly more complex two-way ANOVA, the ANOVA table provides values of mean squares for subjects or patients (**PMS**), raters (**RMS**), and error (**EMS**). We shall not concentrate on the details of estimation of the components of eqn. (2.2.3) (see Fleiss[2] or Streiner and Norman[3]) but simply note that ρ_{xa} is estimated by

$$r_{xa} = \frac{n(\text{PMS} - \text{EMS})}{n \times \text{PMS} + k \times \text{RMS} + (nk - n - k)\text{EMS}} \tag{2.2.8}$$

where n is the number of subjects (patients) in the study.

In reporting the results of a reliability study, it is important that investigators give some idea of the precision of their estimates of reliability, for example by giving an appropriate standard error or, even better, an appropriate confidence interval. The subject is beyond the scope of this chapter, however, and the interested reader is referred to Fleiss[2] or Dunn[4] for further illumination.

Finally, what about qualitative measures? We shall not discuss the estimation and interpretation of κ in any detail here but simply point out that for a binary (yes/no) measure one can also carry out a two-way analysis of variance (but ignore any significance tests since they are not valid for binary data) and estimate r_{xa} as above. In large samples r_{xa} is equivalent to κ.[3] A corollary of this is that κ is another form of reliability coefficient and, like any of the reliability coefficients described above, will vary from one population to another (i.e. it is dependent on the prevalence of the symptom or characteristic being assessed).

Prevalence estimation

Following Dunn and Everitt,[5] we ask the following questions of a survey report.

- Do the authors clearly define the sampled population?
- Do the authors discuss similarities and possible differences between their sampled population and the stated target population?
- Do the authors report what sampling mechanism has been used?
- Is the sampling mechanism random? If not, why not?
- Exactly what sort of random sampling mechanism has been used?
- Do the methods of data analysis make allowances for the sampling mechanism used?

Of course, it is vital that what counts as a case should be explained in absolute detail, including the method of eliciting symptoms (e.g. structured interview schedule), screening items, additional impairment criteria, and so on, as well as operational criteria or algorithms used in making a diagnosis. In the following we concentrate on the statistical issues. First, we consider survey design (and the associated sampling mechanisms), and then we move on to discuss the implications of design for the subsequent analysis of the results.

Survey design

Here we are concerned with the estimation of a simple proportion (or percentage). We calculate this proportion using data from the sample and use it to infer the corresponding proportion in the underlying population. One vital component of this process is to ensure that the sampled population from which we have drawn our subjects is as close as possible to that of the target population about which we want to draw conclusions. We also require the sample to be drawn from the sample population in an objective and unbiased way. The best way of achieving this is through some sort of random sampling mechanism. Random sampling implies that whether or not a subject finishes up in the sample is determined by chance. Shuffling and dealing a hand of playing cards is an example of a random selection process called simple random sampling. Here every possible hand of, say, five cards has the same probability of occurring as any other. If we can list all possible samples of a fixed size, then simple random sampling implies that they all have the same probability of finishing up in our survey. It also implies that each possible subject has the same probability of being selected. But note that the latter condition is not sufficient to define a simple random sample. In a systematic random sample, for example, we have a list of possible people to select (the sampling frame) and we simply select one of the first 10 (say) subjects at random and then systematically select every tenth subject from then on. All subjects have the same probability of selection, but there are many samples which are impossible to draw using this mechanism. For example, we can select either subject 2 or subject 3 with the same probability (1/10), but it is impossible to draw a sample which contains both.

What other forms of random sampling mechanisms might be used? Perhaps the most common is a stratified random sample. Here we divide our sampled population into mutually exclusive groups or strata (e.g. men and women, or five separate age groups). Having chosen the strata, we proceed, for example, to take a separate simple random sample from each. The proportion of subjects sampled from each of the strata (i.e. the sampling fraction) might be constant across all strata (ensuring that the overall sample has the same composition as the original population), or we might decide that one or more strata (e.g. the elderly) might have a higher representation. Another commonly used sampling mechanism is multistage cluster sampling. For example, in a national prevalence survey we might chose first to sample health regions or districts, then to sample post codes within the districts, and finally to select patients randomly from each selected post code. (See Kessler[6] and Jenkins *et al.*[7] for discussions of complex multistage surveys of psychiatric morbidity.)

One particular design that has been used quite often in surveys designed to estimate the prevalence of psychiatric disorders is called two-phase or double sampling. Psychiatrists frequently refer to this as two-stage sampling. This is unfortunate, since it confuses the two-phase design with simple forms of cluster sampling in which the first-stage involves drawing a random sample of clusters and the second-stage a random sample of subjects from within each of the clusters. In two-phase sampling, however, we first draw a preliminary sample (which may be simple, stratified, and/or clustered) and then administer a first-phase screening questionnaire such as the General Health Questionnaire (see Chapter 1.8.1). On the basis of the screen results we then stratify the first-phase sample. Note that we are not restricted to two strata (likely cases versus the rest), although this is perhaps the most common form of the design. We then draw a second-phase sample from each of the first-phase strata and proceed to give these subjects a definitive psychiatric assessment. The point of this design is that we do not waste expensive resources interviewing large numbers of subjects who not appear (on the basis of the first-phase screen) to have any problems. Accordingly, the sampling fractions usually differ across the first-phase strata. However, it is vital that each of the first-phase strata have a reasonable representation in the second-phase, and it is particularly important that all of the first-phase strata provide some second-phase subjects. The reader is referred to Pickles and Dunn[8] for further discussion of design issues in two-phase sampling (including discussion of whether it is worth the bother).

Analysis of the results

Here we are particularly concerned with the last of the questions posed at the beginning of the section. In fact, it is a question that should be asked not only of prevalence surveys but of all investigations whether they are epidemiological surveys, intervention studies, or laboratory experiments. How was the design incorporated in the analysis? Frequently the required information is missing. Either the authors are ignorant of the implications of the design, or the journal editor has insisted that technical details are stripped from the report, or both.

Consider a hypothetical sample of 100 participants who have contributed to an estimate of prevalence of, say, depression using a definitive psychiatric interview.

Seventy of the participants have been given a diagnosis of depression. What is a valid estimate of prevalence? What is the standard error of the estimate? Assuming that the data have arisen through simple random sampling, the prevalence p is estimated by 0.70 and its variance is given by

$$\mathrm{Var}(p) = \frac{1}{np(1-p)} \tag{2.2.9}$$

where n is the sample size. The standard error is then given by the square root of this expression.

Suppose that we are now told that the results were obtained from a two-phase survey. The size of the first-phase sample was 300. Of these, 100 were screen positive and 200 were screen negative. The second-phase sample consisted of 70 screen positives, of whom 65 were found to be depressed on interview, together with 30 screen negatives, of whom 5 were found to be depressed on interview. The estimate of prevalence is given by

$$\begin{aligned} p &= P(\text{screen +ve}) \times P(\text{interview +ve}|\text{screen +ve}) + P(\text{screen} - \text{ve}) \\ &\quad \times P(\text{interview +ve}|\text{screen}-\text{ve}) \\ &= (100/300) \times (65/70) + (200/300) \times (5/30) \\ &= 0.42 \end{aligned} \tag{2.2.10}$$

where $P(A)$ should be read as 'probability of A' and $P(A|B)$ should be read as 'probability of A given B' or 'probability of A conditional on B having occurred'. The vertical '|' should not be confused with division, represented by '/'.

The prevalence estimate from the two-phase survey is considerably lower than if simple random sampling had been assumed. How has this arisen? Obviously the second-phase sample has been enriched for people who are likely to be depressed. The sampling fraction for the screen positives is 70/100, that is each second-phase participant can be thought of as representing 100/70 of screen positives from the original sample. Similarly, the sampling fraction for the screen negatives is 30/200, and each second-phase participant represents 200/30 screen-negative participants from the first-phase sample. The reciprocal of the sampling fraction is called the sampling weight. The total weighted second-phase sample size is $70 \times (100/70) + 30 \times (200/30) = 300$, the first-phase sample. Similarly, the total weighted number of cases of depression is $65 \times (100/70) + 5 \times (200/30) \approx 126$. The latter is the estimate of the number of cases in the first-phase sample. Hence the estimate of prevalence is 126/300 = 0.42, as before. To recapitulate in a slightly more technical way, if the ith individual in the second-phase sample is assigned a sampling weight w_i, and if the interview outcome y_i has a value of 1 if the ith subject is a case and is 0 otherwise, then the weighted prevalence estimate is given by

$$p = \Sigma w_i y_i / \Sigma w_i \tag{2.2.11}$$

where Σ means 'sum over all observations in the second-phase sample' and x_i is simply an indicator that the observation is, indeed, a second-phase observation ($x_i = 1$ for everyone). This estimator is an example of the well-known Horwitz–Thompson estimator from the sampling survey literature[9] but it is not particular familiar to psychiatrists or medical statisticians. We shall discuss the use of weighting adjustments again below.

Returning to our original two-phase calculations, let $A = P$(screen +ve) and $B = 1–A = P$(screen –ve). Also, let $p = P$(interview +ve|screen +ve) and $q = P$(interview +ve|screen –ve), so that eqn. (2.2.10) becomes

$$p = Ap + Bq \tag{2.2.12}$$

The variance of the estimate of prevalence from the two-phase design is given by[10]

$$\mathrm{Var}(p) = \frac{A^2 p(1-p)}{n_1} + \frac{B^2 q(1-q)}{n_2} + \frac{(p-q)^2 AB}{n_3} \tag{2.2.13}$$

where n_1 is the number of first-phase screen positives and n_2 is the number of first-phase screen negatives (and $n = n_1+n_2$ is the total (first phase) sample size).

Validation of screening questionnaires

It is frequently the case that data from a two-phase survey which has been designed to estimate prevalence are also used to examine the characteristics of the screen questionnaire (in particular, sensitivity and specificity). Readers who are unfamiliar with these concepts are referred to Chapter 2.7 or to Goldberg and Williams.[11] Sensitivity is the proportion of true cases who are screen positive. Specificity is the proportion of true non-cases who are screen negative. The trouble is caused because we used the screen first and then differentially subsampled to carry out the definitive diagnostic interview. Readers familiar with the use of Bayes' theorem will realize how to solve the problem, but here we use another version of the Horwitz–Thompson estimator:

$$\text{Sensitivity} = \Sigma w_i y_i z_i / w_i y_i \tag{2.2.14}$$

and

$$1\text{–specificity} = \Sigma w_i (1-y_i) z_i / \Sigma w_i (1-y_i) \tag{2.2.15}$$

where, as before, y_i indicates whether the ith subject was a true case of depression (1 = yes, 0 = no). This ensures that the calculations in eqn (2.2.14) are only being carried out on the true cases and, similarly, that the calculations in (2.2.15) are only being carried out on the non-cases. Again, w_i is the second-phase sampling weight. The new variable z_i indicates whether the screen result was positive (1 = yes, 0 = no). An alternative, and perhaps easier, approach is to split the second-phase sample into two: cases and non-cases. Estimation of sensitivity and specificity in these two subfiles (assuming that they are being stored on a computer) is then computationally exactly the same as the weighted estimation of prevalence discussed in the previous section. In the first file, sensitivity is simply the weighted sum of the screen positives divided by the weighted sum of the cases. Similarly, in the second file, specificity is the weighted sum of the screen negatives divided by the weighted sum of the non-cases.

Many readers will be familiar with the idea of choosing a range of cut-points for the screen questionnaire and then estimating sensitivity and specificity at each of the choices. A plot of sensitivity against 1—specificity is called a receiver operating characteristic (**ROC**) curve. If the screen is of no use, then the plot will be a straight line through the origin with unit slope. A good screen will produce a convex curve (the greater the area between the observed curve and that indicated by a straight line with unit slope, the better the screen is at discriminating between cases and non-cases). It is sometimes said that one cannot investigate ROC curves using two-phase data. This view is, in fact, mistaken. One can think of the two-phase sampling design as a mechanism by which one can deliberately introduce the analogues of verification bias.[12] Note that there is no necessity to restrict the first-phase stratification to just two strata (potential cases versus non-cases) to define the sampling fractions for the second-phase of the survey. We start by calculating observed sampling fractions for each discrete outcome of the screening questionnaire. These define the corresponding sampling weights. We then consider all the possibilities for defining z_i in eqns (2.2.14) and (2.2.15)—there is no need for the z_i to correspond to the way that the second-phase sampling fractions were determined. We then repeatedly use eqns (2.2.14) and (2.2.15), keeping the weights constant as we change the definition of the z_i. One important point to bear in mind is that if the characteristics of the screen are not fairly well known beforehand and if one of the major aims of the survey is to carry out an ROC analysis, then this is not a particularly efficient design to use. It would be better to go back to the simple random sample—all subjects assessed by both screen and interview.

If one needs, say, confidence intervals for estimates of sensitivity and specificity, it is relatively straightforward to do this via a weighted logistic regression (see next section). The file can be split into cases and non-cases and then, using appropriate software (see below), one fits a logistic model containing a predictor variable

which has the value of 1 for all subjects (i.e. just fitting a constant). One then obtains the confidence interval for the intercept term in the output. Finally, the inverse of the logistic transformation of the lower and upper confidence limits will yield the corresponding limits for the sensitivity (specificity) itself. Note that the interval will be asymmetric and will be within the permitted bounds of zero and unity.

Modelling patterns of risk

Henderson (see Chapter 2.7) has introduced the idea of an odds ratio to measure the association between a suspected risk factor and disease. In a linear logistic model the response variable is the natural logarithm of the odds (of disease). Therefore the difference between two groups on this logistic scale (i.e. $\log(a/b)$–$\log(c/d)$ using Henderson's notation) is equivalent to the logarithm of the odds ratio (i.e. $\log(ad/bc)$). This provides us with an easy way to calculate confidence intervals for odds ratio: log(odds ratio) or $\log(ad/bc)$ is normally distributed with variance $1/a + 1/b + 1/c + 1/d$ (the corresponding standard error is the square root of this variance). The 95 per cent confidence interval for the log(odds ratio), for example, is then the point estimate plus or minus 1.96 standard errors. Taking exponents (antilogarithms) of these limits provides the corresponding limits for the odds ratio itself. The exponent of the parameter estimate in the output of the logistic regression run provides the point estimate for the corresponding odds ratio.

The great advantage of logistic regression is that it enables us to model the potential effects of several risk factors simultaneously. It allows us to adjust for the effects of suspected confounder(s) in assessing the effects of a risk factor of interest. Logistic regression can also be generalized to cope with the use of sampling weights, either to cope with data missing by design (as in a two-phase survey) or to allow for non-response and/or attrition.[13] However, one must be very wary of using weights in software packages that do not explicitly deal with sampling weights. Many packages have weighting functions but these are interpreted as frequency weights—the number of times the observation has been made instead of the number of times it might have been made (as in the case of a sampling weight). The use of frequency weights, as opposed to sampling weights, produces standard errors, and confidence intervals that are far too small. This is not a subtle effect; it can make an enormous difference to a *P* value, giving the impression of a highly significant effect when, in reality, there is little or nothing there.[14] We illustrate this point by reference to a two-phase survey of psychiatric morbidity in Cantabria in Northern Spain.[15,16] The weighted prevalence estimate from these data is 31 per cent. The appropriate 95 per cent confidence interval (**CI**), obtained using sampling weights is (26 per cent, 40 per cent). The naive use of frequency weights produces a 95 per cent CI of (28 per cent, 35 per cent), which is much too narrow. The odds ratio indicating how much higher the prevalence of disorder is in women compared with men is 2.02 with a 95 per cent CI of (0.86, 4.74). The naive use of frequency weights gives the same point estimate (2.02), but here the 95 per cent CI is (1.45, 2.77); again, this is much too narrow. In the analysis of a similar study from Verona in Northern Italy, Dunn *et al.*[14] found a corresponding odds ratio of 2.85 with a 95 per cent CI of (1.31, 6.19). The *P* value for this odds ratio is about 0.008. The incorrect use of frequency weights gives us a 95 per cent CI of (2.31, 3.53) and a corresponding *P* value of less than 0.00001—at least an 800-fold difference!

Evaluating treatment effects

Readers will be familiar with the challenges posed by confounding in trying to validly infer an effect of an exposure on the development of illness from data arising from an observational study (or epidemiological survey). We can model patterns of risk (as in the above section) but we can never be sure that we have allowed for all possible sources of confounding (i.e. the effects of unmeasured variables that are associated with the exposure of interest and also influence outcome) in assessing the effect of a particular risk factor. The same challenges apply to the use of observational data to the evaluation of the effect of a treatment or other intervention. Although it may be possible to obtain valid treatment effect estimates from observational data,[17,18] the ideal is to use a randomized experiment. Allocation of treatments by randomization ensures that there are no systematic selection effects (i.e. no biases arising from hidden confounding) and enables the investigator to obtain valid measurements of uncertainty (i.e. valid p-values, standard errors, and confidence intervals).

How do we define a causal effect of treatment? Following Rubin[19] we define it as the comparison between potential outcomes or counterfactuals. For a patient who has received treatment we define the treatment effect as a comparison between the outcome that we have observed after the receipt of treatment (Y_t, say) with that we would have observed if, contrary to fact, the same patient had not received the treatment (Y_c, say the subscript c indicating a control condition). For a patient who has not received treatment we compared the observed outcome (Y_c, in this case) with the unobserved counterfactual (Y_t). Typically, we might be interested in the difference (Y_t–Y_c) but ratios might also be of interest. We define the Average Causal Effect (ACE) of treatment as the average (*Ave*—over the whole of the population of interest) of the individual treatment effects, that is

$$\text{ACE} = \text{Ave}(Y_t - Y_c) \tag{2.2.16}$$

But, of course we can only ever observe either Y_t or Y_c, not both. We can never observe an individual treatment effect and therefore cannot obtain a direct estimate of the average. But we note that

$$\text{ACE} = \text{Ave}(Y_t) - \text{Ave}(Y_c) \tag{2.2.17}$$

and if we could obtain valid estimates of $\text{Ave}(Y_t)$ and $\text{Ave}(Y_c)$ then the problem would be solved. The only sure way of knowing that we have a valid estimate of these two averages (i.e. no selection biases) is to make sure that the allocation of treatment is completely random. Hence the Randomized Controlled Trial (RCT). Of course, we have to ensure that we have eliminated or reduced all other potential sources of bias (e.g. by masking treatment allocation from the people assessing outcomes) and one must not automatically assume that randomization has led to a perfect trial. In the critical appraisal of a clinical trial report, one might ask:

- What is the target population for the evaluation of the treatment, and were the trial participants representative of this population?
- Were the treatment and control conditions clearly defined and operationalized? In particular, was the control condition convincing?

- Were outcomes clearly defined and reliably measured?
- Was the trial adequately powered (i.e. was the number of randomized participants adequate for the job at hand)?
- Was randomization used to allocate treatment and how was the randomization actually implemented?
- Was it possible to blind mask treatment allocation from all those concerned with the assessment of outcomes? What evidence has been provided to indicate that masking has been effective?
- What methods were used to estimate the treatment effects and their precision? Were they fully compatible with the trial design (the randomization procedure)? Did the analysis take account of everyone randomized? In particular, did the analysis deal adequately with missing outcome data?
- If the trial used a non-standard design (randomization of groups of participants rather than of individuals; use of group-based therapies; and so on) were the power calculations and methods of statistical analysis appropriate for this design?

Estimation of treatment efficacy in the presence of non-compliance

What if the trial participants, despite giving their consent to be randomized, do not receive the treatment to which they were allocated? In a drug trial the participants may not take the tablets, or take less than the prescribed amount. They may even receive the active medication despite being allocated to the placebo (control) condition. In a psychotherapy trial they may not turn up to all or even any of the planned sessions of therapy. The standard method of analysis (and justifiably so) is based on the so-called Intention-to-Treat (ITT) principle: we analyse as randomized. We evaluate the effect of the offer of treatment as opposed to its receipt. But what do we do if we wish to evaluate (estimate) the effect of the treatment actually received? Two commonly used methods of analysis are called per Protocol and As Treated estimators. In the first method the effect of randomization is evaluated after first discarding the people who did not adhere to (or comply with) their allocated treatment. In the second, we compare the outcomes of all those who receive the treatment with all of those who received the control condition, regardless of their random allocation. Both methods are potentially flawed—they take no account of possible selection effects (confounding). A much better approach is to estimate the effect of randomization in that subgroup of participants who would always have complied with their treatment allocation whatever the outcome of the randomization. We call this subgroup the Compliers (the rest being non-compliers), and we aim to estimate the Complier-Average Causal Effect of Treatment (CACE).[20,21] In effect we are obtaining an ITT effect for the Compliers. Randomization ensures that, on average, the proportion (P) of Compliers is the same in each arm of the trial. The overall ITT effect is a weighted average of the ITT effect in the Compliers and the ITT effect in the non-compliers (the weights being P and 1-P, respectively). If we are prepared to assume that there is no direct effect of randomization on outcome (in particular, there is no effect of randomization on outcome in the non-compliers) then

$$\begin{aligned} \mathrm{ITT}_{\mathrm{All}} &= P.\mathrm{ITT}_{\mathrm{Compliers}} + (1-P).\mathrm{ITT}_{\mathrm{non\text{-}compliers}} \\ &= P.\mathrm{ITT}_{\mathrm{Compliers}} \end{aligned} \qquad (2.2.18)$$

It follows that

$$\mathrm{CACE} = \mathrm{ITT}_{\mathrm{compliers}} = \frac{\mathrm{ITT}_{\mathrm{All}}}{P} \qquad (2.2.19)$$

It is easy to show that in a trial in which no-one allocated to the control condition gets access to the (potentially) active treatment the proportion of Compliers (P) is estimated by the proportion of Compliers in the treatment group (this follows directly from randomization). In the situation in which participants allocated to the control condition can get access to treatment P is estimated by the difference between the two randomized groups with respect to the proportion of participants receiving treatment. Considering everyone randomized, eqn (2.2.19) is the ratio of the ITT effect on outcome to the ITT effect on receipt of treatment. Note that $\mathrm{ITT}_{\mathrm{All}}$ and CACE ($\mathrm{ITT}_{\mathrm{Compliers}}$) share the same null hypothesis (when one is zero, so is the other) and a significance test for one of them is equivalent to the corresponding significance test for the other. The estimation of the CACE is simply a way of adjusting the overall ITT estimate to allow to attenuation in the presence of non-compliance. It will not reveal a significant treatment effect when we already have a non-significant ITT estimate.

We do not advocate the replacement of ITT estimates by CACE estimation, but we do recommend that investigators supplement their primary ITT analyses with more detailed explanatory methods, particularly when there are situations in which non-compliance is strongly associated with subsequent loss to follow-up (i.e. missing outcome data). Valid ITT (and any other) estimates are particularly difficult to obtain in the presence of missing data. This is an active area of theoretical development in medical statistics, but the more easily understood methods are now beginning to make the transition to the more easily accessible clinical journals. For example, a relatively non-technical discussion of the potential application to mental health trials is provided by Dunn *et al.*[22,23]

We refer readers to Everitt and Wessely[24] and Dunn[25] for a much more detailed discussion of the methodological pitfalls for RCTs in psychiatry. One important point needs stressing again, however. It is vital that RCTs involve the randomization of sufficient numbers of subjects to be confident that the trial has sufficient power to detect the *minimum* treatment effect that still has *clinical* (as opposed to statistical) significance. This minimum effect should be defined in terms of its importance and *not* by naively observing the results of previous trials or pilot investigations.

Conclusions

The recently published *Encyclopedia of Biostatistics*[26] comprises of six large volumes of chapters such as this one, covering every area of conceivable interest to the statistically interested clinical research worker. Therefore it is inevitable that this chapter should be very restricted. Inevitably, the choice of topics might be thought to be rather idiosyncratic. Areas which might have been covered, but have been ignored, include survival modelling (particularly recent developments in so-called frailty modelling), longitudinal data analysis (with special reference to modelling patterns of attrition), genetics, and a whole range of classical multivariate methods such as principal components and factor analysis, discriminant analysis (although logistic modelling is one of the better methods of discriminant analysis), multidimensional scaling, and cluster analysis.

Henderson (see Chapter 2.7) has also mentioned exciting possibilities for the development of latent trait (item response theory) and latent class models. Several years ago I was often asked to teach trainee psychiatrists all they needed to know about statistics in two 2-h sessions. The first was to cover univariate methods, and the second, multivariate analysis. It cannot be done!

Further information

So, where should the reader go from here? Which are the most useful textbooks? In terms of general medical statistics, the obvious choice is Armitage, Berry, and Matthews. Everitt and Dunn and Everitt provide general introductions to multivariate methodology. Measurement error problems, including structural equation modelling, are covered by Dunn. The role of statistics in genetics is well covered by Sham. Although there are many texts on the use of statistics in psychology and education (e.g. Plewis which includes an introduction to multilevel modelling), the only specialist reference for psychiatrists appears to be that by Dunn.

The contribution of neurosciences

Contents

2.3.1 Neuroanatomy

†R. C. A. Pearson

Introduction

The symptoms, signs, and syndromes of psychiatry, whether organic or biological psychiatric disease or not, in the main reflect alterations in functions which reside in the cerebral cortex, including the limbic lobe, and those structures and pathways closely related to the cortex. These cortical manifestations of psychiatric disease include alterations in thought, language, perception, mood, memory, motivation, personality, behaviour, and intellect. Therefore, this brief account of brain structures and pathways that are important in psychiatry will concentrate on the cerebral cortex and related structures and pathways. Readers who require a fuller account of central nervous system anatomy are referred to the many standard texts, which give a more complete coverage of the subject.

Broadly speaking, neuroanatomy can be subdivided into two parts—the topographical organization of the brain and spinal cord, and the anatomical connections forming functional pathways in the central nervous system. The former is of vital importance clinically, since pathologies rarely respect the boundaries of functional systems, and knowledge of the spatial relationships of different brain structures is increasingly useful as modern imaging methods more accurately visualize detailed brain structure *in vivo*. However, it is the second subdivision of the subject which makes the greater contribution to understanding the biological basis of psychiatric disease, and it is this that will be at the centre of the present account.

The structure and organization of the cerebral cortex

The lobes of the cerebral cortex

A variable pattern of fissures (sulci) and folds (gyri), many of which have specific names, extensively groove the surface of the cerebral hemisphere. A few are relatively constant and are used to subdivide the cerebral hemisphere into lobes, named for the bones of the skull which they underlie (Fig. 2.3.1.1).

The deep lateral sulcus, also called the Sylvian fissure, extends from the uncus, anteriorly and medially, to the parietal lobe, posteriorly and medially. It has a short stem, and anterior, ascending, and posterior rami. The anterior and ascending rami embrace the pars triangularis of the frontal lobe, which houses Broca's motor speech area. The much longer posterior ramus is used in defining the lobes of the hemisphere. The central sulcus is prominent approximately midway along the anteroposterior extent of the

† Dr. Pearson died while this new edition was being prepared. The editors pay tribute to his scientific achievements and to his contributions to this book.

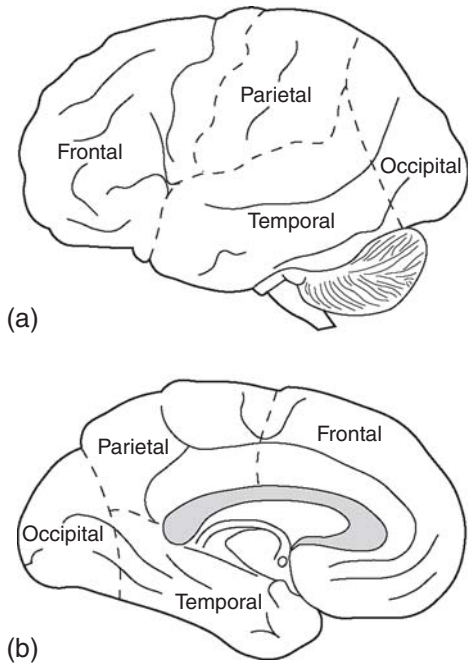

Fig. 2.3.1.1 The lobes of the cerebral cortex.

lateral surface of the hemisphere and, most commonly, extends over the medial margin, where its inferomedial tip is embraced by the U-shaped paracentral lobule. On the lateral surface, it passes from the medial margin, forwards and laterally, to reach the lateral sulcus. The line of the central sulcus closely approximates the line of the coronal suture of the adult skull, i.e. the junction between the frontal and parietal bones; consequently, the sulcus separates the frontal and parietal lobes. The demarcation of the occipital lobe is the parieto-occipital sulcus dorsally and medially, and the pre-occipital sulcus ventrally and laterally, with an imaginary line connecting the two and intersecting the posterior tip of the lateral sulcus. The temporal lobe lies anterior to this line and inferior (ventral) to the lateral sulcus. The deep lateral sulcus broadens out at its fundus, with an area of cortex forming the extensive floor of the sulcus, particularly in its anterior two-thirds. This cortex is the insula, which does not form part of any of the lobes mentioned above. The insula is surrounded by the circular sulcus, and is overhung by the frontal and parietal opercula superiorly, and the temporal operculum inferiorly (ventrally). The anatomical borders of the lobes of the cerebral cortex, and other sulcal and gyral landmarks, are only loosely paralleled by functional boundaries. However, lobar terminology is so firmly embedded in clinical and non-clinical neuroscience that consideration of their anatomical features is essential.

(a) The frontal lobe (Fig. 2.3.1.2)

The precentral gyrus, immediately in front of the central sulcus and continuing onto the medial surface, contains the primary motor cortex. The precentral sulcus usually defines the anterior boundary, and in front of this lies the premotor cortex. The inferior

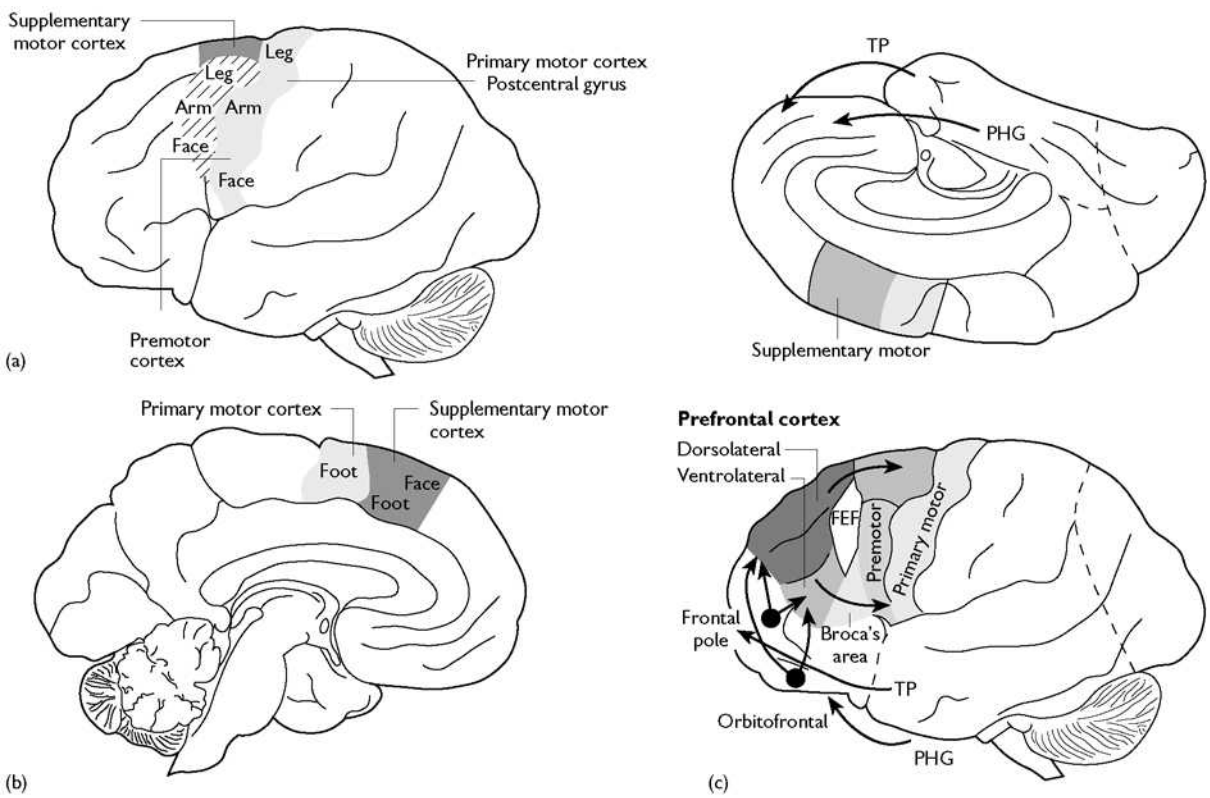

Fig. 2.3.1.2 Motor areas of the frontal lobe: TP, temporal pole; PHG, parahippocampal gyrus; FEF, frontal eyefields.

margin of the sulcus runs into the pars triangularis, which includes Broca's motor speech area. On the medial margin and surface, the cortex includes the supplementary motor area. The lateral prefrontal cortex, in front of these motor and associated areas, is usually grooved by two major horizontal sulci, defining the superior, middle, and inferior frontal gyri. The cortex on the medial surface of the frontal lobe anterior to the prefrontal gyrus forms the medial prefrontal cortex. The concave inferior surface of the frontal lobe, overlying the bony orbit *in vivo*, is the orbitofrontal cortex.

(b) The parietal lobe (Fig. 2.3.1.3)

Behind the central sulcus, the primary somatic sensory cortex (SI), extending onto the medial surface to occupy the posterior part of the paracentral lobule, where the sacral spinal segments are represented, occupies the postcentral gyrus. The postcentral sulcus limits the postcentral gyrus posteriorly. Behind this, the sulcal pattern is variable, but one or more horizontal intraparietal sulci divide the lobe into superior and inferior parts. The second somatic sensory cortex (SII) is located in the parietal operculum, close behind the inferolateral tip of the central sulcus. Specific sulcal patterns in the transition region between the parietal lobe and the occipital and temporal lobes (the supramarginal and angular gyri) are important landmarks for the detailed localization of language functions.

(c) The occipital lobe (Fig. 2.3.1.4)

The occipital lobe is predominantly involved in vision and visual perception. The medial surface is grooved by the deep horizontal calcarine sulcus, which typically reaches the posterior pole of the hemisphere. Within its walls is the primary visual cortex. This area (area 17 of Brodmann) is often called the striate cortex; in the freshly sliced brain, a thin band of white matter, the stria of Gennari, is clearly visible running in the centre of the cortical grey ribbon. The extent of this stria precisely demarcates the primary visual cortex. Surrounding areas of the medial and lateral surface, the prestriate and peristriate cortex, contain some of the numerous separate visual association areas.

(d) The temporal lobe (Figs 2.3.1.5 and 2.3.1.6)

Two horizontal sulci, the superior and inferior temporal sulci, divide the lateral surface of the temporal lobe into the superior, middle, and inferior gyri. The latter, extending onto the inferior surface, is also known as the inferotemporal cortex. On the medial surface, the collateral sulcus runs from close to the temporal pole to the calcarine sulcus posteriorly. Medial to this is the parahippocampal gyrus. Anteriorly, this curves dorsally and caudally to form the hook-shaped uncus. The entorhinal cortex occupies approximately the anterior third of the parahippocampal gyrus. Lateral to this, in the walls of the rhinal sulcus, lies the perirhinal cortex. The uncus closely overlies the amygdala; the primary olfactory cortex, the piriform cortex, lies immediately in front. The choroid fissure limits the parahippocampal gyrus medially. Passing into the floor of the lateral ventricle, the subicular areas of cortex lead to the hippocampus proper. A detailed consideration of the anatomy of the hippocampus is given below.

The cortex of the temporal operculum contains Heschl's gyri, within which lies the primary auditory cortex. Diverse auditory

association areas surround this, extending into the superior temporal gyrus. The functions of the cortex of the middle temporal gyrus are uncertain, but include complex visual, auditory, and somatic sensory association areas. The inferotemporal cortex is largely concerned with visual perception and cognition. The anatomical pathways that underlie these functions are considered below.

(e) The insula

The anterior margin of the insula, where the cortex becomes continuous with the anterior perforated substance, is known as the limen insulae. Above and below, where the insular cortex rolls round onto the opercula, lies the circular sulcus, the superior and inferior rami of which fuse posterosuperiorly to form the apex of the insula. Several variable sulci mark the insula, but little is known of the functional subdivisions of this cortex; gustatory, somatic sensory, and auditory areas have been described.

The structure of the neocortex

The neocortical grey matter is usually described as having six layers (Plate 1(a)). Wide variation in the nature of this microscopic lamination underlies the subdivision of neocortex into a multiplicity of (usually numbered) areas. At its simplest, two types of neurones make up the grey matter—pyramidal and non-pyramidal (or granular) cells. An apparent predominance of one or other type gives the extremes of granular and agranular cortex, equating with sensory areas (granular) and the motor cortex (agranular). In fact, the proportion of different cell types is constant in all areas. Indeed, with the single exception of the primary visual cortex, the numbers of neurones under a fixed surface area is also constant in all cortical areas. Variations in the size of pyramidal cells in particular lead to an apparent change in proportions. These variations probably reflect differences in the axonal volume of individual pyramidal cells, reflecting the distance and volume of projection fibres from a cortical area.

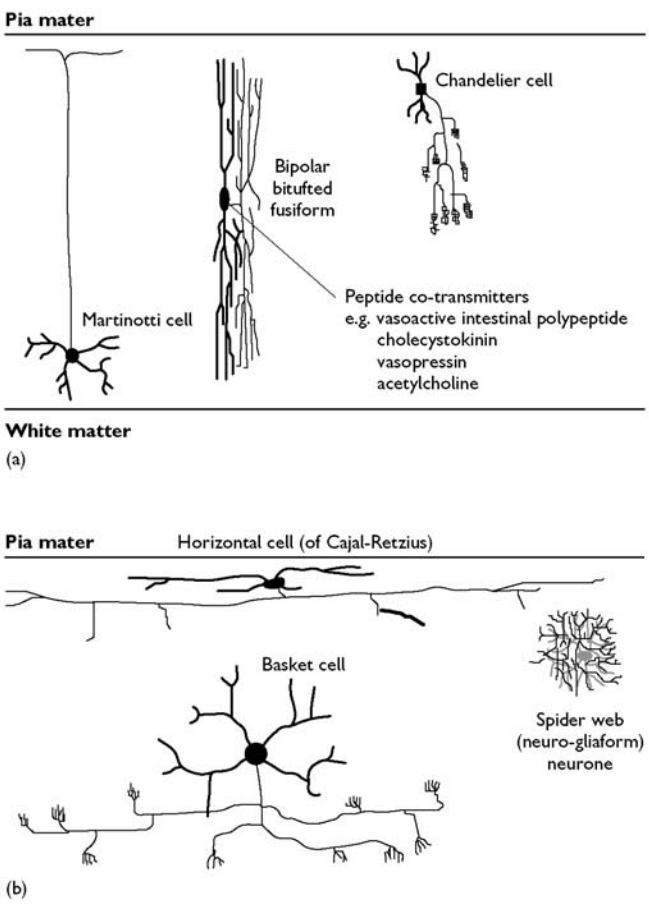

Fig. 2.3.1.7 Inhibitory (GABA-ergic) neurones of the neocortex: (a) vertical; (b) horizontal.

Pyramidal cells have a single main apical dendrite ascending towards the pial surface, and several horizontally spreading basal dendrites. All dendrites bear dendritic spines, which receive synapses (Plate 1(b)). All pyramidal cells use excitatory amino acids as neurotransmitters and have axons which enter the subcortical white matter; hence they are all projection neurones. They constitute approximately 60 per cent of all the neurones in the cortex. A second spiny neuronal type, the spiny stellate cells, is the next most numerous. These also use an excitatory amino acid, most probably glutamate, as their neurotransmitter. Unlike pyramidal cells, however, their axons remain confined to the cortical grey matter; they are interneurones, accounting for a further 25 per cent of cortical neurones. All the other neurones are inhibitory interneurones, using γ-aminobutyric acid (GABA) as their major neurotransmitter. Many also contain one or more neuropeptides, and their content of specific calcium-binding proteins varies. They have a wide range of axonal and dendritic forms, and have been multiply classified in the past. Broadly speaking, they can be grouped into those with horizontal axonal arborizations, those whose axons ramify at right angles to the pial surface, i.e. through the depth of the cortex, and those with radial axons (Fig. 2.3.1.7).

The structure of the allocortex

The allocortex comprises a number of different areas, all with very different structures. They are either limbic or olfactory (or both) and are found predominantly in the medial temporal lobe. The largest of these regions is the hippocampus. Essentially, this includes the three-layered cortex of the hippocampus, together with the transitional areas between it and neocortex, which are variably said to have three, four, five, or six laminae. The hippocampal formation comprises the dentate gyrus, Ammon's horn (CA fields), and the subiculum. Both the dentate gyrus and the CA fields have a prominent single layer of neurones, with an overlying molecular layer and a subjacent polymorphic layer. In the dentate gyrus, the cells are granule cells, whereas in the CA fields they are predominantly large pyramidal cells—the stratum pyramidale. Both cell types are excitatory and are projection neurones. Scattered populations of GABA-ergic inhibitory interneurones are found immediately subjacent to the main cellular laminae and in the molecular layers. The CA fields are numbered 1, 2, and 3, from the subiculum to the dentate gyrus. The subiculum is the zone of transition between the three-layered hippocampus proper, and the entorhinal cortex and cortex of the parahippocampal gyrus laterally. It is sometimes further subdivided into subzones including the presubiculum, between the lateral cortex and the subiculum, and the prosubiculum, between the subiculum proper and CA1 of the hippocampus. The histological appearance of the hippocampus and adjacent areas are shown in Fig. 2.3.1.8, and their connections are considered in detail below.

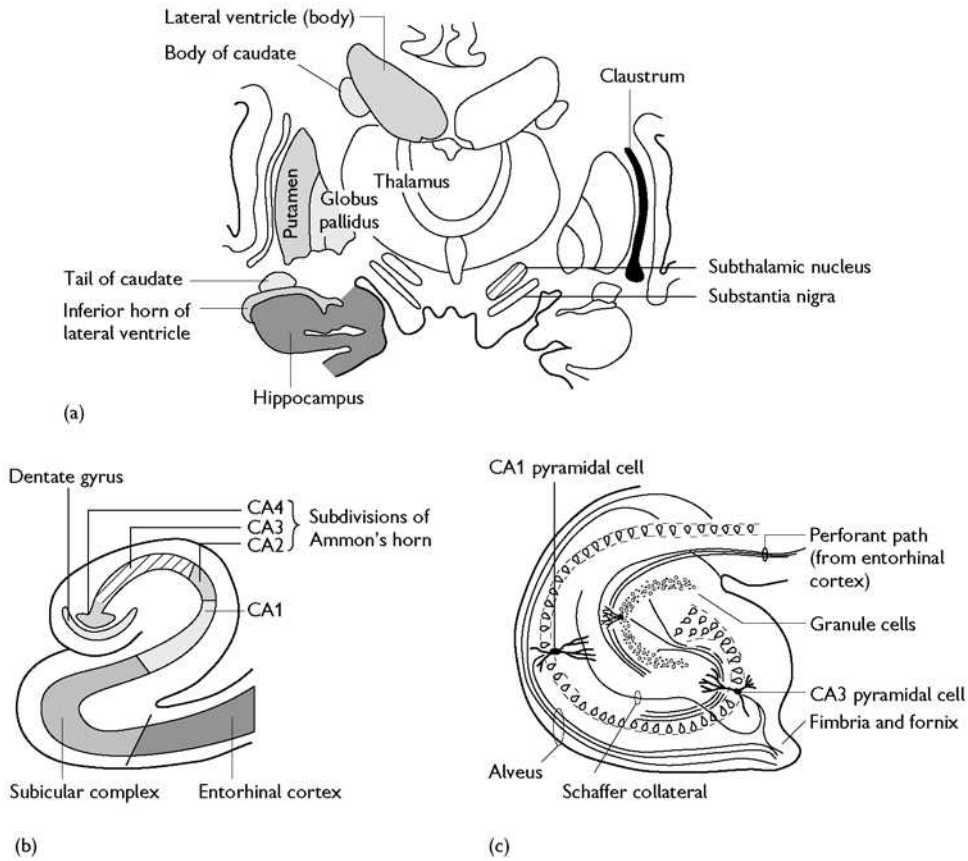

Fig. 2.3.1.8 (a) Hippocampal formation in the temporal lobe; (b) subdivisions of the hippocampal formation; (c) organization of the hippocampus.

Table 2.3.1.1 General connections of the cerebral cortex

Nucleus/area	Afferents	Efferents
Subcortical		
Thalamus		
Principal	+	+
Intralaminar	+	+
Locus coeruleus (NA)	+	–
Raphe (serotonin)	+	–
Basal nucleus (ACh)	+	–
Hypothalamus (histamine)	+	–
SN and VTA (dopamine)	+	–
Claustrum	+	+
Striatum	–	+
Pons	–	+
Superior colliculus and reticular formation	–	+
Specific (e.g. corticospinal)	–	(+/–)
Cortical		
Contra lateral		
Homotopic	+	+
Heterotopic	+	+
Ipsilateral		
Short	+	+
Long	+	+

NA, noradrenaline; ACh, acetylcholine; SN, substantia nigra; VTA, ventral tegmental area.

The general pattern of connectivity of the cortex

All cortical areas share a broadly similar pattern of connections. What differs is the relative quantity of connections in each category, as well as the precise detail of origin and termination. The broad categories of connections which all cortical areas share are most easily seen in a table (Table 2.3.1.1). These will be dealt in detail in subsequent sections.

A central feature of the connections of the neocortex is their organization relative to the cortical laminae (Plate 1(a)). For simplicity, it can generally be assumed that the forward-flowing stream of connections for perception and action use the central laminae, descending projections originate in deeper layers, and feedback and non-specific afferents terminate in both superficial and deep laminae. Thus, in primary sensory areas the thalamic input from the principal nuclei (e.g. the lateral geniculate nucleus in the visual cortex) terminates in layer IV. Projections to higher association areas originate from pyramidal cells immediately adjacent, in layer III. As the ipsilateral association pathway progresses from area to area, the association fibres terminate in this central region, and the thalamic afferents end in superficial and deep laminae. Projections to subcortical nuclei, such as the striatum, arise in layer V, and corticothalamic axons come from layer VI. It is as if the input of major importance, requiring detailed, focused, and faithful transmission, arrives in layer IV and is passed on from the deeper part of layer III. Inputs which moderate or modulate this pass to either side of the central layers, and outputs which are not directly part of this progression arise from deeper layers.

There is a general principle in the organization of connectivity with the cerebral cortex of overlapping connectivity of functionally related areas throughout the range of connections made. In other words, functionally related cortical areas, which are connected with each other, also tend to have overlapping or interdigitating connections with other structures. This is seen on the striatum, the thalamus, the claustrum, the cholinergic basal forebrain, and the pontine nuclei.

Subcortical afferents to the cerebral cortex

The thalamus (Plate 2)

Thalamic nuclei can be classified as specific (principal) or non-specific. In general, the specific nuclei degenerate completely when the cortex is removed, whereas the non-specific nuclei do not. This is because the sole major projection of the specific nuclei is to the cerebral cortex. The non-specific nuclei are the intralaminar and midline nuclei, which project to the basal ganglia as well as to cortex, and the reticular nucleus, which projects only to other thalamic nuclei.

All cortical areas receive afferents from at least one specific thalamic nucleus, and an additional input from the intralaminar/midline nuclei. Corticothalamic fibres reciprocate all thalamocortical projections, probably without exception.

(a) Specific nuclei

The cortical projections of the specific nuclei are shown in Plate 2. Subclassification of the specific thalamic nuclei depends upon their afferent subcortical connections. The primary relay nuclei receive the major sensory pathways—the lateral and medial geniculate nuclei for the optic tract and auditory pathway respectively, and the ventral posterior nucleus for the somatic sensory pathways. The secondary relay nuclei are those which receive a known major subcortical pathway which is not sensory. These are usually taken to include the caudal subdivision of the ventral lateral nucleus, which receives the cerebellar pathway, the anterior division of the ventral lateral nucleus and the ventral anterior nucleus, which both receive fibres from the internal segment of the globus pallidus, and the anterior nuclei, which receive the mammillothalamic tract. The association nuclei are those which were not previously understood to receive a major subcortical pathway, predominantly the medial nucleus and the pulvinar. This view is no longer really tenable, since the pulvinar is now known to receive a major input from the superior colliculus, and the various subdivisions of the medial nucleus receive fibres from the ventral pallidum and the olfactory pathway, amongst others. The subcortical afferents to the principal thalamic nuclei are shown in Plate 2(a).

(b) The non-specific nuclei

The reticular nucleus lies lateral to the main body of the thalamus, separated from it by the external medullary lamina. Cells in the nucleus are inhibitory, using GABA as their neurotransmitter. Excitatory thalamocortical and corticothalamic fibres, passing to and from the main nuclei, traverse the reticular nucleus and give axon collaterals to the reticular nucleus cells. There is a very tight arrangement, whereby the branches of axons from the thalamus to a particular cortical area terminate in the reticular nucleus in close proximity to the corticothalamic axons from the same cortical area. The reticular nucleus cells in turn send their inhibitory axons into the thalamus, to terminate precisely in the nuclei from which they receive a collateral input.

The intralaminar and midline nuclei receive afferents from the major pathways to their adjacent principal nuclei and project to the striatum (caudate, putamen, and ventral striatum) as well as to the cortex. There is a broad topographic relationship in their projection to both areas. The midline nuclei innervate the ventral striatum (nucleus accumbens) and the limbic cortex, including the hippocampal formation. The anterior intralaminar nuclei connect with the prefrontal, parietal, occipital, and temporal cortex, and project to all parts of the caudate. The posterior intralaminar nuclei, of which the centromedian nucleus is the largest, project to the putamen and are reciprocally related to the motor, premotor, and supplementary motor areas of cortex in the frontal lobe. Many axons to the cortex from the intralaminar nuclei are collateral branches of thalamostriate axons. The cortical and striatal areas to which they each project are precisely those parts of the cortex and striatum which are themselves directly connected by corticostriate fibres.

Non-thalamic subcortical afferents to the cerebral cortex

A variety of nuclei send afferents to the cerebral cortex. These fall into two categories: fibres from the so-called isodendritic core of the brainstem and basal forebrain, which are non-reciprocal and aminergic, and the two-way interconnections with the claustrum.

Acetylcholine and the basal forebrain

A system of cholinergic nuclei extend from the septum verum anteriorly, through the nuclei of the diagonal band of Broca to the basal nucleus of Meynert in the substantia innominata, ventral to the globus pallidus, most posteriorly. From these, cholinergic fibres pass to the entire cerebral cortex. Alternative nomenclature for these nuclei uses a numeric system, (Ch1 to Ch4). The anterior cell groups project to the hippocampus and entorhinal cortex, and to the olfactory bulb and cortex. There is an approximate topographic relationship in the projection of the basal nucleus to the neocortex, but with considerable overlap; adjacent or overlapping regions of the nucleus project to widely separated but functionally related and interconnected areas of neocortex. Degeneration of this system is associated with the dementias of Alzheimer's disease and Lewy body disease.

Cholinergic cells in the pedunculopontine nucleus of the midbrain project to the thalamus, particularly to the midline and intralaminar nuclei.

(a) Serotonin, noradrenaline (norepinephrine) and adrenaline (epinephrine): the raphe and associated nuclei

The median group of nuclei of the brainstem reticular formation is made up largely of the various raphe nuclei, all of which use serotonin (5-hydroxytryptamine) as their neurotransmitter. Their projections are very widespread throughout the central nervous system. Broadly speaking, there is a rostrocaudal topography to the efferent projections of these nuclei. The most rostral, notably the dorsal median raphe nucleus in the midbrain tegmentum, send projections to the entire cerebral cortex and striatum. There is a prominent projection to the thalamus, notably to the midline nuclei which in turn project in part to the hippocampal formation.

The serotoninergic raphe-spinal tract, which has important functions in the gating of pain, arises from the most rostral nuclei, the raphe obscurus and the raphe magnus.

The locus coeruleus lies in the dorsolateral pons, immediately deep to the ventricular ependyma. Together with the subceruleus immediately deep to it, this nucleus supplies noradrenergic fibres to most of the central nervous system. Ascending fibres pass to the thalamus and hypothalamus, the entire cerebral cortex (neo- and allocortex), the amygdala, the septal nuclei, and the olfactory bulb. Adrenergic cells in the brainstem do not appear to send ascending projections to the cortex.

(b) Dopamine: the substantia nigra and adjacent nuclei

The major dopaminergic cell group of the midbrain is the pars compacta of the substantia nigra, which projects to the striatum (caudate, putamen, nucleus accumbens, and olfactory tubercle). Two other adjacent nuclei, the ventral tegmental area of Tsai and the pigmented parabrachial nucleus, are also dopaminergic. Together, these three cell groups project rostrally in the medial forebrain bundle to innervate the thalamus and hypothalamus, the hippocampal formation, the entorhinal cortex and amygdala, and widespread areas of the neocortex, especially the prefrontal, orbitofrontal, and cingulate cortex.

(c) Histamine and the posterior hypothalamus

The entire cerebral cortex, including the limbic lobe, receives a histaminergic projection from the tuberomamillary nucleus of the posterior hypothalamus. Postsynaptic receptors appear to be of two types, H1 and H2, with broadly opposing effects.

(d) The cortex and the claustrum

The claustrum is a thin plate of grey matter lying immediately deep to the cortex of the insula, and separated from it by the white matter of the extreme capsule. Medially, the external capsule (Fig. 2.3.1.8(a)) separates it from the putamen. The nucleus receives fibres from and projects to the whole cortex, including the allocortex. The reciprocal connection is topographically organized, but with overlapping zones projecting to widely separated but functionally related and interconnected cortical areas. Many of the neurones of the claustrum have branching axons with collaterals going to two or more such interconnected areas. For example, the superior parietal cortex (area 5) is widely separated from the premotor cortex (area 6) but is connected to it by ipsilateral association fibres, and the two areas are functionally closely related. Both these areas project to and receive from an overlapping zone of the claustrum, and many axons of claustral cells in this zone may branch to both areas.

(e) Modulation of cortical activation and the anatomy of the reticular activating system

Specific information to the cerebral cortex, for example relating to sensory stimuli in the periphery, is relayed via the main thalamic nuclei. The other, diffusely projecting, systems are most likely to be involved in the regulation of cortical responsivity. Such a role has been demonstrated electrophysiologically for the claustrum, and the pharmacology of the antihistamines indicates a role for this transmitter system in the regulation of cortical arousal. The cholinergic input from the basal forebrain is necessary for the proper functioning of the cortex, and its degeneration is associated with cognitive decline and memory impairment. The possible relationship of mesolimbic dopamine pathways to schizophrenia is well known. Similarly, the psychopharmacology of serotonin also implies a major role for this transmitter system in the proper functioning of the cortex. There are two routes by which these 'non-specific' pathways affect the cortex: direct projections, and an indirect pathway through the thalamus. Brainstem nuclei send fibres to the intralaminar and midline nuclei, which in turn send fibres to the entire cortex including the hippocampus. The cholinergic input from the interpeduncular nucleus to the intralaminar nuclei is prominent. Serotonin is particularly concentrated in the midline nuclei. There are other reticular formation projections to these nuclei, but the transmitters remain uncertain. This latter indirect route by which the reticular formation of the brainstem impinges on the cerebral cortex via the thalamus constitutes the reticular activating system. The role of this system in cortical arousal is well documented.

Corticocortical connections

(a) The corpus callosum and the commissural connections of the cerebral cortex

All cortical areas, both send fibres to and receive fibres from the opposite hemisphere, although the connections are not necessarily throughout the whole area. In most of the cortex, commissural fibres pass to the contralateral side in the corpus callosum. The anterior commissure carries fibres that interconnect the anterior third or so of the temporal lobe with its partner, as well as fibres that interconnect the olfactory bulbs on each side. Some fibres in the fornix cross the midline, the so-called commissure of the fornix, to interconnect the two hippocampal formations. Commissural fibres are of two types, homotopic and heterotopic. Homotopic fibres pass from one area of cortex to the same area on the other side. Heterotopic fibres pass from one area to a different, although, often functionally related, area on the other side. As a generalization, the functions of the commissures can be subdivided into two categories. First, they serve to interconnect representations of the contralateral sensory surround across the midline, for example, the representations of the two halves of the body, the two visual hemifields, and so on. In areas containing a lateralized sensory representation, of either the body or the visual field, the callosal fibres are confined, in both origin and termination, to the parts of the area containing a representation of midline and adjacent regions. Thus the representation of the trunk in somatic sensory areas sends and receives commissural fibres, whereas the hand and foot representations are not connected across the midline. Similarly, the vertical meridians in visuotopic representations are interconnected by callosal fibres, whereas the periphery is not. In contrast, the second function of the commissures is to connect areas in one hemisphere with areas on the other side, where the functions of each are represented on only one side, i.e. they are lateralized. Of course, this is most apparent for language areas; for example, objects held in the non-dominant hand cannot be named following callosal section because the sensory cortex of the non-dominant hemisphere cannot communicate across the midline with the language and speech areas in the dominant hemisphere.

(b) Ipsilateral corticocortical association connections

All cortical areas interconnect with other areas in the same hemisphere. The primary sensory areas are in the parietal, occipital, and temporal lobes. From these, parallel pathways emanate in an

approximately hierarchical sequence through multiple areas in the adjacent association cortex, passing towards the medial temporal lobe where all pathways converge on the parahippocampal gyrus and the cortex of the temporal pole. In general, three 'tiers' of association areas can be recognized in this sequence; the first tier receives from the core sensory areas, and the third projects into the temporal pole and the parahippocampal gyrus. Connections passing in the direction of the medial temporal cortex from the primary sensory areas have a feedforward pattern of termination, whereas the reciprocal connections have a feedback character. Although the interconnections of the multiple areas along this sequence of connections are complex, a broad pattern common to all the sensory pathways can be discerned. Essentially, each sensory modality has a core zone in the cortex, comprising three areas. Each of these is linked to the relevant main thalamic nuclei and contains a complete representation of the sensory surround. They are linked together by short association connections passing forwards from the first thalamo-recipient zone in a stepwise fashion to the other two. Two streams of connections, dealing with different aspects of sensory perception, emanate from these into the surrounding association areas. One of these, the ventral stream (the 'stimulus-relevant' or 'what' system), is primarily concerned with a detailed perception and characterization of the stimulus. The second, the dorsal stream (the 'self-relevant' or 'where' system), is concerned mainly with spatial location, particularly in extrapersonal space. Each area in this sensory hierarchy is reciprocally connected to a part of the frontal lobe, where the dual-pathway streams are represented by a dorsal and a ventral prefrontal subdivision, feeding onto the supplementary and premotor cortex, and so to the motor cortex.

(c) Cortical association pathways for vision (Fig. 2.3.1.4)

The three core visual areas are V1 (the primary visual cortex, striate cortex), V2 which surrounds V1 and is contained within Brodmann's area 18, and outside this the V3 complex which is probably still within area 18. From these, feedforward projections pass to areas in the inferior parietal and superior temporal cortices, as the dorsal stream, and to V4, within Brodmann's area 19, at the junction of the occipital association cortex with the inferior temporal gyrus on the medial surface, forming the ventral pathway. Areas in the superior temporal sulcus and middle temporal gyrus form the next two tiers of association cortex for the dorsal pathway. The ventral route progresses via the posterior inferotemporal cortex on to the anterior inferotemporal cortex. Both the anterior inferotemporal and middle temporal cortical areas at the distal end of these two visual association pathways project to the cortex of the temporal pole, and to the parahippocampal gyrus. The parahippocampal gyrus projects to the entorhinal cortex more anteriorly, and the temporal pole connects with the amygdala. The entorhinal cortex provides a major input to the dentate gyrus of the hippocampus via the perforant path as seen in the figure. Similarly, the amygdala projects into the hippocampal formation.

(d) Cortical association pathways for somatic sensation (Fig. 2.3.1.3)

The three core areas for the somatic sensory cortex are Brodmann's areas 3, 1, and 2 on the postcentral gyrus, together constituting the classical primary somatic sensory cortex. Each receives a major input from the ventral posterior nucleus of the thalamus and contains a complete representation of the body. Area 3 projects forwards to areas 1 and 2, and area 1 projects similarly to area 2. All three areas project in a feedforward fashion to the second somatic sensory area in the parietal operculum. This represents the first step on the ventral association pathway. The dorsal pathway begins with the projection of all subdivisions of the primary somatic sensory cortex to Brodmann's area 5 in the superior parietal cortex. Further steps along the ventral pathway are areas in the insula. In the ventral pathway, information flows from the superior to the inferior parietal cortex, and so to the middle temporal gyrus. Areas at the ends of both these paths project onto the parahippocampal gyrus and the temporal pole.

(e) Cortical association pathways for hearing (Fig. 2.3.1.5)

The association pathways from the auditory cortex are less well understood. The three core areas lie along Heschl's gyrus in the temporal operculum, with the classical primary auditory area (AI) most posterior, the rostral auditory area (AII) more anterior, and the rostrotemporal auditory area in front of that. Each of these contains a complete representation of the auditory surround, organized tonotopically, and connects with the medial geniculate nucleus. On either side of these lie multiple auditory association areas, termed the medial and lateral belt areas, representing the first steps along the two association streams of connections, although it is unclear which is 'dorsal' and which is 'ventral' in a functional sense. The medial belt areas have connections with parts of the insula, whereas the lateral belt areas project into the association cortex of the superior temporal gyrus. The first association pathway probably continues through areas of the anterior part of the superior temporal gyrus, and so to the parahippocampal gyrus and the temporal pole. The second continues from the superior to the middle temporal gyrus, and thence to the parahippocampal cortex and the temporal pole.

(f) The olfactory pathway to the cerebral cortex (Fig. 2.3.1.6)

The olfactory pathway is unique among the sensory modalities in having direct access to the cerebral cortex without passing through the thalamus. The primary olfactory receptor neurones of the olfactory mucosa send their axons (the fila olfactaria) through the cribriform plate of the ethmoid bone directly into the overlying olfactory bulb, where they contact the mitral cells in synaptic glomeruli. Axons of the mitral cells pass caudally in the olfactory tract to the anterior perforated substance. Here the olfactory tract splits into medial and lateral olfactory striae. All the mitral cell axons pass in the lateral stria. The medial stria contains axons mainly from the anterior olfactory nucleus, which are destined for the contralateral olfactory bulb by way of the anterior commissure. The lateral olfactory stria passes to the medial temporal lobe, where the axons terminate in the anterior margin of the entorhinal cortex, the pyriform cortex, and the corticomedial subdivision of the amygdala. All three termination zones interconnect. The olfactory entorhinal cortex and the olfactory amygdala both have connections with their non-olfactory partners, i.e. with the more posterior entorhinal subdivisions and the basolateral part of the amygdala respectively.

(g) The limbic cortex and the amygdala (Figs 2.3.1.6 and 2.3.1.8)

The latter stages of the sensory association pathways all converge on the entorhinal cortex, the perirhinal cortex, and the amygdala, which are themselves interconnected. These in turn project to the hippocampus. The perirhinal cortex lies lateral to the entorhinal

cortex in the banks of the rhinal fissure. It appears to receive afferents from the later stages of the sensory association pathways, notably from the temporal pole, and is extensively interconnected with the amygdala, the entorhinal cortex, and the hippocampus. The amygdala projects to the CA pyramidal cells, notably to CA1. The entorhinal input to the hippocampus arises from cell clusters in layer II and forms the perforant pathway, with axons terminating on the dendrites of granule cells of the dentate gyrus. Additional entorhinal fibres pass to the CA pyramidal cells. Axons of the dentate gyrus granule cells pass out into the molecular layer of the CA fields, notably CA3, where they synapse on the apical dendrites of pyramidal neurones. CA3 pyramidal cells project out via the fimbria, but also send collateral axons to synapse with the pyramidal cells of CA1 in particular. The activity of pyramidal neurones in the CA fields is regulated by inhibitory GABA-ergic interneurones in the molecular layer and by the basket cells, which are also GABA-ergic, sited immediately subjacent to the pyramidal layer. The latter inhibitory neurones have axons that branch around the pyramidal cell bodies, forming the baskets of terminal fibres from which they are named. CA1 sends some fibres into the fornix, but projects heavily to the subicular complex. The major output of the hippocampal formation comes from the subicular complex, and passes out into the fornix via the alveus and fimbria. The projection of fibres in the fornix to the hypothalamus, including the mamillary nuclei, is considered below. However, some hippocampal efferent fibres bypass these nuclei and enter the mamillothalamic tract without synapsing. Rather they pass directly to the anterior thalamic nuclei, where they terminate. From the anterior thalamic nuclei, of which there are several subdivisions, axons project to the cortex of the cingulate gyrus along the whole of its length, extending into the parahippocampal gyrus inferiorly. Fibres forming the cingulum bundle interconnect these medial cortical areas, running predominantly from anterior to posterior and ending in the parahippocampal gyrus, so that they reach the entorhinal cortex. This completes Papez's circuit and defines the structures of the limbic lobe—hippocampal formation, mamillary nuclei and anterior thalamus, cingulate cortex, parahippocampal gyrus and cingulate cortex. The term 'limbic system' is often extended to include structures, such as the amygdala, which have strong connections with these components.

(h) Association connections of the frontal lobe (Fig. 2.3.1.2)

The hierarchical sequence of connections in the sensory association pathways outlined above is reflected in a similar sequence passing from association areas of the prefrontal cortex back towards the primary motor cortex of the precentral gyrus. The two streams of connections are tightly linked together by long association pathways, with each tier of connections in the sensory association pathways interconnected with an area of the frontal lobe. The medial temporal areas, including the entorhinal cortex, the perirhinal cortex and the parahippocampal gyrus are closely interconnected with areas in the orbitofrontal cortex. The temporal pole is reciprocally connected with the frontal pole (Brodmann's area 10). The tiers of sensory association areas in the parietal, occipital, and temporal cortex are interconnected with the dorsolateral and ventrolateral prefrontal association cortex, occupying Brodmann's areas 9, 46, and 45. Broadly speaking, the association areas on the dorsal stream of connections for each modality interconnect with the dorsolateral prefrontal areas 9 and 46. In contrast, the ventral stream areas interconnect with the ventrolateral prefrontal cortex in areas 45 and 46. Like the sensory association areas, these regions seem to separate functionally into a dorsal hierarchy, dealing with internally generated actions, and a ventral hierarchy related to externally guided behaviours. Connections from the dorsolateral prefrontal cortex pass preferentially to the supplementary motor cortex, whereas the more ventrally placed prefrontal cortex feeds into the premotor cortex. Both the supplementary and the premotor cortex feed into the primary motor cortex of the precentral gyrus. The frontal eye-field (Brodmann's area 8), which has major ipsilateral association connections with the visual areas in the occipital lobe, is strategically placed between the prefrontal and premotor areas. It also receives ipsilateral association connections from the dorsolateral and ventrolateral prefrontal association areas.

(i) Speech areas of the cerebral cortex

Because speech and language are not present in the subhuman primate species commonly used for neuroanatomical investigation of cortical connections, little is known about the connections of these in the human. The posterior speech area (Wernicke's area) occupies a large extent of the posterior temporal and inferior parietal cortex at the posterior limits of the superior temporal and lateral sulci, and is often taken as extending anteriorly along the superior temporal gyrus. It includes the angular and supramarginal gyri (Fig. 2.3.1.9). This would represent a region where the association pathways of all three modalities—somatic sensation, vision, and hearing—lie close together. It would include many auditory association areas along the superior temporal gyrus. Within the frontal lobe, Broca's area occupies the pars triangularis between the anterior and ascending rami of the lateral sulcus. It is closely adjacent to the face area in the lateral premotor cortex. Similarly, the medial speech area lies on the medial surface immediately in front of the face representation in the supplementary motor cortex. It is, perhaps, not unreasonable to suppose that these two areas function to some extent as the premotor and supplementary motor speech areas.

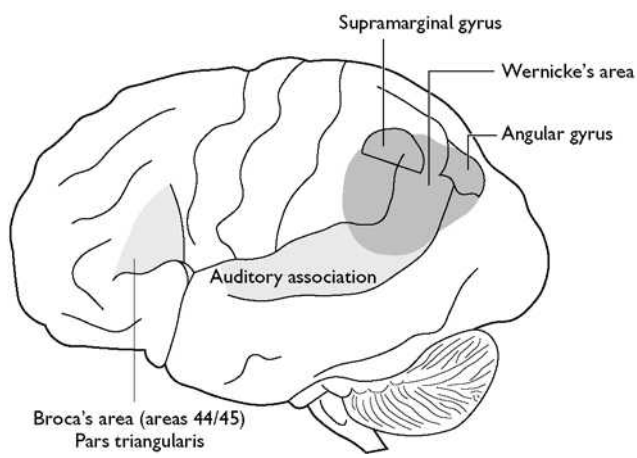

Fig. 2.3.1.9 Auditory association cortex and Wernicke's sensory speech area.

Subcortical efferent pathways of the cerebral cortex

The corticostriate pathway and the basal ganglia (Fig. 2.3.1.10)

The anatomical definition of the basal ganglia comprises those deep grey matter nuclei that develop from the telencephalic (cerebral) vesicle. Strictly, this would include the components of the striatum, the globus pallidus, the amygdala, and the claustrum. Because these latter two are better considered with the cortex and limbic system respectively, they are usually excluded from the term basal ganglia. Similarly, because of their close anatomical and functional relationship with the striatum and globus pallidus, the substantia nigra and subthalamic nucleus are usually included with the basal ganglia. The caudate and putamen are developmentally, anatomically, pharmacologically, and functionally a single structure, secondarily subdivided by the development of the internal capsule. The two fuse below the inferior margin of the anterior limb of the internal capsule to form the nucleus accumbens. This fusion comes to the surface of the hemisphere at the anterior perforated substance, an area sometimes called the olfactory tubercle. Together, the caudate, putamen, nucleus accumbens, and olfactory tubercle make up the striatum. The globus pallidus consists of two parts, an external segment (GPe) and an internal segment (GPi), separated by a thin white-matter lamina. Both segments extend ventrally in the region of the substantia innominata, below the anterior commissure, to form the ventral pallidum. The pars reticulata of the substantia nigra (SNpr) is developmentally, anatomically, pharmacologically and functionally a part of the internal segment of the globus pallidus, which has been separated off by the development of the fibres of the internal capsule passing into the crus cerebri of the midbrain. Therefore, in this account the basal ganglia and related nuclei will comprise the striatum, GPe, GPi-SNpr, and the subthalamic nucleus (see Fig. 2.3.1.10).

The entire cerebral cortex projects to the striatum. The putamen receives predominantly from the sensorimotor cortex around the central sulcus. The caudate receives the input from most of the parietal, occipital, temporal, and frontal lobes. The limbic areas, including the entorhinal and perirhinal cortex, the hippocampus, and the amygdala, project to the ventral striatum (nucleus accumbens and olfactory tubercle) and the adjacent ventral portion of the head of the caudate. The corticostriate pathway arises from pyramidal cells predominantly in layer V of the cortex and is excitatory, using glutamate as its neurotransmitter. The termination of the pathway is broadly topographically organized, but with considerable interdigitation or overlap of the projections from different cortical areas. Individual cortical areas project to a longitudinal strip of striatum orientated anteroposteriorly. The strips receiving from the frontal lobe extend more rostrally, whereas those receiving from the parietal, occipital, and temporal lobes extend more caudally. Anteriorly, zones receiving projections from interconnected areas in the frontal lobe interdigitate or overlap; centrally, zones receiving from frontal areas overlap with zones connected to areas within the parietal, temporal, or occipital cortex with which the frontal areas are connected by ipsilateral association fibres. More posteriorly, interconnected sensory association areas

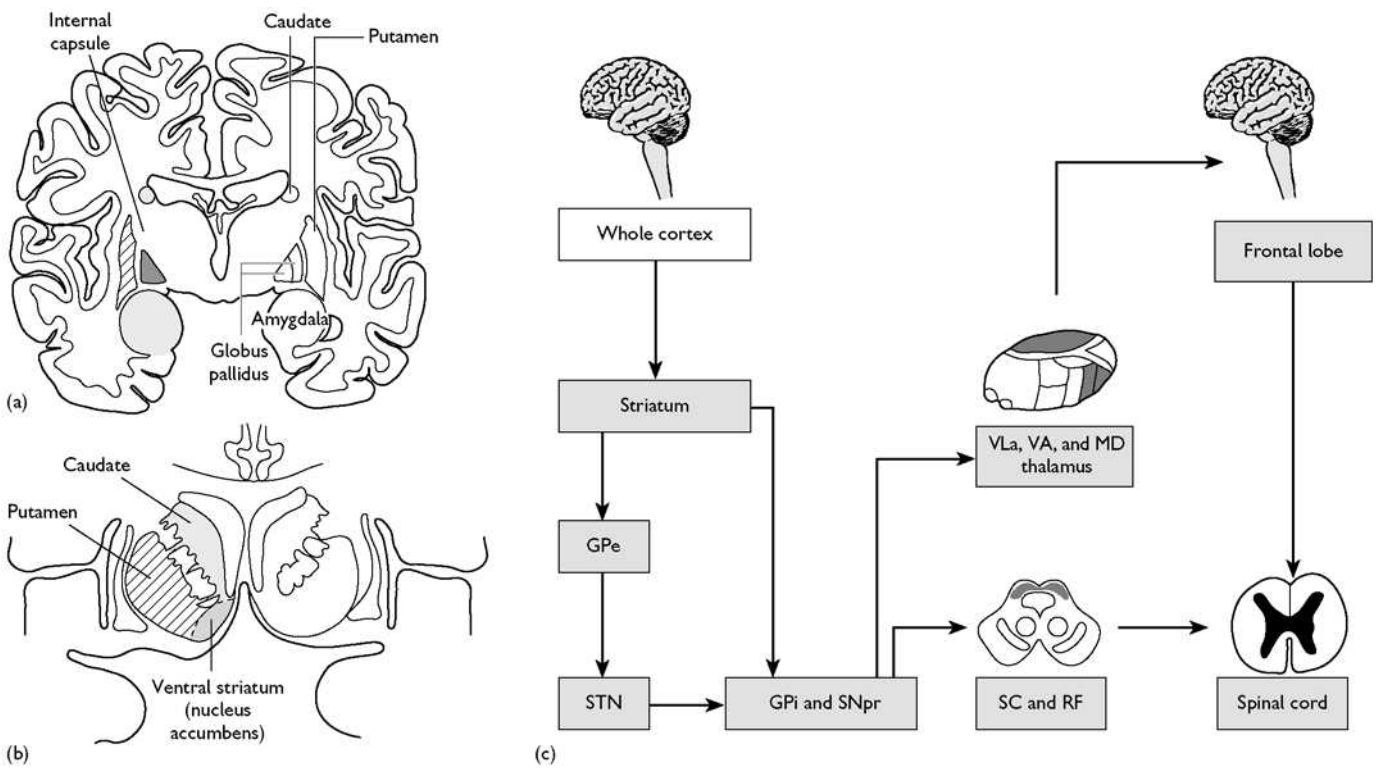

Fig. 2.3.1.10 The corticostriate pathway and the basal ganglia: (a) component nuclei of the basal ganglia; (b) striatum; (c) major pathways through the basal ganglia. GPe, external segment of the globus pallidus; STN, subthalamic nucleus; GPi, internal segment of the globus pallidus; SNpr, pars reticula of the substantia nigra.

project to overlapping zones in the striatum. The striatum itself is compartmentalized, on the basis of acetylcholinesterase (AChE) histochemistry, into AChE-poor patches (striosomes) and AChE-rich matrix. The cortex projects into both compartments, but with a slightly different laminar origin. Pyramidal neurones in the deeper part of lamina V project to the patches, whereas more superficial lamina V cells and some lamina III cells project to the matrix. It is possible that apparently overlapping corticostriate projections from different cortical areas are segregated into the different compartments. The projection from a single cortical area may switch between compartments along the anteroposterior length of its zone of termination. The intralaminar nuclei of the thalamus sends excitatory (glutamatergic) axons to the entire striatum. The nuclei project to those parts of the caudate or putamen which receive from the cortical areas and to which the particular intralaminar nucleus projects. Many, if not all, interconnected areas in the frontal, parietal, occipital, and temporal lobes also receive a shared projection from a single intralaminar nucleus. Thus, there is a tightly organized but complex topographical relationship between the connections of functionally related cortical areas with each other, with the striatum, and with the intralaminar nuclei of the thalamus. A closely similar relationship is seen in the cortical connections of the claustrum and the basal forebrain, and possibly even in the cortical projection to the pontine nuclei. Another major projection to the striatum is dopaminergic and comes from the pars compacta of the substantia nigra and adjacent nuclei. There is some topography in this projection, with the lateral and central parts of pars compacta of the substantia nigra projecting to the caudate and putamen. The medial part and the adjacent nuclei, such as the ventral tegmental area, project to the ventral striatum. The effect of dopamine on striatal neurones appears to be different in the two compartments. Additional striatal afferents come from the brainstem raphe nuclei (serotonin) and the amygdala (to the ventral striatum and the head of the caudate).

The output of the striatum passes to all parts of the globus pallidus (the ventral pallidum, GPe, and GPi-SNpr). These fibres are inhibitory, using GABA as their neurotransmitter. Here, the pathway through the basal ganglia separates into a direct and an indirect route, ultimately passing to the thalamus. Fibres from the striosomes (patches) of the striatum are rich in substance P (as well as being GABA-ergic) and project to GPi. Axons from GPi go directly to the anterior part of the ventral lateral nucleus and the adjacent ventral anterior nucleus of the thalamus, forming the direct route. Neurones in the striatal matrix compartment contain enkephalin as a cotransmitter with GABA and project to GPe. Axons from GPe go to the subthalamic nucleus, which in turn projects to GPi (the indirect pathway). The ventral pallidum has equivalent pathways, but the final destination of the pallidal output is the mediodorsal nucleus of the thalamus. All efferents from the globus pallidus are GABA-ergic and inhibitory. The neurones of the subthalamic nucleus are glutamatergic and excitatory. Activation of the striatal output through the direct pathway leads to a reduced tonic inhibition of the thalamus. In contrast, activation via the indirect pathway leads to increased activation of GPi, and hence increased inhibition of the thalamus. The balance between these opposite effects is crucial in the normal functioning of the basal ganglia. Disruption of this balance is used to explain much of the pathophysiology of the extrapyramidal disorders. The ventral anterior and rostral ventral lateral nuclei of the thalamus project mainly to the premotor and supplementary motor areas of the frontal lobe. The ventral pallidal pathway through the mediodorsal thalamus feeds onto the prefrontal association areas. The major pathways through the basal ganglia are summarized in Fig. 2.3.1.10(c)).

The corticopontine pathway and the cerebellum

There is a major projection from the cortex to the pontine nuclei. The extent to which individual cortical areas contribute to this pathway varies. The greatest projection comes from the regions around the central sulcus, which also contribute to the pyramidal tract (see below). However, there is a substantial projection from the prefrontal cortex and a significant number of fibres from the occipital lobe. Many fewer corticopontine axons arise from temporal neocortex, although some areas send some and it is possible that most areas send at least a few.

The pontine nuclei send their axons to the cerebellar cortex of the lateral parts of the posterior lobe. They terminate as mossy fibres, contacting granule cells. Axon collaterals pass, in addition, to the lateral dentate deep cerebellar nucleus. The anterior lobe and the midline and paramedian region of the posterior lobe are related to the spinocerebellar inputs. The flocculonodular lobe is connected to the vestibular pathway. The Purkinje cells of the cerebellar cortex send inhibitory fibres to the deep cerebellar nuclei, and it is from these that the output of the cerebellum arises. The intermediate (globose and emboliform) and medial (fastigial) deep nuclei project to the red nucleus and the vestibular nuclei and reticular formation. The dentate nucleus projects to the posterior part of the ventral lateral nucleus of the thalamus. This in turn provides the major thalamic input to the primary motor cortex of the precentral gyrus. In this way, the neocortical input to the cerebellum is transmitted via the pontine nuclei,and to the motor cortex via the thalamus.

The fornix and the cortical projection to the hypothalamus

Fibres leaving and entering the hippocampus form a thin white-matter covering on the ventricular surface, deep to the ependyma, called the alveus. These fibres pass into the fornix via the fimbria. The fornix passes initially posteriorly and superiorly, then anteriorly, curving around the outer curve of the lateral ventricle and angling towards the midline in its course. The fornices of the two sides come together at about the junction of the posterior third and anterior two-thirds of the corpus callosum. Many fibres pass across the midline, the commissure of the fornix, and turn caudally to enter the contralateral hippocampus. The two fornices, united in the midline, are suspended from the corpus callosum by the septum pellucidum as they arch over the roof of the third ventricle and the choroid fissure of the body of the lateral ventricle. They turn ventrally, immediately in front of the interventricular foramen of Monroe. The two fornices separate, and each divides into an anterior and a posterior column, passing in front of and behind the anterior commissure. The anterior column carries axons to and from the septal nuclei CA3, CA1, and the subiculum project to the lateral septal nucleus. This has diverse efferent projections to the hypothalamus, the epithalamus, and the midline thalamus, but also projects to the adjacent medial septal nucleus. The medial septal nucleus is the major source of cholinergic fibres to the hippocampus via the fornix. The posterior column of the fornix curves posteriorly through the hypothalamus, giving off many fibres to

medial and lateral hypothalamic nuclei. It ends in the mamillary nuclei, which in turn project via the mamillothalamic tract to the anterior thalamus. This projection is partially bilateral.

There is a major input to the hypothalamus from the amygdala, via the stria terminalis, a white-matter tract that follows the curve of the caudate nucleus around the lateral ventricle, lying between the caudate and the thalamus. The connections between the hypothalamus and amygdala are reciprocal.

Direct projections to the cortex from the hypothalamus have been discussed earlier. Direct projections from neocortex to the hypothalamus have been described, but their extent and distribution are disputed. If they exist in the human, they probably arise from the prefrontal/orbitofrontal and insular cortex.

The corticobulbar and corticospinal pathways

The direct projection of the cortex to the brainstem and spinal cord, the pyramidal tract, arises from the cortex in front of and behind the central sulcus. About 40 per cent of fibres arise from the primary somatic sensory cortex and the adjacent superior parietal lobe. In the frontal lobe, axons arise from the primary motor, premotor, and supplementary motor areas. Apart from the direct innervation of the spinal cord and motor nuclei of the cranial nerves, direct cortical fibres innervate the red nucleus, the vestibular nuclei, the reticular formation, and the superior colliculus. In the case of the first two of these, the origin of the fibres is probably very similar to the areas of origin of the pyramidal tract. In contrast, the cortical projections to the reticular formation and superior colliculus have a much wider origin, and may include most neocortical areas to a greater or lesser degree.

The contribution of neuroanatomy to psychiatry

The above is a necessarily abbreviated account of the anatomy of the central nervous system, centring on the organization and connections of the cortex including the limbic lobe. Topographical neuroanatomy has been ignored, despite its importance in the reading of modern images of the brain in living patients. For psychiatry, the importance of the connectionist view of the brain lies in the contribution it can make to the understanding of the normal and pathological functioning of the central nervous system. Present-day neuropsychology and cognitive neuroscience are aimed towards understanding the highest levels of central nervous system processing and function. It is these areas or systems that are commonly involved in the signs and symptoms of major psychiatric disease. It is to the pathways underlying cognition, perception, memory, mood, and attention that the psychiatrist interested in the pathophysiology of mental illness must turn his or her attention, and it is this area that the above account has attempted to review.

2.3.2 Neurodevelopment

Karl Zilles

Neural induction

The central nervous system originates from the midline region of the embryo as a specialized area of ectoderm, the neuroectoderm, or neural plate. FGF (fibroblast growth factor) signalling and BMP (bone morphogenetic protein) as well as Wnt (wingless gene) inhibition are required as steps for neural induction.[1] However, the complete set of factors and their respective interactions are presently not sufficiently understood in the mammalian embryo. As the neuroectodermal cells proliferate the neural plate is transformed into an indentation, the neural groove. The lateral parts of this groove approach each other and join in the midline, forming the neural tube. The folds begin to fuse in the central part of the groove but the most rostral and caudal parts close only later, leaving initially rostral and caudal neuropores. A small transitional zone between the neural plate and the surrounding ectoderm provides the cells of the neural crest, which develop into the postganglionic cells of the sympathetic and parasympathetic nervous system, the sensory neurons of the spinal ganglia and ganglia of cranial nerves, Schwann cells, and chromaffine cells of the suprarenal glands.

Neural tube formation requires a controlled expression of cell adhesion molecules in the lateral folds of the neural groove. If the rostral neuropore fails to close, the development of the forebrain is impaired leading to anencephaly. If the caudal neuropore fails to close, the most severe result is rachischisis, a malformation with a dorsally exposed neural groove. The mildest result is spina bifida occulta which is a cleft of a vertebral arch covered by epidermis.

As development continues, the neural tube and crest move to a position between the ectoderm and the notochord. The rostral part of the neural tube differentiates into the brain; the caudal part (behind the fifth somite) differentiates into the spinal cord.

Organogenesis of the central nervous system

The embryonic brain has three vesicular enlargements: the forebrain, telencephalon and diencephalon, the midbrain, mesencephalon, and the hindbrain, rhombencephalon. Because the brain grows much faster than the rest of the embryo, it becomes deflected ventrally. A dorsally convex cephalic flexure marks the border between hindbrain and midbrain, and a cervical flexure marks the border between spinal cord and hindbrain (Fig. 2.3.2.1). The ventrally convex pontine flexure forms the hindbrain. During week 5, the forebrain differentiates further into the rostral telencephalon and the more caudal diencephalon. The telencephalon consists of two

hemispheric vesicles connected by a thin lamina terminalis, the most dorsal part of which develops into the commissural plate, the *Anlage* of the corpus callosum. The ventral part of the lamina terminalis differentiates into the anterior commissure. The central cavity of the diencephalon (the third ventricle) is connected with the cavities of the hemispheric vesicles (the lateral ventricles) by the interventricular foramen. The diencephalon develops bilateral evaginations, the eye vesicles, which differentiate into the retina and the optic nerve. Meanwhile the hindbrain becomes subdivided into a rostral metencephalon and a caudal myelencephalon.

The cerebellum starts to develop from the metencephalon during week 6 (Fig. 2.3.2.1). At first, the enlarged central cavity of the neural tube (the future fourth ventricle) has a thin roof plate bordered by two thickenings of the neural tube, the rhomboid lips, which merge in the midline. These thickenings develop into the cerebellar hemispheres, while the midline part develops into the vermis of the cerebellum. Fissures appear in the cerebellar hemispheres, forming the anterior and posterior lobes and the uvula.

The rhombencephalon is temporarily divided into eight rhombomeres,[2] whose borders are specified by specific combinations of transcription factors (e.g. Hox, Krox, Wnt genes) disappear during further development. Local expression of homeobox genes leads to the formation of the pallium and the ganglionic hill in the forebrain.

The hindbrain develops in close association with the visceral archs, which appear during week 4. It innervates these archs and the organs derived from them by a group of branchial nerves, which later become the trigeminal (V), facial (VII), glossopharyngeal (IX), vagal (X), and accessory (XI) cranial nerves. Other cranial nerves develop connections between the hindbrain and peripheral organs not derived from the visceral archs. They are the oculomotor (III), trochlear (IV), abducens (VI), vestibulocochlear (VIII), and hypoglossal (XII) nerves. The olfactory (I) and optic (II) nerves arise separately as evaginations of the forebrain.

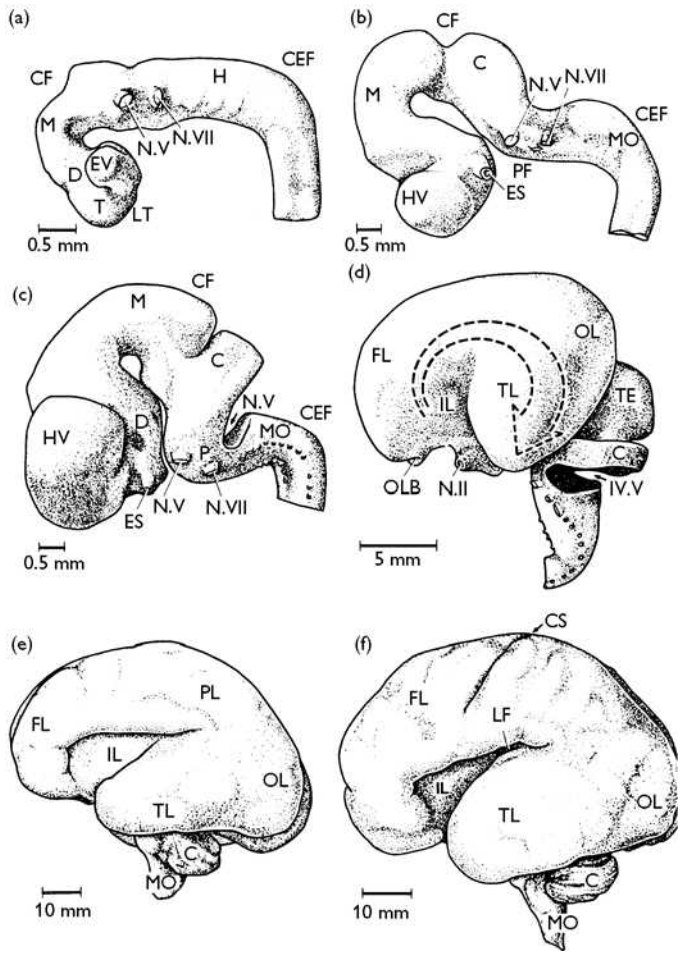

Fig. 2.3.2.1 Development of the human brain. Brains of (a) 4 mm, (b) 10.4 mm (c), 13.8 mm, and (d) 53 mm human embryos, and (e) 21 week and (f) 24 week fetuses. C, cerebellum or cerebellar *Anlage*; CEF, cervical flexure; CF, cephalic flexure; CS, central sulcus; D, diencephalon; ES, eye stalk; EV, eye vesicle; FL, frontal lobe; H, hindbrain; HV, hemispheric vesicle; IL, insular lobe; LF, lateral fissure; LT, lamina terminalis; M, mesencephalon; MO, medulla oblongata; N.II, optic nerve; N.V, trigeminal nerve; N. VII, facial nerve; OL, occipital lobe; OLB, olfactory bulb; P, pons; PF, pontine flexure; PL, parietal lobe; T, telencephalon; TE, tectum; TL, temporal lobe; IV.V, fourth ventricle.

Histogenesis of the spinal cord

The neural tube initially consists of a single layer of neuroepithelial cells surrounding a central canal filled with the cerebrospinal fluid. The outer surface of the future spinal cord has an external limiting membrane, and the inner surface bordering the central canal has an inner limiting membrane. The entire wall of the early neural tube is called the ventricular zone.[3]

The cells of the ventricular zone proliferate, and the surface of the spinal cord enlarges. The cord then thickens as cells divide further to produce a multilayered epithelium. The daughter cells have different potentialities: one type of cell (the neuroblast) retains the capability for mitosis, whereas another type (the proneurone) is postmitotic and represents an immature neurone. The proliferation of neurones is almost complete around birth.

Some neuroepithelial cells develop into precursors of glial cells, glioblasts, which differentiate into astroglial, oligodendroglial, and microglial cells. The first glioblasts differentiate into radially extended cells spanning the entire width of the wall of the spinal cord (the same occurs in the cerebral hemispheres and the cerebellar cortex as described below). During later development these cells are transformed into ependymal cells and astroglia.

The histogenesis of the spinal cord starts at the cervical level and progresses in a caudal direction. After week 3, a longitudinal sulcus limitans is recognizable on the inner surface of the neural tube, dividing the wall into dorsal (alar) and ventral (basal) plates. The dorsal plates of both sides are connected by a thin roof plate, and the ventral plates by a thin floor plate. The dorsal plate differentiates into a sensory zone, the dorsal horn of the adult spinal cord, and the ventral plate differentiates into a motor zone, the ventral horn. The sympathetic preganglionic neurones form the lateral horn, which is present only at thoracic levels. The subdivision into dorsal and ventral plates is functionally important not only in the spinal cord, but also in the brainstem (see below).

During week 5, three concentrically organized zones—a cell-dense ventricular zone, a less-dense intermediate or mantle zone, and a superficially located marginal zone free of neuronal cells—develop in the wall of the spinal cord. Proneurones leave the ventricular zone and migrate along radial glial cells into the intermediate zone where they become organized into cell groups, nuclei. The motor neurones develop the axons of the ventral root, and the processes from spinal ganglionic cells grow into the spinal cord to

form the dorsal roots. Synapses develop first in the motor zone, and later in the sensory zone, during the weeks 10 to 13.

During the third month, the ventricular zone is reduced to a small rim surrounding the central canal and is finally transformed into the ependymal cell layer. The intermediate zone becomes organized into dorsal, ventral, and (at thoracic levels) lateral horns. The ascending and descending fibre tracts of the spinal cord are increased in size in the marginal zone. During weeks 14 and 15, oligodendrocytes begin to myelinate these fibre tracts. The corticospinal, or pyramidal, tract is visible for the first time during week 14 and reaches its target neurones, mainly motor neurones of the ventral horn, between weeks 17 and 29. The myelination of the pyramidal tract is completed between the first and second postnatal years. This late myelination explains the presence of the Babinski reflex in newborns and its disappearance during the first 2 years.

Histogenesis of the brainstem and cerebellum

At the level of the fourth ventricle the various zones of the hindbrain are arranged in a lateral-to-medial sequence (somatosensory-viscerosensory-visceromotor-somatomotor). In the hindbrain, proneurones not only migrate radially, as in the spinal cord, but also tangentially and longitudinally. This complex migration and the growth of fibre tracts lead to changes of the lateral-to-medial sequence of cranial nerve nuclei (e.g. the facial nucleus) in the adult.

In the cerebellum, between weeks 10 and 11, neuroblasts migrate from the ventricular zone through the intermediate zone into an area (the external granular layer) at the surface of the marginal zone. During weeks 12 and 13, proneurones from the ventricular zone begin to migrate along radially extended glial cells, Bergmann glia, into a region below this external granular layer, where they form the Purkinje cells of the ganglionic layer of the cerebellar cortex. Other proneurones from the ventricular zone develop into the cerebellar nuclei. Proneurones from the external granular layer then migrate inwards to form the internal granular layer and the basket and star cells of the molecular layer. The migration of cerebellar proneurones is not completed until the first postnatal year. During weeks 16 and 26, synapses develop and afferent fibre systems begin to form. The external granular layer finally disappears during the first 2 years of life, leaving the three-layered organization (molecular, ganglionic, and internal granular layers) of the adult cerebellar cortex.

Histogenesis of the cerebral cortex

Initially, the entire wall of the hemispheric vesicle consists of very densely packed mitotic cells. These cells undergo more than 28 mitotic rounds in the human brain.[4] In week 5, this develops into an inner cell-dense periventricular zone and an outer cell-poor marginal zone. In week 6, postmitotic proneurones leave the inner periventricular zone and form an intermediate (mantle) zone between the marginal and periventricular zones. By the end of week 6, the periventricular zone is further subdivided into a cell-dense ventricular zone and a less cell-dense subventricular zone.

During week 8, the cortical plate between the marginal and intermediate zones is formed by proneurones which have migrated along radial glial cells from the ventricular and subventricular zones through the intermediate zone.[3–7] A single radial glial cell can span the entire distance between the ventricular and pial surfaces. As the proneurones 'climb' to the cortical plate along the processes of the radial glial cell, they produce a vertically oriented cortical cell column. This radially guided migration is responsible for the architectonic organization of cortical layers II–VI. It is a prototype of the cortical map of the adult brain.[8] A further feature of cortical migration is the inside-to-outside layering, with the earliest proneurones being found in the deepest layers of the cortical plate and the latest in the most superficial layers. Thus layers V and VI of the adult cortex are generated before layer IV, and layer IV is generated before layers III and II. When cortical proneurones are migrating radially, their 'stop signal' is Reelin, produced by specialized cells (Cajal–Retzius cells) in the marginal layer. In this way, Reelin organizes the inside-to-outside layering of the cortex.[4] In addition to Reelin, the microtubule-associated protein (LIS1), Doublecortin (DCX), and the tumour-suppressor p73 are crucial for the normal migration of the proneurones. These radially migrating cells develop into the glutamatergic projection neurones (pyramidal neurones) of the cortex. At the same time there is much tangential migration of cells born in the ganglionic eminence, migrating into the cortical *Anlage*, and developing into γ-aminobutyric acid producing (GABAergic) cortical interneurones.[4,9]

Regional differences in the development of the cortical plate subdivide the hemisphere into segments. The lateral segment, with a well-developed cortical plate and presubplate, develops into the neocortex. The mediodorsal segment, with a wide marginal zone and a thin-folded cortical plate, develops into the archicortex, including the hippocampus. The mediobasal segment, with its inconspiciously developed cortical plate, is the precursor of the palaeocortex. The basolateral segment, ganglionic eminence, generates cortical interneurones (see above) and develops into the corpus striatum, the amygdala, and the septum.

During weeks 10 and 12, the axons of the serotoninergic and noradrenergic neurones contribute to the first synapses in the marginal and presubplate zones, where neurotrophin receptors (see below) are expressed. During the following 3 weeks, the subplate zone develops as axons grow in from the basal forebrain and thalamus, dendrites enlarge, and synapses form. From weeks 16 to 24, the cortical *Anlage* has a small marginal zone, a wide cell-dense cortical plate, and a very wide and less cell-dense subplate.

The transformation into the adult neocortical pattern starts between weeks 25 and 34 as the migration and proliferation of proneurones diminishes. Dendrites begin to differentiate and synapses begin to develop in the deepest cortical layers, progressing to the most superficial layer. Before birth, six cortical layers can be recognized in all regions of the neocortex. In the postnatal period, layer IV (inner granular layer) disappears as part of the differentiation of the motor cortex, leaving the five-layered agranular neocortex of the motor region.[10] Shortly before birth, the subplate, the subventricular zone, and most of the ventricular zone disappear, neuronal proliferation ceases, and the intermediate zone is transformed into the white matter of the pallium. The remaining ventricular zone contributes to the ependymal layer of the ventricular surface.

Dendritic and axonal differentiation continues after birth and into adult life. Synaptogenesis reaches a maximum during the first

postnatal year, but continues at a lower rate during childhood. The myelination of the vestibular system is finished shortly before birth, that of the somatosensory, visual, auditory, pyramidal, and extrapyramidal fibre tracts is nearly complete by the end of the third postnatal year, and that of the associative fibre tracts in the cerebral hemispheres is continued until the second decade.[11] The key change in synapses after birth is pruning; the density of synapses in the adult brain is half that in neonates.

The development of the neocortex is summarized in Fig. 2.3.2.2.

Hemispheric shape and the formation of gyri

The spherical shape of the early foetal hemisphere is transformed into the adult shape by differing rates of growth in the various regions of the telencephalon (Fig. 2.3.2.1). The future insular lobe grows less than other telencephalic regions, so that by the eighth month it is covered by the frontal, parietal, and temporal lobes. In the adult brain the insula is completely buried in the depth of the lateral fissure.

The extensive growth of the parieto-occipito-temporal association cortex leads to a bend in the temporal lobe around the lateral fissure. At the same time the temporal pole is pushed rostrally. This direction of growth (Fig. 2.3.2.1(d)) also affects the structures situated dorsomedially, i.e. the archicortex with the hippocampus, the corpus striatum, and the lateral ventricles. The corpus striatum is split by the ingrowing fibres of the internal capsule into the caudate nucleus and the putamen. The head of the caudate is situated ventrolaterally to the corpus callosum in the frontal lobe, and the tail of the caudate is located in the temporal lobe dorsal to the inferior horn of the lateral ventricle. The hippocampus forms its largest extension (the retrocommisssural part) in the temporal lobe, bends around the posterior end (splenium) of the corpus callosum, and reaches a position on top of the corpus callosum (the supracommissural part). The precommissural part of the hippocampus ends in front of the genu of the corpus callosum.

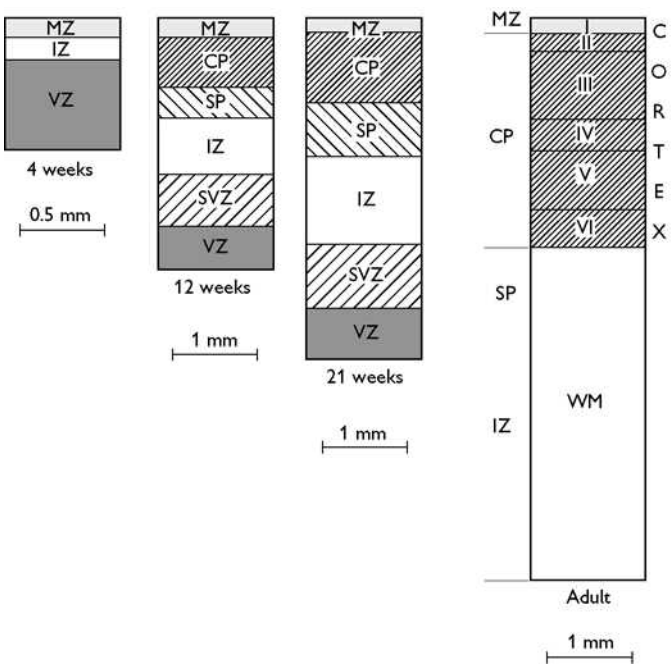

Fig. 2.3.2.2 Development of the neocortex between 4 weeks of gestation and adulthood. Roman numerals indicate the six cytoarchitectonically defined layers of the neocortex, which originate from the marginal zone (layer I) and the cortical plate. CP, cortical plate; IZ, intermediate zone; MZ, marginal zone; SP, subplate; SVZ, subventricular zone; VZ, ventricular zone; WM, white matter.

After the appearance of the lateral fissure, the neocortical surface develops many sulci and gyri. The central, collateral, cingulate, parieto-occipital, superior temporal, and calcarine sulci appear between weeks 16 and 21, followed by the pre- and postcentral, frontal, temporal, and intraparietal sulci. Highly variable secondary and tertiary sulci develop between week 29 and birth, when all sulci have been formed.[12,13]

The reasons for the formation of gyri in many mammalian brains, including the human brain, are not completely understood. Since the basic organization of the cerebral cortex is vertically oriented, with cell columns positioned side by side, growth of the cortex inevitably leads to a considerable enlargement of the cortical surface. A large unfolded cortical surface would have two disadvantages: the volume of the skull would increase to such a degree during foetal development that a normal delivery would be impossible; the distance between cortical regions interconnected by intrahemispheric projection fibres would increase and with it the information transmission time. Gyri allow the maximal cortical surface in the minimal volume, and they increase the speed of neural transmission between neighbouring cortical areas. Recent measurements show that gyrification is greatest in the association cortices. Although all gyri and sulci are present at birth, the depth of the sulci increases until two-thirds of the cortical surface is hidden in them.[12]

Genetic factors during development

The co-ordinated expression, in space and time, of many genes underlies neurodevelopment. Mutations in these 'neurodevelopmental genes' are increasingly being recognized as causes of developmental neurological disorders such as cortical dysplasia and epilepsy; they may also be relevant to learning disability and schizophrenia. Different gene families are involved in the major component processes of neurodevelopment, such as organogenesis, neurogenesis, neuronal migration, synaptogenesis, and programmed cell death (apoptosis).[14,15] The details are beyond the scope of this book, but a few examples are given here.

Neurotrophins (growth factors) are genes which, as their name suggests, are critical for neuronal growth and survival, especially via their influence on apoptosis which is promoted by insuffiency of neurotrophins such as nerve growth factor and inhibited by enhanced nerve growth factor functioning. The effects of neurotrophins are mediated by specific tyrosine kinase (Trk) receptors (Table 2.3.2.1). Classical neurotransmitters and their receptors are also involved in neurodevelopment, both directly in the formation of synaptic connections and indirectly through regulation of neurotrophins and Trk receptors; particular roles have been shown for glutamate, acting via *N*-methyl-D-aspartate receptors, as well as for γ-aminobutyric acid (GABA) and acetylcholine.

Table 2.3.2.1 Important neurotrophins, their sites of synthesis in the central nervous system, receptors, and target structures

Neurotrophin	Site of synthesis	Receptors	Target structures
NGF	Hippocampus Neocortex	TrkA, $p76^{NTR}$	Cholinergic neurones in the basal forebrain
BDNF	Hippocampus Neocortex	TrkB. $p75^{NTR}$	Dopaminergic neurones in the midbrain; retinal ganglionic cells; cholinergic neurones in the basal forebrain
NT-3	Hippocampus Cerebellum	TrkC, $p75^{NTR}$	Dopaminergic neurones in the midbrain; neurones of the nucleus mesencephalicus nervi trigemini; neurones of origin of the pyramidal tract

NGF, nerve growth factor; BDNF, brain-derived neurotrophic factor; NT-3, neurotrophin 3.

2.3.3 Neuroendocrinology

Charles B. Nemeroff and Gretchen N. Neigh

Definitions and principles

In the late 1950s, a controversy arose in endocrinology and neuroscience concerning whether neurones are capable of manufacturing and secreting hormones; that is to say, is it possible that certain neurones subserve endocrine functions? Much of the ensuing debate, which persisted for approximately two decades, was centred on two major findings. First, led by a husband and wife team, the Scharrers, a number of neurohistologists working with mammalian as well as with lower vertebrate and invertebrate species documented the presence—by both light and electron microscopy—of neurones that had all the characteristics of previously studied endocrine cells. They stained positive with the Gomori stain, which is claimed to be specific to endocrine tissues, and they incorporated granules or vesicles containing the endocrine substance purportedly released by these cells. The second major avenue of investigation centred around the brain's control of the secretion of the pituitary trophic hormones, which in turn were long known to control the secretion of the peripheral target endocrine hormones such as thyroid hormones, gonadal steroids, adrenal steroids, etc. A critical observation by several investigators had earlier demonstrated the existence of a vital neuroendocrine system, namely the magnocellular cells of the paraventricular nucleus of the hypothalamus that synthesized vasopressin and oxytocin, the nonapeptides that are transported down the axon to the nerve terminals of these neurones in the posterior pituitary (neurohypophysis) and released in response to physiological stimuli. For example, the release of vasopressin, or the antidiuretic hormone, as it is commonly named, acts as a critical regulator of fluid balance, and oxytocin is known to regulate the milk-letdown reflex during breast feeding.

It is now firmly established that neurones are indeed capable of functioning as true endocrine tissues, synthesizing and releasing substances, known as (neuro)hormones, which are released directly into the circulatory system and transported to distant sites of action. The release of vasopressin from the posterior pituitary gland and its action on the kidney is one often cited example; the action of the hypothalamic release and release-inhibiting factors on the anterior pituitary trophic hormone-producing cells is another.

Pleiotropic roles—endocrine factors and neurotransmitters

Although, it was clearly important to document the ability of neurones to function as neuroendocrine cells, particularly those in the central nervous system (CNS), the focus on an artificial classification system with clear demarcations of endocrine versus neuronal versus neuroendocrine, quickly lost its heuristic value. Indeed, we now recognize that the very same substance, often function at one site as an endocrine substance and at another as a neurotransmitter. Thus, adrenaline (epinephrine) functions as a hormone in the adrenal medulla and as a conventional neurotransmitter substance in the mammalian CNS. Similarly corticotrophin-releasing factor (CRF) functions as a true hormone in its role as a hypothalamic hypophysiotrophic factor in the hypothalamic anterior pituitary complex, yet it is apparently a 'conventional' neurotransmitter in cortical and limbic brain areas. It may act as a paracrine substance in the adrenal medulla (see Fig. 2.3.3.1). Thus, the field has progressed to the stage where we now strive to characterize the role of a particular chemical messenger in a particular region or endocrine axis. The traditional endocrine and neurotransmitter roles for several peptides alluded to above are firmly established, but the equally important paracrine roles for such substances, namely the secretion of a substance from one cell where it acts upon nearby cells, remain largely unexplored. This is, perhaps, best illustrated in the gastrointestinal tract where several peptides that function as hormones or neurotransmitter substances in other sites, including the CNS, act to influence local cellular function. Examples would include vasoactive intestinal peptide, cholecystokinin, and somatostatin.

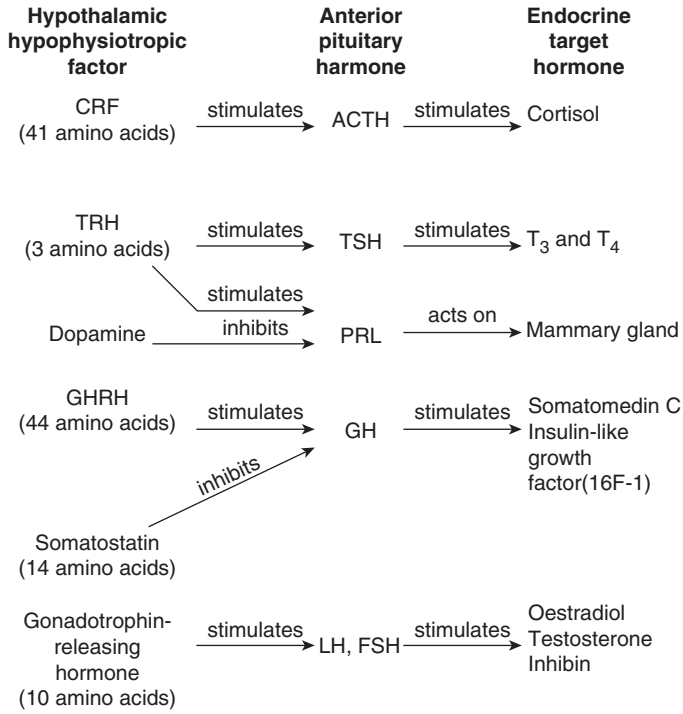

Fig. 2.3.3.1 Hormones of the hypothalamic-pituitary-end-organ axes: CRF, corticotrophin-releasing factor; TRH, thyrotrophin-releasing hormone; TSH, thyroid-stimulating hormone; T_3, tri-iodothyronine; T_4, thyroxine; PRL, prolactin; GHRH, growth-hormone releasing hormone; GH, growth hormone; LH, luteinizing hormone; FSH, follicle-stimulating hormone.

Neuroendocrinology

Neuroendocrinology thus, comprises the study of the endocrine role of neuronal or glial cells as well as the neural regulation of endocrine secretion, with a major portion of the latter consisting of the biology of the various hypothalamic-pituitary-end-organ axes and the major neurohypophyseal hormones, vasopressin and oxytocin. Because of the elegant and precise regulation of peripheral endocrine hormone secretion, afforded in part by the feedback of peripherally secreted hormones at pituitary and a variety of CNS sites, the actions of such hormones on the brain has become an integral part of this discipline. The related discipline of **psychoneuroendocrinology** arose with the realization that there are binding sites (receptors) for peripheral hormones within the CNS that have little to do with the feedback regulation of the hypothalamic-pituitary-end-organ axes, and the further recognition of the seminal role of the CNS in regulating endocrine function, for example in the effect of stress on several such measures. Often cited as beginning with the pioneering observations of Berthold, who reported that removing roosters' testosterone-secreting gonads abolished their sexual behaviour, psychoneuroendocrinology has been expanded to include the effects of hormones on behaviour, as well as the study of endocrine alterations in psychiatric disorders and, the converse, psychiatric symptomatology in endocrine disorders. Indeed, this stepchild of neuroendocrinology and psychosomatic medicine has been one of the most rapidly growing areas of research in psychiatry, now boasting an international society (International Society of Psychoneuroendocrinology), an annual meeting, and its own journal (Psychoneuroendocrinology).

Neuroendocrine window

One of the most commonly used strategies in the 1970s and 1980s, still in occasional use today, is the so-called neuroendocrine 'window' strategy. Until the relatively recent development and availability of functional brain-imaging techniques, the brain remained relatively inaccessible for study, with the exception of cerebrospinal fluid (CSF) and postmortem tissue studies. With the emergence of the monoamine theories of mood disorders and schizophrenia, many investigators attempted to draw conclusions about the activity of noradrenergic, serotonergic, and dopaminergic circuits in patients with various psychiatric disorders by measuring the basal and stimulated secretion of pituitary and end-organ hormones in plasma. There is little doubt that such an approach has severe limitations, but the results, now coupled with more modern approaches, have contributed to the substantial progress made in elucidating the pathophysiology of mood and anxiety disorders and, to a considerably lesser extent, schizophrenia. One assumption of the neuroendocrine window strategy is that the monoamine-containing neurones that regulate endocrine secretion are disordered (or not disordered) to the same extent as those monoamine circuits posited to be involved in the pathophysiology of the disorder under study. Such an assumption may well be true in neural circuits in which the cells of origin are found in a circumscribed area and project to widely diffused areas of the CNS (for example, the serotonergic and noradrenergic projections to the forebrain from the raphe and locus coeruleus cells in the brainstem, respectively). In contrast are the various dopaminergic circuits in the CNS, with their well-known topographic point-to-point

distribution. Thus, there is little reason to believe that the activity of the major dopamine-containing hypothalamic projection, the tuberoinfundibular system, with perikarya in the arcuate and periventricular hypothalamic nuclei and projections to the median eminence, is in any way related to the activity of the mesolimbicocortical dopamine pathway, with cell bodies in the ventral tegmentum of the midbrain and projections to the nucleus accumbens, amygdala, and cortical regions. This latter pathway has been implicated in the pathophysiology of schizophrenia. Thus, the study of the dopamine modulation of prolactin secretion in schizophrenia is unlikely to inform about the nature of limbic and cortical dopamine neuronal alterations in this devastating disorder.

Hypothalamic-pituitary-end-organ axes

Because a large portion of neuroendocrinology relevant to psychiatry is concerned with the hypothalamic-pituitary-end-organ axes, alterations in each of these systems in patients with a major psychiatric disorder are described later in this chapter. To avoid repetition, a generic description of the hierarchical organization of the various components of these systems is briefly outlined here. More comprehensive reviews of this subject are available.[1] In general, the hypothalamus contains neurones that synthesize release and release-inhibiting factors. These peptide hormones, summarized in Fig. 2.3.3.1, are synthesized by a process beginning with transcription of the DNA sequence for the peptide prohormone. After translation in the endoplasmic reticulum and processing during axonal transport and packaging in the vesicles in the nerve terminals, the now biologically active peptide is released from nerve terminals in the median eminence and secreted into the primary plexus of the hypothalamohypophyseal portal vessels. They are transported humorally to the sinusoids of the adenohypophysis where they act on specific membrane receptors on their specific target: the pituitary trophic hormone-producing cells. Activation of their receptors results in the release or inhibition of release of the pituitary trophic hormone. The increase or decrease in pituitary trophic hormone secretion produces a corresponding increase or decrease in end-organ hormone secretion. Thus **gonadotrophin-releasing hormone** (**GnRH**), a decapeptide, induces the release of the gonadotrophins, luteinizing hormone, and follicle-stimulating hormone from the anterior pituitary gland, which in turn stimulate the secretion of oestrogen and progesterone in women, and testosterone in men. The exogenous, intravenous administration of GnRH, comprises the GnRH stimulation test, a very sensitive test of hypothalamic-pituitary-gonadal (**HPG**) axis activity. Such stimulation tests are thought to be a sensitive measure of the activity of the axis because it is influenced by GnRH secretion, gonadotrophin secretion, and feedback at the pituitary and brain by gonadal steroids. The organization of, and major feedback mechanisms thus far demonstrated in the hypothalamic–anterior pituitary–end-organ axes are illustrated in Fig. 2.3.3.2.

In summary, neuroendocrinology (and the related discipline psychoneuroendocrinology) broadly encompasses the study of the following:

- the neural regulation of peripheral, target-organ hormone secretions, pituitary trophic hormone secretions, and secretions of the hypothalamic-hypophysiotrophic hormones;
- the role of neurotransmitter systems in the regulation of the above;

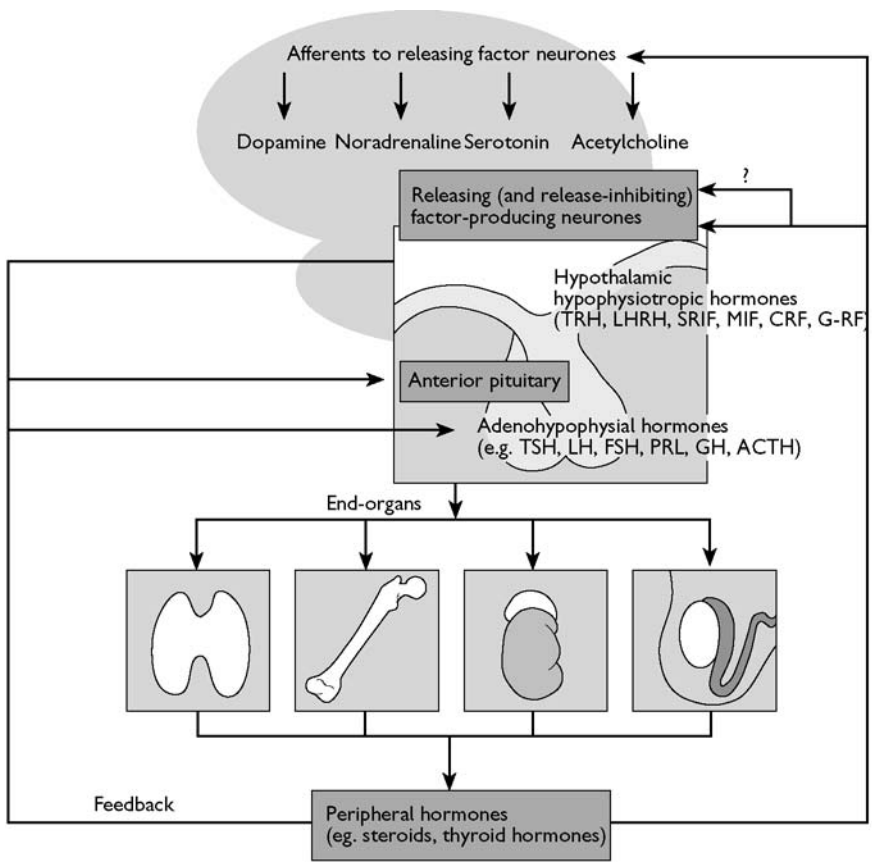

Fig. 2.3.3.2 Relationships between brain neurotransmitter systems, hypothalamic peptidergic (releasing-factor) neurones, anterior pituitary, and peripheral endocrine organs, illustrating established feedback loops: LHRH, luteinizing-hormone releasing hormone; SRIF, somatostatin; MIF, melanotrophin release-inhibiting factor; GHRF, growth-hormone releasing factor. Other abbreviations as in Fig. 2.3.3.1.

- the hormone effects of each of the endocrine axes on the CNS, alterations in the activity of the various endocrine axes in major psychiatric disorders, and conversely the behavioural consequences of endocrinopathies;
- the effects of target gland hormones on the CNS in normal individuals—for instance, the effects of synthetic glucocorticoids on memory processes.

The hypothalamic-pituitary-thyroid axis

It has been recognized for more than a century that adult patients with hypothyroidism exhibit profound disturbances in CNS function, including cognitive impairment and depression. In more recent years, attention has focused on more subtle alterations of the hypothalamic-pituitary-thyroid (**HPT**) axis in depressed patients. **Hypothyroidism** is most frequently subclassified as in four grades as follows:

- Grade 1 hypothyroidism is classic primary hypothyroidism (increased **thyroid-stimulating hormone** (**TSH**), decreased peripheral thyroid hormone concentrations, and an increased TSH response to **thyrotrophin-releasing hormone** (**TRH**)).
- Grade 2 hypothyroidism is characterized by normal, basal thyroid-hormone concentrations, but an increase in basal TSH concentrations and an exaggerated TSH response to TRH.
- Grade 3 hypothyroidism can only be detected by a TRH-stimulation test; patients have a normal basal thyroid hormone and TSH concentrations, but an exaggerated TSH response to TRH.
- Grade 4 hypothyroidism is defined as normal findings on the three thyroid axis function tests noted above, but the patients have antithyroid antibodies.

Left untreated, most, if not all, patients' progress from grade 4 to grade 1 hypothyroidism. Several studies have revealed an inordinately high rate of HPT axis dysfunction, largely hypothyroidism, in patients with major depression. In our pilot study, patients with comorbid depression and anxiety were especially likely to exhibit HPT axis abnormalities, especially the presence of grade 4 hypothyroidism, i.e. symptomless autoimmune thyroiditis. Patients with other major psychiatric diagnoses including schizophrenia and anxiety disorders appear to exhibit normal HPT axis function. For patients who require thyroid hormone replacement secondary to thyroid ablation, Bunevicius *et al.*[2] recently reported that treatment with a combination of **tri-iodothyronine** (**T3**) and **thyroxine** (**T4**) is optimal for mood and cognitive function, rather than the standard medication of T_4 alone.

In addition, a blunted TSH response to TRH is observed in approximately 25 per cent of patients with major depression. This observation, first reported by Prange *et al.*[3] and Kastin *et al.*,[4] more than 25 years ago, has been replicated in many studies. Unfortunately, the pathophysiological underpinnings of this observation remain obscure, though there is considerable evidence that it may be due, at least in part, to chronic hypersecretion of TRH and subsequent TRH-receptor downregulation in the anterior pituitary gland. Indeed, our group[5] and others have reported elevated TRH concentrations in the CSF of drug-free depressed patients.

TRH was the first of the hypothalamic-releasing factors to be chemically characterized. Immunohistochemical and radio-immunoassay methods revealed a heterogeneous brain distribution of TRH. This was the first in a series of experimental results that led to the inexorable conclusion that this peptide, and, as discussed below, other release and release-inhibiting hormones, function in extrahypothalamic brain regions as neurotransmitter substances. Thus, TRH has been shown to produce direct brain effects, independent of its action on the pituitary thyrotrophs. Antidepressant effects of intravenously and intrathecally applied TRH have been reported,[3] but the results have not been confirmed in large, controlled clinical trials.[6] In contrast, several reports over the last 30 years have documented the efficacy of T_3 (25–50 mg daily) in both accelerating the rate of onset of antidepressant response,[7] and in converting antidepressant non responders to responders,[8] the later confirmed in the recent NIMH-funded STAR-D trial.[9] Studies also suggest that T_4 (100–300 μg daily) supplementation is a viable strategy for increasing the response to antidepressants.[10] These studies were initiated when it became apparent that patients (and laboratory animals) with hypothyroidism do not respond to antidepressant agents. This led to the hypothesis that patients with subtle forms of hypothyroidism (grades 2–4) may not respond optimally to antidepressants unless they are adequately treated with exogenous thyroid hormone. With the cloning of the thyroid hormone receptor and its localization within the CNS, studies of its regulation in depression, as well as the regulation of TRH biosynthesis, can now be conducted in postmortem brain tissue.

The hypothalamic-pituitary-adrenal axis

Although, first identified in crude form in 1955 by Saffran *et al.*,[11] **corticotrophin-releasing factor** (**CRF**) was not chemically identified until 1981 by Vale and colleagues.[12] This discovery finally permitted the comprehensive assessment of hypothalamic-pituitary-adrenal (**HPA**) axis activity, and also led to scrutiny of the role of this peptide, which is now known to co-ordinate the endocrine, immune, autonomic, and behavioural effects of stress in a variety of psychiatric disorders.

CRF hypothesis of depression

Most investigators would agree that the most important finding in all of biological psychiatry is the hyperactivity of the HPA axis observed in a significant subgroup of patients with major depression. The magnitude of HPA axis hyperactivity has been reported to be correlated to the severity of the depression.[13] Literally thousands of reports on this subject have appeared since the original and independent observations of research groups led by Board, Bunney, and Hamburg, as well as by Carroll, Sachar, Stokes, and Besser. These studies, conducted from the late 1950s to the 1980s, applied the tests largely developed for the diagnosis of Cushing's syndrome to patients with major depression and other psychiatric disorders. A panoply of such tests, ranging from urinary free-cortisol, to CSF levels of cortisol, to the dexamethasone suppression test led to the inexorable conclusion that a sizeable percentage of depressed patients exhibited HPA axis hyperactivity. Our group and others, focusing on the mechanism(s) responsible for these findings, documented adrenocortical enlargement[14] and pituitary gland enlargement[15] in depressed patients, using CT and magnetic resonance imaging (**MRI**) respectively. The hypersecretion of cortisol is associated with hypersecretion of ACTH (and its co-secreted

product of the precursor pro-opiomelanocortin), which due to its trophic properties also causes adrenocortical gland enlargement. Both direct measurements of CRF in CSF,[16] and of CRF and gene expression for CRF (CRF mRNA expression) in postmortem tissue confirmed the hypothesized hypersecretion of CRF in depressed patients.[17] In addition, CRF hypersecretion results in CRF1 receptor downregulation observed in both receptor binding studies[18] and CRF mRNA expression studies conducted on post-mortem tissue from suicide victims.[19] Like the hypersecretion of cortisol, CRF hypersecretion normalizes upon recovery from depression. Indeed, there is now considerable evidence, derived from both preclinical and clinical studies, that CRF neuronal hyperactivity is reduced by treatment with several antidepressants including paroxetine and fluoxetine, the selective serotonin-reuptake inhibitors (**SSRIs**), reboxetine (the noradrenaline-reuptake inhibitor), venlafaxine (the dual noradrenaline/serotonin-reuptake inhibitor), desipramine (the tricyclic antidepressant), and tranylcypromine (the monoamine oxidase inhibitor), as well as by electroconvulsive therapy.[20]

When patients who are drug free but depressed are given CRF intravenously, they exhibit, as a group, a blunted ACTH response compared with normal control subjects. This is believed to be secondary to either the downregulation of CRF receptors on the corticotrophs after long-standing CRF hypersecretion and/or intact negative feedback of the hypersecreted cortisol at anterior pituitary and higher CNS centres. As with the other measures of HPA axis function, this endocrine abnormality normalizes upon recovery from depression. Indeed, persistent alterations in HPA axis function, whether due to dexamethasone non-suppression or CSF-CRF hypersecretion, is the harbinger of a poor response to antidepressant treatment. In recent years, Holsboer *et al.*[21] have pioneered the use of the combined **dexamethasone-CRF test**, in which patients are given the synthetic glucocorticoid and the following day receive a standardized CRF stimulation test. The results reveal that this test has a much greater sensitivity in detecting increases in HPA axis activity; it has now been used to detect axis alterations in the first-degree relatives of depressed patients who have never been symptomatic, raising for the first time the question of a trait (vulnerability) component to this measure.[22]

Space constraints preclude a more comprehensive discussion of this rich literature, but a few additional points are certainly worth interjecting. First, a robust preclinical literature has documented the depressogenic and anxiogenic effects of exogenously administered CRF in laboratory animals. When CRF was directly injected into the central nervous system it produced effects reminiscent of the cardinal symptoms of depression in patients, including decreased libido, reduced appetite and weight loss, sleep disturbances, and neophobia. Indeed, newly developed CRF1-receptor antagonists represent a novel putative class of antidepressants. Such compounds exhibit activity in virtually every preclinical screen for antidepressants and anxiolytics currently employed, and in an open study a CRF1 receptor antagonist was shown to possess antidepressant properties.[23] A second CRF receptor, the CRF2 receptor, exhibits genetic polymorphism (i.e. it occurs in more than one naturally occurring isoform or splice variant), and it is believed to utilize the urocortins as endogenous ligands. The long-term consequences of cortisol hypersecretion in depression are just now being scrutinized. One such sequela appears to be neuronal loss in the hippocampus, one of the major feedback sites for glucocorticoids in the CNS. This has now been documented by structural brain-imaging studies that utilized MRI techniques.[24] If the degeneration of neurones that represent glucocorticoid feedback sites indeed occur in depressed patients, then this should further increase HPA axis hyperactivity, which would explain the many reports of increasing adrenocortical hyperactivity of elderly depressed patients when compared with matched younger depressed patients.

Future studies will focus on the development of positron emission tomography (**PET**) ligands for both the glucocorticoid receptor and the CRF receptor, the role of the CRF binding protein—a unique protein which binds CRF in extracellular fluid and in plasma, preventing its availability to act on its receptor—and the role of the CRF peptidase, which degrades the peptide, in normal and pathological states. Finally, are the studies from our group and others, which have documented the long-term persistent increases in the HPA axis and extrahypothalamic CRF neuronal activity after exposure to early untoward life events—for example, child abuse and neglect in both laboratory animals (rats and non-human primates) as well as in both male and female patients.[20,25,26] This phenomenon has been posited to underlie the now well-documented association between early abuse and neglect and increased vulnerability to mood disorders.[27–29] Indeed, we have recently demonstrated single nucleotide polymorphisms (SNPs) of the CRF1 receptor that confer vulnerability or resistance to the development of depression after exposure to child abuse.[30] An early intervention strategy using CRF receptor antagonists may prevent such long-term alterations in the central nervous system.

HPA axis and other psychiatric disorders

HPA axis alterations have also been investigated in other psychiatric disorders. When depression is comorbid with a variety of other disorders such as multiple sclerosis, Alzheimer's disease, multi-infarct dementia, Huntington's disease, and others, both CRF hypersecretion and HPA axis hyperactivity are common. There is little evidence for HPA axis dysfunction in schizophrenia. In contrast, at least one anxiety disorder, post-traumatic stress disorder, is associated with extrahypothalamic CRF hypersecretion, as evidenced by elevated CSF concentrations of CRF,[31] but normal or reduced measures of adrenocortical activity. Finally, CRF neuronal degeneration is now well known to occur in the cerebral cortex of patients with Alzheimer's disease,[32, 33] an effect which temporally occurs prior to the better-studied cholinergic neuronal involvement. With the reduction in CRF concentrations in the cerebral cortex there is a reciprocal increase in CRF receptor density. Whether modification of the disease-associated effects on the CRF neuronal system in the cortex and hippocampus represents a novel strategy for the treatment of this common dementing disorder remains unclear at the present time.

The hypothalamic-growth hormone axis

Although the HPA and HPT axes have been more closely scrutinized in patients with psychiatric disorders, there is virtually universal agreement that the blunted growth-hormone response to a variety of provocative stimuli (particularly clonidine, an α2-adrenergic agonist) in depressed patients is the most consistent finding in affective disorders research.[34] The mechanism underlying this

phenomenon remains obscure, but it is of particular interest that, at least in some studies, it appears to persist upon recovery from depression, suggesting that it is a trait marker for depression vulnerability. There are reports of similar findings with other growth hormone-provocative stimuli, such as the use of apomorphine, desipramine, or levodopa. In addition, the blunted growth-hormone response to clonidine in depressed patients is particularly robust in those who have recently attempted suicide. Clearly, further work in this area is warranted, especially in the context of several reports of alterations in basal growth-hormone secretion in this disorder. The nature of this alteration is a reduction in the normal nocturnal rise in growth-hormone secretion, though this is not a universally agreed-upon finding. Alterations in growth-hormone secretion in other psychiatric disorders (particularly schizophrenia) have also been reported, though the results may have largely been due to long-term treatment of such patients with dopamine-receptor antagonists, antipsychotic drugs.

The secretion of growth hormone and the regulation of this axis are distinct from that of the other endocrine axes for several reasons. First, this is the one axis in which two hypothalamic-hypophysiotrophic hormones have unequivocally been shown to play a physiological role. The first discovered was **somatostatin** or **growth hormone-inhibiting hormone**. It is distributed in the CNS not only in cells of the periventricular nucleus of the hypothalamus, which projects to the median eminence, but in a variety of extrahypothalamic areas as well. Indeed, somatostatin is known to function as a CNS neurotransmitter and is of particular interest to psychiatrists because of its early involvement in the Alzheimer's disease process. Our group and others have documented the marked reduction in somatostatin concentrations in this dementing disorder.[33] In addition, somatostatin concentrations are markedly elevated in the basal ganglia of patients with Huntington's disease;[35] the pathological implications of this finding remain obscure. In contrast to the other peptide receptors described above in which one or at most two receptor subtypes have been identified, several distinct somatostatin receptor subtypes have now been structurally identified. Such diversity suggests the possibility of specific receptor-subtype agonists and antagonists as putative therapeutic agents.

Several years after the elucidation of the structure of somatostatin, the long-postulated **growth hormone-releasing factor** (**GHRF**) was found. This peptide has the most limited CNS distribution of all the hypothalamic-releasing hormones thus far studied. The vast majority of the peptide is found in the arcuate nucleus of the hypothalamus from where it projects nerve terminals to the median eminence. Unlike the other axes, the growth-hormone axis is also unique in not having a single target endocrine gland. Indeed, growth hormone does stimulate the release of **somatomedin C** from the liver and it also exerts direct effects on a variety of targets including bone and muscle. Most, but not all, investigators have reported a blunted growth-hormone response to GHRF in depressed patients, but the total number of patients studied pales in comparison to the TRH- and CRF-stimulation test data. There are no data published on somatomedin C responses to GHRF in depressed patients. No published studies are available in which GHRF concentrations or GHRF-mRNA expression have been studied in postmortem tissue of depressed patients and matched controls, an obvious study in view of the data reviewed above.

The hypothalamic-pituitary-gonadal axis

In view of the remarkable gender differences in the prevalence rate of depression, the relatively high rates of postpartum depression, as well as the reduction in libido that is so characteristic of depression, it is plausible to posit a reduction in HPG axis activity in depressed patients. Therefore, it is somewhat surprising that so little research has been conducted on HPG axis activity in depression and other psychiatric disorders. Indeed, a comprehensive database on this extraordinarily important area is simply not available, but the field has been reviewed.[36] A series of older studies documented no differences in basal gonadotrophin levels in depressed patients when compared to controls. The **gonadotrophin-releasing hormone** (**GnRH**) stimulation test has only been administered to a relatively small number of depressed patients; although the results revealed a blunted or normal response, no firm conclusions can be drawn from this limited data set. Indeed, such studies require control for menopausal status, menstrual-cycle phase, use of oral contraceptives, as well as the measurement of baseline progesterone, oestrogen, and gonadotrophin plasma concentrations. One remarkable finding relevant to these questions is the remarkable effectiveness of the GnRH agonist, leuprolide, in the treatment of the premenstrual syndrome. It is believed to act by producing a chemical ovariectomy through a marked downregulation of adenohypophyseal GnRH receptors and the expected resultant reduction in gonadotrophin and gonadal steroid secretion. Long-term treatment with this compound could theoretically result in bone-density reductions and a risk of cardiovascular disease. Therefore, supplementation with oestrogen and progesterone has been suggested in combination with leuprolide, though there are reports that such a strategy reduces the effectiveness of the treatment.

GnRH was the second of the hypothalamic-hypophysiotrophic hormones to be chemically characterized. It is relatively limited in distribution to hypothalamic regions and to the preoptic area and septum. It stimulates the secretion of both luteinizing hormone and follicle-stimulating hormone in both men and women. GnRH is known to act by stimulating GnRH receptors in the anterior pituitary gland, which results in the increased synthesis and release of the pituitary gonadotrophins, in turn causing the release of oestrogen and progesterone in women and testosterone in men. There is some evidence that oestrogens, which have receptors localized extensively throughout the CNS, may possess some antidepressant activity, in perimenopausal and postpartum depression, though the data is far from clear.[37] There are hints from the clinical trial literature that postmenopausal women on oestrogen replacement may respond better to treatment with fluoxetine than women who are not receiving such treatment,[38] though the database is small and fraught with many confounds. Further, emphasizing the potential role of sex steroids in affective disorders is the clinical study that demonstrates that in hypogonadal depressed men, testosterone treatment possessed antidepressant properties.[39]

The hypothalamic-prolactin axis

Prolactin, a pituitary hormone which acts on the mammary gland, plays a critical role in lactation. Unlike the other axes described, this axis is unique in having a non-peptide release-inhibiting factor, dopamine. In addition, although there is relatively strong

evidence for the existence of a prolactin-releasing factor, its isolation and characterization has not yet been realized. One of the difficulties in completing this task is the presence of TRH, which is a potent prolactin-releasing factor, and may in fact function physiologically in this regard. Interestingly, although the TSH response to TRH in depressed patients is often blunted, the prolactin response is not. Although the results are not unequivocal, most studies have not observed alterations of prolactin secretion in depressed patients.[40] In contrast to this small database is a remarkably large database on the use of provocative tests of prolactin secretion in patients with psychiatric disorders. To summarize briefly, the prolactin response to agents that increase serotonergic neurotransmission such as l-tryptophan, 5-hydroxytryptophan (5-HTP), l-(+)- and d-(+)-fenfluramine, clomipramine, and also to direct serotonin-receptor agonists, is blunted in depressed patients, as well as in patients with cluster-B personality disorder and borderline personality disorder. The available data would suggest that this blunted prolactin response is mediated by alterations in 5-HT1A-receptor responsiveness.

Discussion and summary

Although, the hypothesis that the neuroendocrine window strategy would ultimately provide the long searched for information concerning the nature of monoamine circuit alterations in patients with psychiatric disorders has never been realized, the approach has led to major advances in biological psychiatry. It has led to the **CRF hypothesis of depression**, which is supported by a considerable multidisciplinary database, and this in turn has directed the field towards the development of novel therapeutic approaches, namely CRF receptor antagonists. It also apparently explains the neurobiological mechanisms responsible for the increase in depression (first postulated by Freud in the early part of the 20th century) in patients exposed to trauma during their early life. If CRF is indeed the 'black bile' of depression, responsible for the endocrinopathy of depression, as well as several of the other cardinal features of this disorder, then CRF-receptor antagonists should represent a novel class of antidepressants that will be a welcome addition to the armamentarium. Indeed, a number of pharmaceutical companies are now testing CRF-receptor antagonists as novel anxiolytics and antidepressants in preclinical studies and clinical trials.

In addition to the now widely replicated HPA axis and CRF alterations in depression, are the HPT axis abnormalities. Most depressed patients, in fact, exhibit alterations in one of these two axes. Furthermore, there is the widely replicated blunting of the growth-hormone response to clonidine and other provocative stimuli and the blunted prolactin response to serotonergic stimuli in depressed patients. The vast majority of studies have focused on patients with mood disorders, particularly unipolar depression. Clearly other disorders, including eating disorders, anxiety disorders, schizophrenia, and axis II diagnoses should also be critically evaluated and compared to the literature on depression. The original neuroendocrine window strategy may well have failed in terms of gleaning information about monoamine-circuit activity, but the mechanistic studies that followed have been remarkably fruitful. As repeatedly noted above, the availability of ligands that can be utilized with positron-emission tomography to determine peptide-receptor alterations in the brain and pituitary of patients with psychiatric disorders will advance the field, as will the long-elusive ability to measure receptors for the endocrine target hormones (glucocorticoids, oestrogens, thyroid hormones, etc.) in the brains of patients with these severe mental illnesses.

Finally, it is important to note the increasing database suggesting that depression is a systemic disease with major implications for vulnerability to other disorders. Thus, depressed patients are much more likely to develop coronary artery disease and stroke, and perhaps cancer. They have been shown to have reduced bone density, rendering them more at risk for hip fracture and increasing a variety of measures of inflammation. Such findings may well be mediated by the described endocrine alterations in depression. This should provide a further impetus for investigating the neuroendocrinology of psychiatric disorders.

2.3.4 Neurotransmitters and signalling

Trevor Sharp

By the end of the 19th century it was recognized that signalling from one neurone to the next occurs at specialized contacts – Sherrington coined the term 'synapse'. It took another 50 years for scientists to accept that information passes between neurones principally through the movement across synapses of chemicals and not electrical current. Today changes in chemical transmission at brain synapses are accepted as being key to the successful drug treatment, and cause, of many forms of psychiatric illness. This article focuses on general aspects of chemical transmission and describes some recent advances relevant to psychiatry that point the direction of future research.

Otto Loewi identified the first chemical neurotransmitter, acetylcholine, in 1921. Today evidence suggests that there are many tens if not hundreds of molecules in the brain that have neurotransmitter properties. These molecules include not only the three major classes of neurotransmitters—amines, amino acids and neuropeptides—but also specific purines, trophic factors, inflammatory mediators (chemokines and cytokines), lipids, and even gases. Examples of molecules that serve neurotransmitter functions in the brain are listed in Table 2.3.4.1. This list is not exhaustive and more are likely to be discovered.

Table 2.3.4.1 Examples of neurotransmitters in the brain

Chemical class	Example
Amines	Dopamine Noradrenaline 5-hydroxytryptamine Histamine Melatonin Acetylcholine
Amino acids	γ-aminobutyric acid (GABA) Glutamate Glycine
Neuropeptides	Substance P Leu- and Met-enkephalin Galanin
Purines	Adenosine Adenosine triphosphate (ATP)
Neurotrophic factors#	Neurotrophins (e.g. BDNF, NGF) Insulin-like growth factor (IGF) Vascular endothelial growth factor (VEGF)
Cytokines*	Interleukin-1 (IL-1) Tumor necrosis factor-α (TNF-α)
Chemokines*	CC Chemokines (e.g. Interleukin-8 [IL-8]) CXC Chemokines
Endocannabinoids#	Anandamide 2-Arachidonyl-glycerol (2-AG)
Gases#	Nitric oxide (NO) Carbon monoxide (CO)

*Putative class of neurotransmitters.

#Retrograde messengers.

Basic principles of chemical transmission

Typically a molecule is classified as a neurotransmitter if it is localized in neurones, released from nerve terminals (and often soma and dendrites) on membrane depolarization, and exerts physiological and molecular effects through acting on postsynaptic receptors. However, the degree to which a particular molecule satisfies these criteria may vary. For example, the term 'neurotransmitter' was once used to cover only those molecules that exert fast synaptic effects, whereas molecules that exerted slow synaptic effects were termed 'neuromodulators'. These distinctions are less useful today (and will not be used herein) as it is recognized that many molecules are capable of exerting both fast and slow synaptic effects, depending on the receptor activated. Moreover, it is now recognized that certain molecules transfer information at a synapse in a 'retrograde' direction. In this case the molecules are located in the postsynaptic neurone and, when their synthesis is activated, the molecule diffuses across the synapse to act presynaptically.

The general principles of the chemical transmission at central synapses are similar across all neurotransmitter molecules but there are often important differences between molecules especially across molecules of different size, in particular small molecule transmitters such as amines and amino acids, and peptides (Fig. 2.3.4.1).[1]

Small molecule neurotransmitters

Typically small neurotransmitter molecules such as amines and amino acids are synthesized at the nerve terminal by one or a few enzymatic steps and packaged in small vesicles via proton-coupled vesicular transporters, prior to release into the synapse on arrival of a depolarizing action potential. After release, the neurotransmitter diffuses across the synapse to interact with receptors on the postsynaptic neurone to trigger electrical and/or biochemical changes in the postsynaptic cell. Small molecule neurotransmitters are also released from the soma and dendrites of neurones, one purpose being to interact with presynaptic receptors that signal negative feedback to the neurone.

Once released the small neurotransmitters are selectively taken up by sodium-coupled transporters that are located in the plasma membrane of the nerve terminal or neighbouring cells (neurones or glial cells). This transport terminates transmission at the postsynaptic receptor, maintains low extracellular levels of transmitter, and allows reuse of the neurotransmitter by the neurone. Transport into the nerve terminal also presents the transmitter to catabolic enzymes to generate biologically inactive metabolites, for instance, monoamine oxidase in the case of the amine transmitters.

Neurotransmitter transporters

Advances in cloning technology has lead to new discoveries regarding the structural and pharmacological identity of transporters located on the plasma membrane, as well as vesicular transporters

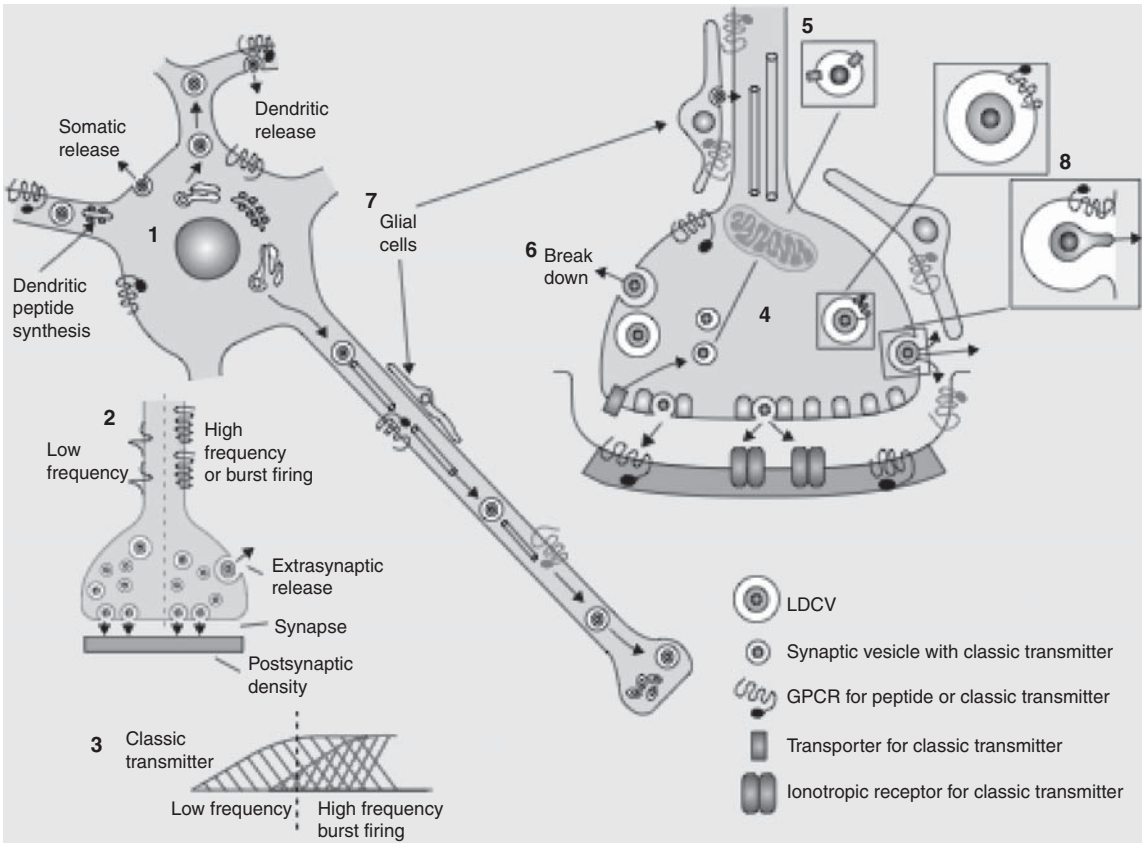

Fig. 2.3.4.1 Summary of the principal steps involved in chemical neurotransmission in the brain. Neuropeptides are synthesized in the cell body and then packaged in large dense core vesicles (LDCVs) that are transported into axons and dendrites (1). Small 'classic' neurotransmitters (e.g. amines and amino acids), are synthesized at the nerve terminal and stored in synaptic vesicles, and released into the synaptic cleft (2). LDCVs contain proteolytic enzymes (convertases) that generate the active neuropeptide from the precursor. Neurotransmitter receptors are either of the G-protein-coupled (metabotropic) or ligand-gated ion channel (ionotropic) type and are present on cell soma, dendrites, axons, and nerve endings (1,4). The small neurotransmitters are released during low and high frequency firing, whereas neuropeptides are preferentially released under burst or high frequency firing (2–4). Small transmitters have reuptake mechanisms (transporters) at both the plasma membrane and the vesicle membrane (5), which terminate neurotransmitter action and allow recycling (4). In contrast, neuropeptides are broken down by extracellular peptidases (6), and replacement occurs via axonal transport. Glial cells can express neurotransmitter receptors and transporters (7). Receptors are trafficked to and from the cell membrane by G-protein interacting proteins (8). Reprinted from The Lancet Neurology, 2, Hokfelt T, Bratfai T, Bloom F, Neuropeptides: opportunities for drug discovery, 465, copyright 2003, with permission from Elsevier.

located inside the nerve terminal.[2] The latter transporters concentrate transmitters in synaptic vesicles prior to release and play a key role in determining the neurotransmitter phenotype of a neurone.[3] A summary of plasma membrane and vesicular transporters is given in Table 2.3.4.2.

Plasma membrane transporters

Specific plasma membrane transporters for the amine neurotransmitters, dopamine (DAT), noradrenaline (NET), 5-HT (SERT), have been identified, sequenced and, investigated in detail at the molecular level because they are the site of action of stimulants such as amphetamines and cocaine, as well as many antidepressant drugs.[2] Indeed, the drug-binding site and the precise molecular mechanism of transporter inhibition by tricyclic antidepressant drugs have recently been revealed.[4]

Molecular cloning techniques have uncovered the genes for four transporters for the inhibitory neurotransmitter GABA; GAT-1, GAT-2, GAT-3 and BTG-1, the latter being localized primarily in the kidney. These transporters are highly homologous but pharmacologically distinct, with GAT-1 and GAT-3 being the most abundant subtypes and present on both neurones and glial cells. Although the significance of these transporters is yet to be fully understood, they display overlapping but different expression patterns in the CNS, suggesting distinct functional roles. The anticonvulsant effect of tiagabine is likely mediated by blockade of GAT-1, and there is much scope for new GABA uptake inhibitors of as yet unclear utility.

Glycine, another inhibitory amino acid transmitter, also has specific transporters located preferentially on the plasma membranes of glial cells in the forebrain (GLYT1) and neurones of the hindbrain and spinal cord (GLYT2). Interestingly, glycine is a positive allosteric co-modulator of glutamate NMDA receptors, and glycine

Table 2.3.4.2 Example of neurotransmitter transporters in the brain

Neurotransmitter	Transporter name
Plasma membrane transporters	
Dopamine	DAT
Noradrenaline	NET
5-Hydroxytryptamine	SERT
GABA	GAT-1
	GAT-2
	GAT-3
	BGT-1 (primarily in kidney)
Glutamate	EAAT-1 (GLAST1)
	EAAT-2 (GLT-1)
	EAAT-3 (EAAC1)
	EAAT-4
	EAAT-5
Glycine	GLYT-1
	GLYT-2
Acetylcholine (choline)	CHT
Vesicular transporters	
Monoamines (dopamine, noradrenaline, 5-HT, histamine)	VMAT1
	VMAT2
GABA	
Glutamate	VGAT
	VGLUT1
	VGLUT2
Acetylcholine	VGLUT3
	VAchT

transport blockade may offer a means to facilitate the functioning of this receptor without incurring excitotoxic effects. The antipsychotic potential of glycine transport blockers is currently under investigation because of consistent evidence of a link between the symptoms of schizophrenia and low glutamate function.[2]

Four transporters for the excitatory amino acid neurotransmitter, glutamate, have been cloned; EAAT1 (excitatory amino acid transporter1; synonym GLAST), EAAT2 (synonym GLT1), EAAT3, EAAT4, and EAAT5.[5] These transporters are located on both neurones (EAAT3) and glial cells (predominantly EAAT1/2) and serve to maintain low extracellular concentrations of glutamate, as well as providing a source of intracellular glutamate for metabolism. Whilst pharmacological blockade of glutamate transport increases excitotoxicity, pharmacologically enhanced EAAT expression appears to be neuroprotective.[6]

Vesicular transporters

Vesicular monoamine transporter 2 (VMAT2) has been identified and shown to be present in neurones of dopamine, noradrenaline and 5-HT (and histamine). In addition, vesicular monoamine transporter 1 (VMAT1) is an integral protein in the membrane of secretory vesicles of neuroendocrine and endocrine cells. Reserpine is a blocker of VMAT and causes depletion of amines, and the drug's tranquillizer effects are directly linked to this action. Acetylcholine is loaded into synaptic vesicles by a distinct transporter, VAchT.

Three homologous vesicular transporters for glutamate, VGLUT1, VGLUT2, and VGLUT3, have been cloned and characterized at the molecular level. Whilst all possess similar molecular properties, they are expressed on different neurone populations.[3] Interestingly, VGLUT3 is found in amine-containing neurones, raising the possibility of glutamate being a co-transmitter in these neurones. The vesicular transporter for GABA is VGAT. Loss of VGAT causes a drastic reduction in release of not only GABA but also glycine, indicating that glycinergic neurones do not express a separate vesicular glycine transporter.

Neuropeptides

Following the chemical identification of the first neuropeptide Substance P in 1971, evidence has accumulated that numerous peptides play neurotransmitter roles in the brain.[1] Some examples are shown in Table 2.3.4.3. The neuropeptides comprise 3–100 amino acids and together with other putative signalling peptides such as growth factors and cytokines, are synthesized in the nucleus by DNA transcription followed by translation from mRNA into precursor polypeptides (Fig. 2.3.4.1). These precursors typically undergo extensive post-translational processing that includes cleavage into smaller peptides by endopeptidases as well as other enzymic modifications. The precursor peptide usually contain an N-terminal signal sequence that directs the transport of newly synthesized protein to the lumen of the endoplasmic reticulum, and then the Golgi complex where the peptide is packaged into vesicles (so called large dense core vesicles) that are transported along the axon to the synapse. This obviates the need for neuropeptide vesicular transporters.

Proteolytic processing of a single precursor peptide often generates not one but a family of biologically active peptides, although the proteolytic steps may be tissue-specific. The opioid peptides provide one of the best worked out examples of this form of processing. Proopiomelanocortin (POMC) is a hypothalamic precursor opioid peptide whose structure contains sequences for adrenocorticotropic hormone (ACTH), α-melanocyte stimulating hormone (α-MSH) and β-endorphin. In the anterior lobe of the pituitary gland POMC is processed to form ACTH, whilst in the intermediate lobe POMC is processed to form α-MSH and β-endorphin. On the other hand, post-translational processing of the opioid precursor peptide, proenkephalin, gives rise to multiple copies of the pentapeptide met-enkephalin as well as a copy of leu-enkephalin, whilst a third opioid precursor, prodynorphin, gives rise to dynorphin. In total, the 3 separate opioid peptide genes give rise to at least 18 endogenous peptides with opiate-like activity.

Multiple proteolytic enzymes have been cloned and extensively characterized, including prohormone convertases that produce striking phenotypic effects when genetically manipulated in mutant mouse models.[7] The therapeutic utility of pharmacological manipulation of neuropeptide synthesis and degradation in the brain has yet to be realized. However, the success of inhibitors of the prohormone convertase that synthesizes angiotensin in the periphery (ACE inhibitors), for the treatment of hypertension, sets an important precedent.

Another mechanism to generate neuropeptide diversity is through alternative RNA splicing of a single gene. For example, in the case of the tachykinins alternative splicing of preprotachykinin gene A mRNA results in 3 splice variants which, after translation and post-translational processing, collectively generate the five biologically active peptides of the tachykinin family (including Substance P).

Table 2.3.4.3 Examples of families of neuropeptides

Opioid peptides	Leu-enkephalin Met-enkephalin Dynorphin β-endorphin Nociceptin
Tachykinins	Substance P Neurokinin A Neurokinin B
Hypothalamic releasing factors	Thyrotrophin releasing factor (TRH) Corticotrophin releasing factor (CRF) Growth hormone releasing hormone (GHRH) Somatostatin
Gut-brain peptides	Cholecystokinin (CCK) Galanin Insulin Neurotensin Neuropeptide Y (NPY) Vasointestinal polypeptide (VIP)
Other peptides	Bradykinin Calcitonin gene-related peptide Melanin concentrating hormone (MCH) Melanocortin Orexin Oxytocin Vasopressin

To date, there is little evidence that neuropeptides are cleared from the synapse by transporters in the plasma membrane, indicating that these particular transmitters are not recycled after release. Rather, evidence suggests that their action is terminated by peptidases that are thought to be located on extracellular membranes. Thus, replenishment of neuropeptides during high levels of synaptic activity is dependent on the proteolytic enzymes that generate the active peptides in the neurones.

A feature of most if not all neuropeptides is their co-localization with classic neurotransmitters. Some of the best examples include co-localization between GABA/dynorphin in movement control pathways (striatonigral neurones), CCK/dopamine in reward pathways (mesoaccumbens neurones), and glutamate/Substance P in pain pathways (dorsal root ganglion neurones). The functional significance of this co-localization is not fully clear but evidence suggests that peptide release requires higher frequencies of neuronal discharge than classic transmitters, and once released the neuropeptide either facilitates or opposes the function of the co-localized transmitter.[1] In a recent example, co-localization between 5-HT and galanin in midbrain raphe neurones was investigated to reveal an action of the peptide on 5-HT feedback mechanisms. This knowledge has been exploited to develop galanin ligands that are under development as novel antidepressant strategies.[8]

Neurotrophic factors

Neurotrophic factors are brain peptides that were originally recognized for their role in supporting growth, differentiation and survival of neurones but today are thought to possess many of the properties of neurotransmitters including neuronal localization and release, and an ability to modulate synaptic function. Moreover, there is evidence that trophic factors signal in a retrograde fashion (see later). Neurotrophic factors are currently named according to the action with which they were originally characterized (brain-derived neurotrophic factor — BDNF, nerve growth factor — NGF) and they comprise many families.[9]

Certain features distinguish neurotrophic factors from neuropeptides (see above). In particular, neurotrophic factors are larger molecules; for example, BDNF has a molecular size of 14 kDa whereas neuropeptides are typically much smaller peptides. Also whilst neuropeptides signal via G-protein coupled receptors (see below), neurotrophic factors signal via direct activation of a class of transmembrane spanning protein kinases called protein tyrosine kinases (Trk receptors) of which four types have been identified so far (TrkA, TrkB, TrkC and p75), and that phosphorylate proteins on tyrosine residues.[10] In some cases, the neurotrophic factor receptor and protein tyrosine kinase reside in the same protein, while in other cases, the receptor recruits an intracellular protein tyrosine kinase. Specific neurotrophic factors signal via specific protein kinases (e.g. NGF – via TrkA, BDNF – via TrkB). Activation of the protein tyrosine kinase triggers cascades of further protein phosphorylation that produce not only trophic effects but also changes in synaptic transmission.

Much recent interest in neurotrophic factors derives from findings that they regulate synaptic transmission in the adult brain, and that neurotrophic factor expression can be modulated through interactions with amine and amino acid neurotransmitters. For example, evidence suggests that repeated administration with amine-targeted antidepressants increases BDNF expression in animal models and depressed patients, whereas decreases in BDNF have been linked to depression. These data contribute to a currently popular hypothesis that changes in BDNF are important to the symptoms of depression as well as the relief of these symptoms by antidepressant drug treatment.[11, 12]

Chemokines and cytokines

Chemokines and cytokines comprise large families of homologous small proteins (6–10 kDa) and differ from neuropeptides and neurotrophic factors in that they are key signalling molecules of the immune system. However, recent findings suggest that these molecules and some of their receptors are also present in the brain in both glial cells and neurones, raising the possibility that they might also have neurotransmitter-like functions. Although the evidence is incomplete, data show that chemokine and cytokine molecules have several of the characteristics that define neurotransmitters including modulation of release of other neurotransmitters or neuropeptides.[13] The pharmacological development of agonists and antagonists that are selective for chemokine and cytokine receptors and can cross the blood-brain barrier, would open an intriguing new era of research in neuroscience.

Retrograde messengers

It is now recognized that in contrast to classical neurotransmitters and neuropeptides, a small number of brain molecules signal information at a synapse in a 'retrograde' direction that is released from the postsynaptic neurone to act on the presynaptic neurone. Molecules falling into this category include certain neurotrophic factors (see above), gaseous molecules and lipid messengers.

Nitric oxide

One putative retrograde gaseous messenger is nitric oxide (NO) that is produced in neurones from the amino acid L-arginine by a neurone-specific isoform of NO synthase (NOS), which has a widespread abundance in the brain. The first evidence of a role for NO as a neurotransmitter came from findings that stimulation of glutamate NMDA receptors by glutamate caused the release of a diffusible messenger, which was subsequently identified as NO.[14] The current thinking is that increased glutamatergic activity triggers in postsynaptic neurones an NMDA-mediated activation of NOS, and then increased synthesis of NO that diffuses across the synapse to enhance presynaptic transmission. The latter occurs at least in part through NO acting on guanylate cyclase to increase production of the second messenger cGMP. In postsynaptic neurones, NO regulates certain protein kinase pathways and gene transcription factors, and also changes cell signalling events by S-nitrosylation.

On the basis of studies on the effects of NO donors, and pharmacological and genetic modulation of NOS, increased NO production is associated with a range of CNS functions including cognition, induction and maintenance of synaptic plasticity, and NO may be neuroprotective under some conditions.[15] However, because excess NO has neurotoxic potential, and because of the difficulty of delivering NO to the CNS without inducing side effects through the many actions of NO on peripheral tissues, the development of NO-based therapies for the treatment of CNS disorders will be very challenging.

Endocannabinoids

Examples of lipid retrograde messengers are the endocannabinoids, which are a recently discovered family of naturally occurring lipids (including anandamide) that interact with cell surface receptors that are targeted by Δ^9-tetrahydrocannabinol (THC). The latter is the principle biologically active constituent of marijuana, the dried leaves of the cannabis plant.[16] In essence, endocannabinoids appear to be to THC what opiate peptides are to morphine.

It is now apparent that endocannabinoids are synthesized enzymically on demand within the postsynaptic neurone and once produced, diffuse across the synapse in a retrograde direction. Endocannabinoids then suppress neurotransmitter release through activation of presynaptic cannabinoid receptors, the main type in the brain being classified CB_1 (analogous in terms of structure and function to opiate receptors but quite distinct pharmacologically).

Many of the central effects of THC, including analgesia, increased appetite and euphoria, are thought to be mediated by CB_1 receptors. Since CB_1 receptors have a powerful influence on synaptic transmission in the brain and have limited distribution in the periphery (although CB_2 receptors are abundant in the immune system), drugs targeting these receptors and/or the enzymes involved in endocannabinoid synthesis and metabolism may have interesting therapeutic possibilities. Such drugs are currently under investigation as analgesic and anorectic agents, amongst many others.

Neurotransmitter receptors

Neurotransmitter receptors are located on the cell surface of both pre- and postsynaptic neurones, and as a general rule can be divided into two main types; one type activates an ion channel that is intrinsic to the receptor (ligand-gated ion channel, sometimes called ionotropic receptor), the other type activates a GTP binding protein which acts as a transducer between the receptor and effector system (G-protein coupled receptor [GPCR], sometimes called metabotropic receptor). An exceptions to this general rule are certain trophic factors and cytokines which signal via direct activation of a unique class of protein kinases, protein tyrosine kinases. In addition, steroid hormones signal in the brain by crossing the plasma membrane and activating receptors in the neuronal cytoplasm that translocate to the nucleus where they bind DNA and function as transcription factors.

Ligand-gated ion channels typically comprise a multimeric plasma membrane receptor complex (4–5 subunits each with 4 transmembrane spanning domains) that gate the influx of ions to evoke fast changes in synaptic signalling. GPCRs comprise a superfamily of single proteins (7 transmembrane spanning domains) that evoke slower changes in synaptic signalling through the generation of second messengers and interactions with intracellular signalling pathways.

One of the most remarkable advances in molecular neuropharmacology in the last 20 years, which has been made possible through advances in molecular cloning technology and the virtual completion of the human genome project, has been the discovery of huge diversity in neurotransmitter receptors. This complexity takes the form of not only several hundred GPCRs[17] but also considerable heterogeneity in ligand-gated ion channels produced through the assembly of multiple receptor subunits.[18, 19]

Most, and probably all, neurotransmitters have more than one receptor type, which were once classified solely according to their pharmacological properties, but today are grouped more precisely in terms of their pharmacological, functional, and structural properties. Many neurotransmitter receptor subtypes have been cloned and their distribution within the brain is known; the challenge is to turn these advances at the molecular level into a better understanding of synaptic function, and novel therapies. Neurotransmitter receptors are too numerous to describe individually but examples are shown in Table 2.3.4.4 and recent detailed reviews are available elsewhere.[10]

Ligand-gated ion channels

The amino acids glutamate and GABA are, respectively, the principal fast excitatory and inhibitory transmitters in the brain and exert their effects via ligand-gated ion channels. However, other transmitters are also capable of fast transmission via ligand-gated ion channels and these include acetylcholine (nicotinic receptors), 5-HT (5-HT_3) and ATP (P_{2X}). However, to date there is no known neuropeptide with a ligand-gated ion channel.

Ligand-gated ion channels for glutamate

Glutamate elicits fast excitatory effects by activating ligand-gated ion channels on postsynaptic membranes of which there are three types; α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA) receptors, N-methyl-d-aspartate (NMDA) receptors and less abundant kainate receptors, all of which were originally named according to their preferred synthetic agonist and gate cations (Na^+, K^+, and Ca^{2+}) with varying degrees of selectivity. There is likely to be additional heterogeneity because each receptor can be assembled as a tetramer of one or more of multiple subunits. For instance, AMPA receptors can be formed from tetramers of combinations of

Table 2.3.4.4 Examples of neurotransmitter receptors

Transmitter	Receptor	Signal transduction
Dopamine	D_1 family (Dopamine D_1, D_5)	Adenylate cyclase (G_s)
	D_2 family (Dopamine D_2, D_3, D_4)	Adenylate cyclase ($G_{i/o}$)
Noradrenaline	α_1 family ($\alpha_{1A,B,D}$)	Phospholipase C (G_q)
	α_2 family ($\alpha_{2A,B,C}$)	Adenylate cyclase ($G_{i/o}$)
	β family ($\beta_{1,2,3}$)	Adenylate cyclase (G_s)
5-hydroxytryptamine	5-HT_1 family (5-$HT_{1A, B, D,E, F}$)	Adenylate cyclase ($G_{i/o}$)
	5-HT_2 family (5-$HT_{2A, B, C}$)	Phospholipase C (G_q)
	5-HT_3	Cation channel
	5-HT_4	Adenylate cyclase (G_s)
	5-HT_5 family (5-$HT_{5A, B}$)	Not certain
	5-HT_6	Adenylate cyclase (G_s)
	5-HT_7	Adenylate cyclase (G_s)
Acetylcholine	M_1 (muscarinic)	Phospholipase C (G_q)
	M_2	Adenylate cyclase ($G_{i/o}$)
	M_3	Phospholipase C (G_q)
	M_4	Adenylate cyclase ($G_{i/o}$)
	M_5	Phospholipase C (G_q)
	Nicotinic (α1–10, β1–4, δ, ε, γ)	Cation channel
GABA	$GABA_A$ (α1–6, β1–3, γ1–3, σ1–3, δ, ε, π, o)	Chloride channel
	$GABA_B$	Adenylate cyclase ($G_{i/o}$)
Glutamate	AMPA ($GluR_{1–4}$)	Cation channel
	NMDA (NR_1, $NR_{2A–D}$, $NR_{3A–B}$)	Cation channel
	Kainate ($GluR_{5–7}$, KA_1, KA_2)	Cation channel
	Group I family ($mGluR_{1/5}$)	Phospholipase C (G_q)
	Group II family ($mGluR_{2–3}$)	Adenylate cyclase ($G_{i/o}$)
	Group III family ($mGluR_{4'6,7,8}$)	Adenylate cyclase ($G_{i/o}$)
Tachykinin (including substance P)	NK_1	Phospholipase C (G_q)
	NK_2	Phospholipase C (G_q)
	NK_3	Phospholipase C (G_q)
Opioid	δ	Adenylate cyclase ($G_{i/o}$)
	κ	Adenylate cyclase ($G_{i/o}$)
	μ	Adenylate cyclase ($G_{i/o}$)
Galanin	GAL1	Adenylate cyclase ($G_{i/o}$)
	GAL2	Adenylate cyclase ($G_{i/o}$)
	GAL3	Adenylate cyclase ($G_{i/o}$)
Adenosine	A_1	Adenylate cyclase ($G_{i/o}$)
	A_2 family ($A_{2A, B}$)	Adenylate cyclase (G_s)
	A_3	Adenylate cyclase ($G_{i/o}$)
ATP	P2X family ($P2X_{1-7}$)	Cation channel
	$P2Y_1$	Phospholipase C (G_q)
	$P2Y_2$	Phospholipase C (G_q)
	$P2Y_4$	Phospholipase C (G_q)
	$P2Y_6$	Phospholipase C (G_q)
	$P2Y_{11}$	Phospholipase C (G_q)
	$P2Y_{12}$	Adenylate cyclase ($G_{i/o}$)
	$P2Y_{13}$	Adenylate cyclase ($G_{i/o}$)
	$P2Y_{14}$	Phospholipase C (G_q)
Cannabinoid	CB1	Adenylate cyclase ($G_{i/o}$)
	CB2	Adenylate cyclase ($G_{i/o}$)

four subunits (GluR1–GluR4) and NMDA receptors from two subunits (NR1, NR2). There are a large number of naturally occurring variants of both AMPA and NMDA subunits generated through RNA editing and alternative splicing.

The pharmacological and functional significance of this complexity is not yet clear although evidence suggests that certain agents are able to distinguish between different receptor assemblies.[10] Interestingly, recent data suggest that changes in AMPA receptor subunit composition at the postsynaptic membrane cause differences in ion (Ca^{2+}) permeability that change synaptic efficacy, the best-characterized form of which is long-term potentiation (LTP), a widely accepted neurophysiological correlate of learning and memory.[19]

An interesting feature of many ligand-gated ion channels is the presence of multiple chemically-sensitive sites (allosteric modulatory sites), in addition to the site(s) which bind the natural transmitter ligand. This is the case for both the AMPA and NMDA receptors. Thus, in addition to the glutamate binding site AMPA receptors are sensitive to 'AMPAkines' which comprise a chemically diverse group of agents that potentiate the function of the receptor in *in vitro* models, and elicit associated procognitive effects *in vivo*.[20] Non-glutamate sites on the NMDA receptor include a site for Mg^{2+} that is the source of a voltage-dependent NMDA receptor block which requires membrane depolarization to open, as well as positive modulatory sites for glycine and polyamines. Whilst glutamate is released from presynaptic terminals in an activity-dependent fashion and acts as a neurotransmitter, glycine and the polyamines act as extracellular modulators that are present at more constant levels. The latter binding sites are under investigation as a possible source of NMDA receptor enhancing agents that do not suffer the potential excitotoxic effects of agonists at the glutamate site.[21]

Ligand-gated ion channels for GABA

GABA elicits fast inhibitory effects by activating the $GABA_A$ receptor ion channel complex. $GABA_A$ receptors are heteropentameric membrane proteins that form a GABA-gated chloride channel. There are at least 18 types of $GABA_A$ receptor subunits (α1–6, β1–3, γ1–3, Π, δ, θ and p1–3). Although studies co-expressing different $GABA_A$ receptor subunits indicate the potential for several hundreds if not thousands of $GABA_A$ receptor subunit combinations, studies on $GABA_A$ receptor subunit distribution and abundance in native brain tissue indicate that the number of naturally occurring types of $GABA_A$ receptors may be of the order of 10 or fewer.[22]

As with the glutamate ionotropic receptors, $GABA_A$ receptors have a number of allosteric modulatory sites including those sensitive to certain endogenous steroids, anaesthetic agents (for example alfaxalone) and alcohol (ethanol). However, the vast majority of $GABA_A$ receptors are characterized by their sensitivity to benzodiazepines. Both genetic and medicinal chemistry approaches have been used to identify the pharmacological significance of $GABA_A$ receptor subtypes, and specifically to determine whether the multiple behavioural effects of benzodiazepines such as diazepam (sedation, anxiolysis, amnesia, motor in-coordination etc.) can be attributed to specific $GABA_A$ receptor subunit combinations.[18]

In particular, studies with point-mutated mice have revealed that the sedative effect of diazepam is mediated by α1-containing $GABA_A$ receptors, whereas the anxiolytic action is mediated by α2/α3-containing $GABA_A$ receptors. Moreover, findings that ligands with selective actions at α2- and/or α3-containing $GABA_A$ receptors display anxiolytic activity, raise the possibility of future benzodiazepines with behaviourally selective actions. Interestingly, α5-containing $GABA_A$ receptors may be an important site of action of alcohol. The $GABA_A$ receptor subunit(s) targeted by steroids and anaesthetics to produce the CNS inhibitory effects of these agents are currently under investigation.

G-protein coupled receptors

Almost all neurotransmitters signal effects via GPCRs and most neurotransmitters signal via more than one type of GPCR. For example, the amine 5-HT possesses 14 receptor subtypes (comprising seven receptor families, 5-HT_{1-7}), 13 of which are GPCRs and one is a ligand-gated ion channel. Each 5-HT GPCR has high affinity and selectivity for 5-HT but individually the receptors demonstrate different selectivity for other ligands, arise from different (but homologous) genes, and are formed from different protein sequences with different distributions and signalling effects.[23] Since several 5-HT GPCRs can co-localize at a single synapse, the signal received by a postsynaptic neurone may be quite complicated. This complexity for 5-HT can be seen in many other transmitters including dopamine (D_{1-5}), glutamate ($mGluR_{1-8}$), noradrenaline ($\alpha_{1A,B,D}$, $\alpha_{2A,B,C}$, β_{1-3}), endocannabinoids (CB_{1-2}) and neuropeptides (Table 2.3.4.4).

Typically GPCRs comprise a single membrane protein with seven transmembrane spanning domains, an N-terminus facing the extracellular space, a C-terminus facing the cytoplasm, and several intracellular transmembrane domain linking loops. The N-terminus of some GPCRs ($mGluR_{1-8}$, $GABA_B$) contains the ligand binding site, while for most GPCRs the predicted ligand binding site lies within the transmembrane domains. Both the C-terminus and the third transmembrane intracellular loops are targets for phosphorylation by protein kinases; the third intracellular loop is the main site of G-protein interaction.

G-proteins

Each G-protein is a heterotrimer comprised of α, β and γ subunits that dissociate on binding of ligand to the GPCR. On dissociation, the α subunit binds GTP and through intrinsic GTPase activity directly regulates a number of specific downstream effector enzymes and ion channels. The β/γ subunits are also biologically active and regulate some of the same effector proteins.

There are four major types of G-proteins, Gs, Gi, Gq and G_0 that produce the following signalling effects; activation of adenylate cyclase, inhibition of adenylate cyclase, activation of phospholipase C and interaction with Ca^{2+} and K^+ channels, respectively. Changes in the activity of adenylate cyclase results in altered intracellular levels of the 'second messenger' cyclic adenosine monophosphate (cAMP). Similarly, phospholipase C (PLC) alters intracellular levels of inositol triphosphate (IP_3) and diacyl glycerol (DAG). Altered levels of these second messengers trigger changes in activity of specific signalling cascades and ultimately changes in physiological responses (see below).

The opening of ion channels in response to neurotransmitter-induced GPCR activation leads to direct effects (excitatory or inhibitory) on the electrical properties of neurones, albeit on a slightly slower timescale than effects produced by ligand-gated ion channels. Almost all neurotransmitter classes are able to evoke

changes in ion channel opening via GPCRs, and some may be clinically important. For example, the α_2-adrenoceptor-induced opening of K^+ channels on noradrenaline neurones that causes a fall in noradrenergic activity and release, may contribute to the anxiolytic and sedative properties of α_2-adrenoceptor agonists such as clonidine. On the other hand, the 5-HT_{2A} receptor-induced closing of K^+ channels on cortical neurones that causes an increase in cortical neurone activity, may underlie the psychotic effects of LSD and related hallucinogens.[23]

GPCR regulation

Recent discoveries of interactions between GPCRs and other intracellular proteins have lead to a new understanding of how the receptors are regulated and trafficked to and from the plasma membrane. Studies commencing on the β-adrenceptor, have identified two families of regulatory proteins called β-arrestins and GPCR kinases (GRKs). Within seconds of being activated by an agonist the GPCR is phosphorylated by a GRK on the C-terminal cytoplasmic tail and other intracellular domains. This phosphorylation promotes the interaction of β-arrestins with the GPCR, which limits the signal duration, and causes loss of sensitivity to agonist activation, and then receptor internalization from the cell surface.[24]

In addition to β-arrestins the C-termini of GPCRs associate with a large variety of transmembrane or soluble proteins, termed 'GPCR-interacting proteins' (GIPs). Some GIPs are themselves GPCRs that form homo- or heterodimers, while other GIPs are ionic channels, ionotropic receptors and proteins that control GPCR trafficking[25]. One interesting example of a GIP is the molecule p11, which reportedly functions to traffic a 5-HT GPCR (5-HT_{1B}) to the plasma membrane. Evidence suggests that p11 expression is reduced in postmortem brain of patients committing suicide, and that mice with genetic deletion of p11 have a depressive-like phenotype.[26]

Small G proteins

In addition to the G-proteins associated with GPCRs, there is a super family of 'small G-proteins' which also bind GTP and possess intrinsic GTPase activity but these are not modulated by agonist binding. Rather, small G-proteins function as molecular switches that control several cellular processes ranging from vesicle trafficking and exocytosis (e.g. Rab) to assembly of cytoskeletal structures (e.g. Rho). Among the best characterized small G-proteins are those that comprise the Ras family. Numerous types of cell signals including those of most neurotrophic factors converge on Ras and related proteins to regulate MAP-kinase pathways.

Second messengers

The generation of the second messengers cAMP and DAG by adenylate cyclase and phospholipase C, respectively, leads to activation of protein kinases that add phosphate groups to specific protein targets to change their activity and ultimately trigger diverse physiological responses (Fig. 2.3.4.2). Enzymes called phosphatases,

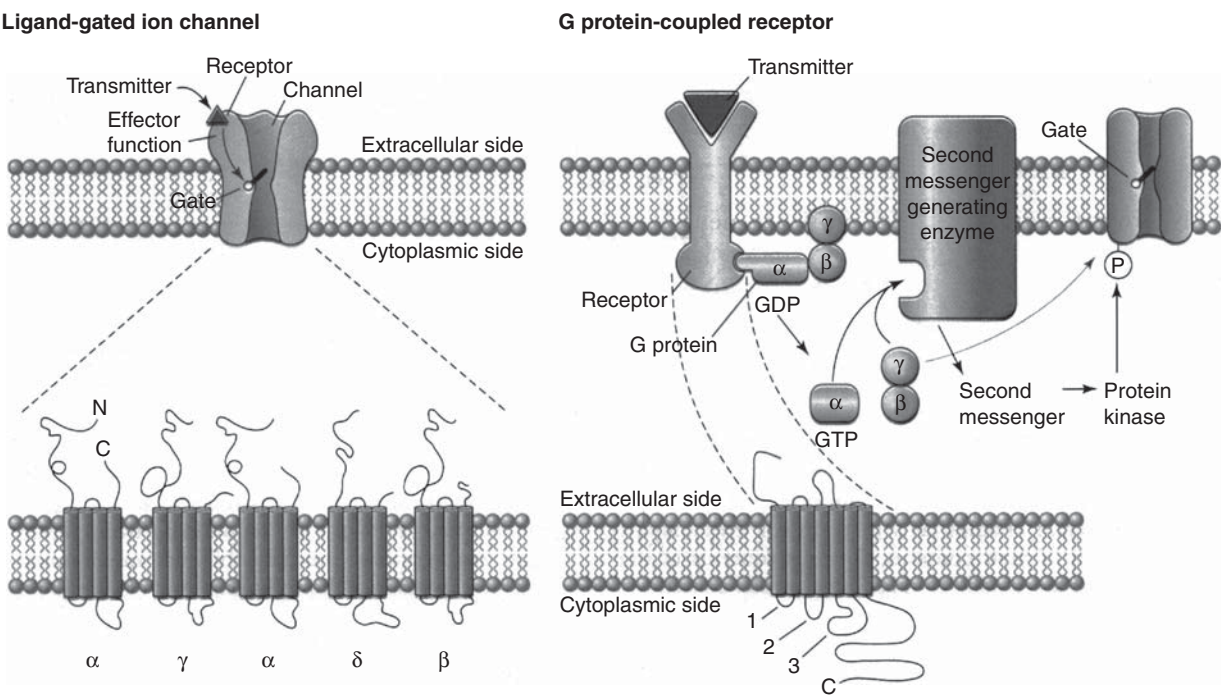

Fig. 2.3.4.2 Diagrammatic representation of ligand-gated ion channel and G-protein coupled receptors. Ligand-gated ion channels comprise multiple protein subunits that form a central pore in the plasma membrane. On binding of the neurotransmitter, this receptor mediates fast excitatory or inhibitory transmission depending on whether the pore gates cations or chloride ions, respectively. G-protein coupled receptors comprise a single membrane spanning protein. On binding of the neurotransmitter, this receptor mediates slow transmission by enabling the dissociation of the G-protein into α subunit monomer and β/γ subunit dimer, both of which may activate an effector enzyme to generate a second messenger. Also, the β/γ subunit dimer may directly interact with ion channels. Second messengers may also indirectly modulate ion channels through phosphorylation by activating protein kinases. Reproduced from Nestler EJ, Hyman SE and Malenka RC (2001) *Molecular Neuropharmacology*, p. 64, Copyright 2001, McGraw-Hill, New York.

which remove the phosphate groups, oppose these signalling effects. Guanylate cyclase is a cytosolic enzyme which also generates a second messenger, cGMP. As noted above, guanylate cyclase is activated by NO to produce effects on presynaptic function.

Based on molecular cloning studies, nine forms of adenylate cyclase have been identified (I–IX) and each exhibits a distinct distribution in brain and peripheral tissues.[27] The full implication of this complexity is not yet understood but it suggests that regulation of cAMP formation varies depending on the form of adenylyl cyclase expressed in neuronal cells.

Both cAMP and cGMP are degraded by phosphodiesterases (PDEs) which are expressed in numerous forms (types 1–11) in brain and periperal tissues.[10] At high concentrations, caffeine and related methylxanthines inhibit PDE and this action contributes to the pharmacological effects of these drugs. Much effort is being made to develop inhibitors that are selective for brain-specific forms of PDE. Rolipram inhibits all isoforms of PDE4; this drug showed promise as an antidepressant, but its clinical utility was limited by peripheral side effects. However, because the PDE4 enzymes comprise a number of isoforms, an inhibitor of one isoform may lead to the development of an effective antidepressant without the side effects of rolipram.

GPCR-induced activation of PLC causes the breakdown of phosphatidylinositol, resulting in the generation and recycling of the second messengers, IP_3 and DAG (phosphoinositide cycle). Both IP_3 and DAG produce downstream signalling effects, IP_3 through the mobilization of intracellular calcium stores and DAG through activating a protein kinase. There are two major isoforms of PLC in brain, β and γ, the β isoform being predominantly responsible for mediating the effects of GPCRs linked to Gq.

After its formation, IP_3 is recycled via a series of dephosphorylations to form inositol which is used in the regeneration of phosphatidylinositol. Interestingly, lithium, which is an important drug in the treatment of manic depressive illness, inhibits one of the enyzymes involved in the recycling of IP_3 (inositol-1-monophosphatase) and causes inositol depletion. Because inositol does not easily enter the blood-brain-barrier, brain inositol levels are thought to fall and production of the second messengers diminishes. It is a popular hypothesis that inositol depletion is responsible for lithium's clinical effects but this remains unproven. Indeed, lithium is known to interact with a range of signalling systems including various ion channels, adenlyate cyclases and protein kinases. Recent interest has focussed on the inhibition by lithium and mood stabilizing anticonvulsants such as valproate, of glycogen synthase kinase 3β that has a range of targets and effects ranging from formation of inositol to trophic mechanisms.[28]

Downstream signalling cascades

The activation or inhibition of second messenger signalling cascades by GPCRs can profoundly change the intracellular environment of a neurone by regulating the activity of protein kinases and other proteins, including gene transcription factors and even enzymes involved in regulation of chromatin structure. Consequently, these cascades may regulate gene transcription and protein synthesis and activate multiple downstream effectors, including those that form the cytoskeleton or contribute to mechanisms underlying synaptic plasticity. Such effects can have long-lasting effects on neuronal function. Increasing evidence suggests that the neuroadaptive responses to repeated psychotropic drug administration are underpinned by changes in gene expression that result in the remodelling of synaptic function and structure. This thinking has been applied to explain a range of processes including compulsive recreational drug use as well as the therapeutic action of antipsychotic drugs.

As an example, the past decade has seen the evolution of a fascinating theory to explain the delayed onset of antidepressant effect of drugs like fluoxetine and imipramine that act to inhibit plasma membrane amine transporters (see above). This theory posits that elevated amine levels trigger GPCR signalling cascades that activate gene programmes to enhance neuronal survival and connectivity, the latter having failed because of the adverse effects of stress and other environmental factors.[11, 29, 30] Some of the key genes involved in this process include trophic factors such as BDNF, which may be a trigger for the production of newly formed neurones (Fig. 2.3.4.3). Although this line of thought is driving promising pharmacological strategies for improved antidepressant therapies, our knowledge of the key molecules that are changed by antidepressants to bring about the relief of the symptoms of depression is far from complete.

Concluding remarks

Until recently, studies on the chemistry of synaptic neurotransmission have focused on a small number of neurotransmitters and a narrow group of proteins involved in neurotransmitter function,

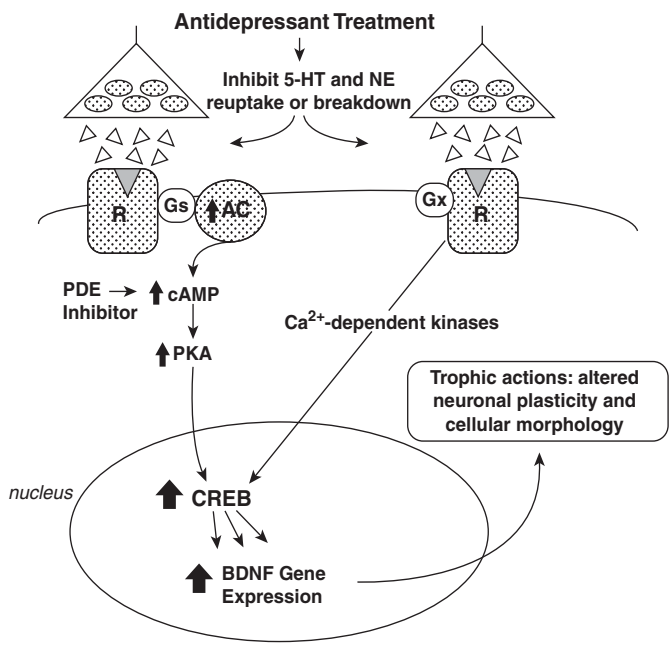

Fig. 2.3.4.3 Hypothetical signal transduction pathways regulated by antidepressant drugs leading to increased neurotrophic factor expression and neurogenesis. Antidepressant treatment increases synaptic amine levels that stimulate GPCRs (Gs) linked to adenylyl cyclase (AC). The subsequent increase in cAMP levels activates cAMP-dependent protein kinase (PKA) which, possibly together with Ca^{2+}-dependent protein kinases, increases the function and expression of the gene transcription factor, cAMP response element binding protein (CREB). CREB enhances the expression of brain derived neurotrophic factor (BDNF) that may underpin trophic effects of antidepressant treatment, including synaptic remodeling and increased neurogenesis. specifically neurotransmitter receptors, transporters and enzymes which bring about neurotransmitter synthesis or degradation. Today, powerful molecular and genetic approaches are being used to identify and understand new proteins and mechanisms involved in neurotransmitter function and control. So far, just a few tens of perhaps thousands of neurotransmitter-related proteins, have been successfully targeted by pharmacological agents that have translated into important treatments of psychiatric disorder but there is promise of many more such treatments to come. Moreover, this huge diversity of neurotransmitter-related proteins is now emerging as a large resource for studies of genetic risk factors of psychiatric disorder and investigations of biological markers of illness diagnosis and progression, and treatment outcome.

2.3.5 Neuropathology

Peter Falkai and Bernhard Bogerts

Introduction

The traditional domains of neuropathology are well-defined organic brain diseases with an obvious pathology, such as tumours, infections, vascular diseases, trauma, or toxic and hypoxemic changes, as well as degenerative brain diseases (e.g. Alzheimer's disease, Parkinson's disease, and Huntington's chorea). Neuropathological investigations of these brain disorders have been rewarding, because patients with any of these conditions can be expected to have gross morphological or more or less specific neurohistological anomalies related to the clinical symptoms of the disorders. Moreover, the type of brain pathology of these well-defined disease entities is quite homogenous. For example, it is highly unlikely that a patient with Parkinson's disease would not exhibit morphological changes and Lewy bodies

in the nigrostriatal system, just as much a person with Huntington's chorea would have a normal striatum, or a patient with Pick's or Alzheimer's disease would have no changes in the cerebral cortex.

In contrast, the history of the neuropathology of psychiatric disorders outside primary degenerative diseases is much more controversial, because no such obvious and homogenous types of brain pathology (as seen in neurological disorders) have yet been detected for the major psychiatric illnesses such as schizophrenia, affective disorders, substance-related disorders, or personality disorders.

The scope of this chapter is to summarize the neuropathological findings in schizophrenia, affective disorders, and alcoholism. Tables 2.3.5.1, 2.3.5.2, 2.3.5.3, and 2.3.5.4 highlight the significant findings. It goes beyond the scope of this chapter to review the large body of literature on the dementias, including specifically Alzheimer's disease. Concerning this matter, the reader is referred to several comprehensive reviews (e.g. Jellinger and Bancher 1998).[1]

Table 2.3.5.1 Gross morphometric findings in schizophrenia

Schizophrenia and other psychotic disorders

Studies between 1898 and 1975

In 1898, Alois Alzheimer (1898)[2] described subtle changes in the neocortex of patients with schizophrenia. Subsequently to Alzheimer, Southard reported cortical atrophy in schizophrenia and mentioned association areas of the cerebral cortex to be most affected in this disorder.[4] Vogt and Vogt and their coworkers reported cellular alterations in the cortex, thalamus, and basal ganglia of schizophrenics.[5] These considerable efforts on the part of many well-known neuroanatomists and neuropathologists to prove schizophrenia to be a primary brain disorder ended in inconsistent and unsubstantiated findings.[6] To a large extent, these inconsistencies can be attributed to a variety of methodological inadequacies including diagnostic uncertainties, inadequate control samples, flawed tissue-handling procedures, variable choice of brain regions for neuropathological studies, limitations in the sensitivity and specificity of classical histological stains, as well as lack of quantitative methods to delineate and analyse subtle brain abnormalities.[7]

Neuropathological findings in schizophrenia since 1975

Advances in the last 30 years have produced more reliable psychiatric diagnostic criteria, improved structural and functional neuroimaging techniques, a large array of highly sensitive and specific molecular probes and labeling procedures, suitable for use in neuropathological studies, and computer-assisted image analysis methodologies. For these and other reasons, there has been a resurgence of interest in the neurobiological substrates of schizophrenia, and contemporary neuropathological studies have enumerated many findings in the brains of patients with schizophrenia (for reviews see[7, 8, 9]). Finally, the recent description of the first risk genes like Neuregulin-1 or Dysbindin has provided this field with reliable research targets.[8, 9] To identify the role of these genes for the pathophysiology of schizophrenia their expression pattern in human brain tissue has to be established in the near future.

(a) Diagnostic neuropathology

Stevens (1982)[10] surveyed the brains of 28 schizophrenic patients for gross and microscopic abnormalities using standard diagnostic stains. She discovered no abnormalities in temporal (including the amygdalohippocampal region), frontal, or parietal lobes or in the thalamus, but detected assorted abnormalities in other regions, including neuronal loss or infarction in the globus pallidus in five patients, increased cerebellar white matter gliosis in five patients, excessive Purkinje cell loss in 13 cases, and, most notably, increased fibrillary gliosis in periventricular, periaqueductal, and basal forebrain regions bilaterally.

In another prospectively accrued series,[10] she found that of 56 schizophrenics five were afflicted with other distinct neurological illnesses (multiple sclerosis, Friedreich's ataxia, epilepsy, stroke) and three had been treated with prefrontal leukotomies. The remaining 48 showed no differences to controls in the frequency of large- or small-vessel cerebrovascular disease, senile plaques, or neurofibrillary degeneration. However, there was an 'increased incidence of unexpected pathology in the schizophrenic group compared with the control group'. Of these 48 schizophrenics, 21 exhibited some degree of focal pathology compared to 12 of 56 controls, but these abnormalities were diverse in nature and location. Holzer staining suggested a significant increase in fibrous gliosis in the cortex, white matter, and periventricular structures, but generally for those brains showing other focal pathology. After removal of these cases, the 'adjusted' group showed no evidence of increased gliosis.

In a series of 101 elderly schizophrenics,[12] Golier *et al.* found only 10 with definite or probable Alzheimer's disease by modern neuropathological diagnostic criteria, 29 with senile plaques, 15 with vascular lesions, two with Parkinson's disease, three with unspecified tumour, and five with 'other' findings.

Another review concluded extensive neuropathological investigations due to lack of any evidence of neurodegeneration or neural injury beyond what typically is observed in brains of individuals without neuropsychiatric illness.[8]

(b) Morphometric studies

Macroscopic findings (Table 2.3.5.1)

Several planimetric postmortem studies of the entire cortex have been performed, some reporting significant reduction of cortical volume (12 per cent) and central grey matter (6 per cent), and others reporting no difference in volumes of cortex, white matter and whole hemispheres between schizophrenics and controls. Others that measured general brain parameters have shown reduced brain length, brain weight, and increased ventricular area/volume.

Since the publication of the first report of reduced tissue volume in temporolimbic structures of schizophrenics,[13, 14] numerous quantitative or qualitative anatomical postmortem studies on limbic structures of schizophrenics have been conducted. The majority of these studies substantiated subtle structural changes (15–20 per cent mean volume reduction) in at least one of the investigated areas, whereas only a few yielded entirely negative results. The findings comprise reduced volumes or cross-sectional areas of the hippocampus, amygdala, parahippocampal gyrus, which were later corroborated by morphometric magnetic resonance imaging (MRI) studies. Figure 2.3.5.1 demonstrates the subtle bilateral volume reduction of the hippocampus in schizophrenics and furthermore visualizes the kind of hypoplastic appearance of the anterior hippocampus, which can be seen in about one third of the patients

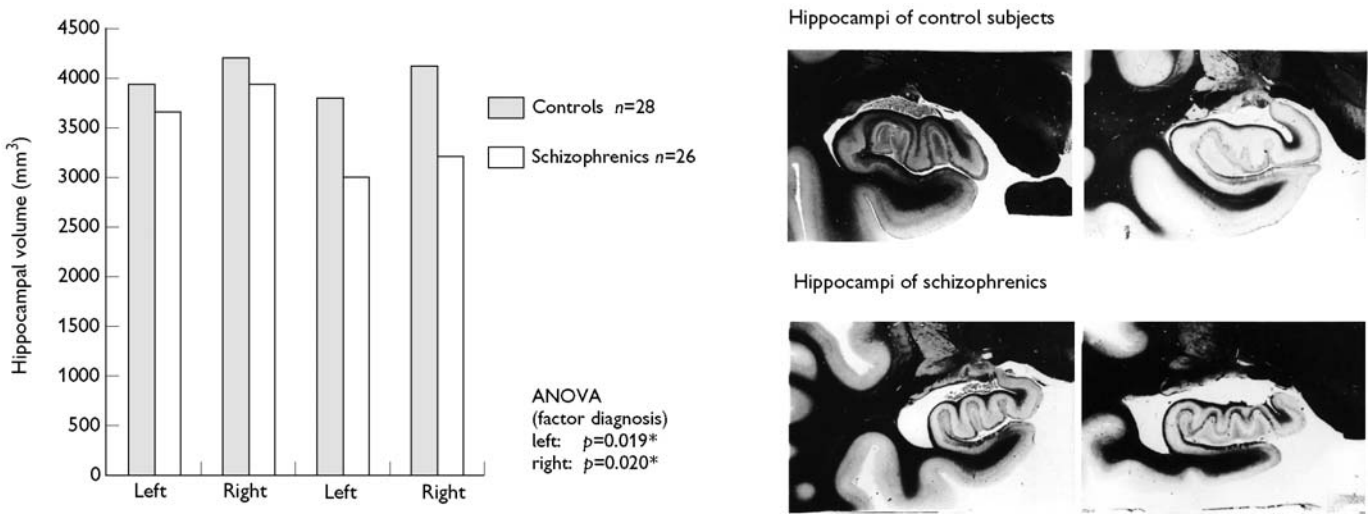

Fig. 2.3.5.1 Left side: hippocampal volumes in schizophrenic patients and controls; Right side: lippocampal atrophy macroscopically seen in about one-third of patients with schizophrenia (upper row) compared to control subjects (lower row) (from Bogerts 1990).

(lower row of the photographs). Other findings in limbic brain regions are left temporal horn enlargement, white-matter reductions in parahippocampal gyrus or hippocampus, and an increased incidence of a cavum septi pellucidi.

Unchanged volumes of the striatum and external pallidum but a subtle volume decrease in the internal pallidal segment were found in brains from the preneuroleptic era. Pallidal volume reduction was due to a reduction in the catatonic subgroup.[15] These initial findings have to be pursued, as longitudinal MRI studies suggest that enlargement of basal ganglia can be seen in schizophrenia as a consequence of treatment with classical neuroleptics, which can be reversed by the use of atypical substances.[16]

After initially finding no volumetric changes in the thalamic nuclei, subsequently the area/volume of the mediodorsal nucleus and anteroventral thalamic nucleus were found to be decreased.[17]

Changes in area measurements of the corpus callosum were described in some studies. The findings, however, are inconsistent; there are reports of increased as well as of decreased midline areas. More consistent are reports of shape abnormalities, in that the sex difference in anterior and posterior callosal thickness in normal controls seems to be reversed in schizophrenics and the mean curvature in the corpus callosum is bent upwards.[18]

Findings of decreased volume of the substantia nigra and the periventricular grey matter as well as no volumetric change in the locus coeruleus await replication.

Microscopic findings (Table 2.3.5.2)

There are a number of studies of neurone number, density, and size in schizophrenia. As summarized in Table 2.3.5.2, the majority of these have focused on the ventromedial temporal and frontal lobes.

In the lateral prefrontal cortex, an increase in neurone density has been reported inconsistently, which may relate to the observed decrease in neurone size (with decreased dendritic arborization and a decreased neuropil compartment).[20] In the anterior cingulate could be observed decreased pyramidal and local circuit neurone density accompanied by increased vertical axon density and altered dopaminergic innervation. These findings have been interpreted as representing disturbed connections in the anterior cingulate.

Within the ventromedial temporal lobe, reduced cell numbers or cell size and abnormal cell arrangements in the hippocampus or entorhinal cortex were described. However, some groups could not confirm cellular disarray in the hippocampus[21] just as little find significant volume and cell number reductions in the hippocampus and entorhinal cortex.[22]

Original studies demonstrating decreased neuronal counts in the mediodorsal and anteriorventral nucleus of the thalamus have been partially supported by subsequent investigations.[17]

The lateral (nigrostriatal) and medial (mesolimbic) parts of the mesencephalic dopaminergic systems have been evaluated and the size of the nerve cell bodies found to be significantly reduced in the medial part by 16 per cent, while the cell numbers were unchanged. The reduced cell size of the medial, mesolimbic neurones were taken to indicate dopaminergic underactivity. Two qualitative reports on degenerative changes in cholinergic cells in the basal nucleus of Meynert of schizophrenics have been published; more recent quantitative studies found normal cell numbers in the basal nucleus of schizophrenics. Volume measurements and cell counts in the noradrenergic locus coeruleus revealed a trend for decreased locus coeruleus volume without loss of neurones, indicating a reduction of neuropil in schizophrenics. These results appear comparable to those described in the substantia nigra, as mentioned above. Investigating the brainstem reticular formation revealed a twofold increased number of the cholinergic neurones of the pedunculopontine nucleus and the dorsal tegmental nucleus as well as a reduced cell size in the locus coeruleus.[23,24] However, these results are not undisputed as newer studies using state of the art stereology demonstrate opposite findings.[25]

Schizophrenia as a disorder of brain maturation

There is evidence from clinical research implicating aberrant neurodevelopmental processes in the pathophysiology of schizophrenia,[26] but there is also a growing literature suggestive of progressive deterioration in the disease for a substantial proportion of patients.[27] It should be noted that abnormal neurodevelopmental processes are not mutually exclusive of neurodegenerative mechanisms in the pathogenesis of complex neuropsychiatric disorders. Indeed, while some genetic disorders are mainly developmental (e.g. fragile X syndrome) and others mainly neurodegenerative (e.g. Huntington's disease), some have both developmental and degenerative pathologies (e.g. Down syndrome). Based on the neuropathological literature of the last 30 years some suggestions can be made concerning the pathophysiology of schizophrenia.

(c) Gliosis

Glial cells, mainly astrocytes (Figs. 2.3.5.2 and 2.3.5.3), show changes in response to almost every type of injury or disease in the central nervous system. Therefore, in typical degenerative brain disorders such as Alzheimer's disease or Huntington's chorea increased glial cell densities are found. Most studies using glial cell counts, neuron-to-glial ratios and glial cell nuclear volumes found no difference between schizophrenics and controls in temporolimbic structures, the thalamus, and cingulate cortex. In our own large-scale study we counted the number of astrocytes in several key regions such as the area surrounding the temporal horn and found no evidence for astrogliosis in schizophrenia (Fig. 2.3.5.3).[28] Although the question of fibrous gliosis (i.e. increase in glial cell fibres) remains more controversial, the well-controlled study by Bruton *et al.* (1990)[11] also rejects fibrous gliosis in schizophrenia.

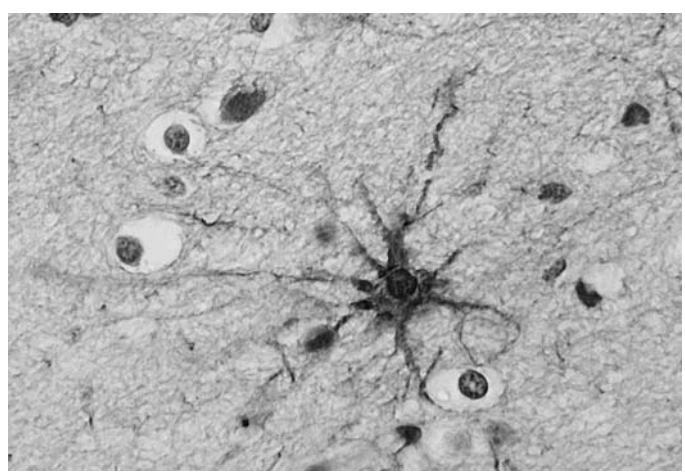

Fig. 2.3.5.2 Macroglia in a control subject: Glial fibrillary acid protein (GFAP) positive astrocyte in the human cortex.

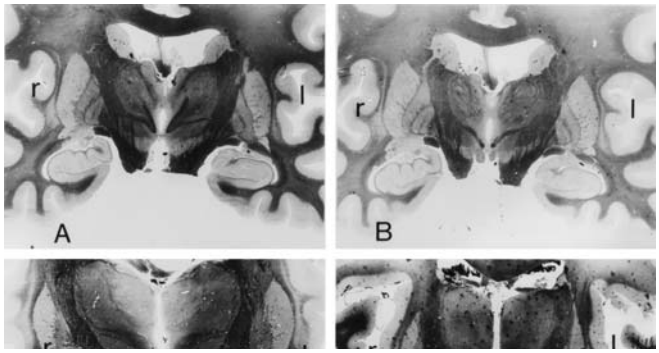

Fig. 2.3.5.3 No significant increase of GFAP positive cells around the left temporal horn in schizophrenia.

Therefore, it seems unlikely that the majority of schizophrenic patients show a considerable degree of astrogliosis. There is, on the contrary, some evidence demonstrating reduced macroglial densities in major depression and schizophrenia.[29] In this respect, specifically the oligodendroglia demonstrates qualitative and quantitative changes in schizophrenia[30] which is an interesting view of the riskgene Neuregulin-1 regulating myelin thickness via these cells. Some recent studies found evidence for the activation of microglia in the cortex of patients with schizophrenia.[31, 32, 33] As microglia respond to neuronal injury within 24 to 48 hours, studies are needed to link psychopathology with these markers. The examination of apoptic processes constitutes another interesting line of research supporting atypical degeneration with schizophrenia. Some recent studies demonstrate low-grade apoptotic processes in circumscribed brain regions in schizophrenia[34, 35] which is in line with other degenerative disorders showing similar features.[36]

(d) Neurohistological indications of disturbed brain development

Subtle cytoarchitectural anomalies were described in the hippocampal formation, frontal cortex, cingulate gyrus, and entorhinal cortex in patients suffering from schizophrenia compared with control subjects. For example, significant cellular disarray in the CA3-CA4 interface was described in the left and replicated in the right hippocampus.[37] This was interpreted as a bilateral migrational abnormality and broadly correlated with the degree of disease severity. One subsequent study was not able to fully replicate these findings, but did confirm a within-case correlation with severity; whereas another examination did not find any significant disarray distinguishing schizophrenics from controls. Another prominent finding was of an abnormal sulcogyral pattern or abnormal gross configuration of the temporal lobe and cytoarchitectonic abnormalities of the rostral entorhinal region as well as of the ventral insular cortex of schizophrenics.[38, 39] The cytoarchitectonic abnormalities of the rostral entorhinal region consisted of heterotopic pre-α-cells in the pre-β-layer (layer III), which would normally belong to the pre-α-layer (layer II). This observation stimulated considerable research, with some studies supporting these findings,[40, 41] while others did not.[42]

In conclusion, cytoarchitectonic abnormalities recently described in different limbic structures in schizophrenia are very subtle and can easily be missed using classical neuropathological methods. Quantifying them often needs sophisticated staining methods, for example, immunohistochemistry, serial sections and a matched control group and even then replicating original findings seems difficult, as outlined above. These findings can be interpreted as a sign for disturbed late neuronal migration or could mirror disturbed programmed cell death as heterotopias are frequently found in the temporal cortex of autopsied children, which seem to disappear in adults.

(e) Summary and pathophysiological conclusions

There is growing evidence for pathomorphological abnormalities in the postmortem brains of patients suffering from schizophrenia. The changes are focused on the frontal lobe and temporolimbic regions. They are subtle, lacking the typical signs of degeneration, and point to problems in prenatal (cell migration) and postnatal (connectivity) periods of brain development. Currently, underlying causes remain ambiguous, but the interaction between genetic and non-genetic factors (e.g. birth complications) is presently discussed on the basis of the recently found risk genes like Neuregulin-1 or Dysbindin.

Mood disorders (Table 2.3.5.3)

The number of published pathoanatomical studies in schizophrenia contrasts with the scant number of neuropathological examinations in affective disorders. In reviewing the world literature up to 1988, Jeste *et al.* (1988)[43] counted 15 neuropathological studies on affective disorders. Seven of them were published between 1949 and 1969, attended to less than four cases, and utilized qualitative tissue evaluation. Searching for 'unipolar depression and neuropathology' and 'bipolar depression', resulted in 56 and 77 hits in pubmed up to 2007, proving this field of research to speed up lately. Comprehensive reviews[44, 45, 46] highlight several aspects in more detail and are suggested for further reading. Table 2.3.5.3 summarizes the most relevant findings from morphometric post-mortem studies.

Macroscopic findings

Four studies examined macroscopic measures such as the gross brain morphology,[47] brain weight and ventricular volume,[48] and the area or volume of specific regions such as the hippocampus, parahippocampal gyrus (Altshuler *et al.* 1990), striatum, globus pallidus, and corpus callosum.[48, 49] In comparison to schizophrenic patients and/or non-psychiatric control subjects, patients with affective disorders revealed caudate lesions,[47] reduced area of the right parahippocampal gyrus,[50] increased brain and reduced ventricular volume.[48]

Microscopic findings

Several studies examined the cytoarchitecture and nerve cell, interneuronal or glial numbers of the pre- and orbitofrontal cortex,[51, 52, 53] entorhinal and insular cortex,[54, 55] anterior cingulated[56, 57] cerebellum,[58] brainstem[49, 59] and the peripheral nervous system.[60] Findings in patients with affective disorders included overall reduced neuronal numbers, together with disurbed cytoarchitecture of entorhinal cortex, reduced neuronal and glial numbers in the prefrontal cortex, the rostroventral insula and dorsal raphe, reduced Purkinje cells in anterior and posterior vermis and hemispheres of the cerebellum, reduced interneuronal numbers in layer II of the cingulate, but increased neuronal numbers of the locus coeruleus and peripheral motor neurone branching. In a series of studies focusing on the hypothalamus in affective disorders, the number of nitric oxide synthase (NOS) positive cells was

reduced in the nucleus suprachiasmaticus[61] and the paraventricular nucleus[62] in patients with affective disorder stressing the importance of this anatomical region for these illnesses.

Summary and pathophysiological conclusions

In summary, the number of postmortem studies on mood disorders is still limited but growing. There is some evidence for changes in key cortical regions, the basalganglia, the hypothalamus and brainstem. Structural brain imaging studies support the notion of mood disorders being associated with regional structural brain abnormalities, in particular regions involved in mood regulation. Because small numbers of subjects were studied, only some postmortem studies distinguished between unipolar and bipolar depression.[49] Nevertheless, recent structural imaging studies regarded this distinction worthwhile. The main abnormalities found in unipolar depression are smaller basal ganglia, cerebellum, frontal lobe and hippocampus, which may reflect disease-course-related atrophy. Bipolar disorder appears to be associated with larger third ventricle, smaller cerebellum, possibly smaller temporal lobe, and perhaps increased amygdala volume on the right side. In both groups, there seems to be an increased rate of subcortical white-matter lesions and periventricular hyperintensities. Whether the rate of subcortical white-matter lesions and periventricular hyperintensities are predictive of a later development of Alzheimer´s disease is yet unclear. Hippocampal plaques and tangles are increased in patients with Alzheimer´s disease with a lifetime history of major depression.[63] Further studies are needed, combining endocrine/biochemical parameters with structural parameters to identify the key regions involved in processes central to mood disorders such as changes in the regulation of the hypothalamic-pituitary-adrenal axis.

Alcoholism (Table 2.3.5.4)

The best known neuropathological feature of alcoholism is Wernicke's encephalopathy, which is characterized by degenerative changes including gliosis and small hemorrhages in structures surrounding the third ventricle and aqueduct (i.e. the mamillary bodies, hypothalamus, mediodorsal thalamic nucleus, colliculi, and midbrain tegmentum), as well as cerebellar atrophy. Most of the clinical features associated with the Wernicke-Korsakoff syndrome including ophthalmoplegia, nystagmus, ataxia, and mental symptoms such as confusion, disorientation, and even coma can be related to damaged functional systems in the hypothalamus, midbrain, and cerebellum.[64] Other important neuropathological manifestations of chronic alcoholism are central pontine myelinolysis, Marchiafava syndrome, and foetal alcohol syndrome (see Chapter 4.2.2.3).

Studies on alcohol-specific brain damage

Most of the changes mentioned above occur in association with thiamin deficiency, which is frequently, but not always, correlated with the long-term use of excessive amounts of alcohol. One major challenge is to identify those lesions caused by alcohol itself (uncomplicated alcoholism)[65] and those caused by other common

Table 2.3.5.3 Morphometric post-mortem studies in affective disorders

alcohol-related factors, principally thiamin deficiency. The following paragraph summarizes recent results in this field, which has been reviewed in detail by others.[65, 66] Brain shrinkage can be found in uncomplicated alcoholism, which can largely be accounted for by loss of white matter. Some of this damage appears to be reversible. However, alcohol-related neuronal loss has been documented in specific regions of the cerebral cortex (superior frontal association cortex), hypothalamus (supraoptic and paraventricular nuclei), and cerebellum. The data are conflicting for the hippocampus, amygdala, and locus coeruleus. No changes are found in the basal ganglia, nucleus basalis, or serotonergic raphe nuclei. Concerning the prefrontal lobe it is interesting to note that although alcohol related pathology affects both neuronal and glial cells, the effects on glia are more dramatic than on neurones.[52] The cellular changes are more prominent and spread across cortical layers in alcohol dependent subjects compared to subjects with mood disorders.[52] As pointed out above, many of the regions being normal in uncomplicated alcoholics are damaged in those with Wernicke-Korsakoff syndrome. Dendritic and synaptic changes have been documented in uncomplicated alcoholics, and these, together with receptor and transmitter changes, may explain functional changes and cognitive deficits that precede the more severe structural neuronal changes.

Summary and pathophysiological considerations

In summary, there is neuropathological evidence showing that alcohol *per se* causes damage to both grey and white matter. White-matter damage is predominant and results in a reduction in brain volume. A component of the white-matter loss appears to be reversible in some cases, given a significant period of abstinence. The grey-matter damage appears to be regionally selective, but many areas of the brain appear to be resistant to damage.

Thiamin deficiency accounts for a major component of the brain damage in alcoholics. Animal models suggest the distribution and extent of neuronal loss to be dependent on the duration of alcohol exposure, the magnitude and mode of exposure (ingestion, inhalation, etc.), the genetic susceptibility of the species, and the strain of animals studied.[65] It has been suggested that alcohol withdrawal may play a role in brain damage, evidenced by the fact that a number of workers have shown loss of granule cells in the dentate gyrus of the hippocampus continuing even after alcohol exposure stops.[67] It was furthermore suggested that up-regulation of *N*-methyl-d-aspartate receptors may lead to withdrawal seizures and enhanced susceptibility to excitotoxicity, which may explain the continuing damage described.[68]

2.3.6 Functional positron emission tomography in psychiatry

P. M. Grasby

Introduction

Positron emission tomography (**PET**) and single-photon emission tomography (**SPET**) are powerful tools for investigating the pathophysiology of psychiatric illnesses and the action of psychotropic drugs. With these techniques monoaminergic, cholinergic, opioid and benzodiazepine receptors, regional cerebral blood flow, glucose and oxygen metabolism can be measured in the living brain (Table 2.3.6.1). Thus, neural function of direct relevance to neurochemical and anatomical theories of psychiatric illnesses can be sampled.

Methodology of PET and SPET[(1)]

In brief, PET and SPET comprise the following:

- The production and incorporation of a positron or gamma-emitting radio-isotope into a molecule of biological interest to form a radiotracer administered to humans (Plate 3).
- The use of PET or SPET cameras to detect the emitted gamma radiation from the decaying radio-isotope and hence the 3D distribution of the radiotracer, over minutes to hours, in living human brain (Plate 4).
- Quantification of a physiological parameter of interest, such as number of available receptors or regional cerebral blood flow, from the mathematical modeling of the measured radio-activity in the brain over time (Plates 5 and 6).

Production of isotopes

Common PET radio-isotopes, produced by a cyclotron, are oxygen-15 ($^{(15)}$O), carbon-11 ($^{(11)}$C), and fluorine-18 ($^{(18)}$F) (with half-lives of 2.03 min, 20.4 min, and 109.8 min respectively) whilst SPET radio-isotopes include technetium ($^{(99m)}$Tc) and iodine-123 ($^{(123)}$I) (with half-lives of 6.02 h and 13.2 h respectively). With appropriate radiochemistry, isotopes can be incorporated into specific molecules to make radiotracers. Following quality control procedures, to estimate specific activity and radiochemical purity, the radiotracer is injected intravenously into subjects lying in the PET camera (Plate 3). Importantly, the total mass of radiotracer injected is very small (typically less than 5 μg) and therefore the radiotracer has no pharmacological effect itself.

PET versus SPET

SPET radiotracers are less diverse than PET tracers. However, SPET is cheaper than PET and less technically demanding, making it more readily available in hospitals and research centres. PET radiochemical procedures require in-house automated rapid synthetic chemistry facilities in dedicated hot cells, whereas SPET chemistry is more straight-forward and does not require such extensive facilities. For research and quantitation purposes, PET is far superior to SPET, although any widespread commercial/clinical application is

Table 2.3.6.1 Established and novel radiotracers for psychiatry

Radiotracer	Application	Comments
PET radiotracers		
$H_2{}^{15}O$	Blood flow	Used to map dysfunctional brain areas involved in psychiatric illnesses. Effectively replaced by functional MRI techniques such as BOLD.
^{18}F-FDG	Glucose metabolism	Used for many resting state studies and nowadays to define psychotropic drug effects.
^{11}C-SCH 23390	Dopamine D_1 receptor	Receptor occupancy studies with neuroleptics. Reports of altered cortical D_1 receptors in drug naive schizophrenics.
^{11}C-NNC 112		
^{11}C-Raclopride	Dopamine D_2 receptor	Robust demonstration of no elevation of striatal D2 receptors in drug naive schizophrenics. Striatal D_2 receptor occupancy studies with many neuroleptics. Frequently used to index dopamine release.
^{11}C-FLB-457	Dopamine D_2 receptor	High affinity ligand; enabling extrastriatal D_2 populations to be measured. Studies in schizophrenia in progress. Binding may be sensitive to endogenous dopamine release.
^{18}F-Fallypride	Dopamine D_2 receptor	High affinity ligand; enabling striatal and extrastriatal D_2 populations to be measured. Binding may be sensitive to endogenous dopamine release.
^{18}F-Fluorodopa	Dopamine synthesis capacity	Radiotracer predominantly imageable in basal ganglia, cortical signal weak. Consistent reports of raised ^{18}FDOPA in schizophrenia.
^{11}C-Flumazenil	Central benzodiazepine receptors	Labels all subtypes of central receptor.
^{11}C-MDL-100907	5-HT_{2A} receptors	Most suitable ligand for imaging 5-HT_2 receptors.
^{11}C-WAY 100635	5-HT_{1A} receptors	Reports of reduced 5-HT1A availability in depressive and anxiety disorders
^{11}C-desmethyl WAY		
^{11}C – FCWAY		
^{18}F - MPPF		
^{11}C-DASB	5-HT transporter	Studies in depressive illness. Occupancy studies of SSRIs.
^{11}C-McN 5652		Used to examine effects of ecstasy
SPECT radiotracers		
^{99m}TcHMPAO	Blood flow	Many resting state and two scan activation studies in psychosis.
^{123}I-Iodobenzamide	Dopamine D2 receptors	Occupancy and dopamine release studies in schizophrenia
^{123}I-Epidepride	Dopamine D2 receptors	Striatal and Extrastriatal D2 receptors. Used to show 'limbic selectivity' of certain neuroleptics
^{123}I-QNB	Muscarinic acetycholine receptors	
^{123}I-CIT	Dopamine and 5-HT reuptake sites	Studies in depressive illness

likely to be SPET based because of the technology restraints and costs associated with PET scanning.

Imaging of radiotracer, data collection, and analysis

PET utilizes the disintegration of positrons emitted from unstable nuclei such as$^{(11)}$C (Plate 4). Emitted positrons travel a short distance in tissue before annihilation by collision with an electron.[1] On annihilation, two high-energy gamma rays are generated with a separation angle of 180° (Plate 4). Radiation detectors (e.g. bismuth germanate), 180° apart and linked in electronic coincidence circuits, detect the resulting gamma radiation and therefore localize the source of radiation to a volume between any two detectors (Plate 3). By arranging rings of detectors around the subject's head and using computer-based back-projection techniques, the distribution of radiotracer within tomographic slices of the brain can be obtained.[1] SPET radioisotopes, in contrast, decay by emitting a single gamma ray and therefore the radiation detectors are not linked in coincidence circuits. State-of-the-art PET and SPET cameras have transaxial spatial resolutions of the order of 4 to 5 mm and can detect subnanomolar concentrations of receptors.[1]

Positron-emitting isotopes can be incorporated into molecules associated with diverse biochemical processes in the brain. For example, the positron emitter$^{(11)}$C can be incorporated into a molecule WAY 100635, which selectively binds to 5-HT_{1A} receptors, and injected intravenously in tracer amounts. Brain regions will show different profiles of radio-activity accumulation over time as the radiotracer binds in areas with a high density of 5-HT_{1A} receptors (medial temporal cortex) whilst in regions with no or sparse receptors (cerebellum), it will be washed out (Plate 5). By this means, specific and non-specific binding can be distinguished. With an appropriate model of the radiotracer's history in tissue over time, a quantitative measurement of 5-HT_{1A} receptor number in tomographic slices of the human brain can be obtained.[1] With some radiotracers (e.g. [11C]diprenorphine to label opiate receptors) it may be necessary to undertake radial artery cannulation to obtain an 'input function'[1] that describes the time course of presentation of radiotracer to the brain (Plate 6), whereas others tracers can be modeled with a 'pseudo' input function from a reference region.

Technical and practical limitations of PET and SPET compared with other imaging modalities

PET and SPET excel in the measurement of neurochemical parameters *in vivo* at very low (subnanomolar) concentration. Such sensitivity cannot be matched by other *in vivo* methods such as proton magnetic resonance spectroscopy (millimolar range). However, radiation dosimetry limits the number of scans that subjects may receive. Full quantitation can often be achieved with PET, unlike

SPET. However, for imaging blood flow change, or its correlates such as BOLD arterial spin labeling (ASL) and functional magnetic resonance imaging (fMRI), now offer the possibility of repeated measures (without radiation exposure) that far exceed that possible with PET- and SPET-based methods of flow mapping. Full quantitation of blood flow is not yet readily achievable with functional MRI without injection of contrast agents. In contrast, MRI based ASL can achieve full quantification. One disadvantage of functional MRI over PET, for some subjects, is the noisy claustrophobic environment of the scanner, but generally subjects and paradigms studied with PET flow mapping can be readily investigated with functional MRI (see Chapter 2.3.8), although all test materials in the vicinity of the scanner have to be non-magnetic.

Structural MRI scanning is often used in conjunction with PET activation and ligand binding techniques. The high-resolution anatomical information contained in MRI images can be used to precisely define areas of activation or radiotracer binding observed in PET studies from single subjects.

PET and SPET, and even functional MRI, have relatively poor temporal resolution (seconds) compared with electrophysiological methods such as EEG, event-related potentials, and magnetoencephalography (milliseconds), but these methods in turn suffer from poor spatial resolution. Attempts to integrate information from these different modalities are a major focus of methodological research in many imaging centres.

PET and SPET imaging strategies in psychiatry

These techniques (see Table 2.3.6.2) are used to either measure brain receptors and neurochemistry, or map functional brain activity via the indices of regional blood flow and glucose utilization.

Table 2.3.6.2 Summary of PET functional brain imaging approaches

Functional brain mapping: rCBF or metabolism is measured as an index of local neural activity

(a) Studies in normal volunteers in which 'activation' paradigms are used to identify functional anatomy that is relevant to psychiatric disorders
(b) Activation studies in patients who are compared with matched control subjects
(c) Studies in which the biological variable (e.g. rCBF) is correlated with a relevant clinical variable (e.g. hallucinations) within the patient group
(d) The longitudinal comparison of patients before and after various treatments and into clinical recovery
(e) Cross-sectional studies of resting-state brain activity in patient groups in comparison with appropriate controls

Radioligand imaging: the specific uptake and binding of radiolabelled tracer compounds is measured

(a) To estimate baseline radioligand uptake at rest in patient groups in comparison with controls
(b) Within-patient group correlations between radioligand uptake and particular symptoms/signs
(c) Longitudinal comparison of radioligand uptake in patients before and after various treatments and into clinical recovery
(d) 'Displacement' or radioligand activation studies designed to detect changes in the levels of intrasynapcic neurotransmitters in response to a pharmacological or cognitive challenge
(e) Investigation of the receptor binding and occupancy characteristics of psychotropic drugs

rCBF, regional cerebral blood flow.

Each approach attempts to define trait and state abnormalities of psychiatric illnesses or the effect of psychotropic drug action.

Because of the technical complexities, it is important to bear in mind the following questions when judging experimental results.

- What assumptions are made about the behaviour of the radiotracer *in vivo*?
- Has the radiotracer been well validated for the apparent physiological parameter measured ?
- Does the mathematical model of the radiotracer's behaviour give a good fit to the raw data?
- Is the spatial resolution of the PET camera sufficient for the regions measured?
- What is the test-test reliability for the PET radiotracer measure?
- How have the raw PET images been modified/treated in the data analysis?
- How have regions of interest been defined?
- Is there a possibility of observer bias in the measurements made?
- What statistical techniques have been used, and are the statistical thresholds appropriate?
- Do the statistics reflect fixed or random effects and the multiple comparisons made?

Measuring brain receptors and neurochemisty

Many neurochemical hypotheses, generated by post-mortem and animal data, can be rigorously tested with PET and SPET in the living brain whilst avoiding many of the confounding variables inherent in *in vitro* techniques. Many receptor systems can be studied (Table 2.3.6.1). For receptor mapping, particular successes in this area are the range of tracers available to image select components of dopaminergic and serotoninergic neurotransmission. For example, with presently available radiotracers it is possible to measure Dopamine D_1, striatal D_2, extrastriatal D_2, Dopamine reuptake sites, index Dopamine synthesis and endogenous dopamine release. For the serotonin system, 5-HT_{1A}, 5-HT_{2A} and 5-HT transporters can be readily measured. However, the rate of discovery of new radiotracers, suitable for use in humans, is relatively slow. Many conditions have to be satisfied to produce a suitable radiotracer for human use including blood-brain barrier permeability, high specific binding, receptor selectivity, absence of radioactive metabolites in brain, and adequate modelling of tracer kinetics (Plate 6). Practically, the increasing use of PET neuroreceptor mapping in the pharmaceutical sector should lead to a greater range of tracer availability due to the large chemical libraries within the industry.

Mapping brain activity by imaging blood flow and glucose metabolism

Regional cerebral blood flow and glucose metabolism are indicators of regional neuronal synaptic activity.[2] Radiotracers for these processes, such as $H_2{}^{(15)}O$ to index blood flow, are used to image brain activity in psychiatric illness. Glucose metabolic mapping using [$^{(18)}$F]deoxyglucose has some disadvantages over flow mapping. Radiation dosimetry limits for [$^{(18)}$F]deoxyglucose and the long half-life of the tracer restrict repeated measurement in a subject over a short time-scale. In contrast,$^{(15)}$ O-based methods allow, for example, 12 measurements of regional blood flow over a 3 h period in a single subject.

The rapid development of PET cameras and automated data analysis techniques in the last few decades has established flow-based functional imaging as a large and active research activity.[2]

As the techniques of regional cerebral blood flow mapping have advanced there has been an equivalent sophistication of experimental design with rest state studies being overshadowed by activation paradigms.[2] In an activation design, subjects are engaged in a specific cognitive task whilst being scanned, for instance generating words, and the blood flow pattern is compared with flow present in a baseline condition such as repeating words. PET activation experiments may involve categorical, correlational, and factorial designs.[2] Although, the more recent advent of fMRI-based methods is now surpassing PET-based methods for functional brain activation mapping, there are certain situations where PET-based methods may be preferred. These include functional measurements in brain areas prone to susceptabilty artifacts in fMRI such as the temporal poles/basal frontal areas. In addition, PET [$^{(18)}$F]deoxyglucose remains a more direct measure of neural activation than all flow-related methods including fMRI and ASL, a potentially important consideration when investigating the central functional effects of CNS drugs that might also alter blood flow directly.

Novel designs and data analysis for PET studies

Developments in this area have been very rapid.[2] Examples would include the use of principal components technique to analyze PET activation data sets and attempts to determine measures of functional and effective connectivity between brain regions activated by a given task. For PET receptor studies, the use of cluster analysis, parametric approaches and simplified reference region models are of considerable interest and are now in common use.[3] Furthermore, attempts are being made to relate PET neurochemical measures to other imaging modalities and genetic factors. Examples of studies in these areas would include explorations of the relationship between densities of 5-HT$_{1A}$ receptors and amygdala reactivity during emotional processing,[4] and influence of genetic polymorphisms on 5-HT$_{1A}$ receptor expression.[5]

Imaging pathophysiology: examples from schizophrenia research

Imaging dopamine receptors

Much research effort has focused on *in vivo* PET/SPET measurement of striatal dopamine D_2-receptor number in schizophrenia following the initial post-mortem reports of increased striatal dopamine receptor number. Initially, using [$^{(11)}$C]N-methylspiperone as a radiotracer, a two- to threefold raised striatal D_2-receptor number in drug-naive schizophrenics was reported.[6] However, subsequently other investigators using [$^{(11)}$C]raclopride, [$^{(11)}$C]N-methylspiperone, [$^{(123)}$I]iodobenzamide, [$^{(76)}$Br]bromolisuride failed to detect such elevations of striatal dopamine D_2-receptor number.[7,8] The different radiotracer methodologies used, the selectivity of radiotracers for dopamine D_2, D_3, and D_4 receptor subtypes, and the clinical characteristics of the patients studied have been advanced as possible explanations for the failure to replicate raised striatal dopamine D_2-receptor number. However, given these conflicting but essentially negative results, attention has shifted in recent years to reports of increased presynaptic dopaminergic function measured with [$^{(18)}$F]dopa[9] and cortical dopamine D_1 receptors measured with [$^{(11)}$C]SCH 23390 and [$^{(11)}$C]NNC 112[10] in schizophrenia. Most recently low density extrastriatal D_2 receptors are being imaged with [$^{(11)}$C]FLB-457 and [$^{(18)}$F]Fallypride. However, the newer patient studies reporting changes of cortical D_1 and extrastriatal D_2 receptors await further replication.

A novel extension to studies utilizing PET/SPET radiotracers for imaging dopamine D_2 receptors has been to index dopamine release during a pharmacological challenge in schizophrenia. Theoretically, PET/SPET has the potential to detect neurotransmitter release associated with behavioural and pharmacological challenges if sufficient endogenous neurotransmitter is released to cause appreciable change (via receptor occupancy) in the number of 'available' receptors that can be 'seen' by a radioligand. For example, pre-dosing animals and human subjects with d-amphetamine, which releases dopamine, results in decreased [$^{(11)}$C]raclopride and [$^{(123)}$I]iodobenzamide binding to dopamine D_2 receptors.[11] Enhanced release of striatal dopamine in acutely symptomatic patients with schizophrenia following pharmacological challenge has been reported in a large cohort.[10,12] In these studies, the displacement of radiotracer (presumably reflecting increased release of dopamine) correlated with worsening of positive symptoms. This important finding of increased dopaminergic responsivity, together with the consistent reports of raised [$^{(18)}$F] FDOPA uptake, provide some of the most convincing *in vivo* evidence to support the hypothesis of subcortical dopamine overactivity in schizophrenia.

Imaging blood flow change, hypofrontality and cortical inefficiency

From the outset of the functional neuroimaging of schizophrenia there has been discussion as to whether the frontal lobes of patients are 'less active' than those of normal subjects.[13] However, hypofrontality, whether at rest or during cognitive challenge, has not been a universal finding in all studies, making it a somewhat unreliable trait marker of schizophrenia. It has been found in about 50 per cent of resting-state studies but more often in activation paradigms.[14] Discrepant results might be attributable to the nature and demands of the task used, task performance, and the symptom profiles of patients studied. For example, Frith *et al.*[15] and Fletcher *et al.* used PET to study paced verbal fluency activations in chronic and acute schizophrenic patients, on and off neuroleptic medication, respectively, and failed to find hypofrontality. But pacing tasks could be criticized on the grounds that slowing the task so that patients and normal subjects perform equally, fails to address a dysfunction that may be expressed when patients are required to produce 'normal' levels of performance. This is a difficult issue to resolve. Pacing patients and controls means that performance levels may be matched, and therefore differences of brain activation are not confounded by the patients' failure to do the task. Yet it may be instructive to image patients attempting to perform a task that stresses (dysfunctional) cognitive processes, produces altered brain activity and hence impaired performance.

Many authors have suggested hypofrontality may be most pronounced in schizophrenic patients who have predominantly 'negative' symptoms. This view has received support from a large cross-sectional study of chronically symptomatic patients where resting blood flow was measured in 30 patients.[16] Within this

group of schizophrenic patients, greater hypofrontality was seen among those with the most pronounced negative symptoms as assessed by factor analysis. That symptoms and not the diagnosis of schizophrenia *per se* may be an important factor in hypofrontality is apparent in one study where poverty of speech (a sign of psychomotor retardation or poverty) was associated with reduced regional cerebral blood flow in the left dorsolateral prefrontal cortex, irrespective of diagnosis of depression or schizophrenia.[17] Some SPET and PET studies also suggest a relationship between hypofrontality and the presence of positive symptoms,[18,19] and hypofrontality (at rest or on activation) may resolve when symptoms improve.[20] Finally, contrary to the earlier notions of hypofrontality an alternative view of 'cortical inefficiency' has been advocated whereby patients with schizophrenia are suggested to have over activation (i.e. hyperfrontality) of frontal areas. In these studies it has been suggested that when patients and controls are performing at similar levels, patients show enhanced cortical activation reflecting the inefficient signal processing within the frontal cortex.[21]

Imaging pathophysiology: examples from depressive disorders

Imaging 5-hydroxytryptamine receptors

Impressive progress has seen the development of new radiotracers for the 5-hydroxytryptamine (**5-HT**) system; hypothesized to be dysfunctional in affective illness and to be the prime target for many antidepressant treatments. In particular, radioligands for 5-HT_{1A},5-HT_{2A} receptors, and the 5-HT transporter, are now established (Table 2.3.6.1).

One notable success is the radioligand [$^{(11)}$C]WAY 100635 for imaging 5-HT_{1A} receptors in the human brain.[22] As many antidepressant treatments alter 5-HT_{1A} receptor function in rodents, and 5-HT_{1A} knock out mice are anxious this ligand is proving useful investigating 5-HT_{1A} receptor populations in depressed or anxious patients before and after treatment. Studies in anxiety and depression are now being reported with suggestions of reductions of 5-HT_{1A} availability in these conditions.[23]

[$^{(11)}$C]N-methylspiperone, [$^{(18)}$F]altanserin, [$^{(18)}$F]ethylspiperone, [$^{(18)}$F]setoperone or [$^{(18)}$F]altanserin, and the SPET tracer [$^{(123)}$I]ketanserin have been used to measure 5-HT_2 receptor number; a receptor implicated in depressive illness, suicidal behaviour, and psychosis. Many of these 5-HT_2 ligands have been hampered by either the lack of selectivity, or the relatively low ratio of specific to non-specific signal obtained in the human brain,[24] although a few studies have appeared, reporting reduced 5-HT_2 receptor number in drug-free depressed patients. Further studies are needed using more selective ligands with higher signal-to-noise ratios, such as [$^{(11)}$C]MDL 100907, a promising selective ligand for 5-HT_{2A} receptors (Table 2.3.6.1). For the serotonin transporter, of the available tracers, [$^{(11)}$C]DASB gives a reasonable signal to noise ratio and studies have convincingly shown that standard efficacious doses of SSRI antidepressants are associated with substantial occupancy at this site.[25] Occupancy at the 5-HTT site occurs after first dosing, and responders and non responders do not differ in terms of SSRI occupancy levels, suggesting 5-HTT occupancy is perhaps a necessary but not sufficient explanation for the antidepressant effect.

Imaging blood-flow change in depressive disorder

Similarly to brain-mapping studies of patients with schizophrenia, regional deficits of neural activity (indexed by cerebral blood flow or glucose utilization) can be detected in the 'resting' brains of depressed patients.[26,27] Many resting-state studies have shown a reduction of regional brain functional activity, most frequently reported in the prefrontal cortex, compared with normal controls. However, the exact location of prefrontal change (dorsolateral, ventrolateral, orbitofrontal, and medial frontal areas) has been variably emphasized by different authors.[26–28]

As demonstrated in schizophrenia, significant associations between cortical activity and cognitive function, symptom clusters, including mood, and response to treatments are apparent.[27,28] Similar to schizophrenia, the resting-state functional brain abnormalities may represent the physiological correlates of aspects of the depressed state such as depressed mood, retardation, or cognitive impairment rather than trait markers of the illness itself.

Psychological challenge paradigms have been applied in studies in depressed cohorts to test whether specific brain regions, subserving select cognitive processes, are impaired in depressed patients. Currently, however, the majority of challenge paradigms in depressed subjects are undertaken with fMRI methods.

Imaging psychotropic drug action

Of direct clinical relevance are imaging studies of antipsychotic drug action where clinical efficacy and side-effects are related to receptor occupancy.[29,30]

Many studies have investigated the occupancy of striatal dopamine D_1 and D_2 and cortical serotonin 5-HT_2 receptors by neuroleptic drugs. Farde's group first demonstrated that clinically efficacious doses of a variety of classical antipsychotics cause between 65 per cent and 89 per cent occupancy of central dopamine D_2 receptors.[29] Higher receptor occupancy [(gt)85 per cent] is associated with an increased incidence of extrapyramidal side effects. Thus, there may be a therapeutic window for occupancy of between 65 per cent and 85 per cent, which is antipsychotic and yet less likely to cause extrapyramidal side effects. In contrast, treatment with classical antipsychotics produces variable levels of occupancy of striatal D_1 receptors. Interestingly, efficacious doses of the atypical antipsychotic clozapine are associated with a relatively low D_2 receptor occupancy (38–63 per cent) and a D_1 occupancy of 38 to 52 per cent.[29] This unexpected finding of low D_2 receptor occupancy, reproduced in different patient groups with both PET and SPET techniques, has challenged theories of a simple relationship between D_2 occupancy *per se* and clinical efficacy. Further evidence for this view comes from studies showing that schizophrenic antipsychotic non-responders have the same levels of dopamine D_2 occupancy as responders and that occupancy occurs as rapidly as 2 h after acute administration of the antipsychotic yet efficacy takes weeks to appear.

PET/SPET is also proving useful in the characterization of atypical antipsychotics. The binding of antipsychotic drugs to central 5-HT_2 receptors is a possible candidate for the mechanism of 'atypicality' and studies suggest high cortical 5-HT_2 occupancy with many atypicals including risperidone (80 per cent) and clozapine (84–90 per cent).[29,30] Other targets for some atypical neuroleptics include the 5-HT_{1A} receptor[31] and in addition, limbic

selectivity (i.e. neuroleptic limbic occupancy > striatal occupancy) is an actively researched explanation for atypicality.[32]

Conclusions

So far, the PET and SPET radiotracer techniques have been immediately valuable in assessing the receptor occupancy effects of antipsychotic drugs and of mapping the neural correlates of dysfunctional cognitive processes and psychiatric symptoms. Although the applications described have not yielded a diagnostic test, the techniques are undoubtedly providing unique information about the pathophysiology of psychiatric illnesses. Such information is likely to be key for the development of truly novel treatments.

Further information

2.3.7 Structural magnetic resonance imaging

J. Suckling and E. T. Bullmore

Introduction

Magnetic resonance imaging (**MRI**) is a versatile and evolving technology for visualizing the structure, function, and metabolism of the living human brain. All kinds of MRI data can be acquired without exposing subjects to ionizing radiation or radioactive isotopes. Installing the hardware for MRI represents a major capital investment, of approximately £1.5 million. For these three reasons of versatility, safety, and (relative) affordability, MRI continues to be the dominant brain-imaging technique in psychiatric practice and research.

In this chapter, we introduce the principles and practicalities of MRI and describe common methods of structural MRI data acquisition and analysis. Chapter 2.3.8 on functional MRI provides greater detail on statistical issues arising in image analysis.

Magnetization

If iron filings are scattered on a piece of paper they will be oriented at random. If a bar magnet is then placed under the paper, the iron filings will align themselves so that each filing lies parallel to the magnetic field produced by the magnet. More technically, we can say that iron filings have a susceptibility to be magnetized by a static magnetic field.

Susceptibility refers both to the effect of a magnetic field on an object, and the effect of that object on the field. Paramagnetic materials, like some metals, tend to be attracted by magnets and cause a local increase in the magnetic field strength. Diamagnetic materials, like carbon and many organic compounds, tend to be repulsed by magnets and cause a local decrease in field strength.

The brain also has a susceptibility to be magnetized. It is largely composed of water and each molecule of water comprises, of course, two hydrogen atoms and one oxygen atom. The hydrogen nucleus is a single positively charged proton, which has a dynamic property called spin. Like all moving charged particles, spinning protons generate a magnetic field. The axis of the magnetic dipole generated by a spinning proton is sometimes called its magnetic moment, and is drawn as a vector.

When the brain is placed in a strong magnetic field, the spinning protons align themselves with the external field, just as iron filings align themselves to the field of a bar magnet. The angle of alignment between each proton's moment and the (longitudinal) axis of the external magnetic field is α. Protons obey the laws of quantum mechanics, and so two modes of alignment or spin states are possible, one with the magnetic moment in the direction of the field ($\alpha = 0°$) and one with the moment in the opposite direction ($\alpha = 180°$). Depending on the strength of the applied field, the spin states have slightly different probabilities, with those protons aligned in the direction of the field in excess by about 5 ppm at an external field strength of 1.5 T. (Magnetic field strength is measured in units of gauss (**G**) or tesla (**T**): 1 T = 10 000 G. The earth's magnetic field is approximately 0.5 G; a child's toy magnet has a field of around 10 G.)

Thus, if the magnetic moments for all spinning protons are averaged, the net, or bulk, magnetization vector for the brain as a whole will have $\alpha = 0°$. The length of the net magnetization vector then represents the strength of longitudinal magnetization (Fig. 2.3.7.1).

Protons aligned with a static magnetic field are not static themselves, they rotate or precess at very high frequency around the axis of the external field. The precession frequency, or Larmor frequency, is constant for a given type of atomic nucleus and external field strength. For protons, the Larmor frequency at 1.5 T is 63.9 MHz. However, although all hydrogen nuclei in the brain precess at the same frequency in the same field, they will not all precess with the same phase. At any given time, different nuclei have reached a different point in their rotation around the external field axis.

Nuclear magnetic resonance

When a wineglass is tapped by a knife, it produces a high-pitched sound of characteristic frequency. If a singer can exactly match that frequency with her voice then the glass will resonate and may break. The basic idea is that if an object has a characteristic frequency of oscillation, exposing it to energy precisely at that frequency will cause a change in physical state.

Analogously, if we supply a pulse of radio-frequency energy at (and only at) the Larmor frequency to a brain located in a magnetic field, the protons within the brain will absorb the energy and resonate—this is nuclear magnetic resonance (**NMR**)—and their angle of alignment α with the external field will increase. If sufficient energy is supplied to cause $\alpha = 90°$, the radio-frequency pulse is called a '90° pulse'. If the net magnetization vector is flipped to an angle $\alpha = 180°$, the radio-frequency pulse is called a '180° pulse'. At the same time as the angle of alignment is increased by radio-frequency irradiation, the phase of precession becomes coherent over all protons. In other words, in place of the random variation in the phase of precession that existed before the radio-frequency pulse, protons are now 'marching in step' with each other around the axis of the external field.

After the radio-frequency pulse has ceased, the resonating nuclei gradually relax back to the equilibrium state of random precession in alignment with the external field. The two components of this relaxation process are characterized by relaxation times. The first relaxation time (T_1), also called the spin-lattice relaxation time, describes the time taken for the strength of longitudinal magnetization to return to 63 per cent of its value before radio-frequency irradiation. This is a measure of the time taken for α to return to zero having been flipped to 90° or 180°. T_1 is determined by interactions between protons and their long-range (molecular) environment

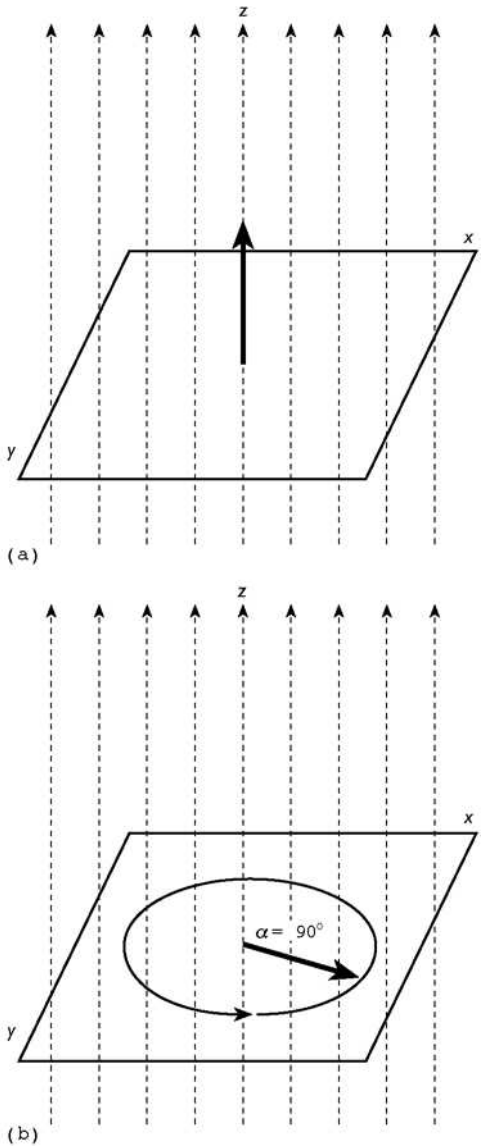

Fig. 2.3.7.1 Net magnetization vector.
(a) In a static magnetic field, the vector is aligned parallel to the longitudinal **z** axis of the field and **α** = 0.
(b) Immediately after a 90° excitation pulse of radio-frequency energy at Larmor frequency, the angle of alignment **α** is increased (transverse magnetization) and the phase of precession in the **x–y** plane is coherent over all protons in the brain. As protons relax following excitation, the angle of the net vector becomes smaller (return of longitudinal magnetization) and the phase of precession becomes more variable from one proton to another (dephasing).

or lattice. The second relaxation time (T_2), also called the spin–spin relaxation time, describes the time taken for the flipped nuclei to stop 'marching in step' around the axis of the field. This process of dephasing begins as soon as the radio-frequency pulse stops, but its rate is determined by the immediate (atomic) environment of the protons. Small variations in the applied magnetic field accentuate spin–spin relaxation, resulting in an observed relaxation time T_2^* which is somewhat faster than the 'true' relaxation time T_2 that would have been observed in an ideally homogeneous field.

As protons relax, they release the energy absorbed from the radio-frequency pulse in the form of a weak radio-frequency signal, which decays at a rate normally determined by T_2^*. This process is called free induction decay, and the emitted signal forms the data from which magnetic resonance images are ultimately constructed.

Magnetic resonance imaging

Spin echo sequence

A widely used MRI technique is the spin echo sequence. A 90° radio-frequency pulse is repetitively applied to the brain with a constant repetition time (TR ms) between consecutive pulses. Following each 90° pulse, protons are excited and then relax. The dephasing component of relaxation can be reversed by applying a second 180° pulse some time (TE/2 ms) after the 90° pulse. Following the first 90° pulse, protons immediately begin to precess idiosyncratically and the emitted signal decays. By reversing this process, the 180° pulse causes rephasing and an increase in emitted signal which has a maximum or echo at TE ms (time to echo) after the initial 90° pulse (Fig. 2.3.7.2).

The spatial location of the radio-frequency signal emitted by free induction decay in a given volume of the brain is encoded in three spatial dimensions by slice-selective radio-frequency irradiation combined with frequency- and phase-encoding gradients. To improve scan time, multiple slices can be excited in an interleaved fashion (multislice acquisition). This means that after the output signal is detected from one slice, and while the net magnetization vector is relaxing back to its equilibrium state, other slices can be excited. The in-plane resolution (voxel size) of the image is determined by the field of view and the number of voxels in the image. Typically, in-plane resolution at 1.5 T is in the order of 0.5 to 2 mm, and slice thickness is 2 mm or more.

Tissue contrast

The outstanding advantage of MRI for the anatomical examination of the brain is the easily visible contrast in the images between grey matter, white matter, and cerebrospinal fluid. In particular, contrast between parenchymal tissues (grey and white matter) has made MRI the imaging research tool of choice for identifying subtle cortical abnormalities in a wide variety of psychiatric disorders.

Tissue contrast in magnetic resonance images is determined by differences in the density of protons, and their physical and chemical environment. A tissue such as the cerebrospinal fluid, that is

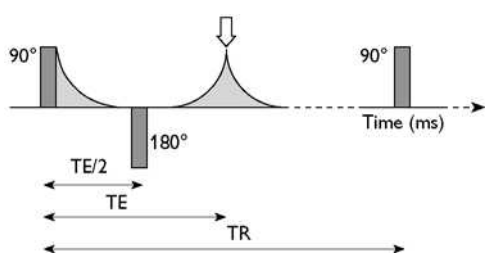

Fig. 2.3.7.2 Spin echo pulse sequence. A 90° excitation pulse of radio-frequency energy is immediately followed by exponential decay of the T_2-weighted signal. A 180° pulse TE/2 ms later causes rephasing of proton spins and an exponential increase in T_2-weighted signal with maximum (echo) TE ms after the 90° pulse. Images are acquired at TE (thick arrow). The protons are allowed to relax completely before the next 90° pulse, TR ms after the previous excitation.

composed largely of water, will have a lower proton density than parenchymal brain tissues. The physicochemical environment of protons has a marked effect on spin-lattice relaxation. If protons are mainly in freely diffusing water molecules, as they are in cerebrospinal fluid, T_1 will be prolonged, whereas if they are mainly bound to large macromolecules, as they are in fat, T_1 will be short (Table 2.3.7.1). Since grey matter contains proportionally less fat than myelinated white matter, T_1 is longer for grey matter. Spin–spin relaxation is likewise determined, in part, by the immediate physical environment of protons in the tissue; liquid tissues will have prolonged T_2 times compared with solid tissues. Other effects on apparent relaxation times (T_2^*) include minute fluctuations or inhomogeneities in the strength of the external magnetic field, which may be due to the local paramagnetic effects of iron-containing compounds such as haemoglobin.

The parameters of the spin echo pulse sequence, repetition time (TR), and time to echo (TE), can be judiciously adjusted to acquire images that are sensitive to or weighted by one or other of these possible sources of tissue contrast.

If TR is long (>1000 ms) and TE is short (<20 ms), contrast in the images will be weighted by differences between tissues in proton density. Proton-density-weighted images show good contrast between relatively hyperintense parenchymal tissue and hypointense cerebrospinal fluid (Plate 7).

If TR is short (<1000 ms) and TE is also short (<20 ms), contrast in the images will be weighted by tissue differences in spin-lattice relaxation. T_1-weighted images show excellent contrast between hyperintense white matter and relatively hypointense grey matter (Plate 7). For this reason, T_1-weighted images are widely used to measure quantitative abnormalities in size or shape of the cerebral cortex.

If TR is long (>1000 ms) and TE is also long (>20 ms), contrast in the images will be weighted by tissue differences in spin–spin relaxation. T_2-weighted images show strong contrast between hyperintense cerebrospinal fluid and parenchymal tissues (Plate 7), unless there is congestion or oedema of the parenchyma, in which case the T_2-weighted signal will be increased. For this reason, T_2-weighted images are widely used to identify acute, inflammatory, and ischaemic lesions.

Structural imaging sequences

An enormous range of sequences are available for brain imaging. For example, fast spin echo imaging provides a pair of dual-echo images with complementary tissue contrasts (proton density and T_2-weighted) for no increase in scan time over the spin-echo sequence. Spins can also be manipulated through changes in the applied magnetic field gradients. These sequences yield images of high-spatial resolution and a range of contrasts. Additionally, there are methods for suppressing signals due to blood flow or fat, improving signals from pathology.

Table 2.3.7.1 Relaxation times at 1.5 T for different tissue types

Tissue type	T_1 (ms)	T_2 (ms)
Grey matter	980–1040	64–71
White matter	740–770	64–70
CSF	>2000	>300
Fat (at 1 T)	180	90

CSF, cerebrospinal fluid.

Diffusion-weighted imaging

Diffusion-weighted imaging can provide information about the organization of white matter tracts in the brain that cannot be obtained by other MRI methods.

The basic idea is that protons move within and between cells by random motion. Typically, a proton may travel around 20 μm in 100 ms by this Brownian motion or diffusion. The rate of proton diffusion is related to how constrained they are by physical barriers such as myelinated cell membranes. The rate of diffusion affects the spin–spin relaxation time, with rapidly diffusing protons tending to relax more quickly. To acquire images that are weighted by differences in diffusion, two extra gradients are briefly applied during a spin echo sequence.[1]

White matter is generally hyperintense in diffusion-weighted imaging because closely packed axonal tracts provide the greatest barrier to the free diffusion of water in the brain. Furthermore, it is possible to deduce from diffusion-weighted imaging data how compactly organized the white matter is, and even to estimate in what direction the fibre tracts are oriented (Plate 8). This information is of considerable interest to psychiatry, since the pathology of many psychiatric disorders may involve the axonal connections between multiple cortical areas.[2]

Safety

MRI is absolutely contraindicated in patients who have any strongly magnetized metal object in their heads. This includes aneurysm clips, reconstructive metal plates, traumatically embedded metal fragments, or implanted electronic devices such as cardiac pacemakers. It is advisable to screen all subjects undergoing MRI by questionnaire for possible contraindications. A skull radiograph is a useful preliminary examination if there is any doubt about the presence of intracranial metal. All subjects need to provide informed consent in writing.

Static magnetic fields used in MRI cause no harmful effects to biological tissue. Rapid switching of field gradients can induce electrical currents in tissue, but at the switching speeds used in MRI these induced currents are several times less than needed for muscle contraction. Since radio-frequency energy can cause heating, limits to the amounts of energy absorbed are set by national standards.

Artefacts

Quality assurance protocols and diligent hardware servicing are necessary to maintain high standards in MRI. Image artefacts refer to loss of image quality (i.e. spatial resolution or tissue contrast) owing to a specific cause. It is often possible to effect a remedy and an awareness of their causes can often pre-empt the problem.

Movement

Subject motion is the most common artefact and has two components: voluntary and involuntary (physiological). The result of voluntary motion during acquisition may be an obvious blurring (Plate 7). The cooperation of subjects is vital and special regard is

required for children, the elderly, and those with neurological or psychiatric disorders who may find the MRI environment disconcerting. The subject's head may be physically restrained by additional padding and by Velcro straps placed across the forehead. Involuntary motion arises primarily from the cardiorespiratory cycle causing pulsation of the blood vessels and cerebrospinal fluid. This is most apparent in structural images showing major arteries.

Susceptibility

Where two materials with very different susceptibilities are closely adjacent, there may be severe distortion of the magnetic field, causing artefactual loss or exaggeration of the magnetic resonance signal. This is clearly seen in an image acquired with a metallic clip placed close to the scalp (Plate 7). Ferromagnetic (highly paramagnetic) materials that may cause artefacts include metallic dental fillings and plates, hairgrips, ear or nose rings, and even some cosmetics. A less obvious form of susceptibility artefact arises if more (diamagnetic) tissue is situated at one end of the image field of view than the other. A field gradient is set-up across the image resulting in signal loss. This is termed bulk susceptibility artefact and is often seen in images of both the head and neck (Plate 7).

Partial volume

Voxel sizes are larger than some scales of anatomical organization in the brain. A voxel may represent a heterogeneous mixture of tissue classes, or be only partially occupied by tissue of a single type. This partial volume artefact is particularly evident at the interface between cortical grey matter and sulcal cerebrospinal fluid, and at the interface between cortical grey matter and central white matter. It causes error in the estimation of tissue class volumes.

MRI hardware

Superconducting magnet

The superconducting magnets used for MRI require liquid helium cooling equipment to keep the temperature low enough (4 K) for superconduction. Cooling consumes the majority of the supplied power. Only a small current is initially required to generate the field, which is then self-sustaining.

Small variations in the homogeneity of the magnetic field give rise to distortions and artefacts. The field is minutely adjusted to improve homogeneity using additional magnets in an automated procedure known as shimming.

Magnetic field gradients are essential to MRI. Rapid switching of gradient coils produces the loud 'knocking' sound associated with magnetic resonance scanners. Three orthogonal gradients are available which are coupled to generate gradients in any direction.

Radio-frequency coil

The function of the radio-frequency coil is two-fold—to transmit the radio-frequency pulses of the imaging sequences and to receive the emitted signal. Head coils used for neuroimaging fit snugly over the subject's head, and are often of a three-dimensional design with good sensitivity throughout the volume they enclose. Surface coil designs are used to image small regions with high-spatial resolution, and phased-array coils combine several surface coils for more extensive coverage.

Computers

MRI produces large quantities of data, which require rapid processing and storage so that images may be viewed and other sequences prescribed during the same session. The computer system is integral to the machine and contains specialized hardware and software for data acquisition and image reconstruction, as well as control of the scanner.

The scanner suite

The room housing the scanner must be specially designed. It must have a reinforced floor and be environmentally controlled to maintain a constant temperature and humidity. The walls and ceiling contain a magnetic shield, which both prevents leakage of the field outside the room and stops FM radio broadcasts from being picked up by the radio-frequency coil.

MRI studies

Case-control design

Structural MRI studies in psychiatry have commonly adopted a cross-sectional or case-control design. This involves scanning two groups of subjects, patients, and matched controls, on a single occasion. The objective is generally to identify anatomical differences in brain structure between cases and controls. In evaluating or planning such a study, it is important to pay attention to several design issues, some of which are summarized below.

Power

What is the power of the study to refute the null hypothesis (zero anatomical difference between the case and control populations) when it is not true? In general, the power of a study is proportional to the sample size (the number of subjects scanned), the effect size (the anatomical difference between populations), and the probability threshold or p value adopted for hypothesis testing. The p value will often be decided in relation to the number of tests conducted—the greater the number of tests, the smaller is the appropriate p value. Therefore, the risk of low power and associated type 2 error is likely to be greatest when differences between two small groups have been multiply tested on the basis of many anatomical variables.

Representativeness

What population is represented by the sample of patients studied, and is this the population of interest? If the ambition of the study is to make inferences about the population of patients with, say, manic-depressive disorder, then it is important that the diagnosis is made according to standard and reliable criteria and that the sampling procedure is such that any patient in that population has an equal chance of being included in the study. This means that the authors of the study will need to sample cases from general practice and the community as well as from hospital clinics and wards. Sampling hospital patients is generally much easier; the patients are already well characterized and hospital treatment facilities are likely to be relatively few in number and close to the scanning unit. However, if only hospital patients are sampled, it follows that inference can only be made about the population of hospital patients, rather than the larger and more general population of individuals with the disorder.

Heterogeneity

Diagnostic categories in psychiatry may subsume considerable heterogeneity in terms of phenomenology and aetiology. For example, patients with a diagnosis of schizophrenia may differ profoundly in terms of positive or negative symptom profiles, cognitive deficit, and genetic or environmental risk factors. These natural sources of heterogeneity may be compounded by differences in treatment. Any or all of these factors may affect brain structure. Studies that simply ignore heterogeneity, or attempt to deal with it by *post hoc* statistical correction, may have less power to detect a group difference than studies which define cases according to refined or subdiagnostic criteria. Thus, studying a sample of schizophrenic patients with high negative symptom scores and marked working memory deficits may be more likely to reveal anatomical abnormalities of frontal cortex than studying an unrefined sample of patients with schizophrenia.

Matching

Ideally, the control or comparison subjects should be indistinguishable from the patients in every characteristic apart from features of the disorder. For example, it is important that cases and controls should be matched for age, handedness, and sex, since all of these factors may affect brain structure. Unfortunately, there are a number of other possible confounding factors that are not so obviously unrelated to presence of the disorder. For example, an unrefined sample of patients with schizophrenia will generally have lower IQ and smaller head size than an age- and sex-matched group of comparison subjects. Should we try to correct these differences as if they were spurious (by either refined sampling or *post hoc* statistical modelling), or should we accept that they represent real features of the disorder? In practice, most published studies tend to correct group differences on global variables by statistical modelling in order to focus attention on regional differences that may be more interesting. A comparable problem arises in relation to medication.

Other designs

A probable future trend in psychiatric MRI research over the next few years is that the hypotheses under investigation will become more concerned with aetiological mechanisms and pathogenetic models and less concerned with the basic question of whether a given group of patients has abnormal brain structure. This shift in hypothetical interest will dictate a shift in design away from case-control or cross-sectional studies.

Longitudinal designs, in which a cohort of volunteers or patients are scanned repeatedly over a period of months or years, are a powerful way of demonstrating normal and abnormal developmental changes in brain structure.[3] They have the obvious disadvantage that they are time consuming to complete and subjects may not attend for multiply repeated examination.

Genetic designs involve subjects that are defined genotypically, rather than phenotypically. Imaging studies of monozygotic twins discordant for a disorder,[4] and of families multiply affected by a disorder, are examples of genetic designs in which there may be complete knowledge about the proportion of genetic information that is shared between subjects but incomplete knowledge about the genetic constitution of each subject.

Overall, there is no single perfect design for an imaging study. Often designing a study will entail finding pragmatic and arguably justifiable solutions to problems. Furthermore, the 'goodness' of a design can really only be judged in relation to the hypothesis under investigation and the methods of analysis applied to the data. The best imaging studies will convey a sense that the design is both ingenious and inevitable, given the hypothesis and available methods, and will also include a frank discussion of the limitations or implications of the particular design adopted.

Data analysis

Clinical analysis

Structural MRI is most often used in clinical practice to exclude non-psychiatric causes for psychopathology. Clinical examination of these cases may also sometimes reveal abnormalities such as hippocampal sclerosis or callosal agenesis which suggest that psychopathology has been determined by birth injury or abnormal development. In assessment of a patient with dementia, MRI may usefully demonstrate signs of vascular disease (such as infarcts or periventricular white matter changes), or a focal pattern of grey matter atrophy suggestive of Pick's disease (frontal cortex) or Huntington's disease (caudate nucleus and frontal cortex). All of these abnormalities may be detected simply by skilled visual examination of the data. However, clinical diagnosis of the subtler abnormalities associated with, say, schizophrenia, obsessive–compulsive disorder, or autism require quantitative analysis of the patient's data and access to normative MRI measurements on appropriately matched samples of the general population. Neither quantitative analysis nor normative databases are widely used in current radiological practice, thus limiting the value of MRI to clinical psychiatry, but this may be expected to change in the future.

Quantitative analysis

There are broadly two requirements for quantitative analysis of structural MRI data. The first is to measure the anatomical structure of the brain (this is often called morphometry). The second is to test hypotheses of interest on the basis of these morphometric variables.[5] Here we shall focus on morphometry.

(a) Morphometry

A widely used method of measuring brain structure from magnetic resonance images is based on the hypothetical expectation that one or more anatomically defined regions of the brain are particularly relevant to the disorder.[6] The area or volume of each of these regions of interest (**ROI**s) can then be measured directly by drawing a line around the region on a computerized display of the data and counting the number of voxels enclosed by the line. Measurements of several ROIs may be combined to produce summary measures of asymmetry[7] or of spatially distributed anatomical systems. The advantages of ROI morphometry are that it is conceptually simple and that it allows measurement of structures (e.g. the hippocampus) or parts of structures (e.g. segments of the corpus callosum) that may be difficult to measure otherwise. Some familiar disadvantages are that it is time consuming and imperfectly reliable. More fundamentally, ROI morphometry is of limited use if it is not obvious in advance what the region of interest is, or there are several possible regions of abnormality (as is likely if the disorder is determined by an insult early in the course of brain development).

Computerized techniques are varied, but commonly adopt an approach summarized in Plate 9. In this scheme, the first step in image processing is removal of extracerebral tissues like skull and scalp leaving an image of the brain alone. The brain image is then segmented into the three main tissue classes. There are a variety of techniques for segmentation or brain tissue classification,[8] but generally the quality of segmentation is improved if multiple images of different contrasts (e.g. proton density, T_2-weighted) are available.

Once the brain image has been divided into its component classes, or even prior to segmentation, it can be automatically registered in a standard anatomical space. The value of making this transformation is potentially two-fold. First, it then becomes possible to compare brain structure between individuals at the spatial resolution of the image, that is in terms of the percentage occupancy of each voxel by each tissue class. This means that one is able ultimately to test anatomical differences between groups over the whole brain in detail, without having to assume a priori that pathological change is located in a particular region.[9,10] The second major advantage of image registration is that the parameters of the transformation used to align the image with the template may themselves be used as measures of brain structure. Thus, if an image represents a brain that is structurally abnormal in some way, the mathematical deformation which must be applied to align it with a standard template may be abnormally great.[11]

(b) Statistical testing

Morphometric variables can be used to test hypotheses by a variety of statistical analyses. For example, the null hypothesis of zero difference in brain structure between two groups can be addressed by a *t*-test of a single ROI or by many thousands of *t*-tests of, say, grey matter occupancy measured at each and every voxel. Similarly hypotheses concerning the relationship between brain structure and psychological function can be addressed by testing the correlation between a morphometric variable and the subjects' scores on a psychometric instrument. Alternatively, the relationships between several morphometric variables may be explored by multivariate methods such as partial least squares.[12]

2.3.8 Functional magnetic resonance imaging

E. T. Bullmore and J. Suckling

Introduction

Functional magnetic resonance imaging (**fMRI**) is a relatively new technique for measuring changes in cerebral blood flow. The first fMRI studies, showing functional activation of the occipital cortex by visual stimulation and activation of the motor cortex by finger movement, were published in the early 1990s.[1–3] In the years since then, fMRI has been used to investigate the physiological response to a wide variety of experimental procedures in both normal human subjects and diverse patient groups. In the next 10 years, fMRI will probably establish a role for itself in radiological and psychiatric practice; currently the clinical role of fMRI is limited to specialized applications such as assessment of hemispheric dominance prior to neurosurgery.[4]

The outstanding advantage of fMRI over alternative methods of imaging cerebral blood flow, such as positron emission tomography (**PET**) and single-photon emission computed tomography (**SPECT**), is that it does not involve exposure to radioactivity. This means that a single subject can safely be examined by fMRI on

many occasions, and that the ethical problems of examining patients are minimized. Functional MRI also has superior spatial resolution (in the order of millimetres) and temporal resolution (in the order of seconds) compared with PET and SPECT.

In this chapter, we provide an introduction to technical issues relevant to fMRI data acquisition, study design, and analysis. An introduction to the basic physical principles of magnetization and nuclear magnetic resonance, and the technology, is given in Chapter 2.3.7.

Many excellent specialist texts covering all aspects of functional magnetic resonance imaging are available for the reader seeking more detailed treatment of the issues.[5–7]

Cerebral activation and blood-flow changes

Try closing your eyes and then opening them again. At the moment that you open your eyes, neurones in the occipital cortex that are specialized for the perception of visual stimuli will show a sudden and dramatic increase in their rate of discharge. There is a short delay (approximately 100 ms) between the stimulus and neural response owing to the propagation of electrical activity from the retina via the optic nerves and tracts to the visual cortex. Later, some 3 to 8 s after stimulus onset, there will be an accompanying change in the local blood supply to the stimulated area of cortex. Blood flow increases without a commensurate increase in oxygen uptake by the visual cortex, leading to a local increase in the ratio of oxygenated to deoxygenated forms of haemoglobin.

The linkage between neural activity and regional cerebral blood flow, sometimes called neurovascular coupling, has been known since Roy and Sherrington first reported 'changes in blood supply in accordance with local variations of functional activity' in 1894. However, the biophysical and biochemical mechanisms for neurovascular coupling are complex and not yet completely defined in detail.[7]

Endogenous contrast agents

The fact that neural activity is linked to local blood flow provides the opportunity for functional MRI. The most common, and non-invasive, approach exploits the paramagnetic properties of iron in deoxygenated haemoglobin as an endogenous contrast agent. Neural activity causes a local reduction in the ratio of deoxygenated to oxygenated haemoglobin, so that the paramagnetic effects of deoxyhaemoglobin are 'diluted'. Since apparent spin–spin relaxation or dephasing is accelerated by microscopic inhomogeneities in the magnetic field due to the presence of paramagnetic contrast agents, the net effect of diluting deoxyhaemoglobin will be to prolong T_2^* times in areas of the brain that receive an increased blood flow as a consequence of neural activity. The haemodynamic effect on spin–spin relaxation can be measured by a T_2^*-weighted signal change (of 3 per cent or less) which is blood oxygen level dependent (**BOLD**).

Imaging sequences for fMRI

Several different pulse sequences can be used to collect MRI data that are sensitive to functionally determined changes in signal strength. Here we will concentrate on gradient echo sequences which, combined with special techniques for very rapid data acquisition, are most widely used to date for fMRI. However, spin echo sequences can also be used for functional MRI data acquisition, and gradient echo sequences can be used for structural MRI.

Gradient echo sequence

The basic principle is similar to spin echo imaging. An initial excitation pulse of radiofrequency energy is supplied at the Larmor frequency to the brain in the presence of a powerful static magnetic field. Protons are excited to a state characterized by increased transverse magnetization and a coherent phase of precession around the axis of the external field. Immediately the radiofrequency pulse has ceased, protons begin to relax back to their equilibrium state of maximum longitudinal magnetization and random phase of precession, emitting a radiofrequency signal by free induction decay.

In gradient echo imaging, the process of spin–spin relaxation (dephasing) is first accelerated by briefly applying a gradient to the magnetic field shortly after the excitation pulse. Then, at some time (TE/2) after the excitation pulse, a second gradient is applied to reverse the process of dephasing, causing rephasing and a signal maximum or echo some time (TE) after excitation. The sequence is repetitively applied with a constant time interval between consecutive excitations (TR).

The objective is to manipulate spin–spin relaxation by brief perturbations of the external magnetic field rather than by supplying additional pulses of radiofrequency energy as in spin echo imaging. Frequency- and phase-encoding gradients are applied to locate the sources of signal in three-dimensional space (see Chapter 2.3.7).

One advantage of gradient echo imaging is that TE and TR can both be shorter than in spin echo imaging, allowing an overall reduction in scanning time. However, if TR is short, spoiler gradients or radiofrequency pulses may be needed to ensure that the protons have returned to equilibrium before the next excitation pulse is supplied. The flip angle α induced by radiofrequency excitation can be adjusted to generate images weighted by different sources of tissue contrast. T_1-weighted images are generated by radiofrequency pulses causing flip angles of the order of 10° to 20°. For functionally sensitive T_2-weighted images, more radiofrequency energy must be supplied in the excitation pulse to give a flip angle approaching 90°.

Echoplanar imaging

The gradient echo sequence equivalent to a fast spin echo sequence is obtained by rapidly applying, or blipping, a series of rephasing gradients following the excitation pulse and dephasing gradient. Gradient blipping is done extremely rapidly (<1 ms), and up to 128 echoes can be generated from a single excitation. Clearly, the advantage of such echoplanar imaging is the speed of acquisition. Multislice images of the entire cortex, with slice thickness of only a few millimetres, can be acquired in 2 s or less. Such high-speed imaging is highly desirable for functional MRI, where we wish to detect physiologically determined changes in magnetic resonance signal with the best possible temporal resolution. However, the hardware required for rapid gradient blipping has only become widely available in the last few years.

Artefacts

The main sources of artefact in functional MRI are the same as for structural MRI (see Chapter 2.3.7).

Movement

Movement of the subject's head during fMRI data acquisition is inevitable, and attempts to eliminate it by fixing the head in the scanner may paradoxically exacerbate the problem. The best approach of minimizing movement is to ensure that the subjects are not unduly anxious about the scanning procedure, that they understand clearly what they are being asked to do, and that they are comfortable in the scanner before data acquisition begins. Experiments should be designed so that they do not require the subject to move extensively; small finger movements required for button pressing do not generally cause severe head movement. However, even very small movements of the head (less than 1 mm) can cause significant artefacts in fMRI data.

Involuntary or physiological movements are mostly due to the cardiorespiratory cycle causing pulsation of the cerebrospinal fluid and vascular spaces. Therefore, these movements often occur at a higher frequency than the frequency of image volume acquisition, and are aliased into the signal as a low frequency confound.

Susceptibility

The susceptibility artefact is exaggerated by gradient echoplanar imaging, typically causing signal loss in inferior temporal and orbitofrontal brain regions close to bone or sinuses. The problem is further compounded if subjects are asked to speak during scanning, since slight deformations of the sinuses associated with overt articulation can cause changes in susceptibility artefact, which can mimic signal changes due to speech-related neural activity. If overt articulation is necessary to monitor the subject's performance on the experimental task, then it is advisable to design the sequence so that images are not acquired while the subject is speaking.

Hardware

The hardware requirements for functional MRI include a superconducting magnet, a radiofrequency coil, computers, and a purpose-built room, as described in Chapter 2.3.7.

Gradient coils

The essential extra prerequisite is gradient coils capable of very rapidly blipping the external magnetic field for echoplanar imaging. The gradients required are small compared with the external field (1 to 10 mT/m) but may need to be applied for less than 1 ms. The speed with which the gradient is switched on, the slew rate, is necessarily fast (up to 200 mT/m/s). Such rapidly changing gradients can cause eddy currents in the gradient coils, adversely affecting the homogeneity of the field. This problem is minimized by actively shielding the coils, which requires yet another set of coils.

Audiovisual equipment

It must be possible to present visual and auditory stimuli to subjects while they are lying with their heads in the bore of the magnet. Headphones are required to clearly present auditory stimuli in the presence of the loud background noise of gradient switching. Visual stimuli can be projected on to a screen, viewed through a periscope. The subject should have access to an alert button. In addition, it is generally useful for subjects to use a button-press device to indicate their response to cognitively demanding experimental tasks. These behavioural data will need to be monitored during scanning.

Experimental design

The basic principle of experimental design in fMRI is to manipulate the subject's experience or behaviour in some way that is likely to produce a functionally specific neurovascular response. It is usually important that the experiment should be designed to allow some other measure of response, for instance a button press, to be monitored simultaneously. We shall illustrate these and other principles by considering how one might design an experiment to identify the regions of the brain that are important in making a (semantic) decision about the meaning of words. As will become clear, no single design is ideal; each has its strengths and weaknesses, and the choice between them should also be considered carefully in the light of the particular hypothesis one is using fMRI to test.

Blocked periodic design

This experimental design, in its simplest form, involves alternately presenting the subject with two conditions: an activation (A) condition and a baseline (B) condition. Each condition is presented for an identical epoch of time. During each epoch, several stimuli are sequentially presented with an interstimulus interval (**ISI**) that is less than the epoch length. The cycle of alternation between A and B conditions is repeated a number of times over the course of each experiment.

For example, during each 30-s epoch of the A condition, we could visually present subjects with a series of 12 common concrete nouns (ISI = 2.5 s) and ask them to decide for each word whether it refers to an animate object (e.g. 'goat') or an inanimate object (e.g. 'bucket'). The subjects could be asked to indicate their decision by pressing one of two buttons: left for living objects and right for non-living objects. During each 30-s epoch of the B condition, we could present words at the same rate, but ask subjects to decide whether they are written in upper- or lowercase letters. This decision could be monitored by button press as in the A condition. The two epochs could be presented alternately, beginning with the B condition, in five cycles for a total experimental time of 5 min. Functional MRI data would be acquired continuously throughout the experiment (Fig. 2.3.8.1).

The rationale for this design is that the two conditions are matched in all respects apart from semantic analysis; words are visually presented at an identical rate, and subjects are asked to signal their decision by an identical device. But while condition A demands semantic analysis of the words (what do they mean?), condition B demands only orthographic analysis (what do they look like?). We assume that only those regions of the brain that are specifically responsible for semantic analysis will show an increased magnetic resonance signal during condition A; those regions responsible for visual perception and motor output will be activated identically under both conditions, and so will not demonstrate a periodic signal change at the frequency of AB alternation. This set of assumptions is sometimes referred to as cognitive subtraction.

Blocked periodic designs can generate robust signal changes in fMRI, as long as the two conditions are not too closely matched. The drawbacks are that it is impossible to assess the response to a single stimulus and the critical assumption of cognitive subtraction may not always be valid. Sometimes two experimental tasks that appear to differ only in terms of one component process may actually invoke entirely different cognitive strategies and so cause activation of entirely different neurocognitive networks.

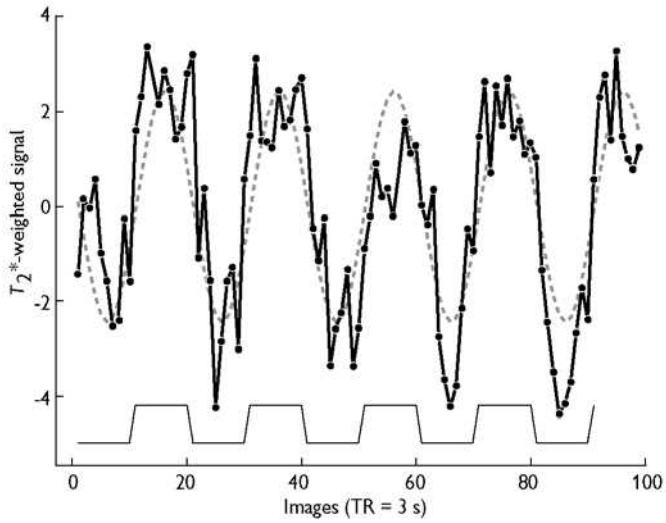

Fig. 2.3.8.1 Design, response, and modelled response for a blocked periodic experiment. The experimental design or input function is represented by a square wave (solid line), which alternates periodically between a baseline (B) and an activation (A) condition. The B condition is presented first, and the BA cycle is repeated five times in the course of the experiment. Images are acquired every 3 s during the experiment, and the T_2^*-weighted signal observed at an activated voxel is shown by points joined by a solid line. There is clearly a signal increase during the A condition. The modelled response is shown by the broken line.

Parametric design

Parametric designs are so called because the same task is presented throughout the experiment but some continuously variable parameter of the task is experimentally manipulated. For example, we could ask subjects to perform the semantic analysis task for 5 min, but continuously vary the interval between consecutive stimuli (words) from 10 s at the start of the experiment to 1 s at the end. Here we are assuming that as the task becomes more difficult, i.e. the interstimulus interval becomes shorter, blood flow to the regions specialized for semantic analysis will increase. The main advantage of this design is that it avoids the assumption of cognitive subtraction; the main disadvantage is that it may lack specificity. Motor and visual cortex, as well as brain regions specialized for semantic analysis, will probably show an increased blood flow as the rate of stimulus presentation is increased.

Event-related design

Event-related designs are composed of a series of individual stimuli. They may be coupled with sequences for very rapid image acquisition so that the temporal pattern of response to a single event can be resolved in detail. An event-related design would be advantageous for our semantic analysis experiment if we were particularly interested in correlating some aspect of the behavioural response to each stimulus, for instance accuracy of decision or reaction time, with the neurovascular response measured using fMRI. A disadvantage of such designs is that signal changes induced by a single trial are generally weak compared with the 2 to 5 per cent signal changes that are typical in blocked periodic experiments.

Beyond a single experiment

Generally, the hypothesis in question demands the investigation of more than a few subjects and/or more than one experimental condition. When designing the studies it is important that randomization should be used appropriately to eliminate confounding effects of the order in which experiments are conducted, and of the order in which different subjects are scanned. Practice on a task may substantially alter the neurovascular response, and so all subjects should receive preliminary training on the task according to a standard protocol. If there is considerable variability between subjects in their ability to perform a task, consider adjusting the difficulty of the task presented in the scanner so that each subject is performing at the same level in terms of accuracy or reaction time. The use of functional MRI to study longitudinal changes by repeated examination of the same subject(s), for instance before and after the administration of a drug, will generally improve the statistical power to detect the effect of interest by controlling for idiosyncratic variability of functional response between subjects.

Data analysis

General principles of data analysis are reviewed here; for more detailed coverage of the issues and the methods implemented in a variety of software packages, see.[5–7]

Movement estimation and correction

The first step in fMRI data analysis is to estimate the extent of head motion during data acquisition and to correct it. Due to the multislice acquisition protocols generally used for fMRI, the magnetic field to which the brain is exposed will change dramatically within the space of a few micrometres at the superior and inferior edges of a selectively irradiated slice. This means that minute head movements (<1 mm) can have disproportionately large effect on magnetic resonance signal.

Head movement occurring at the same time as time as experimental stimuli are present, namely stimulus correlated motion, can artefactually exaggerate the neurovascular response. Head movement occurring randomly with respect to the experimental design is more likely to cause the opposite problem of artefactually attenuating the measured response. Therefore it is essential to use a computerized method for movement estimation and correction.

Statistical models for the neurovascular response

The next step in analysis is to estimate the strength of the experimentally determined signal change in the time series of magnetic resonance signal measurements at each voxel in the image. This requires some sort of model for the response. The simplest model, for a blocked periodic design, is a square wave at the same frequency as the experimental input function. This model assumes that a brain region activated specifically by condition A will show an immediate increase in signal intensity, which is sustained throughout the epoch until the onset of condition B. The problem with this model is that the increase in magnetic resonance signal during condition A is due to changes in blood flow and oxygenation, which are dispersed and delayed by several seconds relative to the onset of condition A. Furthermore, this haemodynamic delay between stimulus onset and measurable response will be variable from one voxel to another. Therefore it is important that the experimental effect should be modelled as an increase in signal intensity that is arbitrarily delayed relative to the onset of the activating stimulus. The most general way of achieving this is to convolve the

experimental input function (the vector coding changes in experimental conditions) with a model of the haemodynamic response. The haemodynamically convolved input function can then be regressed on the fMRI time series at each voxel to estimate the neurovascular response to changing experimental conditions.

In fitting linear regression models to fMRI time series, one important technical issue is that the residuals of the regression will generally not be white noise or serially independent. Rather the residuals will typically have long-range dependency or long memory in time and this will need to be addressed for proper estimation of linear model parameters.[8] There are probably several possible artefactual sources of autocorrelation in fMRI time series residuals—including imperfectly modelled experimental activation, uncorrected head movement, and aliased cardiorespiratory pulsation. However, recently attention has focused on the role of low frequency, spatially coherent, endogenous oscillations of large neuronal ensembles as a source of long memory in fMRI time series.[9] This hypothesis has encouraged studies of the univariate and multivariate properties of fMRI data recorded at rest, i.e. in the absence of experimentally controlled task processing.[10,11]

Activation mapping

The next step in analysis is often to decide which of the several thousand voxels in the image have demonstrated such a strong response to the experiment that it is unlikely to be due to chance. In other words, we want to identify the significantly activated voxels. Let us assume that we have estimated the neurovascular response by the magnitude of a linear model coefficient at each and every voxel, and refer to this as our test statistic. The problem is then to assign a probability to each test statistic under the null hypothesis that the experiment had no effect on the brain. To do this we need to know the probability distribution of our test statistic under the null hypothesis. There are broadly two ways we can know this distribution: we can work it out from mathematical theory, or we can sample it by randomly permuting the data. Theoretical distributions are quicker to evaluate than permutation distributions, but permutation entails many fewer assumptions and is the gold standard against which the validity of theoretical approximations should be checked.

Once we have a probability distribution for the test statistic, we still have to decide what p-value we wish to adopt as our threshold for activation. If we choose a small (conservative) p-value (e.g. <0.00001), only those voxels that demonstrate a very powerful response will be identified as activated. There will be few false-positive or type 1 errors, i.e. almost all the voxels we identify as activated will truly be activated. But there will probably be a large number of false-negative or type 2 errors, i.e. many voxels that are truly activated will not be identified as such. Conversely, if we choose a large (lenient) p-value (e.g. <0.01), there will be a larger number of false-positive errors but a smaller number of false-negative errors. The choice of p-value should be informed by the search volume, or the number of voxels tested for significance. The larger the search volume, the smaller the p-value will need to be for an acceptable degree of type 1 error control. A rule of thumb is that the p-value should be approximately the reciprocal of the search volume. More elaborate methods have been advocated for correcting p-values for large numbers of tests on imaging data.

An alternative approach to testing tens of thousands of voxels against a suitably small probability threshold, with an associated risk of major type 2 error, is to combine information about the experimental response over several voxels. For example, we can initially apply a lenient threshold ($p = 0.05$) to the test statistics estimated at each voxel, and set to zero any voxel that does not have a test statistic greater than the corresponding critical value. The result will be a map of several spatially contiguous clusters, ranging in size from a single voxel to several hundred voxels (Plate 10). We can ascertain the probability distribution for cluster size under the null hypothesis either by theory or permutation. Then we can proceed to identify significantly activated clusters instead of voxels. The advantage of hypothesis testing at cluster level is a greater power to detect significant foci of activation, partly because there will be many fewer clusters than voxels to test, so the p-value can be legitimately increased. The disadvantage is the loss of spatial resolution of activation.

Multivariate approaches

Many of the 'higher-order' cognitive tasks that are likely to be of greatest interest to psychiatric research do not activate a single modular region of the brain. Instead, they typically activate several spatially distinct or distributed regions that together comprise a large-scale neurocognitive network for performance of the task. It may then be of interest to investigate functional integration between different regions or nodes of the network. The simplest way to do this is by estimating the correlation between a pair of fMRI time series observed at different voxels or regions. Large correlations, whether negative or positive, may be described as evidence for functional connectivity. Psychiatric disorders may be characterized by abnormal functional relationships between coactivated regions, or functional dysconnectivity.

More sophisticated techniques for investigating functional relationships between large numbers of voxels or regions include multivariate methods such as principal component analysis, discriminant analysis, and path analysis. These methods are equally applicable to structural MRI data, where they may provide indirect evidence for anatomical connectivity between regions.

Within- and between-group analysis

Once a measure or parameter of experimental response has been estimated in each fMRI time series, the resulting parameter maps can be registered in standard space. There are many possible computational algorithms for spatial registration. The most commonly used at present is an affine transformation, which applies a global and linear rescaling in three dimensions to each individual image. A commonly adopted standard space is that represented in a stereotactic atlas of the brain originally written by Talairach and Tournoux to assist neurosurgeons in locating subcortical structures.[12] In these systems, each voxel is assigned a set of $\{x, y, z\}$ coordinates which define its position. In Talairach–Tournoux space, the coordinates are defined relative to the cerebral midline and a line is drawn between the anterior and posterior commissures (intercommissural or AC–PC line). After registration, parameter maps are usually smoothed by applying a two- or three-dimensional Gaussian filter to accommodate variability in sulcogyral anatomy between subjects and error in spatial registration.

It is then possible to test a wide variety of hypotheses about the response parameters measured over several subjects at each voxel in standard space. For example, one can test the null hypothesis that there is zero mean or median power of experimental response within a group, or the null hypothesis that there is zero difference in the power of response between two groups. It is also possible to

test for correlations between the power of functional response and some behavioural or symptom measure within a group.

Visualization

The final result of fMRI data analysis will often be visualized as a map in standard space. The background for the map will generally be a grey-scale image of cerebral anatomy, such as a structural MRI dataset with fine spatial resolution and good tissue contrast between grey and white matter. In this case, one should beware of the potential discrepancy in geometric distortion between images of the same brain acquired using different sequences.

The background image will often be combined with, or substituted by, a rectangular grid allowing any feature of interest to be referred directly to the appropriate atlas of standard anatomical space. If the image is displayed as a series of two-dimensional slices, the *z* coordinate for each slice in standard space should also be displayed and the left and right sides of the right clearly indicated.

Voxels or clusters that demonstrate a significant effect are generally coloured against the grey-scale background image (Plate 11). A range of colours can be used to encode additional information. For example, the haemodynamic delay of response at each generically activated voxel may be colour coded by a continuous spectrum. Other strategies for visualization include use of three-dimensional rendering to show foci of activation in the context of the sulcogyral anatomy of a whole hemisphere, and 'flat mapping' whereby the template image is deformed to a smooth sphere and then mapped to a plane before activation foci are superimposed on it.

2.3.9 Neuronal networks, epilepsy, and other brain dysfunctions

John G. R. Jefferys

Introduction

The dynamics of highly interconnected networks of neurones are fundamental to both normal and pathological functioning of the brain.[1,2] Epilepsy is perhaps the most dramatic example of a dysfunctional neuronal network,[3] characterized by intense and highly synchronous neuronal activity, but more subtle dysfunction is associated with other conditions, such as schizophrenia.[4]

This chapter will largely focus on the hippocampus, and to a lesser degree on the neocortex. The hippocampal formation is implicated in several important psychiatric and neurological problems. The hippocampus and amygdala are often the site of epileptic foci, which can lead to problems in learning and memory, emotion, anxiety, and other problems. This kind of epilepsy is variously known as temporal lobe epilepsy, complex partial seizures, or limbic epilepsy. The hippocampus and associated limbic areas have been linked both to affective disorders and to psychoses. This chapter will consider the cellular organization of the hippocampus and then outline aspects of the emergent properties of neuronal networks in the hippocampus and speculative role in psychiatric disorders. Cellular and network mechanisms of focal epilepsy, and learning impairments associated with limbic epilepsy will be reviewed.

Hippocampal organization

Anatomy

The hippocampus resembles the neocortex in containing a majority of excitatory neurones, the pyramidal cells, and granule cells, which use glutamate as their neurotransmitter (E in Fig. 2.3.9.1).[1,2] Most of the remaining 10–20 per cent of neurones in the hippocampus are inhibitory, and use γ-aminobutyric acid (GABA) as their neurotransmitter (I in Fig. 2.3.9.1). The inhibitory neurones fall into several distinct subtypes according to where their axons go (and hence which cells they inhibit), where their cell bodies are, the shapes of their dendrites, whether they contain more than one transmitter, and whether they contain particular calcium-binding proteins. This chapter will ignore most of the diversity of interneurones.[5]

There are many more excitatory pyramidal cells (E and triangles) than inhibitory interneurones (I and circles). As with most neurones, they receive inputs onto their dendrites and somata (the latter contain the nucleus and are represented by a triangle or circle). The level of simplification is clear from the observation that each pyramidal cell receives tens of thousands of synapses. Axons from other regions, known as afferents, make excitatory synapses (e) with both pyramidal cells and interneurones. Most of the interneurones make inhibitory synapses (i) onto pyramidal cells. The inhibition of the pyramidal cell is called 'feed-forward' (f.f.) when the interneurones were excited by afferent axons and 'feed-back' (f.b.) when they were excited by pyramidal cells. Interneurones also inhibit each other forming a mutually inhibitory network (m.i.); this network is important in some kinds of physiological network oscillation (see text). Finally, pyramidal cells make excitatory synapses onto each other (r.e.), which can lead to epileptic discharges if not held in check by inhibitory mechanisms.

Evoked responses

Each hippocampal (or neocortical) area receives 'afferent' synaptic inputs from other areas. Most afferents are excitatory; stimulating them provides a convenient tool to study the operation of the neuronal circuits involved. The responses evoked in hippocampal neurones typically start with an excitatory postsynaptic potential. If the excitatory postsynaptic potential is strong enough, it will result in an action potential triggered at a low-threshold zone near the cell body, probably a short distance down the axon. The excitatory postsynaptic potential is followed by a fast and a slow inhibitory postsynaptic potential. Both the fast inhibitory and excitatory postsynaptic potentials are due to ligand-gated channels where the transmitter receptor is part of the same molecular structure as the ion channel. In the case of inhibition this is the $GABA_A$ receptor, which allows chloride ions to pass. In the case of excitation it is a variety of glutamate receptors, which are permeable to sodium, potassium, and in some cases calcium ions, and which are further subdivided into α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA)/kainic acid, *N*-methyl-D-aspartate (NMDA) and other classes. The slow inhibitory postsynaptic potential is due to $GABA_B$ receptors, which are G protein coupled and use second messengers to open separate potassium channels. Many other kinds of G-protein couple receptors exist, and often are involved in modulating neuronal excitability or synaptic function.

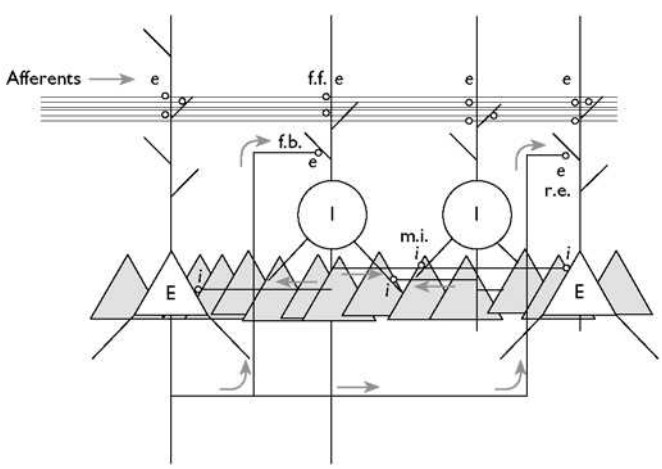

Fig. 2.3.9.1 Schematic illustration of hippocampal neuronal network.

Inhibitory neurones can be triggered both by activity in the principal cells (pyramidal or granule), resulting in recurrent or feedback inhibition, and directly by the incoming afferents, resulting in feed-forward inhibition. Experimentally, the synchrony of the stimulation of the afferent input imposes synchrony on the response with the useful consequence that the extracellular currents generated by the activity of individual pyramidal or granule cells can summate (because the cells are located in tight layers) and produce large 'field potentials' comprising a population excitatory postsynaptic potential, followed by a population spike.

Field potentials evoked by local stimulation are over in 10 to 20 ms and the slowest intracellular components end within a few 100 ms to 1 s. However, stimulation can have much more prolonged effects. The best known of these is long-term potentiation, in which a brief train of stimuli can result in an increase, lasting hours or days, in the response to a fixed test stimulus. The modest conditioning event and the enduring consequence make long-term potentiation an attractive model of learning and memory, although the evidence that it really is the direct cellular substrate for learning remains circumstantial.[6] It is perhaps more likely that long-term potentiation provides an artificial experimental tool that depends on cellular and molecular mechanisms that may also be involved in learning and/or other plastic changes in synaptic strength.

Local circuits

Hippocampal neurones are not just arranged as a simple synaptic relay where afferents excite target cells to produce an output depending on the size of the input and the state of inhibition at that time. Instead there exists a complex synaptic network, or local circuit, interlinking neurones of all kinds (Fig. 2.3.9.1 gives a very much simplified illustration of some of the salient features of hippocampal local circuits). This chapter considers two kinds of emergent network activity that arise from this organization: focal epilepsy and gamma rhythms.

Experimental approaches

Unravelling the cellular and network mechanisms of emergent network phenomena depends on a combination of electrophysiology, pharmacology, anatomy, and realistic computer simulations.[2,7] Two practical issues may need a brief introduction.

Brain slices have played a pivotal role in developing theories on the operation of neuronal networks. Slices about 0.4 mm thick are cut from the brains of deeply anaesthetized or recently killed experimental animals, or sometimes from humans undergoing

neurosurgery. Brain slices can survive many hours *in vitro* in an artificial cerebrospinal fluid, usually equilibrated with 95 per cent oxygen and 5 per cent carbon dioxide (with bicarbonate providing a pH buffer). If the slices are prepared under sterile conditions, they can survive for weeks as 'organotypic slice cultures'. In both cases the visualization of the anatomy of the living slice helps locate electrodes, the mechanical stability greatly simplifies recordings from inside neurones, and the lack of a blood–brain barrier facilitates drug applications and changes in ion concentrations. Brain slices have proved immensely popular and successful, but it is important to remember that they are only one tool in the armoury needed to study brain function, and that ultimately results from them must be put in the context of the whole organism.

Realistic computer simulations provide the means to determine whether what we know at one level, for instance of the properties of individual neurones and their interconnections, are necessary and sufficient to explain the emergent properties at the next level, here of circuits of a few thousand neurones. The most useful models for this purpose are tightly constrained by experimental data, and ideally are used to make experimentally testable predictions. Mostly they consist of several 'compartments' to represent the anatomy of the neurone's dendrites and soma. Each compartment consists of several differential equations representing specific ion channels, which may be gated by membrane potential, extracellular neurotransmitters, or intracellular calcium. Large number of neurones can then be wired together in larger-scale simulations, using biologically realistic anatomical connectivity and synaptic properties.[2,7]

Emergent properties of hippocampal networks

Hippocampal rhythms

The organization of hippocampal networks (Fig. 2.3.9.1) leads to several distinct kinds of oscillation, which can be considered as 'emergent' properties of the network. Perhaps the most prominent rhythm in the hippocampus is theta (3–7 Hz), which, at least in rats, is associated with spatial navigation,[8] and may play a role in memory.[9] Theta results from interactions of the hippocampus with two other limbic structures, the septum and the entorhinal cortex. Often superimposed on theta is a faster rhythm known as gamma (30–100 Hz). The best evidence we have now is that gamma is generated by local circuits in the hippocampus and that inhibitory neurones play a crucial role.[2] The role of gamma in the hippocampus remains unclear; in the neocortex it has been implicated in higher cognitive processes such as the 'binding' of individual sensory features into coherent perceived objects.[10]

Networks for gamma rhythms

The first strong clue that inhibitory neurones played a central role in gamma rhythms came from hippocampal and neocortical slices in which fast excitatory postsynaptic potentials had been blocked by drugs. Excitation by pulses of glutamate or agonist drugs acting at metabotropic (i.e. G-protein-coupled) glutamate receptors resulted in rhythmic inhibitory postsynaptic potentials in the gamma frequency band. A series of experimental tests of predictions from realistic computer simulations showed that this gamma rhythm was generated by the mutual inhibition of inhibitory neurones, which produced a synchronous interruption of the fast discharge the metabotropic glutamate receptor activation would otherwise have evoked. These interruptions lasted for a time, of the order of 25 ms, that depended on the time course of the inhibitory postsynaptic potentials in interneurones. We named this phenomenon 'interneuronal network gamma'.

During interneuronal network gamma pyramidal cells generate rhythmic inhibitory postsynaptic potentials, but do not reach threshold unless they are driven by some other input. Another kind of gamma rhythm occurs when slices are exposed to cholinergic drugs such as carbachol, and/or to non-desensitizing glutamate agonist drugs such as kainic acid. Here each pyramidal cell fires on some cycles of the rhythm,[11,12] so that on average some fluctuating fraction of pyramidal cells fires on each cycle. This is closer to the situation *in vivo*.[13]

Significance of fast coherent cortical oscillations

Rhythms such as gamma have been linked with sensory processing and with perception and other cognitive functions. They may be disrupted in people with some degree of cognitive impairment, for instance normal age-related cognitive decline,[14] or there may be a more general disruption of cortical rhythms in more severe conditions such as schizophrenia.[4] The complexity of the circuits responsible for cortical oscillations means that individuals with apparently normal number of neurones and neuronal organization may still have rather subtle changes on their synaptic networks that can have profound effects on collective oscillations and behaviour.

Gamma rhythms are intimately linked with epilepsy. Coherent neural activity at gamma frequencies is associated with some kinds of epileptic activity. Gamma rhythms are disrupted in at least one chronic model of epilepsy associated with learning impairments. Finally, the ideas behind the synaptic network mechanisms of the two kinds of phenomena have much in common.

Epilepsy—an emergent property of neuronal networks

Epileptic discharges typically involve excessively synchronous activity in principal neurones. In experimental focal epilepsy this excessive synchronization is due to the mutual excitation of pyramidal cells in the hippocampus, neocortex, or related areas. The essential idea is of a chain reaction. Areas that are especially prone to epileptic discharges have strong synaptic interconnections between their principal cells (e.g. the pyramidal cells of the CA3 region of the hippocampus or layers 3 and 5 of the neocortex). Activity in a few pyramidal cells can propagate through the synaptic network to recruit the whole population of neurones. Normally this propagation is held in check by inhibitory neurones; if the control mechanism is ineffective then epileptic discharges result. In experimental models the balance of synchronization versus control is compromised by treatments that weaken inhibition (usually by drugs such as bicuculline or picrotoxin), strengthen excitation (incubating brain slices in solutions lacking magnesium ions) or strengthen synaptic potentials in general (4-aminopyridine). Combined experimental and theoretical studies of such models have led to some general principles.[7] Synchronous epileptic discharges will result under the following conditions.

1 Connections between excitatory neurones are divergent, that is each connects to more than one postsynaptic excitatory neurone.

2 Connections between excitatory neurones are powerful enough to make their postsynaptic cells fire with a high probability. Precisely how high a probability can be depends on factors such as the connectivity and size of the network. The 'intrinsic' electrical properties of the neurones are important. Many epilepsy-prone areas have cells with prominent voltage-sensitive calcium currents, which are more prolonged than the classical voltage-sensitive sodium currents of the axonal action potential, and which cause neurones to fire bursts of fast sodium action potentials. Such intrinsic bursts greatly amplify transmission between pyramidal cells.

3 The network is large enough to allow all the neurones to link together. The critical mass for a network where the probability of any two cells being directly connected is 1 per cent, and the probability of one cell exciting its target cells is approximately 50 per cent, works out at about 1000 to 2000 neurones.

These features explain experimental brief epileptic discharges very effectively. The brain contains inhibitory mechanisms, both synaptic (inhibitory postsynaptic potentials, presynaptic inhibition) and intrinsic (voltage- and calcium-sensitive potassium channels), to terminate hypersynchronous discharges. Other mechanisms are needed to overcome the burst-termination mechanisms for the crucial transition to full-blown seizures lasting tens of seconds to minutes. These include slower synaptic mechanisms (both *N*-methyl-D-aspartate and metabotropic glutamate receptors, GABA, which paradoxically can become depolarizing if present in excess), non-synaptic mechanisms (potassium accumulation, electric fields), and abnormal activity arising in axons (ectopic spikes, gap junctions).

Convulsant drugs can trigger seizures in normal brains. People with epilepsy have a reduced seizure threshold that means they have seizures without an obvious triggering chemical or event. The reasons are far from clear, but may include abnormalities in intrinsic properties of neurones or in the connectivity of the neurones. Improvements in non-invasive imaging and in neuropathology increasingly reveal misplaced neurones and other more or less subtle anatomical malformations in many focal epilepsies, which suggests that the local circuitry is disturbed.

Other kinds of epilepsy have very different mechanisms. Absence epilepsy is the other major class where cellular mechanisms are relatively well understood. They involve the interaction of the thalamus and neocortex, although the received wisdom on the underlying mechanism has recently been challenged by experiments on one of the key animal models of absence epilepsy.[15]

Epilepsy—learning and memory

Patients with temporal lobe epilepsy can have problems with learning and memory. Antiepileptic drugs can have marked side effects, but the observation that chronic animal models of temporal lobe epilepsy also have impairments in learning and memory suggests that this is not the only cause. Memory impairments could result from gross damage, such as hippocampal sclerosis. Gross hippocampal pathology will have effects similar to experimental lesions of the hippocampus, but the observation that at least some of the chronic animal models lack gross hippocampal pathology does not support neuronal death as being the sole cause of impaired learning and memory.

At least two chronic experimental epilepsies have either limited or no cell loss during their induction. These are kindling and stereotaxic injection of a minute dose of tetanus toxin. The tetanus toxin model results in a well-characterized and enduring impairment of learning and memory, which outlasts the active epileptic syndrome in all except a few rats that show relapse. The absence of medication and of gross cell loss suggest that the psychological impairments in this model have some functional cause. Long-term potentiation remains intact, at least over a period of up to an hour. There is an association of learning impairment with the size of population spikes recorded from the same rats *in vivo* and under anaesthesia. Inhibition remains impaired in rats at a stage (>3 months after injection) when they had gained remission from epileptic seizures, but retained learning impairments.[16,17] Abnormalities of the cellular electrophysiology of the postepileptic phase can lead to disruption of network properties, including gamma rhythms, which may, in time, provide a link to the behavioural problem.

Humans with limbic epilepsy often do have substantial hippocampal damage, and this will contribute to learning impairments. The experimental evidence suggests that even in the absence of gross hippocampal damage learning impairments can arise as a result of functional disruption of the hippocampal network.

Conclusions

Understanding the operation of networks of neurones provides valuable insight into a range of neurological and psychiatric diseases. The role of synaptic networks of excitatory neurones in focal epilepsies is now well established. The ways in which brief epileptic discharges transform into events lasting as long as full seizures are starting to be clarified, and may offer new avenues for developing rational therapies. New ideas on the generation of physiological rhythms suggest novel models of psychiatric and neurological problems ranging from impairments in learning and memory in limbic epilepsies to (more speculatively) the disruption of sensory perception in psychoses. Real clinical cases will inevitably be much more complex, but the ideas and models outlined above will aid the understanding of the underlying mechanisms.

2.3.10 Psychoneuroimmunology

Robert Dantzer and Keith W. Kelley

Introduction

Mind-body literature, in the form of magazines and self-help books on stress and healing, is full of definitive claims for the existence of powerful influences of emotions and psychosocial stressors on the immune system, leading to onset or progression of cancers or infectious diseases. This literature often makes explicit reference to research in psychoneuroimmunology to support these claims. Psychoneuroimmunology is a multi-disciplinary field that has grown rapidly during the last three decades at the crossroads of immunology, behavioural neurosciences, neuroendocrinology, and psychology. It studies mechanisms and functional aspects of bidirectional relationships between the brain and the immune system. Although still controversial, there is evidence that psychological events including emotions can and do influence the outcome of infectious, autoimmune, and neoplastic diseases via modulation of cells of the immune system. A surprising finding has been that immune events occurring in the periphery also affect mood, behaviour, and metabolism by modulating brain functions, thereby providing a biologically important link between the immune system and brain. The original discovery that activation of the innate immune system in the periphery causes clinical signs of sickness that are processed in the brain is now being extended to the involvement of the immune system in depressive disorders. This new information has solidified the idea that neurotransmitters, neuropeptides, neural pathways, and immune-derived signals such as cytokines are the minimal essential elements that permit the immune system and brain to communicate with one another. These new data offer the unexpected conclusion that the immune system is likely to be involved in not only how emotions affect health but also how immune events regulate the development and expression of emotions.

Brain influences on immunity

Early investigations

The concept that stressors can have a negative impact on immunity and ultimately induce a reduction in host resistance to infectious pathogens and even to tumour progression is not new. As a follow-up of the early studies of Hans Selye on stress, several scientists demonstrated in the 1950s and 1960s that laboratory rodents exposed to various stressors, including inescapable painful electric shocks, displayed an altered resistance to viral, bacterial, and parasitic infections. These effects of stressors were accompanied by decreases in antibody responses to the specific microbial pathogen under study. In view of the already demonstrated immunosuppressive effects of glucocorticoids and the pivotal role of glucocorticoids in the stress response, pathophysiological mechanisms of the immunosuppressive effects of stressors were easy to determine. However, it was already clear at that time that mechanisms of the effects of stressors on immunity were not that simple since decreases as well as increases in immunity could be observed, depending on the immune response under study, the type of stressor and the time point at which the stressor took place during the mounting of the immune response. Furthermore, administration of glucocorticoids at physiological instead of pharmacological doses had little effect on some aspects of immunity and evolution of the disease process.

There was little innovation in this field until the 1980s when a few pioneer immunologists and neuroscientists decided to work together in order to understand how the central nervous system communicates with the immune system. One impetus for this was the demonstration that immune responses can be submitted to Pavlovian conditioning in apparently the same way as the salivary response, as discovered by Robert Ader at the University of Rochester.[1] Mice exposed to a new taste paired with an immunosuppressive agent such as cyclophosphamide during the development of an antibody response were found to display further decreases in antibody titres when re-exposed to the taste alone in

the absence of any immunomodulating agent. For this to occur, there must be pathways of communication from the brain to the immune system that are activated by the taste paired with cyclophosphamide. The search for these pathways of communication resulted in the demonstration of innervation of the primary (thymus) and secondary (spleen and lymphoid nodes) lymphoid organs by the sympathetic nervous system.[2] Sympathetic efferent nerves enter lymphoid organs with the vasculature but ultimately separate from blood vessels to innervate the parenchyma, where both B and T lymphocytes reside and can proliferate. Sympathetic fibres innervating lymphoid organs contain all the neurotransmitter machinery of other sympathetic neurones, including noradrenaline and neuropeptides such as substance P, neuropeptide Y (NPY), and calcitonin gene-related peptide (CGRP). This implies that the chemical composition of the microenvironment in which lymphocytes are present ultimately depends on activity of the autonomic nervous system. These findings gained in prominence when it was discovered that specific subsets of leukocytes have receptors for these neuronal communication signals.

Receptors within the immune system

In addition to cytoplasmic receptors that bind steroid hormones including glucocorticoids and sex hormones, lymphocytes, and other cells of the immune system have been found to have membrane receptors that bind and respond to most neurotransmitters and neuropeptides and are quasi-identical to brain neurotransmitter and neuropeptide receptors. As supported by an important body of literature, activation of these receptors in leukocytes has functional consequences on immune responses whether immunity is measured in vivo or in vitro.[3] As an typical example, growth hormone (GH), a pituitary hormone known for its growth-promoting activity and with no known immune function, was shown to restore the resistance of hypophysectomized rats to an infection with *Salmonella typhimurium*, with an efficacy comparable to that of a tetracycline antibiotic or the macrophage-stimulating factor interferon-gamma (IFN-γ).[4,5] These results obtained in vivo were replicated in vitro.[6] GH activated highly purified populations of pulmonary macrophages in the same way as IFN-γ. Both factors were able to prime macrophages triggered with opsonized zymosan to secrete superoxide anion O_2^-, an index of macrophage activation, even if GH was less active in this system than IFN-γ. Antibody blocking studies demonstrated that the priming activity of GH was independent of IFN-γ, and vice versa the activity of IFN-γ was distinct from that of GH. This priming had functional consequences since both IFN-γ and GH increased the capability of macrophages to kill *Pasteurella multocida*. Since most of the effects of GH on its target cells are mediated by the local production of insulin-growth factors (IGF), the capability of IGF-I to prime alveolar macrophages in vitro was also tested and found to be similar to that of GH, although the priming effects of GH were independent of the local production of IGF-I.[7] Other studies were showing at the same time that non-stimulated as well as immune-activated leukocytes were able to produce a GH-like peptide that was identical to pituitary GH,[8] conferring credibility to the important hypothesis that communication signals originally identified in the neuroendocrine system can actually be used by immune cells. In the same vein, corticotropin-releasing hormone (CRH), the main regulator of the hypothalamic–pituitary–adrenal axis, has been identified in the immune system in which it functions as an autocrine/paracrine mediator of inflammation.[9] In particular, CRH causes degranulation of mast cells and the release of histamine and several proinflammatory mediators.

The neuropeptides that are contained in sympathetic nerve endings that innervate lymphoid organs can play an important role in the modulation of the fine balance between the different populations of T helper (Th) cells that regulate cellular and humoral immunity. Th1 cells normally produce IFN-γ and interleukin-2 (IL-2), and both promote cellular immunity. In contrast, Th2 cells normally produce IL-4 and IL-10 that down-regulate cellular immunity and promote humoral immunity. CGRP and NPY drive Th1 cells towards the production of IL-4 whereas Th2 cells are driven by somatostatin and CGRP to produce IL-2 and IFN-γ.[10] If these effects that were observed in vitro are also true under in vivo conditions, they provide a possible mechanism by which stress can polarize immune responses in the direction of either Th1 or Th2 cells.

A recent potentially important discovery is that of the inhibition exerted by the parasympathetic nervous system on the production of proinflammatory cytokines by macrophages. Direct electrical stimulation of the peripheral vagus nerve that innervates the liver inhibited the production of proinflammatory cytokines by Kupffer cells in response to a lethal dose of endotoxin and prevented development of septic shock.[11] This vagal function was termed the cholinergic anti-inflammatory pathway[12] and it is mediated by nicotinic acetylcholine receptors containing an alpha-7 subunit.

Neural influences on the immune system

Since the immune system makes use of communication signals and receptors that are identical to those used by the central nervous system, the immune system should be very sensitive to neural influences. Besides the cholinergic anti-inflammatory pathway already mentioned, many data attest to the fact that brain events have an impact on immune responses. For instance, lesions in the neuroendocrine brain have profound influences on immunity. As an example, destruction of the tubero-infandibular region of the hypothalamus in mice persistently abrogates natural killer cell cytotoxic activity without altering T and B cell populations, but cortical and sham lesions had only a short-lived effect.[13] In other studies, ablation of the left sensori-motor cortex decreased cellular immunity whereas ablation of the right sensory-motor cortex increased it, showing that brain influences on immunity are lateralized.[14] This lateralization phenomenon was later demonstrated to exist in the absence of any lesion since left-handed mice, labelled as such based on their predominant use of the left paw to reach a food pellet in a tube that only enabled them to use one paw, displayed higher cellular immune responses than right-handed mice.[15] The mechanisms for this lateralized influence of the brain on immunity are still elusive.

The impact of stressors on immune responses represents another example of the influence of brain events on immunity. At the time these studies were carried out it was already well known that the influence of psychosocial stressors on the hypothalamic–pituitary–adrenal axis are not simply a function of the intensity and duration of the stressors but also depend upon their psychological features. Novelty, predictability, and controllability are the key factors that ultimately determine the neuroendocrine impact of stressors. It was therefore not surprising that the same psychological features were pivotal in the influence of stress on immunity. For instance,

rats exposed to inescapable electric shocks 24 h after injection of syngenic tumour cells displayed more rapid tumour growth and a higher mortality rate than rats exposed to controllable electric shocks, despite the fact that the intensity and duration of electric shocks were exactly the same in both groups.[16] Lack of control had the same influence on the rejection of non-syngenic tumours[17] and cellular immunity as measured by the proliferative response of lymphocytes to T-cell mitogens.[18] It cannot be inferred that uncontrollability is always immunosuppressive. Lack of control over the occurrence of electric shocks was later found to increase rather than decrease humoral immunity, as measured by antibody titres against sheep red blood cells injected into rats that were submitted chronically to controllable or uncontrollable electric shocks.[19] The same difference in the way the immune system responds to an uncontrollable stressor was confirmed in an experiment in which mice were exposed to the odour of a stressed congener. A 24 h exposure to this stressor decreased the cellular immune response, as measured by proliferation of T cells to mitogens and natural killer cell cytotoxicity, but increased antibody titres against keyhole limpet haemocyanin.[20]

Stress and the immune system

Studies of the influence of stress on the immune system have also been carried out in human subjects in experimental settings or in real-life conditions. In these studies, the immune end points are either measured on blood lymphocytes or deduced from the result of an already existing pathological process. The group of Janice Kiecolt-Glaser at Ohio State University in Columbus is certainly the pioneer in this field. For instance, first year medical students were shown to display a reduction in the production of IFN-γ by circulating leukocytes and a reduced cytotoxicity of natural killer cells during the end of the year examination period, and these changes were independent on lifestyles.[21] As a result of extensive studies on different populations at risk, such as spouses experiencing marital conflict, caregivers of patients with Alzheimer's disease, and aged subjects, Kiecolt-Glaser's group proposed that negative emotions and stressful experiences can contribute to prolonged infection and delayed wound healing. In addition, negative emotions were proposed to directly produce the production of proinflammatory cytokines and therefore increase the risk for a spectrum of conditions associated with ageing, including cardiovascular disease, osteoporosis, arthritis, type 2 diabetes, certain cancers, frailty and functional decline, and periodontal disease.[22]

The influence of stressful life events on immune responses also appear to be modulated by coping strategies, as exemplified by a study carried out on susceptibility to upper respiratory tract illness in an adult population sample.[23] In a little less than 30 per cent of a population sample of adults between 18 and 65 years of age, the occurrence of clinical episodes of upper respiratory tract illness over a 15-week period was more frequent in those individuals who experienced high life event stress both before and during the study period. The impact of life events was buffered by an avoidance coping style.

In accordance with the hypothesis that negative emotions negatively impact the immune system, major depressive disorders were initially thought to be associated with depressed immune responses. This association has been confirmed for the number of circulating lymphocytes, proliferative response of lymphocytes to non-specific mitogens, and natural killer cell cytotoxicity.[24,25] However, more recent studies have revealed signs of activation of the innate immune system in at least some forms of depression.[25,26]

Although most of the literature deals with the influence of stressors and negative emotions, positive emotions have also been studied in their relation to immune events. In graduate students vaccinated against hepatitis B, dispositional positive affect was associated with a greater antibody response to vaccination.[27] The same trait was associated with decreased vulnerability to upper respiratory infections. Dispositional optimism, as defined by generalized positive expectations for the future, is positively related to measures of cellular immunity in cancer and HIV patients only when stressors are brief, relatively straightforward and controllable whereas the reverse relationship is observed when stressors are complex, persistent, and uncontrollable.[28]

Mechanisms of the relationship between stressful life events, emotions, and immunity are rarely investigated because of the many biobehavioural pathways that can be implicated in mediating relationship. In view of the postulated immunosuppressive effects of glucocorticoids, it has been important to demonstrate that not all effects of stress on immunity are mediated by activation of the hypothalamic–pituitary–adrenal axis. As an example, implantation of a corticosterone pellet after adrenalectomy in rats that were submitted to inescapable electric shocks so as to prevent the stress-induced increases in plasma corticosterone did not alter the decreased proliferative response of blood lymphocytes observed in stressed rats.[29] Evidence for a role of the sympathetic nervous system was provided by experiments using beta-adrenergic receptor antagonists or sectioning of the sympathetic nerve innervating the spleen. For instance, administration of propranolol prevented the decreased lymphoproliferative response in rats re-exposed to the cage in which they had been previously exposed to inescapable electric shocks.[30] Other possible biological mediators are CRH and endogenous opioids. In the clinic, the search for possible biological mediators of the relationship between stress and immunity is not easily found, and often confounded by the impact of stress and negative emotions on illness behaviour, via for instance deterioration in health-promoting behaviour and alterations in symptom perception.[31]

Susan Lutgendorf at the University of Iowa recently summarized the current view of interactions between health behaviours and psychosocial and biological factors that can combine to affect a multitude of disease outcomes in a biopsychosocial model (Fig. 2.3.10.1).[32]

The immune system as a true sensory organ

In a recent longitudinal study on the relationship between positive affect and clinical signs during a bout of influenza in volunteers inoculated with rhinovirus or influenza virus, production of inflammatory mediators by cells of the innate immune system in the nasal secretions was associated with reduced positive affect.[33] Since 1-day lagged analyses showed that daily production of inflammatory mediators predicted lower positive affect on the next day, it was difficult to interpret these findings in terms of the previously described relationship between emotions and immunity, negative emotions, or decreased positive affect increasing innate immunity. On the contrary, the authors interpreted their findings as supporting a causal association between pathogen-induced local cytokine production and changes in positive affect.

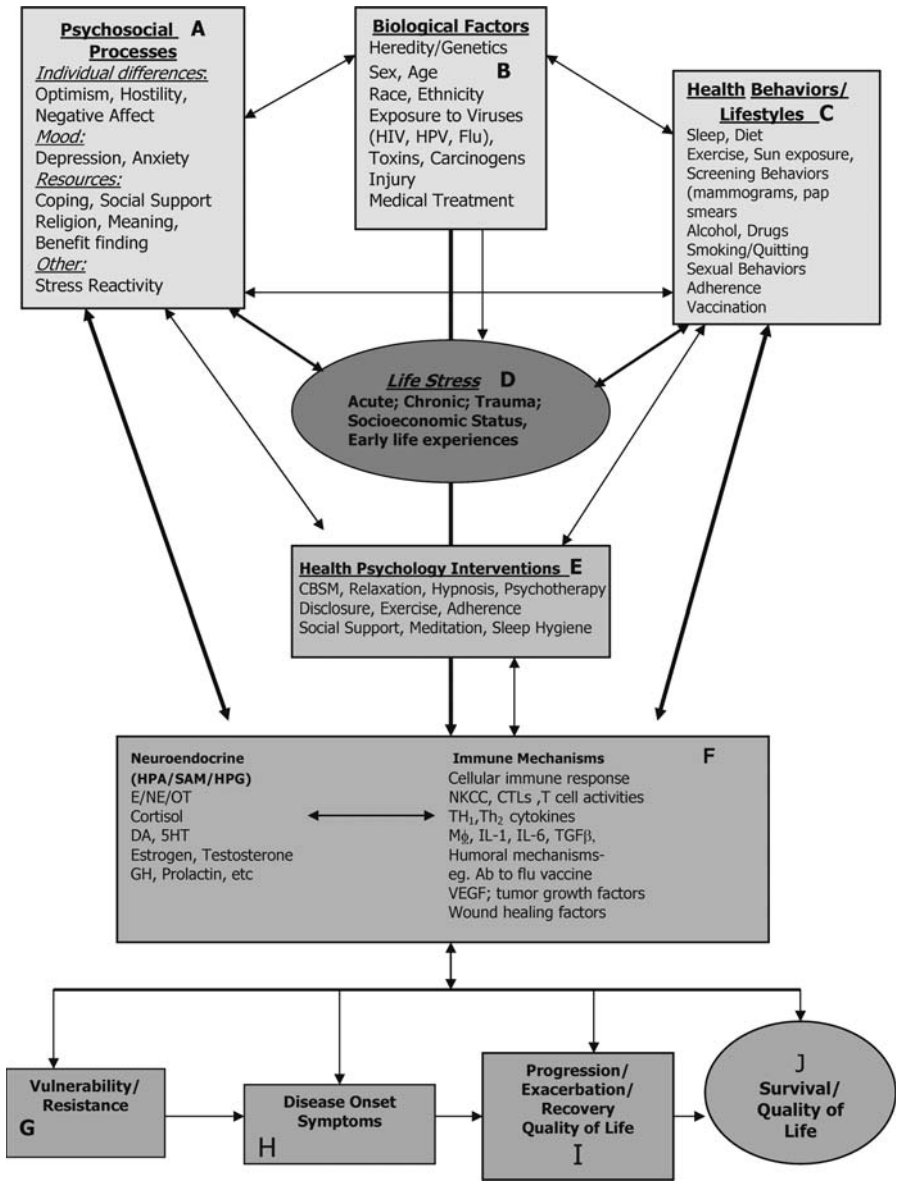

Fig. 2.3.10.1 The figure illustrates the biopsychosocial model in health psychology. The interaction between psychosocial processes (Box A), biological factors (Box B), and health behaviours (Box C) leads to a vulnerability (or resistance) to illness (Box G), disease onset and symptoms (Box H), progression, exacerbation, recovery, with concomitant quality of life (Box I), and survival with concomitant quality of life (Box J) via processes involving neuroendocrine and immune mechanisms (Box F). Effects of life stress (Box D) are filtered through psychosocial processes (Box A) and health behaviours (Box C) in their resultant effects on downstream mechanisms. Health psychology interventions (Box E) can modulate effects of psychosocial processes and health behaviours on neuroendocrine and immune mechanisms and on resultant health outcomes. There are also pathways between biobehavioural factors and disease outcomes not involving neuroendocrine or immune mechanisms, but other pathways are not included in this figure. Psychosocial processes (A) encompass psychological and social factors, particularly those that involve interpretation of and response to life stressors. These include personality variables (e.g., optimism, hostility, and negative affect), mental health and mood variables (e.g., depression and anxiety), coping, social support, spirituality, and sense of meaning. Health behaviours (C) include drug and alcohol use, smoking, sleep, nutrition, exercise, adherence to medical regimens, physical examinations, risk screenings, and risky sexual behaviours, among others. Health psychology interventions (E) can be used to alter psychosocial processes (A: e.g., decrease depression, increase coping) or improve health behaviours (C: e.g,. smoking cessation) to provide a more positive influence on neuroendocrine and immune factors and perhaps slow disease progression/exacerbation. Interventions include cognitive behavioural stress management (CBSM), relaxation, hypnosis, meditation, emotional disclosure, adherence-based interventions, sleep hygiene, exercise, social support groups, psychotherapy, imagery, distraction, behavioural pain management, yoga, massage, biofeedback, drug/alcohol prevention/rehabilitation, psychotherapy, and behavioural conditioning. These interventions can be used at all points of the trajectory of the disease or condition. Box F shows selected mechanisms involved in the bidirectional interactions between neuroendocrine and immune axes that mediate the relationships between biobehavioural factors (A–D) and disease outcomes (G–J). This by no means is an all-inclusive list of mechanisms, but it represents some of the commonly studied factors in this literature. Once vulnerability (G) has been established, continued interaction with positive or negative psychosocial factors (A: e.g., depression/social support), disease factors (B), adaptive/maladaptive health behaviours (C) and stress (D) will contribute to expression (or lack thereof) of disease symptoms (H), disease-free intervals/progression/exacerbation, and quality of life (e.g., functional, physical, emotional, and social well-being) (I), and survival (J). HPA, hypothalamic–pituitary–adrenocortical axis; SAM, sympathoadrenomedullary axis; HPG, hypophyseal pituitary gonadal axis; OT, oxytocin; DA, dopamine; 5HT, seratonin; GH, growth hormone; NKCC, natural killer cell cytotoxicity; CTLs, cytotoxic lymphocytes; $M_{Ð}$, macrophage; IL-1, interleukin 1; IL-6, interleukin 6; TGFÐ, transforming growth factor beta; Ab, antibody; and VEGF, vascular endothelial growth factor. (Reprinted from Brain Behaviour and Immunity, 17(4), ASK Lutgendorf and Es Costanzo, Psychoneuroimmunology and health psychology: an integrative model, 225–32, Copyright 2003, with permission from Elsevier.)

To understand this interpretation, it is necessary to replace the relationship between the immune system and the brain in the context of regulatory immunophysiology. If the brain communicates with the immune system via neuroendocrine factors and autonomic neuronal pathways, it is probably because the immune system needs the brain to regulate its function and do what it cannot do by itself, (i.e., engage the whole organism in the fight against microbial pathogens). If this is the case, then it ensues that the immune system needs to inform the brain of its state of activity. In other words, brain-to-immune communication pathways need to be activated by immune-to-brain communication pathways. This interpretation makes the immune system a true sensory organ, specialized in the detection of the non-self and able to transmit this information to the brain.

Looking through the mirror: immune modulation of emotions and mood

The isolation, cloning, and expression of proinflammatory cytokines and their receptors in the late 1980s, coupled with the discovery of pathogen-associated molecular patterns (PAMPs) and their pathogen recognition receptors (PRRs), are two of the major advances in immunology that set the stage for defining immune-to-brain communication pathways. Interleukin-1 (IL-1) is a prototypical proinflammatory cytokine that is released from activated macrophages following activation of some PRRs. Other proinflammatory cytokines include tumour necrosis factor (TNF-α), IL-6, and IL-8. Injection of IL-1 or TNF-í, either systemically in the form of intraperitoneal administration or centrally via an intracerebroventricular route, induces the classical signs of illness, including fever, activation of the hypothalamic–pituitary–adrenal axis, and sickness behaviour, as evidenced by decreased interaction with the physical and social environment, reduced appetite, disappearance of body care activities, fatigue, malaise, and mild cognitive impairments.[34–37] These actions take place in the brain since pretreatment of rats with the specific antagonist of IL-1 receptors into the lateral ventricles of the brain significantly impairs the ability of systemic IL-1 to cause behavioural deficits.

At the molecular and cellular levels, it is now clear that IL-1 and other proinflammatory cytokines produced by activated innate immune cells in the periphery during the inflammatory response induce expression of the same cytokines in innate immune cells of the brain, including meningeal and perivascular macrophages, microglial cells in the brain parenchyma and mast cells. Peripheral cytokines are relayed to the brain via a humoral pathway involving the action of PAMPs on PRRs located in circumventricular organs at the interface of the brain and periphery and a neural pathway involving activation of the afferent nerves that innervate the body region in which the inflammatory response takes place. At the organism level, this central representation of the peripheral inflammatory response imposes a new mode of functioning on the brain so as to allow the organism to better cope with infection. The elevated body temperature actively maintained by the increased thermogenesis and decreased thermolysis that characterizes the fever response promotes a number of immune events and reduces microbial proliferation. At the same time, zinc and iron that are normally essential for cellular multiplication are sequestered and acute phase proteins including complement proteins are synthesized by hepatocytes to help killing microbial pathogens. The increased glucocorticoid levels that occur as a consequence of the hypothalamic effect of cytokines negatively feed back on activated innate immune cells and significantly limit the intensity and duration of the inflammatory response. Sickness behaviour itself helps to reduce physical activities detrimental to thermogenesis and facilitates the reduction of thermolysis. It also limits the spread of infection within the social group by reducing social activities and reduces pain that is enhanced by proinflammatory cytokines.

Once an infection, and therefore cytokine synthesis, resolves over the time course of a few days, behavioural symptoms of sickness normally disappear. However, if the infection does not resolve, or if there is ongoing autoimmune inflammatory processes of a chronic nature, such as rheumatoid arthritis, multiple sclerosis, inflammatory bowel disease, the synthesis of cytokines and their downstream products continues to be elevated. The chronic action of proinflammatory cytokines acting in the brain has now led to the hypothesis that these very same proteins are somehow involved in development of affective disorders such as depression. In the clinic, this hypothesis is supported by the high prevalence of major depressive disorders that is observed in patients with a chronic inflammatory condition[38] and the observation that chronic administration of recombinant IL-2 and/or IFN-α to cancer or hepatitis C patients induces alterations in mood that are characteristic of depression. In the laboratory, acute or chronic activation of the peripheral immune system induces depression-like behaviour that is apparent even when sickness behaviour has dissipated.[39] A leading candidate protein for this effect is a cytokine-activated enzyme known as indoleamine 2,3 dioxygenase (IDO)[40] which has an ubiquitous cellular localization and is also present in the brain. This enzyme degrades tryptophan, an essential amino acid that is required for the synthesis of the mood-regulating neurotransmitter serotonin. Increased degradation of tryptophan associated with inflammation results in a relative deficit in brain serotonin neurotransmission that can precipitate depression and an increased production of tryptophan neuroactive derivatives, including kynurenine, 3-hydroxy kynurenine, and quinolinic acid. These molecules act as agonists or antagonists of the NMDA receptor. Since brain IDO enzymatic activity is increased during activation of the peripheral immune system, these molecules gain access to the brain because they freely cross the blood–brain barrier. In addition, these metabolites are also produced in the brain.

There is accumulating evidence that activation of immune-to-brain communication pathways is responsible not only for the adaptive sickness behavioural response and the maladaptive syndrome of depression that develops in vulnerable individuals but also for the symptom burden that is experienced by physically ill patients, including fatigue[41] (see Fig. 2.3.10.2), pain[42], sleep disorders,[43] and impaired learning and memory.[44]

Concluding comments

A few years ago, scientists who proffered the idea that mood disorders could be induced by an infective process were considered heretic. That view has changed considerably with the discovery that cytokines from the immune system act as elements that permit active communication between the brain and the rest of the body. Indeed, it was in 1984 when a pioneering scientist in psychoneuroimmunology, J. Edwin Blalock, proposed that the immune system

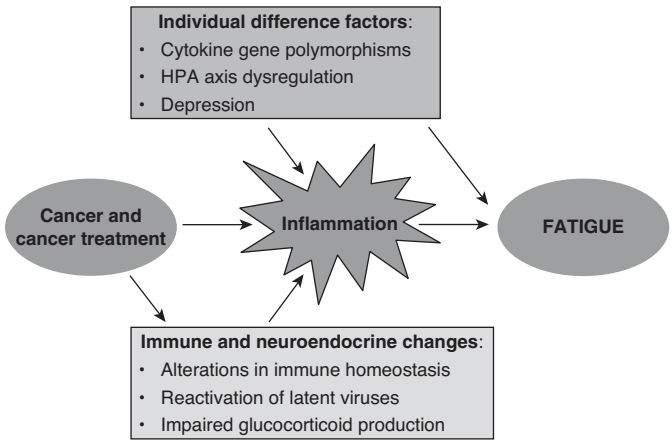

Fig. 2.3.10.2 Potential mechanisms for cancer-related fatigue. Cancer and its treatment can activate the proinflammatory cytokine network, leading to symptoms of fatigue through cytokine effects on the central nervous system. Chronic inflammation may develop when cancer and cancer treatments induce long-term changes in immune homeostasis, including alterations in immune cell subsets, alterations in expression and signaling of Toll-like receptors, and latent virus reactivation. Cancer-related changes in neuroendocrine function may also contribute to chronic inflammation, particularly impairments in glucocorticoid production that result in ineffective control of inflammatory processes. In addition, individual difference factors may increase the risk for chronic inflammation following cancer diagnosis and treatment. Potential risk factors include single nucleotide polymorphisms in cytokine genes, alterations in HPA axis function, and depressive symptoms. Of note, HPA dysregulation and depression may also have direct effects on fatigue. is really a sixth sensory system.[45] Humans cannot see, smell, touch, hear, or taste pathogenic micro-organisms. However, cells of the immune system, whether they be T cells, B cells, macrophages, microglial cells, or dendritic cells are uniquely endowed with the molecular machinery to detect an endless array of pathogens. One way that the immune system informs the brain that a pathogen has entered the body is by immune cells recognizing these invaders. These leukocytes respond by releasing proinflammatory cytokines, which act as messenger systems to alert the brain that something is amiss in the periphery. The foundation for this conceptual system has strengthened during the last 20 years. It forms the intellectual basis for the notion that emotions are regulated by the immune system, and the immune system affects expression of emotions.

The contribution of genetics

Contents

2.4.1 Quantitative genetics

Anita Thapar and Peter McGuffin

Patterns of inheritance

Our understanding of how traits and disorders are passed from one generation to the next began with the work carried out by an Augustinian monk, Gregor Mendel. Although Mendel's published work in 1866 was initially ignored, its rediscovery at the beginning of the twentieth century heralded the beginning of modern genetics. Mendel's experiments on pea plants and his observations of the patterns of inheritance of certain characteristics led to the development of his particulate theory of inheritance. It was only later in 1909 that the units of inheritance that he had described were named genes and alternative forms of a gene were termed alleles. It was also at this time that the terms phenotype, used to describe the observed characteristic, and genotype, used to refer to the genetic endowment, were introduced.

Mendel's laws

Mendel examined clear-cut dichotomous characteristics such as smooth versus wrinkled coats in peas. He first noted that when parents of different types were crossed, the first generation (F1) offspring displayed **uniformity** of that characteristic. He inferred that this uniformity was due to one phenotype being dominant and the other being recessive. Thus, when homozygous parents AA and aa produced heterozygote Aa offspring, these offspring displayed the phenotype of the AA parent rather than manifesting a phenotype intermediate to those of both parents.

Mendel then demonstrated that when the F1 heterozygotes (Aa) were intercrossed (Aa × Aa), **segregation** resulted in the second F2 generation showing recessive and dominant phenotypes in the ratio of 1 to 3. He then inferred that this F2 generation consisted of three types (AA, Aa, and aA, aa) occurring with a probability of 1:2:1.

Finally, Mendel showed that when the transmission of two different phenotypic traits was studied, they showed **independent assortment**. We now know that independent assortment occurs when the genes coding for these traits are either located far apart on the same chromosome or are on different chromosomes (see linkage).

Single-gene disorders

Although disorders showing a simple Mendelian pattern of inheritance are rare, they tend to be clinically severe and collectively impose a significant burden.

For **autosomal dominant** disorders to manifest themselves, only one disease allele is necessary, i.e. both heterozygotes as well as homozygotes (those who carry both disease genes) will be affected. In most instances, where there is one affected parent who is a heterozygote for the disease, approximately 50 per cent of the offspring will show the disorder. Autosomal disorders tend to be severe and manifest themselves in every generation. Huntington's disease and acute intermittent porphyria are examples of autosomal dominant conditions that are often present with psychiatric symptoms.

Autosomal recessive conditions such as phenylketonuria require the presence of two disease alleles to show clinical manifestations of the disorder. Thus, they often appear to skip generations. These disorders usually occur in the offspring of two 'carrier' heterozygote parents and are more common where there is a high rate of consanguinity (e.g. marriages between cousins) as these inbred populations will show greater homozygosity at all loci.

The other group of single-gene disorders consists of **sex-linked** conditions such as fragile X syndrome. Normal females have two X chromosomes whereas normal males have one X chromosome and one Y chromosome. Thus, for recessive disorders on the X chromosome, if the mother is a carrier (X*X) and assuming that the father is unaffected (XY), half of her sons will manifest the disorder (X*Y) and half of her daughters will be carriers (X*X). Where the father is affected by an X-linked recessive condition, all the daughters will be carriers. As sons have to inherit their

X chromosome from their mother, there will be an absence of father to son transmission. X-linked dominant conditions are extremely rare.

Continuous traits

Mendel's laws are based on the transmission of dichotomous characteristics, yet many important human phenotypes such as height, weight, and blood pressure are continuously distributed. However, we are able to show that Mendelian principles can also be applied for these types of quantitative traits.

Let us first consider a phenotype measured on a continuous scale which results from the influence of a single gene with two alleles A_1 and A_2 (see Fig. 2.4.1.1). We can now describe the phenotypes of the three possible genotypes in terms of a quantitative value on the continuous scale. A_1A_1 has a value of $-a$; A_2A_2 has a value of $+a$; and A_1A_2, the heterozygote, has a value of d. When $d = 0$, A_1A_2 lies exactly half way between A_1A_1 and A_2A_2, that is the genetic contribution is entirely additive. When $d = -a$, A_2 is recessive to $A_1$and when $d = +a$, A_2 is dominant to A_1.

At the simplest level, we assume that there are no dominance effects and that there is no mutation, selection, migration, or inbreeding in the population. If p is the frequency of allele $A_1$and q is the frequency of A_2 in the population where $p + q = 1$ then the frequency of genotypes can be expressed as follows:

$$\begin{matrix} A_1A_1 & A_1A_2 & A_2A_2 \\ p^2 & 2pq & q^2 \end{matrix}$$

This is known as the Hardy–Weinberg equilibrium. If we now simplify further and state allelic frequencies where $p = q = 0.5$, then the phenotypic values of A_1A_1, A_1A_2, and A_2A_2 would be distributed in the population with relative frequencies of 1:2:1.

Now if we consider a trait which results from two genes each of which has two alleles of equal frequency and additive effect, there would be five possible phenotypic values with relative frequencies of 1:4:6:4:1. Overall as the number of genetic loci (n) increases, the number of phenotypic values increases ($2n + 1$) and the distribution of phenotypic values more closely approximates a normal distribution. It is thought that most quantitative or continuous traits result from the additive action of genes at many loci which is otherwise known as **polygenic** inheritance. Where familial transmission is explained by environmental factors as well as by multiple genes, we then call this a **multifactorial** mode of inheritance.

Complex disorders and irregular phenotypes

(a) Polygenic/multifactorial threshold models

Most common human psychiatric and medical disorders such as schizophrenia, diabetes, and heart disease do not show a Mendelian pattern of inheritance. Neither can they be considered as continuous traits in that people are described as being affected or unaffected.

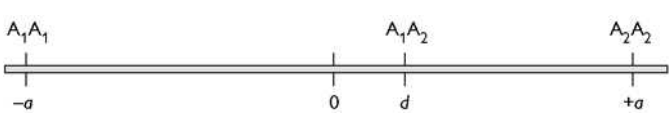

Fig. 2.4.1.1 A phenotype, measured on a continuous scale, resulting from a single gene with two alleles A_1 and A_2.

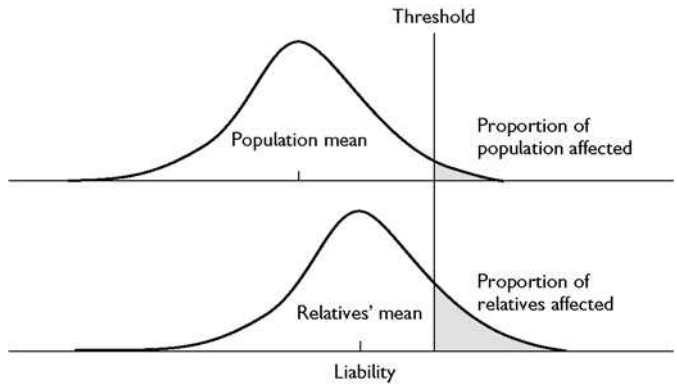

Fig. 2.4.1.2 A polygenic or multifactorial threshold model of disease transmission.

However, these conditions could be regarded as quasi-continuous in that those who are affected can be graded along a continuum of severity. It is possible to extend this to assume that there is an underlying liability to develop the disorder which is continuously distributed in the population. Those who pass a certain threshold manifest the condition. If the underlying liability to develop the disorder is inherited in a polygenic or multifactorial fashion, then we can assume that the distribution will be approximately normally distributed (Fig. 2.4.1.2). The genetic liability of relatives of affected individuals will be increased and their liability distribution will be shifted to the right (Fig. 2.4.1.2). Thus, the proportion of relatives above the disease threshold will be greater compared with the general population. If we know the proportion of affected relatives of probands and the proportion of those affected in the general population, it is possible to calculate the correlation in liability between pairs of relatives using this type of model.

(b) Single major locus model and atypical patterns of Mendelian inheritance

An alternative to a polygenic model of complex disease is a single major locus model. Single-gene disorders do not always show typical Mendelian patterns of inheritance. For example familial transmission can be modified by variable **expression** and **penetrance**. Some conditions can show great variability in terms of clinical expression. For example neurofibromatosis, an autosomal dominant disorder can express itself as the full blown disorder or merely as a few café-au-lait spots. Penetrance is defined as the probability of manifesting the disorder given a particular genotype. For Mendelian disorders this is always 1 or 0, but irregular patterns of inheritance may occur because of incomplete penetrance where the probability of manifesting the disorder is greater than 0 but less than 1.

Finally, there are now molecular explanations for other types of unusual patterns of inheritance for single genes. Anticipation where disorders show a progressively earlier onset and greater severity with subsequent generations is now known to be explained by heritable unstable nucleotide repeat sequences (see later). Huntington's chorea and fragile X syndrome are examples of disorders caused by heritable unstable repeats. For some conditions such as the Angelman syndrome and the Prader–Willi syndrome, manifestation of the disorder depends on the parental origin of the gene. This is known as imprinting.

(c) Other models

Alternative explanations of how complex conditions such as psychiatric disorders are inherited include mixed and oligogenic patterns of transmission. A mixed model includes a major gene and a polygenic/multifactorial contribution. However, for many of these disorders, genes of major effect may not exist. It may be that these irregular phenotypes are best explained by oligogenic models where the co-action or interaction of a small number of genes contributes to the disorder. These issues remain to be resolved by molecular genetic studies (see later).

Components of phenotypic variation

We will now consider the different influences that contribute to phenotypic variation in a population. The total variation in an observed trait (phenotype v_p) at the simplest level (ignoring non-additive effects) can be partitioned into a proportion due to genetic influences (v_g), a component explained by shared environmental factors (v_c), and a remainder accounted by non-shared environmental factors which includes error (v_e):

$$v_p = v_g + v_c + v_e$$

Shared or common environmental influences are aspects of the environment that result in greater similarity of family members for a given phenotype. Non-shared environmental factors refer to environmental influences that have effects which are specific to individuals and that contribute to phenotypic differences between family members.

Although we have so far only considered one type of genetic contribution, the genetic variance v_g can be further subdivided into variance due to additive genetic influences (v_a) and dominance effects (v_d).

The relative influence of genetic factors is expressed as **heritability** and when defined as the proportion of the total phenotypic variance attributable to additive genetic variance, is known as **narrow-sense heritability**:

$$h_n^2 = v_a / v_p.$$

Heritability is also sometimes used to describe the proportion of variance explained by the *total* genetic variance (additive and non-additive genetic variance) and it is then known as **broad-sense heritability**:

$$h_b^2 = v_a / v_g.$$

Similarly we can estimate the proportion of the total phenotypic variance explained by shared environment where $c^2 = v_c/v_p$ and the remaining proportion attributable to non-shared environmental factors and error (e^2).

It is important to remember that the estimate of heritability and the contribution of shared environment and non-shared environment are proportions of total variation within a given population, i.e. these parameters tell us about sources of difference between individuals in a population and have no meaning at an individual level. For example, if an individual was selected from a population where IQ had been shown to have a heritability of 50 per cent, it could not be said that 50 per cent of that individual's IQ was determined by genes. Another important point is that these estimates are specific to the population studied and may differ for other populations. Finally, the contribution of genetic and environmental influences to a phenotype does not allow any inferences about the extent to which that phenotype is modifiable by environmental factors. For example, phenylketonuria is a Mendelian condition that is determined by the presence of a single-gene mutation. Yet the clinical manifestations of the syndrome are prevented by dietary intervention.

Non-additive genetic effects

So far we have simplistically assumed that phenotypic variation is influenced in an additive fashion. However, the contribution of genes and environment is more complex than this. We have already referred to genetic **dominance** effects where there is non-additive interaction of alleles within a locus. Another potential source of influence is the non-additive interaction between alleles at different loci which is known as gene–gene interaction or **epistasis**.

Gene–environment interaction

Gene–environment interplay represents another important form of non-additive genetic contribution to complex phenotypes.[1] The term gene–environment interaction (G × E) is used here to refer to individual genetic differences in response to specific environmental factors. In the presence of gene–environment interaction, individuals who are at genetic risk of a disorder do not manifest the condition unless they are exposed to a specific environmental risk factor. Gene–environment interaction also means that not all those exposed to an environmental risk factor will show disorder. Later, we consider direct investigation of gene–environment interaction through molecular genetic studies. Twin and adoption study designs have also been used to examine G × E, in an indirect way. Here, genetic liability is inferred by virtue of having affected relatives rather than through possession of a specific genetic risk variant.

Gene–environment correlation

Gene–environment correlation further adds to the complexity of interplay between genes and environment. Gene–environment correlation arises when a person's genotype is correlated with the environment that they are exposed to. For example, sociable parents not only endow their children with genes but also provide an environment that encourages greater sociability in their children (passive gene–environment correlation). Moreover, positive gene–environment correlation would result where a sociable child actively seeks out more situations where socializing occurs (active gene–environment correlation) or where he or she evokes friendly responses in others (evocative gene–environment correlation). There is evidence that many important environmental risk factors in psychiatry (for example, life events) do correlate with genetic risk for specific disorders (for example, depression). Where that is the case, genetically sensitive designs are needed to investigate whether environmental risk factors have true environmentally mediated risk effects on disorder or whether the association has arisen because of genetic factors contributing to both the environmental risk exposure and disorder.

The presence of gene–environment interaction and gene–environment correlation highlights that the action of genes and environment must be considered together. Another important point is that in traditional twin study designs, G × E and G − E correlation effects are subsumed within the heritability estimate or in some circumstances the environmental variance component (see twin studies).

Research methods

Family, twin, and adoption studies

So far we have considered the theoretical basis of inheritance and possible sources of phenotypic variation and familial resemblance. Clearly, the investigation of the genetic basis of psychiatric disorders first requires us to examine to what extent genes and environment contribute to a given disorder or trait. Secondly, we need to know how genes and environmental influences exert their risk effects and finally we have to investigate the genetic basis of disorders at a molecular level.

Traditional methods in psychiatric genetics research include family, twin, and adoption studies. Family studies enable us to examine to what extent a disorder or trait aggregates in families. Familiality of a disorder can of course by explained by shared environmental influences as well as by shared genes. Twin and adoption studies allow us to disentangle the effects of genes and shared environment.

Family studies

(a) Methods

Family studies allow us to determine whether a disorder aggregates in families by examining the rate of disorder in the relatives of affected individuals (probands) and comparing this with the rate of disorder in the general population or in a control group. Alternatively we can compare the frequency of disorder in the relatives of probands with the frequency among relatives of a control group of normal individuals or those with another disorder.

There are two types of family studies. The **family history** method is more economical in that the psychiatric history is taken from the proband. However, given that most individuals are unlikely to know as much about family members as about themselves, this method results in an underestimate of diagnoses in relatives. A more thorough but more time-consuming approach is the **family study** method where all available relatives are directly interviewed.

(b) Ascertainment

An important issue is how a family study sample is ascertained. Ideally, probands should be ascertained independently from each other. This is unlikely to pose a problem for rare disorders. However, for more common conditions where a series of cases is collected, for example, by consecutive referrals of the disorder to a particular hospital, it is possible that families included in a family study contain more than one proband. This is known as multiple incomplete ascertainment. Complete ascertainment, where all affected individuals in a given population are included, is rarely possible and in most instances probands are identified after some selection process (e.g. referrals to a particular hospital). Thus, factors influencing selection, such as comorbidity and help seeking may also influence observed patterns of familial aggregation.

(c) Age correction

For genetic studies, we are interested in the proportion of individuals who have ever had the disorder (lifetime prevalence) rather than the proportion who show the disorder at one point in time (point prevalence). However, a difficulty encountered when carrying out family studies is that the observed rates of disorder will also depend on the age of the individual, the risk period for the disorder, and whether or not the individual has lived through that risk period. Thus, some members may not yet have reached the age of risk for the disorder, some are currently unaffected but will become affected at some later point, and others may have died whilst still unaffected. The most appropriate method is to correct for age and express the rate of disorder in relatives as the **morbid risk (MR)** or lifetime expectancy.

There are many methods of age correction, of which the Slater-Stromgen adaption of Weinberg's shorter method is the most straightforward. The MR of the disorder can be estimated as the number of affecteds (A) divided by the *bezugsziffer* (BZ) where the BZ is calculated as:

$$\sum_{i}[a1]w_i + A$$

and where w_i is the weight given to the ith unaffected individual based on their current age. The most accurate approach is to use an empirical age of onset distribution from a large separate sample, for example a national registry of psychiatric disorders, to obtain the cumulative frequency of disorder over a range of age bands, from which weights can be derived.

Another approach is to carry out life table analysis. The distribution of survival times (or times to becoming ill) is divided into a number of intervals. For each of these one can calculate the number and proportion of subjects who entered the interval unaffected and the number and proportion of cases that became affected during that interval as well as the number of cases that were lost to follow-up (because they had died or had otherwise 'disappeared from view'). Based on these, the numbers and proportions 'failing' or becoming ill over a certain time interval (usually taken as the entire period of risk) can be calculated. A further alternative is to use a Kaplan Meier product limit estimator. This allows one to estimate the survival function directly from continuous survival or failure times instead of classifying observed survival times into a life table. Effectively this means creating a life table in which each time interval contains exactly one case. It therefore has an advantage over a life table method in that the results do not depend on grouping of the data.

Twin studies

Identical or monozygotic twins, by virtue of arising from the fertilization of one egg, share 100 per cent of their genes. Non-identical or dizygotic twins are from two fertilized eggs and like full biological siblings share on average 50 per cent of their genes. Thus, assuming that monozygotic twins and dizygotic twins share environment to the same extent, monozygotic twins would share greater similarity than dizygotic twins for a disorder that is genetically influenced. Twin studies are an important method for disentangling the effects of genes and shared environment and can be used to estimate the contribution of genetic influences, shared environmental factors and non-shared environmental factors to the total variation for a given trait or disorder.

For continuous traits, twin similarity is expressed as an intraclass correlation coefficient where:

$$r_{mz} = h^2 + c^2$$

$$r_{dz} = 0.5h^2 + c^2$$

Thus, from observed monozygotic and dizygotic correlations for a given trait we can calculate heritability from the above equations where $h^2 = 2(r_{mz} - r_{dz})$, $c^2 = 2r_{dz} - r_{mz}$, and e^2 is the remaining variance $= 1 - h^2 - c^2$ (see path analysis below).

For dichotomous characteristics (e.g. affected with a disorder and unaffected), twin similarity is expressed as concordance rates. A **pairwise concordance rate** is estimated as the number of twin pairs who both have the disorder divided by the total number of pairs. However, where there has been systematic ascertainment, for example a twin register, it is preferable to report a **probandwise concordance rate** which is calculated as the number of affected twins divided by the total number of cotwins.

(a) Ascertainment

One potential source of bias in twin studies stems from ascertainment procedures. For example, affected twins referred to a specific study or volunteer samples are likely to include more twin pairs who are monozygotic and who are concordant. Ascertainment of twin pairs through hospital registers overcomes this problem to some extent, but for some disorders may be biased by the process of referral. Population-based samples overcome these biases, although when examining disorders rather than traits extremely large sample sizes are required to obtain an adequate number of affected individuals.

(b) Zygosity

A further potential source of error is in the assignment of zygosity. Ideally zygosity should be determined by DNA typing. However, it may be more practical to use a twin similarity questionnaire which includes questions such as whether the twins share the same hair/eye colour, and whether they look alike as two peas in a pod. This method of assigning zygosity is simple and inexpensive with a reported accuracy of over 90 per cent.

(c) Equal environments assumption

It is sometimes argued that a major drawback to the twin study method is that monozygotic twins may experience a more similar environment and may be treated more similarly than dizygotic twins. However, where there is evidence that monozygotic twins share greater environmental similarity than dizygotic twins it is difficult to infer whether this contributes to their similarity for the disorder or whether this is the consequence of greater genetic similarity. There have been several approaches adopted to further explore this issue.

In some studies questionnaire measures of environmental sharing (e.g. being dressed alike as children, sharing friends) have been used. These suggest that environmental sharing is indeed greater for monozygotic twins than for dizygotic twins. However, it appears that for many traits and disorders such as cognitive ability, personality, depressive symptoms, and depressive disorder this degree of similarity for childhood environment does not account for monozygotic twin similarity for the trait. One way of disentangling cause and effect is to use direct observational studies. Although this method has not been much used, one study of young twins suggested that the greater similarity of parental responses to monozygotic twins compared to dizygotic twins appeared to be elicited by the twins themselves.

An alternative method of examining the effects of environmental sharing is to study twins who are mistaken about their zygosity. However, most studies which have used this method suggest that perceived zygosity is a less important influence on twin similarity than true zygosity.

Finally, the most powerful means of examining the effects of environmental sharing is to look at monozygotic twins who have been reared apart. However, such twin pairs are rare and have mostly been ascertained in a biased fashion. Nevertheless, studies of reared-apart twins have informed us that there is a substantial genetic contribution to cognition, personality, and psychosis.

(d) Comparability of twins

The final potential criticism of the twin method is whether twins can be regarded as representative of the general population given some important differences. Twin births are relatively common (1 in 80 births), although the number of dizygotic twins varies in different countries and is influenced by factors such as maternal age and multiparity, a family history of twins and increasingly, the use of fertility drugs. Twins are more likely to experience greater intrauterine and perinatal adversity and the experience of being brought up as a twin is unusual in itself. There is also some evidence that depression is more common in mothers of young twins than among mothers of singletons. However, these differences are only important if they result in different rates of disorder or symptoms in twins compared to singletons. So far there is little evidence to suggest that the rate of psychiatric disorder in twins is any higher than amongst singletons.

Adoption studies

Adoption studies provide another means of teasing apart the effects of genes and environment. The basic method of the adoption study lies in comparing the rates of disorder in biological relatives and adoptive relatives. There are three main types of adoption study.

1 **The adoptee study**: Here the rate of disorder in the adopted-away offspring of affected individuals is compared with the rate of disorder in control adoptees whose biological parents are unaffected.

2 **The adoptee's family study**: In this design, the rate of disorder in the biological relatives of affected adoptees is compared with that among the adopted relatives.

3 **The cross-fostering study**: This allows us to examine gene-environment interaction by comparing the rate of disorder in adoptees who have unaffected biological parents and affected adoptive parents with the rate of disorder in adoptees who have affected biological parents and unaffected adoptive parents.

Although adoption studies allow us to examine the effects of both genes and environment, there are several potential drawbacks to the method. First, adoption is in itself an unusual event and there is a tendency for higher rates of some psychiatric difficulties such as antisocial personality traits amongst adoptees. Second, adoptive placements are not random in that adoption agencies are likely to attempt to match adoptive and biological parents for physical, social, and other characteristics. Nevertheless, despite these difficulties, adoption evidence has given much support to the role of both genes and environment for traits and behaviours such as cognitive ability and criminality.

Methods of analysis

Although the statistical methods used in quantitative genetics may seem complex, the principles are straightforward. We will now consider the methods of analyses that are most commonly used for examining the contribution of genetic and environmental factors, to psychiatric disorders and traits.

Path analysis

Path analysis provides a simple diagrammatic method of estimating the contribution of genetic and environmental factors. The basic path diagram in Fig. 2.4.1.3 shows the sources of resemblance for phenotypes (P_1 and P_2) in a pair of siblings. Using the rules of path analysis, the correlation between the siblings (r_{sib}) is derived by multiplying the path coefficients for each connecting path and then summing these coefficients. Thus

$$r_{sib} = h \times r_g \times h + c \times c.$$

The genetic correlation r_g is 1 for monozygotic twins who share 100 per cent of their genes in common and is 0.5 for full siblings or dizygotic twins. Thus, using path analysis we obtain the equations described earlier where

$$r_{mz} = h^2 + c^2$$
$$r_{dz} = {}^1/_2h^2 + c^2$$

Model fitting

Although we can simply estimate h^2, c^2, and e^2 from the equations above for more complex data, solving multiple linear equations becomes difficult. We may also wish to test alternative models, for example one where there is no genetic contribution or one where shared environmental influences are dropped. Model fitting allows us to first statistically test how well a given model explains the observed data and to then compare different models.

Computer packages such as Mx[2] are all based on the same principles. The raw data are read into the program and the researcher supplies the initial starting values for the unknown parameters (h, c, and e for a full genetic model). The program then iterates with different parameter estimates until values are found which give an optimum fit (usually this involves maximizing a likelihood function or minimizing a χ^2). The goodness of fit of the model is then assessed by examining the χ^2 goodness of fit where a smaller value indicates a better fit.

The fit of a reduced model (R) can then be compared against the full model (F) by subtracting the χ^2 values ($R - F$). Alternatively the fit of models can be compared by using the likelihood ratio test where twice the difference between the log likelihoods for each model (this approximates a χ^2 distribution) is calculated.

(a) Application of model fitting

So far we have considered the influence of genes and environment on variation in a single phenotype using a traditional twin design.

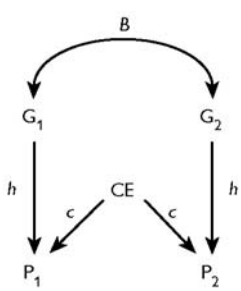

Fig. 2.4.1.3 A single path model of the sources of resemblance between twins or pairs of siblings. G_1 and G_2 are genotypes with correlation B, CE is common environment, P_1 and P_2 are phenotypes, and h and c are path coefficients.

This type of analysis is known as univariate genetic analysis. However the most interesting questions in psychiatry are best addressed by more testing more complex models (See Kendler and Prescott[3] for excellent examples). Designs that involve measuring the same phenotype over time and several phenotypes at the same time (e.g. depression and anxiety) have been used to investigate comorbidity, the aetiological contribution to developmental changes over time and diagnostic boundaries. Studies that have employed such methods have yielded interesting findings. For example, there is evidence that the same set of genes, but different non-shared environmental factors influence anxiety and depressive disorders (and symptoms). The contribution of genetic factors to depressive symptoms and IQ has been found to increase in adolescence compared to childhood. Family and twin studies of autism suggest that there is familial and genetic loading for a broader cognitive and social phenotype in relatives of those with narrowly defined autism.

There have also been imaginative extensions of the twin design that have allowed investigation of different questions. Each type of design has its own set of strengths and weaknesses. Thus having a variety of available methods is invaluable. Examples of different but related designs include studies of the children of twins,[4] studies combining twins, siblings, half siblings, step siblings, and families of twins.[5]

(b) Multiple regression analysis

Another commonly used method of analysing twin data is multiple regression analyses.[6] Here the score of the co-twin C is predicted by the score of the proband twin P, the coefficient of the relationship or zygosity R and an interaction term PR. The partial regression coefficients provide direct estimates of heritability and shared environment. The advantage of this method is that it can then also be used to test whether the magnitude of genetic contribution of extreme scores for a continuous trait differs from scores within the normal range. For example, such analyses suggest that the contribution of genetic factors to variation in very low IQ scores is low, unlike the contribution to IQ variation across the 'normal range'.

Twin and adoption study methods for investigating gene–environment interplay

Traditional twin study designs and analysis of MZ twin similarity and difference that include both measured aspects of the environment (e.g. reported life events) and phenotype (e.g. depression) can be used to test the extent to which the association of environmental factors with psychopathology is mediated by genetic and environmental pathways (gene–environment correlation). For example, one twin study showed environmentally mediated risk effects of childhood maltreatment on antisocial behaviour but different findings for corporal punishment where there were genetically mediated effects.[7] Twin studies have also been used to demonstrate the importance of G × E. Kendler and colleagues (1995)[8] showed that those at higher genetic risk of a major depressive disorder (inferred by lifetime ever diagnosis of major depression in MZ and DZ co-twins) were more sensitive to the depressogenic effects of adverse life events.

Adoption study designs provide a useful method for testing gene–environment interaction as post-natal environmental risk

factors (apart from the very earliest) are experimentally separated from genetic risk. Such studies have shown evidence that the risk of antisocial behaviour is much higher in those who are not only at higher genetic risk (by virtue of having a parent with antisocial behaviour) but who are also exposed to adverse rearing environments in the adoptive home.

Gene mapping

A more direct approach to locating and identifying genes involved in psychiatric disorders is to attempt to map them. Gene mapping technology has advanced at an astonishing pace over the past 20 years. Early studies in psychiatric disorders such as schizophrenia[9] had to rely purely on 'classical' genetic markers such as HLA antigens blood groups and various protein polymorphisms. Capabilities in systematic gene mapping, which involves mounting a search throughout the whole genome (i.e. the 22 pairs of autosomes and the sex chromosomes), only became possible after the discovery of markers based on variation in DNA length. The first of these were the restriction fragment length polymorphisms and these have largely been supplanted by single nucleotide polymorphisms (SNPs). Informative combinations of markers are known as haplotypes. The Human Genome Project has led to a detailed map of common variation in the human genome. This public database of more than one million SNPs[10] provides information about the patterns of linkage disequilibrium between these markers that can guide selection of 'tagging SNPs' for gene mapping studies. Such marker maps allow the genes contributing to traits or diseases to be located. The methods for mapping are linkage and association. Gene mapping is discussed further in Section 2.4.2.

Gene regulation

The human genome is much more complex than previously thought.[11] Gene activity and expression (the process by which proteins are made) is regulated by inherited DNA and RNA, non-inherited mechanisms (epigenetics), endogenous biological factors such as hormones and environmental factors operating externally to the individual organism (e.g. toxins, psychosocial stress).

For example, non-coding sequences of DNA were previously thought to be 'junk DNA'. There is increasing evidence that this is not the case and that such regions may play an important role in regulating gene activity. Gene activity is also altered by environmental factors.[11] Animal studies have now shown that environmental factors can alter the genome through measurable biological mechanisms, that these changes can be passed onto the next generation and be subject to modification. For example, maternal care giving behaviour early in life, notably high levels of licking and grooming of rat pups, has an effect on brain glucocorticoid receptor expression and sensitivity to stress in the offspring.[12] This effect is observable even when non-genetically related pups are fostered to mothers who have low levels of licking. This 'programming effect' appears to be mediated by structural modifications of DNA. The molecular mechanisms explaining this 'epigenetic marking' are beginning to be identified and include DNA methylation and histone acetylation. These non-inherited effects persist over two generations and in animals appear to be possibly reversible.

Linkage

In linkage studies, rather than just studying the segregation of a disease in families, the co-segregation of the disease and a set of genetic markers is investigated. The aims are, first, to detect linkage, indicated by the disorder and the marker co-occurring more often than would be expected by chance (i.e. not showing Mendelian independent assortment) and, second, to estimate the distance between a linked marker and the gene conferring to susceptibility to the disorder.

It is possible to detect linkage only in families containing at least one parent who is a double heterozygote (i.e. heterozygous at both the marker and the disease loci). Technically such families are referred to as double back-cross or intercross/intercross matings but, for simplicity, we will just focus on the double back-cross type (Table 2.4.1.1). The table shows a double heterozygote parent where the alleles *A* and *B* are on one chromosome with *a* and *b* on the other. Consequently offspring of the types *aaBb* or *Aabb* result from recombination or crossing over between the homologous pair of chromosomes during meiosis. These types of offspring are called **recombinants**. Offspring of the same type as the parents (i.e. *AaBb aabb*) are non-recombinant. We can then simply define the recombination fraction, θ, as the number of recombinants divided by total number of offspring.

For two loci that are very widely separated on the same chromosome (and all pairs of loci carried on to two different chromosomes) independent assortment occurs and θ = 1/2. When the two loci are close together dependent assortment may be observed indicated by a recombination fraction of less than a half. The size of the recombination fraction depends on the physical distance between the two loci and (within certain limits) is proportional to it, so that for loci that are very close together recombination rarely occurs and θ tends to zero. Genetic distances estimated by linkage studies are measured in centimorgans (cM) with 1 cM the equivalent of a recombination fraction of 0.01. For reasons that are not fully understood, recombination occurs more frequently in female than in male meioses. Hence, the size of the female human genome expressed in centimorgans is larger than the male genome. The sex-averaged size of the human genome is about 3700 cM. With reasonable sample sizes major gene effects can be confidently detected over distances of around 10 to 15 cM. Hence, a whole genome search can be carried out using 200 to 300 polymorphic markers, provided they are approximately evenly spaced. A **polymorphism** can be defined as a gene or sequence of DNA that occurs in two or more common forms. Classically, 'common' means an allele frequency of at least 1 per cent. SNP markers are common

Table 2.4.1.1 Double back-cross mating

		Parent 1	***x***	**Parent 2**
		AB/ab		ab/ab
Offspring	*AB/ab* Non-recombinant	*Ab/ab* Recombinant	*aB/ab* Recombinant	ab/ab Non-recombinant
No linkage	1/4	1/4	1/4	1/4
Linkage	(1–θ)/2	θ/2	θ/2	(1–θ)/2

and biallelic. Sometimes combinations of allelic variants across different markers (haplotypes) are analysed in gene mapping studies.

Linkage analysis

The standard method of carrying out linkage analysis in humans is the lod score approach devised by Morton.[9,13] Essentially, for a given set of data, lod scores are calculated over a range of values of θ between 0 and 0.5. Where the lod score reaches a maximum, provides the best (or maximum likelihood) estimate of θ. The lod score is so called because it is the common **l**og of the **od**ds that θ has a certain value θ′; rather than a value of 0.5, i.e.

$$\text{lod} = \log_{10}\frac{\text{probability}\ (\theta = \theta')}{\text{probability}\ (\theta = 0.5)}.$$

By convention, a lod of 3 or more is accepted indicating that linkage has been detected, while a lod of −2 or less indicates that linkage can be excluded at that particular value of θ. A lod of 3 corresponds to odds on linkage of 1000:1 and to a nominal *P* value of 0.0001. This therefore seems at first sight to be a very stringent criterion. However, linkage between two loci taken at random is inherently unlikely[13] and Morton's[9] original argument took into account the low prior probability of linkage to arrive at a criterion that gave a posterior probability, or reliability, of 95 per cent. More recently researchers have been concerned about the effects of carrying out many statistical tests in a genome-wide search for linkage and have sought to set an approp riate level of lod score to compensate for this. In fact, as it turns out, the original suggestion of a lod of about 3 is close to recent calculations of what lod is required to conclude in favour of genome-wide significance.[13]

As originally devised, the lod method deals purely with regular Mendelian traits. However, it can be readily adapted for detection of single genes that have incomplete penetrance by applying the general single major locus model discussed earlier. The main drawback is that the model (as specified by the penetrance values, and less critically the gene frequency) must be known accurately. Where the model is mis-specified there is a high risk that linkage will fail to be detected.

A further difficulty is that diseases may show locus heterogeneity, i.e. there may be two or more different (and unlinked) loci where mutations result in similar phenotypes. There are many instances of this among rare Mendelian diseases. A good example is Usher's syndrome causing deafness and retinitis pigmentosa, which can result from mutations in any one of six different genes. Subforms of common diseases can also show locus heterogeneity, the most relevant to psychiatry being early onset familial Alzheimer's disease where autosomal dominant forms can result from mutations in three different genes, called presenilin 1, presenilin 2, and amyloid precursor protein. Although methods exist for detecting linkage in the presence of heterogeneity these have not so far in practice been of great help in psychiatric or other common disorders. Rather, the most frequent general strategy has been to focus on multiplex families (i.e. those containing multiple members with the disorder under study) and to make the following simplifying assumptions.

1 There are major gene subforms of the disorder in at least some families.

2 Although the mode of transmission is unknown, a reasonable guess at the defining parameters can be made.

3 Although there may be locus heterogeneity in the disorder as a whole, within any given family there is likely to be homogeneity.

This has worked very well for several disorders, including, as we have just mentioned, Alzheimer's disease, but it initially produced a rather confusing set of results from studies of schizophrenia and bipolar disorder. The most likely cause of this is that assumption 1 is incorrect and that subforms of these conditions resulting from major genes are very rare or perhaps non-existent. Consequently most recent studies use other linkage methods that do not rely on any assumptions about the mode of transmission. These concentrate on affected siblings or other pairs of relatives both affected by the disorder.

Methods based on relative pairs

The underlying principle of the affected sib-pair approach is simple. For any given locus the probabilities that siblings share 0, 1, or 2 alleles that are identical by descent from their parents is respectively ¼, ½, ¼. On the other hand, if both members of a sib pair are affected by the same disease and we are studying a locus close to a gene that confers susceptibility to that disease, there will be increased allele sharing. This will occur irrespective of the mode of transmission of the susceptibility gene and hence simple non-parametric statistics can be used to test whether there is any perturbation of the expected identical-by-descent proportions. Affected sib-pair methods are therefore robust and are now generally considered to be the method of choice in detecting linkage in oligogenic or polygenic disorders. In order to be certain that a pair of siblings share alleles identical by descent, one needs to know their parents' genotypes. Otherwise it could be that a shared allele identical by state results from one of the pair having inherited it from the father and the other from the mother. However, an advantage of using highly polymorphic single sequence repeat polymorphisms is that it may not always be necessary to genotype parents, i.e. where the population is reasonably homogenous and where gene frequencies can be estimated, it is possible to compute the likelihood that a pair who share one or two alleles identical by state are truly identical by descent. This means that in return for a fairly modest reduction in power (because one is now dealing with a probability rather than a certainty of counting alleles that are identical by descent) there is a halving in the amount of genotyping that needs to be done.[20] In our own experience, the other advantage of being able to make do without parental genotypes is that they are often difficult to obtain in adult-onset disorders such as schizophrenia. Significant regions of genetic linkage for disorders, notably schizophrenia, bipolar disorder, and autism that have been shown across different studies or found in pooled analyses have now been identified. Another use of sib-pair methods is in studying continuous traits (e.g. height, weight, personality test scores) to attempt to detect the quantitative trait loci that contribute to their heritability.[14] One approach is to select probands who have extreme scores on some quantitative measure and investigate the extent to which marker allele sharing by siblings predicts the regression to the population mean of the siblings' scores.[14] This has been successfully used in mapping a quantitative trait locus contributing to reading ability in children. Unfortunately the drawback of such methods and of sib-pair linkage approaches generally is that they are only capable of detecting moderately large effects. This means that a quantitative trait locus contributing less than about

10 per cent of the variance, or a disease susceptibility locus conferring a relative risk of less than 2, will probably require very large samples running into several hundreds, perhaps thousands, of pairs. If we assume that most common diseases and complex behaviours involve the combined action of many genes of small effect, complementary strategies based on allelic association are required.

Association

In their classic form, allelic association studies are more straightforward to carry out than linkage studies. A sample of cases affected by a disorder (or subjects who have scores higher than a given threshold on a quantitative measure) is compared with controls who do not have the disorder (or subject whose scores are near average). The frequency of alleles at the marker locus is then compared in the two groups. The significance of the difference can then be compared in the usual way for contingency table analysis using a χ^2 test (or Fisher's exact test if expected frequencies are small). In addition to significance it is useful to have a measure of the strength of association. A variety of statistics can provide this but probably the most useful and intuitively appealing is the **relative risk**, i.e. the proportion of cases among those carrying the marker allele or risk factor, P_1, divided by the proportion of cases among those not carrying the factor, P_2. As we can calculate from Table 2.4.1.2, RR = $P_1/P_2 = (a/(a + b))/(c/(c + d))$. If the disorder is uncommon, i.e. a and c are small relative to b and d, RR can be approximated by another, easier-to-obtain statistic, the odds ratio, OR = $a \times d/(b \times c)$. If a positive marker disease association has been found the odds ratio will be significantly greater than 1.

Before the current era of molecular genetics many association studies of disease with classical markers were carried out most notably with blood groups and with the HLA system. One of the earliest well-replicated findings was an association between blood group O and duodenal ulcer. The odds ratio was less than 2 in most studies and Edwards[15] pointed out that the proportion of variance in liability to the disorder explained by the association was only about 1 per cent. Even though later disease association studies on HLA, with other diseases such as type I diabetes and various auto immune disorders were stronger, it has been pointed out that here too only a small proportion of variance is accounted for. Although this could in one respect be considered disappointing, it demonstrates that allelic association can detect small gene effects in polygenic or multifactorial traits and may therefore prove to be more useful than linkage.

How does allelic association arise and what does its detection tell us? There are three principal mechanisms of association. The first is linkage disequilibrium. Normally pairs of alleles at two different loci occur together no more often than would be expected by chance (i.e. they are in 'equilibrium'). In most cases this is the result of independent assortment. However, even if loci are linked they will usually approach equilibrium very rapidly with the proportion of associated alleles decreasing by $1 - \theta$ each generation. Only where the two loci are very close together does disequilibrium tend to persist. For example, where the distance is 1 cM corresponding to a recombination rate of one meiosis in 100, the time taken for an association to go half way to equilibrium is 69 generations. For a distance of 0.1 cM the time taken is 693 generations, or about 20 000 years. The second cause of association is when a polymorphism within a gene itself has a functional effect which results in susceptibility to a disease. The third, and in most cases least interesting, phenomenon is population stratification. This occurs where there has been recent admixture of populations or two or more ethnically distinct populations living side by side with little interbreeding. If the populations differ in terms of the frequency of alleles of the genetic markers and in the frequency of the disease being studied, marker disease associations can arise if there is not careful ethnic matching of patients and controls.

Another way of overcoming stratification is not to study unrelated cases and controls but to study families and derive the controls 'internally'. The most familiar method in current use is the transmission disequilibrium test.[16] This requires affected individuals to have at least one parent who is heterozygous at the test locus. The affecteds can therefore each receive one of two alleles from such parents. A 2 × 2 contingency table can then be constructed on whether a particular allele is the transmitted or the non-transmitted allele. This is illustrated in Table 2.4.1.3 for a marker with two alleles, A_1 and A_2. The entries in each cell of the table, a, b, c, and d are counts of the number of parents transmitting or not transmitting each allele to their affected offspring. The significance of the transmission disequilibrium test is simply assessed by a McNemar χ^2 test.

Finally, it is becoming increasingly accepted to actually test for population stratification in the laboratory by examining whether random gene variants not thought to be involved in disease, differ in cases and controls. Assuming that stratification can be overcome there are broadly two ways to proceed with association studies. The first is candidate gene association studies and the second is whole genome association studies.

(a) Candidate gene association studies

Functional candidate gene studies concentrate on polymorphisms in or near genes that encode for proteins that are likely to be involved in the disorder. This has so far been the commonest type of association study in psychiatry as in most other common diseases, and there are some interesting early results relating to, for example, polymorphisms at the serotonin *5-HT$_{2a}$* receptor gene in schizophrenia[17] and the dopamine *D4* receptor gene in attention-deficit-hyperactivity disorder.[18] Positional candidate gene studies involve selecting genes that are in regions implicated by linkage.

Table 2.4.1.2 Case-control allelic association

Marker	*N* affected	*N* unaffected
Present	*a*	*b*
Absent	*c*	*d*

Table 2.4.1.3 Transmission disequilibrium test: affected subjects with at least one parent heterozygous for allele A

	Non-transmitted	
Transmitted	**A_1**	**A_2**
A_1	*a*	*b*
A_2	*c*	*d*

X^2.1 df = $(b–c)^2/(b + c)$

This approach, fine mapping using association to narrow down a region discovered by linkage, has for example resulted in identification of a susceptibility locus, *KIAA0319*,[19] involved in reading disability. Another positional strategy involves obtaining clues about the potential position of a susceptibility gene from individual families who present with a disorder and have a specific region of a chromosome disrupted. For example, a study of Scottish families with translocations involving a region on chromosome 1 and schizophrenia and bipolar disorder led to identification of a susceptibility gene *DISC1* for schizophrenia.[20]

(b) Whole genome association (WGA) studies

The second approach, which has only recently become technically feasible, is to attempt a systematic search through the entire genome with the aim of detecting linkage disequilibrium or direct association. It follows from what we have discussed earlier that a genome-wide search for linkage disequilibrium or direct association has a particular attraction in the study of polygenic disorders in that it should be capable of detecting genes of small effect. Very high throughput genetic analysis involves hydridizing DNA into many thousands of oligonucleotides on microarrays and allows a very large number of biallelic single nucleotide polymorphisms (SNPs) to be tested very rapidly and at comparatively low cost. Cost can be reduced even further by performing the initial screening by DNA pooling. Such methods[21] combine samples from groups of patients and groups of controls processing them in batches. Positive findings can then be followed up by doing individual genotyping. Thus if pools consist of say 100 individuals, the initial cost of genotyping is reduced 100-fold. Against this, some information is lost by DNA pooling and accurate construction of pools is difficult and time consuming. The problem of multiple testing can be overcome either (as in the DNA pooling approach), by carrying out a two-stage analysis with fairly liberal test criteria in the first stage followed by stringent criteria in the second stage, or by simply setting a very stringent criterion at the beginning. It has been shown for example that, even with an alpha level set at 1×10^{-6}, detection of linkage disequilibrium with genes of small effect is feasible with realistic sample sizes.

As we write, WGA studies are being completed using commercially available microarrays containing 500 000 SNPs.[22] Such studies present formidable challenges including the need for very large samples of subjects to provide adequate power of detection and problems of multiple testing and handling of huge amounts of data. Nevertheless, WGA studies have already led to the identification of susceptibility genes for common non psychiatric disorders (e.g. macular degeneration and diabetes) and the initial results of several WGA studies of psychiatric disorders including schizophrenia, bipolar disorder, and ADHD will soon be available or have already been published.[23]

Molecular genetic studies investigating gene–environment interplay and intermediate phenotypes

Genetic variants do not necessarily confer risk for a psychiatric disorder unless in the presence of a specific environmental risk factor. Molecular genetic studies allow a direct test of whether the association of a specific gene variant with disorder is contingent upon exposure to a specific environmental factor. There are a number of important methodological issues that need to be considered when investigating G × E.[24] Most importantly, in testing for G × E, there is the problem of multiple testing given the potential for testing a large number of gene variants and environmental risk factors. Thus, there need to be good *a priori* hypotheses before selecting a specific gene variant and environmental measure. Despite these caveats, there is increasing evidence of the likely importance of G × E in psychiatry as a number of findings have now been replicated. The presence of G × E also provides one potential explanation (amongst others) for non-replication of genetic association findings across different studies.

To date the strongest evidence of G × E has been for a gene variant that affects MAOA enzymatic activity and which appears to increase the risk of antisocial behaviour only in the presence of childhood maltreatment.[25] There is also evidence to suggest that possession of a gene variant that affects function of the serotonin transporter (5HTT) increases the risk of depression in the presence of life events.[26,27] A potentially clinically important type of G × E research is pharmacogenetics. Here the aim is to identify genetic variants that influence clinical response and the risk of side-effects upon exposure to specific types of medication. The hope is that such approaches may lead to a more individually tailored approach to prescribing.

As gene variants associated with psychiatric disorder are identified, and variants that affect gene function recognized, there is an increasing need to identify the intermediate biological pathways and mechanisms. This has led to an increasing amount of research on potential intermediate phenotypes that may account for the link between risk factor and psychiatric outcome. Most interest to date has focused on measures of brain function and structure, assessed through imaging studies[28] as well as neurocognitive, biochemical, and physiological traits. For example, the functional variant in the 5HTT that is associated with depression in the presence of adverse life events appears to be associated with amygdala hyper-responsivity to stress. There is also some evidence that a functional COMT gene variant plays an important role in dopamine clearance in the prefrontal cortex and is associated with prefrontal cortical functioning, assessed through cognitive task performance and fMRI. It is hoped that this new era of imaging genetics together with other areas of neurobiological research will help elucidate the risk pathways that lead from genetic and environmental risk factors to psychiatric disorder.

2.4.2 Molecular genetics

Jonathan Flint

Introduction

The transformation of the LOD score (an acronym for log of the odds ratio), from obscurity as a footnote in medical genetics, to celebrity as multiple choice test item in professional examinations in psychiatry, epitomizes the invasion of genetics, and particularly molecular genetics into psychiatric research. Moreover, like other celebrities caught up in fast moving fields, LOD scores are likely to return to their humble origins within a few years. As molecular genetic approaches to mental health move away from simply identifying genes and DNA sequence variants towards functional studies of increasing complexity, newcomers to the field have to master an expanding literature that covers diverse fields: from quantitative genetics to cell biology, from LOD scores to epigenetics. This chapter takes on the task of making the reader sufficiently familiar with the broad range of subjects now required to follow the progress of psychiatric genetics in the primary literature.

A number of achievements have to be highlighted. Foremost among these is the completion of the human genome project. Announced annually from 2001[1–3] and thereby begging the question as to what constitutes completion, the human genome project is now an essential biological resource. As expected, the ability to sequence whole genomes has transformed the way genetics is carried out, perhaps most egregiously with the rise of bioinformatics as a core discipline: discovery now takes place using the internet rather than the laboratory. Anyone with an interest in human biology should look at the frequently updated information at http://www.ensembl.org or http://genome.ucsc.edu.

Without the human genome two other critical developments would have been impossible: the ability to analyse the expression of every gene in the genome and the ability to analyse (theoretically at least) every sequence variant. Both developments also depend on miniaturization technologies that enable the manufacture and interrogation of initially thousands and then millions of segments of DNA. In addition, results from the International Haplotype Map (HapMap) project,[4] which catalogues common variation in the human genome have been crucial in making it possible to take apart the genetic basis of common, complex disorders such as depression, schizophrenia, and anxiety.

Few disciplines are more burdened with jargon than molecular genetics. This is partly due to the proliferation of molecular techniques, but it is also partly intrinsic to the subject; the only unifying principle is evolution, which often operates in a very ad hoc fashion. Biological solutions to the problems posed by selection result in the adaptation of existing structures to new uses, rather than to the invention of purpose-built systems. Consequently there are few general lessons to be learnt and the novice simply has to become adept at recognizing the acronyms and neologisms that decorate the literature. The material in this chapter aims to equip the reader with the necessary terminology. It begins with the structure and function of DNA, an essential starting place for a number of reasons.

Nucleic acid structure and function

The chemical constituents of genetic information are deoxyribonucleic acid (**DNA**) and ribonucleic acid (**RNA**). Both molecules consist of linear chains of nitrogenous bases bound to a sugar (ribose) and a phosphate backbone. Because of the way the sugars are joined together, one end of each nucleic acid strand will have a terminal sugar residue in which the carbon atom at position number 5 of the ribose molecule is not linked; the other end has a free carbon atom at position 3. These two ends are termed the 5′ (5 prime) and 3′ (3 prime) ends respectively.

It is usual to describe a DNA or RNA sequence by writing the order of bases in a single strand, in the 5′ to 3′ direction. DNA contains four nitrogenous bases: adenine (A), guanine (G), cytosine (C), and thymine (T). RNA differs in that it contains uracil instead of thymine.

Two structural differences between DNA and RNA are important for understanding nucleic acid function. First, DNA has a hydroxyl group on part of its sugar constituent whereas RNA has a hydrogen atom. The result is that, in most biological environments, RNA is much more unstable than DNA. Second, RNA normally exists as a single molecule, whereas DNA is a double helix in which two strands are held together by weak hydrogen bonds between opposed base pairs (**bp**), C joined to G and A to T. The sequence of one strand can therefore be inferred from the other. The two strands are said to be complementary to each other, and this property is exploited whenever DNA is copied (during meiosis, mitosis, or *in vitro* processes such as amplification of DNA using a polymerase chain reaction).

As befits an unstable molecule, RNA mediates the expression of genetic information; its production and degradation are tightly controlled. RNA is translated into a linear order of amino acids in proteins according to a three-letter code (e.g. GAA encodes the amino acid glutamine). DNA acts as a template for the production of RNA in a process termed as transcription. But DNA is more than a stable repository of encoded protein sequence information; it also contains information that controls the transcription of RNA.

Disorders of the template function of DNA are the molecular basis of inherited dispositions and illness, and are the subject matter of genetics. By contrast, gene expression (the transcription and translation of RNA) is not entirely genetically predetermined. It is highly regulated, but in response to changes in the cellular environment which in turn reflect changes in the state of the organism. Disorders of gene regulation are now emerging as important causes of disease.

Genome organization

DNA within cells is packaged into chromosomes in the cell nucleus, with a tiny amount (16 569 bases containing 37 genes) in the mitochondria. Since mitochondria in the fertilized egg are maternally derived, mitochondrial inheritance is through the female lineage. Although small, mitochondrial disorders contribute substantially to degenerative disorders including ageing. More important is nuclear DNA.

As of 2007, the size of the nuclear genome is 3 253 037 807 bp (3.3 gigabases) containing 21 662 known and 1064 novel genes (http://www.ensembl.org). Packing such a large molecule into a cell is done at a number of levels, with profound consequences for gene function. At the first level, 147 bp lengths of DNA are wrapped around octamers of proteins known as histones. These nucleosomes are the fundamental units of the state of packaged DNA known as chromatin.

Packaged DNA is itself organized into 22 autosomal chromosomes, one inherited from the mother and one from the father, and two sex chromosomes, X and Y. Each chromosome pair exchanges stretches of DNA during sexual division (meiosis) in a process called recombination (without which genetic mapping, the basic method of finding disease genes, would be impossible). Chromosomes have three functional elements: origins of replication, centromeres, and telomeres. Replication origins are required to initiate DNA replication and maintain chromosome copy number. Their molecular structure is unknown. Centromeres are responsible for the segregation of chromosomes during cell division. Their molecular nature is also not understood, but they are visible in light microscopy as a constriction where the duplicated chromosomes (called chromatids) are held together. Chromosomes are said to have two arms, separated by the centromere which, despite its name, is not always at the centre. Short arms are termed p (*petit*) and long arms q (*queue*). Telomeres are the ends of chromosomes and their molecular nature is well understood. They consist of long stretches of the sequence TTAGGG without which the chromosome is unstable, tending to break apart and fuse with itself or to other chromosomes.

No one has found any general principles that organize genetic material within chromosomes. Rather than being an efficiently organized plan of the organism consisting of precise drawings, the genome resembles a working copy written over countless rough drafts and discarded versions, among which there are literally thousands of jottings and scribbles, most irrelevant to the final structure. While there are examples of gene families clustered in the same chromosomal location (for instance genes involved in immune regulation are clustered on chromosome 6p), more commonly the position of genes on chromosomes does not reflect functional similarity. For example, genes expressed only in one tissue, or at one stage of development, are often immediately adjacent to widely expressed housekeeping genes.

Genes and the regulation of gene expression

DNA is transcribed into RNA, which in turn is translated into protein. Transcription involves the excision of large portions of transcribed RNA (by RNA splicing enzymes) and modifications to the ends of the RNA molecule (capping of one end and polyadenylation of the other). The final product, messenger RNA (**mRNA**),

contains a central section, translated into protein, and flanking non-coding regions. The consequence of these manipulations is that DNA and mRNA are not coterminous; sections of DNA that encode mRNA (termed exons) are interrupted by often very large stretches of DNA that are not translated (termed introns) (Fig. 2.4.2.1).

Gene expression is controlled in a number of ways, predominantly at the level of transcription (but posttranscriptional processing and translational control are important for some genes). While knowledge in this area is still rudimentary, but advancing fast, it has already led to new insights in disease aetiology: understanding theories of the neurobiology of depression now requires familiarity with chromatin remodelling; epigenetic effects are often invoked in molecular biology of intellectual disability. Below I summarize information about the relevant molecular processes.

1. **Transcription factors:** transcription factors exercise control over gene expression. Transcription occurs when RNA polymerases manufacture RNA from the template DNA, a process that requires the help of transcription factors, proteins that recognize and bind to specific DNA sequences (note that transcription factors can also repress transcription). Although transcription factor-binding sites are found close to a gene, at a 5′ region known as the promoter (see Fig. 2.4.2.1), they may also be situated far away, sometimes within other genes. The characterization of these control elements remains a major challenge for genome research and is currently a focus of the ENCODE project, a continuation of the human genome project whose aim is the comprehensive identification of all the functional elements in our genome (http://genome.ucsc.edu/ENCODE/).

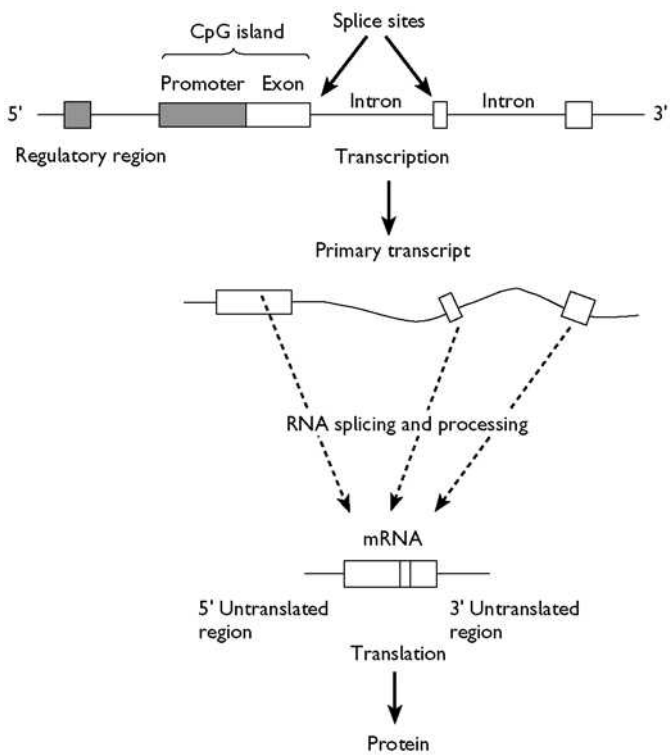

Fig. 2.4.2.1 At the top of the figure the organization of a gene in genomic DNA is shown. Unshaded boxes correspond to coding regions (exons) and the two shaded boxes correspond to control regions. The control region immediately 5′; of the first exon, where transcription is initiated, is known as the promoter and often has a characteristic sequence composition. In almost all ubiquitously expressed genes (and in many tissue-specific genes) it is unmethylated, GC rich, and has a relative excess of the dinucleotide CpG. The region, which typically contains the first exon as well as the promoter, is called a CpG island. The boundaries between exons and introns are called splice sites and are conserved; introns virtually always start with the sequence GT and end with the sequence AG. The entire genomic region is transcribed into a primary transcript (bold arrow) which is then processed to excise the introns. Many human genes undergo alternative splicing to yield a number of different mRNA products. Mature mRNA is then translated into a protein product.

Transcription factors typically control the expression of a number of genes, reflecting the presence of a hierarchical structure of coordinated gene expression. Consequently mutations in transcription factors have effects on different, seemingly unrelated phenotypes, a phenomenon called pleiotropy. The constellation of phenotypic abnormalities seen in intellectual disability syndromes can be explained in this way. For example mutations in the X-linked ATRX gene result in an anaemia (α-thalassaemia), a characteristic facial appearance, profound developmental delay, neonatal hypotonia, and genital abnormalities.[5] The gene contains sequence motifs indicating that it belongs to a group of proteins that bind to chromatin and is involved in chromatin remodelling, discussed below.[6]

2. **DNA methylation:** gene inactivation is associated with DNA methylation, predominantly the addition of methyl groups to cytosine bases. DNA methylation occurs almost always at CpG dinucleotides, and most CpGs in the genome are methylated.[7] DNA methylation represses gene expression in two ways: first, modification of cytosine inhibits the association of some DNA-binding factors with their DNA recognition sequences, and second proteins that recognize methyl-CpG can repress transcription from the methylated DNA. Methylation of DNA does not change the DNA sequence itself, as it is reversible, but the methylation status is maintained when cells divide. Consequently the change is referred to as epigenetic modification.

   DNA methylation is critical for imprinting, a form of gene regulation in which transcripts are expressed from only one of the two parental chromosomes. Although there are relatively few imprinted genes (about 60 are currently documented, although sequence features in the region of known imprinted promoters implicate 600) imprinting is an important phenomenon in neurobiology for three reasons[8]: (i) There is evidence from studies of embryos that maternally expressed genes enhance and paternally expressed genes reduce brain size, indicating that at least some imprinted genes are likely to be involved in neurodevelopment.[9] (ii) Disorders of imprinting are important in intellectual disability syndromes: Rett syndrome, Prader–Willi syndrome, Turner syndrome, and Angelman syndrome.[10] (iii) Imprinting is involved in X chromosome inactivation, the mechanism by which cells compensate for males having just one copy of the X chromosome while females have two.[11] The X chromosome contains a disproportionately high density of loci affecting cognition and since males always inherit their X chromosome from their mother, the presence of X-linked imprinted genes is believed to contribute to sexually dimorphic effects.

   The biology of imprinting is complex and not fully understood. In germ cells and in pre-implantation embryos, all methylation

patterns are removed, and then re-established.[12] About half of identified imprinted genes are clustered within imprinting centres (IC) which carry the allele-specific methylation marks established at this developmental stage. Most maternally silenced imprinted genes are repressed by promoter methylation. No protein-coding imprinted gene has been found that is repressed by paternal methylation derived from the sperm (presumably because of active demethylation of the paternal genome). Importantly, paternal repression is achieved, at least in some cases, by using a transcript on the opposite strand (an antisense transcript). Promoter methylation of the antisense transcript (usually resulting from oocyte-derived methylation) represses its transcription and thus activates the protein-coding gene epigenetically.

Some evidence, obtained by examining females with a single X chromosome (Turner syndrome females), indicates that imprinted genes on the sex chromosomes influence brain structure and function.[13] Since the single X chromosome is inherited from either the mother or father, it is possible to compare the effects attributable to a maternally or paternally imprinted chromosome. Maternally expressed X-linked genes have been reported to influence hippocampal development, while paternally expressed genes influence the normal development of the caudate nucleus and thalamus in females. Using Turner syndrome patients, Skuse and colleagues have suggested that a paternally expressed allele is associated with enhanced social–cognitive abilities.[14] A similar observation has been found in a mouse model of Turner syndrome, lending weight to the view that imprinted genes are involved in cognitive processes.[15]

3. **Chromatin remodelling:** the nucleosome forms a barrier to transcription, primarily because DNA has to be free of nucleosomes for it to be accessible to transcription factors and the large complex of proteins that constitutes RNA polymerase. To some extent the organizational information of where nucleosomes are positioned is embedded within DNA sequence, in a nucleosome code; but the nucleosome is not a static unit. It too has dynamic properties and exerts an effect on transcription. Furthermore, like methylation, the effects are heritable, providing a second form of epigenetic modification to DNA (X inactivation also involves this form of epigenetic modification).

   Histones (the proteins that constitute nucleosomes) are subject to a large number of modifications (acetylation, ubiquitination, methylation, ADP-ribosylation, and sumolation of lysine residues; and phosphorylation of serines and threonines) of which two, lysine acetylation and methylation, have been most heavily studied. Histone modifications can influence each other and may also interact with DNA methylation, in part through the activities of protein complexes that bind modified histones or methylated cytosines. These, and other proteins that remodel chromatin, control genes involved in the development and activity of the central nervous system.

   Chromatin remodelling has attracted attention as a possible mechanism for bringing about persistent change subsequent to an environmental stressor.[16] Two examples are relevant. Meaney and colleagues have reported that heritable differences in stress reactivity in rats depend on variation in parenting, not variation in DNA.[17] Adult offspring of mothers that show higher levels of licking, grooming, and arched-back nursing (high-LG-ABN) are less fearful and show more modest hypothalamic-pituitary axis responses to stress than offspring of 'low-LG-ABN' mothers.[18] How are these maternal effects, or other forms of environmental programming, sustained over the lifespan of the animal?

   Variations in maternal care were found to alter the methylation status of a promoter of the glucocorticoid receptor gene. Central infusion of a histone de-acetylase inhibitor enhanced histone acetylation of the glucocorticoid receptor promoter in the offspring of the low-LG-ABN mothers. Analysis of the promoter showed that CpG dinucleotides were hypomethylated. In consequence, the maternal effect on hippocampal glucocorticoid receptor expression and the hypothalamic-pituitary axis response to stress were both eliminated.[19] This finding suggests that there is a causal relation between epigenetic modifications, glucocorticoid receptor expression, and the maternal effect on stress responses.[20]

   Nestler's group invoked chromatin remodelling as an explanation for the long-lasting behavioural change induced by antidepressants.[21] Chronic defeat stress in rodents is reversed by chronic (but not acute) antidepressant treatment, a model for the action of antidepressant action in our own species. Chronic defeat stress and chronic antidepressant treatment are associated with reciprocal, long-lasting changes in expression levels of brain derived neurotrophic factor (BDNF). This is in turn associated with lasting changes in chromatin architecture at the corresponding BDNF gene promoter. Furthermore, down-regulation of a histone de-acetylase (Hdac5) by chronic antidepressant treatment was necessary for the therapeutic efficacy of the antidepressant.

4. **Small RNAs:** small RNAs include micro RNAs (miRNAs) and small interfering RNAs (siRNAs) directly or indirectly alter gene transcription.[22,23] siRNAs, derived from double-stranded RNAs (dsRNAs), control cleavage of other transcripts and can themselves direct the production of dsRNA by RNA-dependent RNA polymerase; they are also implicated in recruiting heterochromatic modification that leads to transcriptional silencing.

   The extent of siRNA involvement in eukaryotic gene regulation is still unclear. Micro RNAs specify posttranscriptional gene repression by base pairing to the messages of protein-coding genes. They represent nearly 1–5 per cent of all genes in higher eukaryotes and have been implicated in developmental timing and neuronal patterning. They are believed to facilitate the transition between developmental stages and therefore are likely to have an effect on the expression and evolution of most mammalian mRNAs.

   Only 3 per cent of the genome codes for protein.[24] However, that is not to say that the remaining 97 per cent is inactive; in fact the number of transcripts is at least 10 times as great as the number of genes.[25,26] What this means in terms of function is not clear, but along with the discovery of small RNAs it has forced a re-evaluation of what is meant by a gene. The idea that a gene is a section of DNA transcribed into RNA, which in turn encodes a protein, fails to capture the gamut of RNA species, some of known function (such miRNAs), some with only suspected function. The emerging complexity of gene function and the multiple species that need to be included in any definition of a

gene has dramatically increased our understanding of molecular pathogenesis.

Genetics and genotyping

Chromosomes are not stable structures. They rearrange during meiosis, recombining material between the paternal and maternal chromosomes. The mechanisms of recombination are not relevant for understanding neurobiology, but without recombination we would not be able to track mutations. This section describes the basic methodologies currently used. To follow it, and the many reports in the literature, it is essential to be familiar with genetic terminology. A brief reminder is provided next.

A position on a chromosome is called a locus, a general term which can refer to a gene or a segment of DNA with no known function. DNA sequences that differ at the same locus are called allelic variants. Since we have two copies of each chromosome, by definition we have two alleles at each locus. If these alleles are identical the individual is said to be a homozygote; if they are different, the individual is a heterozygote. It follows that for a locus with two alleles (that is one which is di-allelic, as are the single nucleotide polymorphisms that form the basis of almost all genetic mapping experiments), then there are three possible genotypes. For example, if the alleles are either C or T, the possible genotypes are CC, CT, and TT, whose frequencies in a population, in the absence of migration, mutation, natural selection, and assortative mating, are a simple function of allele frequencies (this phenomenon is termed Hardy–Weinberg equilibrium).

The relationship between alleles at different loci is important for genetic mapping. Assume there are two loci on the same chromosome, separated by approximately 1 megabase (Mb). The loci are again di-allelic, the first with alleles C and T, the second with alleles A and G, so that there are nine possible two-locus genotypes: ATCC, TTCG, AAGG etc. Consequently, the chromosomes of an individual with the two-locus genotype ATCG could be any of the following four: A-C, A-G, T-C, or T-G. This combination of alleles along a chromosome is known as a haplotype. If recombination occurs between the two loci it will break-up the haplotype, so that the offspring of someone with the haplotype A-C on one chromosome and T-G on the other may inherit the novel haplotype A-G. The probability at which this occurs depends on the genetic distance between the two loci. For 1 Mb in the human genome this probability is approximately 1 per cent per meiosis, or 1 cM.

Molecular mapping depends on the availability of genetic markers across the genome. The genome is replete with DNA sequence polymorphisms whose only known use is to enable geneticists to map disease genes. On average, every 1000 bp will contain 1.4 bases that differ between two randomly chosen individuals, almost all of which have no phenotypic consequence. In addition, there are small runs of repeated sequence (most commonly CA) which differ in length between individuals. At least one of these short tandem repeats (**STR**s), or **microsatellites**, is found every 50 kilobases (**kb**) and they also have no known phenotypic consequences. There are other more complex sequence polymorphisms, but single nucleotide polymorphisms (**SNP**s) and microsatellites are the most useful for identifying disease genes.

Genotyping of genetic markers almost always starts by amplifying DNA using the polymerase chain reaction (PCR). PCR requires the following reagents: a DNA polymerase; a pair of oligonucleotides (also referred to as primers), which are synthetic single-stranded DNA, usually between 15 and 25 bases long, complementary to two sequences on opposite strands of the target DNA; the target DNA itself; all four nucleotides, usually present in excess; appropriate buffer and cofactors for the reaction. The reaction proceeds in a cycle of three steps: (1) the mixture is heated to over 90°C for 1 min to separate the complementary strands of target DNA, (2) the mixture is cooled, to about 50°C, so that the oligonucleotides anneal to their complementary sequence in the target DNA and allow the DNA polymerase to bind (oligonucleotides are required to prime the polymerase), and (3) the temperature is adjusted to allow the polymerase to function in the extension component of the reaction. Typically the polymerase is from a thermophilic bacterium with a permissive temperature of 72°C. Products from the first cycle serve as targets for a second round of amplification and so on, for up to about 40 cycles.

The method used to genotyping the PCR product depends on the nature of the sequence variant. Microsatellite genotyping involves discriminating the length of the PCR products, usually accomplished by separating the fragments by electrophoresis, in which an electrical current causes smaller fragments to migrate more quickly than larger fragments through a matrix. Typically a fluorescent label is incorporated into the amplified DNA allowing the PCR products to be detected by a laser, a method that allows automated analysis.

SNP genotypes can also be worked out from differences in molecular weight. For example, the nucleotide added to a primer complementary to sequence immediately preceding a SNP in the PCR fragment will depend on the genotype of the individual. The small difference between a primer with a C nucleotide added to its end (reflecting the presence of a G nucleotide in the PCR fragment) compared to the same primer with the addition of a T nucleotide, can be determined using a mass spectrometer. However, most high-throughput genotyping methodologies (required for whole genome association studies) exploit the specificity of DNA hybridization: while two complementary single strands of DNA stick (or hybridize) together (ATTGAC will anneal to TAACTG) a single base mismatch will prevent hybridization (ATTGAC will not anneal to ATAGAC). Consequently, a SNP can be detected by determining whether primers hybridize to the PCR fragment. By labelling the primers, for example, with a fluorescent dye, the hybridization can be visualized, and, using the same technology that builds computer semiconductors, millions of primers can be manufactured on a small piece of glass, allowing the simultaneous detection of millions of SNPs.

Genetic mapping: linkage and association

For genetic disorders that arise from a mutation in a single gene, behaving in a Mendelian fashion (dominant, recessive, or sex-linked inheritance), disease gene identification is conceptually straightforward. Marker alleles follow Mendelian laws of segregation so that it is possible to determine if a marker is co-segregating with a disease in a family and to test the result statistically using methods described in Chapter 2.4.1. The expected result is an estimate of the probability that an allele and a disease locus will recombine; the lower the probability, the closer together the two loci are on the chromosome. The statistical test gives the likelihood that the estimate of recombination distance between a marker and a mutation

is correct. If the likelihood is acceptably high, then the next task is to reduce the genetic interval as much as possible and to identify a causative mutation. Access to the human genome makes it straightforward to identify all genes within a given interval (go to one of the two websites mentioned above) and the ease of DNA sequencing (many companies make this service available) makes it possible to screen candidates by a brute force approach: enough is known about sequence codes to recognize a mutation that will disrupt gene expression, and this can be experimentally verified by looking at the production and structure of mRNA.

A good example of the success of gene mapping in pedigrees is the identification of a mutation in the FOXP2 gene in a family that has a language disorder. The phenotype is complex, including both verbal and non-verbal cognitive impairments. However, the inheritance pattern is straightforward: it fits a model in which a single mutation in one copy of the gene is sufficient to cause disease. By using markers from across the genome, a region on chromosome 7 was identified that co-segregated with the defect and a mutation in a transcription factor, FOXP2, subsequently identified.[27,28]

Pedigree-based linkage works well when the disease follows Mendelian laws of segregation and has led to the identification of many genes involved in intellectual disability and dementia. However, pedigree-based methods for disorders where the genetics does not fit a simple Mendelian pattern have been much less successful. The methods (described in Chapter 2.4.1) typically ask whether affected siblings in a family (usually just a pair) share the same allele at a locus: the more often sharing is observed, the closer the markers locus is inferred to be to the disease gene. The relative failure of the affected sibling pair strategy is almost certainly because of the small contribution that each locus contributes to disease susceptibility.

Neil Risch and Kathleen Merikangas pointed out in 1996 that if the genetic effect size attributable to a single locus is small (that is to say it would increase the risk of developing the disease less than two-fold) then the number of families required using a pedigree method would be impractically large.[29] However, a direct test of association between genetic marker and disease gene had much greater power. Simply by genotyping a marker and determining whether the distribution of genotypes was significantly different between a set of unrelated cases and unrelated controls, small effects could be detected with relatively small sample sizes. The drawback was the need to test variants in every gene, possibly requiring researchers to genotype a million individual markers. Surprisingly, Risch and Merikangas showed that the objection to mounting such a study was not statistical, but technological.

Two advances made whole genome association studies feasible. First, as described above, technologies are available for genotyping on an appropriate scale. Second, an enormous catalogue of SNPs has been compiled. As of April 2007, 11 577 475 SNPs have been identified and mapped on the human genome. Fortunately, not all these variants need to be genotyped for mapping disease genes. It was found that many SNPs were highly correlated with each other, because recombination is less likely to disrupt haplotypes of closely linked markers than of more distantly spaced markers (a phenomenon termed linkage disequilibrium (LD)). Consequently, aetiological variants can be expected to be in LD with one or more SNPs. By genotyping a carefully selected set of markers (called 'tagged SNPs') most of the common variation in the genome can be assayed. However, for this strategy to be practical, a haplotype map of the genome was first required that catalogues the distribution of LD in different populations (since LD patterns are a product of population history, as well as of recombination distance). Genotyping on an immense scale in multiple populations was undertaken by the International Haplotype Map (HapMap) consortium,[4] and the results, regularly updated, are available on the internet (http://www.hapmap.org).

The molecular basis of psychiatric disorders: Mendelian disorders

There are a number of conditions in psychiatry that arise from mutations in single genes (Mendelian mutations). As a rule, such disorders are rare and, importantly, they account for very few, if any, instances of common disorders: depression has never been attributed to a Mendelian mutation (though some single mutations, such as Huntington disease, do include a mood disorder in their phenotype). Nevertheless, rare single gene mutations can provide important clues to the aetiology of more common conditions: for example, mutations in neuroligins, identified as a rare cause of autism, suggest that the pathophysiology lies in abnormalities of synaptic function.

In general, the molecular basis of Mendelian mutations in psychiatry is typical of other human genetic disorders in that they arise primarily from changes to one, or a few, nucleotides. These are described below under the heading point mutations. However, there are two exotica: triplet repeats and imprinting defects.

Point mutations

Changes in a single base pair (e.g. from C to T) of the coding sequence of the gene may alter the function of the protein (**mis-sense mutations**), result in premature termination of the protein product (**non-sense mutations**), or create or destroy a splice site. In addition, deletions (of a single base pair or many megabases of DNA) and insertions (again of any size) disrupt transcription and translation of a gene. Deletions or insertions that do not affect a multiple of three bases alter the way that the message is translated and are known as frame-shift mutations. While none of these mechanisms is special to psychiatric genetics, describing the mutational basis of a genetic disorder is an initial step in understanding how the disorder arises; what the DNA sequence change does to the protein gives a clue to the protein's function (if unknown) and to the pathogenesis of the condition. Analysis of mutants causing dementia, isolated by positional molecular cloning, are an example.

The presenilins are ubiquitously expressed transmembrane proteins in which mutations give rise to about 40 per cent of familial Alzheimer's disease.[30] More than 160 mutations in the presenilin genes have been identified. Almost all are mis-sense mutations. Why are there no frame-shift or non-sense mutants? Mis-sense mutants alter an amino acid in the protein and therefore can alter its function. One clue about the nature of the functional change comes from looking at where mutations occur within the protein, thereby discerning whether some parts of the molecule are more frequently involved than others. The distribution of mutations in the presenilins is indeed non-random; mutations occur at residues which are the same in both presenilin genes, lying on one side of the α helix in transmembrane domains, predominantly in exon 8. Thus the mutational spectrum highlights key residues for

understanding the protein's functions.[31,32] The mutations in presenilin result in a gain of function: they alter the ratio of the two forms of amyloid that constitute neuritic plaques, one of the histological hallmarks of the Alzheimer's disease.[33,34]

Where a gene's function is known, the distribution of mutations may reveal the likely pathogenesis. For example, mutations in the tau gene cause frontotemporal dementia with Parkinsonism (Pick's disease).[35,36] The most common mutation occurs in the 5′ splice site of exon 10, resulting in overproduction and accumulation of one form of tau; mutations in other regions of the gene lead to accumulation of a different form of the protein. The position of the mutations in tau indicate that they cause disruption of tau microtubule binding, which may cause cell death by the degeneration of microtubules or through an increase in unbound tau.

Triplet repeats

One mutational mechanism is unusual and deserves special comment: expansion of trinucleotide repeats.[37] Its importance in psychiatry is that it occurs in at least 16 neurological disorders, some with behavioural phenotypes (such as Huntington disease). No one knows why trinucleotide repeat expansions tend to be found in disorders of the central nervous system. The mechanism was first discovered in 1991 as the cause of fragile X syndrome,[38,39] a common form of inherited X-linked intellectual disability.

The mechanism is important because it explains some otherwise unusual features of the phenotype. Table 2.4.2.1 lists the diseases associated with triplet repeats. At each locus there is a normal range of copy numbers above which the repeat array becomes unstable: the larger the number of copies, the more unstable the allele and in general the more severe the disease. Repeats increase and decrease in size both in somatic and germ line tissues, with two important consequences. First, it may not be possible to infer the severity of the condition from a blood test, since the repeat length in the brain may not be the same as in the lymphocytes (this is an example of somatic mosaicism). Second, as the repeat length increases in successive generations, the age of onset may decrease (this is called anticipation). For instance the age of onset of myotonic dystrophy ranges from birth to adulthood.

Genomic rearrangements and gene dosage effects

A number of disorders, primarily those associated with intellectual disability, have been found to be due to chromosomal rearrangements. Down syndrome (trisomy 21) is by far the most common, accounting for about a third of all cases with moderate to severe retardation.[40] Chromosomal rearrangements can be extremely complex, like the nomenclature used to describe them.

Abnormalities of the number of chromosomes result in aneuploidy. Deletion of part or an entire chromosome is termed a monosomy (or haploinsufficiency); an extra copy of either part of or an entire chromosome is called trisomy. A general term to describe either loss or excess of chromosomal material is aneusomy. Most chromosomal abnormalities involve small regions of aneusomy and consequently are known as segmental aneusomy syndromes or contiguous gene syndromes.[41]

Table 2.4.2.1 Triplet repeat diseases

Disease		Repeat unit	Gene	Normal repeat	Expanded repeat	Mechanism
Fragile X syndrome	FRAXA	(CGC)n	FMRP	6–60	>200	Loss of function
Fragile XE syndrome	FRAXE	(CCG)n	FMR2	4–39	200–900	Loss of function
Friedrich ataxia	FRDA	(GAA)n	Frataxin	6–32	>200	Loss of function
Myotonic dystrophy type 1	DM1	(CTG)n	DMPK	5–37	50–10 000	RNA-mediated
Myotonic dystrophy type 2	DM2	(CCTG)n	ZNF9	10–26	>75	RNA-mediated
Fragile X–associated tremor ataxia syndrome	FXTAS	(CGG)n	FMR1	6–60	60–200	RNA-mediated
Huntington disease	HD	(CAG)n	Huntingtin	6–34	36–121	Polyglutamine expansion
Spinocerebellar ataxia	SCA1	(CAG)n	Ataxin1	6–44b	39–82	Polyglutamine expansion
Spinocerebellar ataxia	SCA2	(CAG)n	Ataxin2	15–24	32–200	Polyglutamine expansion
Spinocerebellar ataxia	SCA3	(CAG)n	Ataxin3	13–36	61–84	Polyglutamine expansion
Spinocerebellar ataxia	SCA6	(CAG)n	CACNA1A	4–19	10–33	Polyglutamine expansion
Spinocerebellar ataxia	SCA7	(CAG)n	Ataxin7	4–35	37–306	Polyglutamine expansion
Spinocerebellar ataxia	SCA17	(CAG)n	TBP	25–42	47–63	Polyglutamine expansion
Spinobulbar muscular atrophy	SBMA	(CAG)n	Androgen receptor	9–36	38–62	Polyglutamine expansion
Dentatorubral-pallidoluysian atrophy	DRPLA	(CAG)n	Atrophin	7–34	49–88	Polyglutamine expansion
Spinocerebellar ataxia	SCA8	(CTG)n	SCA8	16–34	>74	Unknown
Spinocerebellar ataxia	SCA10	(ATTCT)n	10–20	500–4500		Unknown
Spinocerebellar ataxia	SCA12	(CAG)n	PPP2R2B	7–45	55–78	Unknown
Huntington disease-like 2	HDL2	(CTG)n	Junctophilin	7–28	66–78	Unknown

The distribution of rearrangements in the genome is not random, reflecting instead the involvement of higher-order architectural features.[42] Regions susceptible to rearrangement are frequently flanked by, or contain, region-specific repeat sequences, or low-copy repeats. In general, recurrent rearrangements, or those of common size and having clustered breakpoints, most frequently result from homologous recombination between repeats.[43]

Chromosomal rearrangements in psychiatric patients other than those with intellectual disabilities are rare, but their occurrence has led to some important discoveries. Deletions on the end of chromosome 22q cause a syndrome that includes a psychosis often indistinguishable from schizophrenia, thus prompting an intense investigation of this region of the genome.[44] Characterization of patients with translocations and psychosis also led to the identification of a gene called DISC1 (for **d**isrupted **i**n **sc**hizophrenia)[45] and screening for chromosomal rearrangements in patients with Tourette's syndrome led to the identification of mutations in a Slit and Trk-like family member 1 (SLITRK1) gene.[46]

The phenotypes of chromosomal rearrangements are thought to arise because of the loss, in the case of monosomy, or addition, in the case of trisomy, of dosage-sensitive genes, of unrelated function, that happen to lie next to each other on the chromosome. However this is not always the case, as the examples of Prader–Willi syndrome and Angelman syndrome show.

Imprinting defects

A number of diseases can be attributed to a failure to establish, maintain, or recognize methylation. Rett syndrome is a progressive neurodevelopmental disorder that occurs almost exclusively in females, with an incidence of between 1/10 000 and 1/15 000 live births.[47] Most females with Rett syndrome are usually heterozygous for a *de novo* mutation in methyl-CpG-binding protein MeCP2, a protein that induces the recruitment of protein complexes involved in histone modifications and chromatin remodelling. Prader–Willi syndrome and Angelman syndrome are both caused by loss of function of imprinted genes on the proximal long arm of human chromosome 15.[48] Prader–Willi syndrome occurs if the paternal chromosome 15 is missing, Angelman syndrome if the maternal. In a few per cent of patients the disorder is due to aberrant imprinting and gene silencing.

Non-coding RNA

The discovery that small RNA molecules regulate gene expression has occurred too recently for us to know the importance of mutations in this system as a cause of disease. Examples are however beginning to be reported: a point mutation was shown to create a new promoter, driving a novel transcript that in turn silenced a neighbouring gene.[49] There is one example from neuropsychiatric genetics, in which mutations in the binding site for microRNA hsa-miR-189 have been identified as a cause of Tourette's syndrome.[46] These complex mechanisms are difficult to detect without a detailed understanding of gene regulation, which is likely to come in future years.

The molecular basis of psychiatric disorders: complex disorders

Genetic attempts to dissect common psychiatric conditions have been very slow to yield robust results. For every paper that reports a positive association between a genetic variant and schizophrenia, anxiety or alcohol abuse, another can be found that fails to replicate the finding.[50] There are at least three explanations for the difficulties in arriving at agreement. One is that scientific journals afford more importance to positive than negative results; for example, there have been more than 40 studies investigating the relationship between a variant of the dopamine D2 receptor and alcohol abuse. By plotting the effect size of each study against the year of publication, a clear and statistically significant negative correlation is found: studies with the largest effects are published first.[51] Publication bias almost certainly exists in other studies, but has rarely been systematically examined.

Second, a number of commentators have pointed out that the sparse success of genetic linkage and association studies in complex traits can be explained by the low power of individual studies.[52] Meta-analytic techniques that make it possible to combine data from many individual studies have revealed that the odds ratios attributable to individual susceptibility loci are commonly less than 1.3.[53] Analysis of obesity, Type 2 diabetes and breast cancer shows that it is possible to obtain association results that replicate, but that tens of thousands of subjects are required.[54,55] There is no reason to believe that psychiatric disorders will be any different in this respect; it is simply that no study has reported data from enough cases.

A third reason for the inconsistencies is that interaction between genes can obscure the signal attributable to the main effect of the locus.[56] Gene interaction, or epistasis, means that the phenotype depends on the allelic configuration of a number of loci. For example, if there are two alleles (*i* and *j*) at a susceptibility locus on chromosome 1 and two alleles at a susceptibility locus on chromosome 2 (*l* and *m*) then in an epistatic interaction disease will only manifest in those individuals with allele *i* on chromosome 1 and allele *m* on chromosome 2. Imagine a population in which allele *i* on chromosome 1 is common. Genetic association tests of the effect of allele *m* on chromosome 2 will detect an effect. But the same test, when carried out in a population where allele *i* is rare, will not detect an effect, even though allele *m* is present at equivalent frequencies in both populations.

Epistasis is suspected to be important, but there are currently no well-documented examples in psychiatric genetics. More attention, and more information, is available for a similar phenomenon called gene by environment interaction (GXE). Interaction between genes and environment is said to occur if disease manifests only when specific alleles are exposed to a given environment. For example, individuals with one allele (called *s* (for short)) at the promoter of the serotonin transporter may have an increased chance of developing depression, but only if they have been exposed to stressful life events.[57] Individuals with the *l* (for long) allele are protected against the effect of this environmental stressor and are less likely to become depressed. GXE hides genetic association in the same way as epistasis. In the presence of GXE, unless differences in the environmental stresses experienced by subjects are taken into consideration, contradictory results may be obtained from testing a genetic association between the serotonin transporter polymorphism and depression in different populations.

The advent of whole genome association studies applied to large case-control cohorts is beginning to unravel the molecular basis of common complex diseases. These studies are proving to be successful, in that they are identifying small numbers of loci that can be replicated in independent samples. However, since most studies

find at best a handful of loci contributing to disease susceptibility, the results show that the bulk of the genetic predisposition to complex disease is almost certainly due to loci with much smaller effects than those found to date. There are also indications that many of the variants will be extremely rare, possibly even private to individual families.

One important indicator of the importance of rare variants is the poor coincidence between the location of whole genome association hits and those from linkage studies. It is important to bear in mind that linkage and association are detecting different signals: linkage will detect an effect when there are multiple different variants in the same gene (allelic heterogeneity). However, allelic heterogeneity dramatically reduces the power of genetic association, so that signals will be missed. Re-sequencing of genes has also led to a greater appreciation of the role of rare variants. Although individually rare, non-synonymous sequence variants in certain genes are cumulatively frequent and are known to influence quantitative traits, such as plasma lipoprotein levels[58]; it may prove to be true also for behavioural phenotypes.

Finding rare non-synonymous variants in genes should not obscure the importance of aetiological variants that lie outside genes. It had been thought that the spectrum of sequence variants in complex disease would be similar to mutations found from the analysis of Mendelian conditions: that is to say variants in the coding regions of genes, the splice sites, or the promoters. However, SNPs with robust, replicated results for association with complex disease are usually found nowhere near coding regions; they are located outside genes, in regions not known to have any function. Furthermore, when genes implicated by genetic association in psychiatric disease have been entirely sequenced, no obvious abnormalities are seen. This is true, for example, of the genes believed to be involved in schizophrenia (dysbindin and neuregulin).

Genome-scanning technologies have also uncovered an unexpectedly large amount of structural variation in the human genome, including deletions, duplications, and large-scale copy-number variants, as well as insertions, inversions, and translocations. A global survey of copy-number variants identified 1447 regions, covering 360 Mb (a remarkable 12 per cent of the genome), revealing a considerable contribution to overall genetic heterogeneity.[59] Critically, these variants were found in supposedly disease-free populations. It is possible that copy-number variants play an important part in the aetiology of common psychiatric disorders. For example, genome-scanning of autism has found copy-number variants in 10 per cent of cases of sporadic autism and in only 1 per cent of controls.[60]

Functional analysis

The armamentarium of molecular genetics tools wielded in the onslaught on the genetic basis of psychiatric disorders is impressive, expensive, and at the same time relatively uninformative about the neurobiology of the illnesses. As genes are identified an equally complex technology is being applied to working out what those genes do. The last section of this chapter provides a guide to the relevant molecular biology.

One of the most fruitful ways of investigating gene function is through genetic manipulation of animals, for example, by introducing a copy of the gene into a mouse or mutating the mouse version of the gene. Both approaches work because exogenous DNA can integrate into chromosomes. If the site of integration can be targeted, rather than being random, the exogenous DNA can be used to create mutations in specific genes.

Transgenic mice are made by injecting DNA (usually, but not necessarily, human) into fertilized mouse oocytes. Integration is a rare and random event and almost always involves multiple copies entering at a single site, making interpretation of some transgenic experiments difficult. More specific genetic manipulation is achieved by exploiting homologous recombination in embryonic stem (**ES**) cells. DNA containing a mutated copy of the gene of interest in tandem with a selectable marker (e.g. an antibiotic resistance gene) is introduced into ES cells. In a small number of cases the exogenous DNA recombines with, and consequently replaces, the cell's copy of the gene. ES cells are isolated from embryos and can be grown in flasks while retaining the potential to develop into any tissue. Once they have been genetically manipulated and re-injected back into a pregnant mouse, the resulting embryo is a mixture of mutant and normal cells. If some of the ES cells contribute to the germ line of the embryo, then its offspring will be heterozygote mutants, from which homozygotes can be bred.

One important reservation should be borne in mind when assessing studies that have used gene targeting: the genetic background of a mutant can have an effect on the mutant.[61] Most targeting experiments use the ES stem cells derived from substrain 129 mice, which are crossed with another inbred line. The choice of inbred line into which the mutation is bred can be critical because many inbred lines have specific behavioural phenotypes; for instance, the inbred strain DBA/2 shows poor hippocampal-dependent learning and C57BL/6 mice are poor avoidance learners.[62]

Improvements in knockout technology have had a major impact on neurobiology. Rather than simply knockout genes, homologous recombination can be used to change part of a gene, for example, by substituting one amino acid to another, a process referred to as a knock-in technology. The development of binary systems, where two engineered lines are crossed, has given experimenters remarkable control over gene expression: genes can now be turned on, or off, by feeding the animal a compound that penetrates to the cell nucleus, such as tetracycline.[63] The tetracycline transactivator (tTA) is used as a transcriptional switch to drive the expression of a gene of interest. The tTA system requires the use of two lines of transgenic mice. In one line the expression of the tTA protein is driven by a tissue or cell-type-specific promoter; in the second, a gene of interest is placed downstream of the tet operator (tetO) and a promoter. The tTA protein binds to the tetO sequence and induces transcription. However, when the tetracycline is present, it binds to tTA and prevents it from binding to tetO and this halts transcription.

Binary systems also make it possible to generate mutations that are restricted to specific cell or tissue-types. This is done by introducing sequences recognized by an enzyme, cre recombinase, on either side of the gene of interest. Cre is a site-specific DNA recombinase derived from a bacteriophage that recognizes 34 bp sequences termed loxP sites. Cre catalyses the deletion of DNA flanked by a pair of loxP sites (the DNA is said to be floxed). Again the experimental system requires two lines: in one the gene of interest is floxed; in the other, cre is driven by a tissue-specific promoter so that its expression is restricted to the cells of interest. Consequently, the gene is only deleted in that subset of cells.

Targeted homologous recombination, combined with conditional control, has proved so successful a method for investigating gene function, that three major mouse knockout programmes are underway worldwide, working together to mutate every gene in the mouse genome using this technology. I have chosen a few examples on the application of the technology to illustrate the remarkable power of the approach and reveal why it has generated such interest in the neuroscience research community.

One of the earliest was the genetic demonstration of the effect of a brain-subregion-restricted NMDA receptor knockout on spatial memory.[64] Following the discovery that high-frequency stimulation of the hippocampal input fibres can result in long-lasting enhancement of synaptic transmission, long-term potentiation (LTP) has been subject to extensive investigation. The induction of LTP is blocked by amino-phosphonovaleric acid (AP5), an antagonist of the NMDA subset of glutamate receptors. A voltage-dependent magnesium block and high calcium permeability mean that the receptor can be opened by glutamate only when the postsynaptic neurone is depolarized, thereby allowing the receptor to function as a detector and integrator of coincident activity at the synapse. Unsurprisingly, the demonstration that infusion of AP5 into the ventricles of rats impaired spatial learning generated intense interest in the potential role of the NMDAR as a crucial component of memory. Furthermore, since disorders of working memory have been documented in schizophrenia, NMDAR dysfunction has attracted the attention of psychosis researchers. The genes encoding the receptor were identified in the early 1990s. There are seven subunits (NR1, NR2A–D, and NR3A and B), of which the NR1 subunit is the only one that is indispensable for the formation of a functional receptor.

Functional investigation of the NR1 receptor using gene knockout technology proved to be impossible because NR1-knockout mice do not survive for more than a day after birth: the receptor has a crucial role in the midbrain for breathing. This is a general problem with constitutive knockout technology: lethality before, or just after birth is common. Tonegawa and colleagues used the conditional technology to get over this problem. They floxed the NR1 receptor and crossed the mouse to a line in which cre recombinase was under the control of a promoter of a gene expressed in the hippocampus.[65] Because the recombinase was predominantly active in the CA1 region of the hippocampus, the NR1 gene could be knocked out postnatally in CA1 pyramidal cells.

The mouse strain had apparently normal growth and was fertile, but was severely impaired in a test of spatial learning.[65] Furthermore, recording of neuronal activity indicated a loss of coherent spatial representation in the hippocampus.[66] The conditional knockout provided strong evidence that NMDAR activity and NMDAR-dependent synaptic plasticity in the hippocampus are crucial for spatial learning. The importance of CA1 NMDARs in the acquisition of hippocampus-dependent memory was subsequently extended to various non-spatial tasks, including recognition of novel objects, and fear conditioning.

Advances in genetic engineering have also been critical in shaping views of the neurobiology of anxiety and depression. There are a large number of publications reporting anxiety phenotypes associated with constitutive knockouts, implicating so many genes that as one reviewer points out 'the overall message one takes away from these studies is that normal anxiety requires normal neuronal functioning. Disrupt such functioning in any of a number of different ways and anxiety-like behaviour is likely to be disrupted—not a very specific or informative conclusion'.[67] Application of the more focused molecular technology has been more informative.

Benzodiazepines bind the α-subunit of the pentameric receptor, enhancing the efficacy of GABA in activating the receptor. By introducing a histidine to arginine mutation into the genes encoding each of the α1, α2, and α3 subunits and by testing mutants for behavioural abnormalities, it has been possible to determine that the α2 isoform is responsible for the anxiolytic effects, but not the sedative or amnesic, effects of benzodiazepines in mice.[68–70] These results have encouraged a search for isoform-specific medications, since a drug specific for the α2 subunit might reduce anxiety while having little or no sedative effects.

The importance of developmental, as well as tissue-specific effects, has also emerged from the use of conditional knockouts. While knockouts of the 5-HT1A serotonin receptor indicated the importance of this gene in anxiety, the mechanism by which it exerts an effect was not appreciated until Hen and colleagues developed a tissue-specific, inducible rescue of the 5-HT1A knockout.[71] A mutant line, in which the 5-HT1A promoter was replaced with a tTA responsive element, was crossed with a line in which the tTA protein was under the control of a promoter expressed in the hippocampus and cortex (the CaMKII promoter). The tTA protein induced expression of the 5-HT1A receptor in postsynaptic target tissues, but not in the serotonergic neurones of the dorsal raphe nucleus. Rescue of the knockout restored normal anxiety-like behaviour, demonstrating that the lack of postsynaptic receptors, rather than presynaptic, causes the anxiety phenotype. Furthermore, by giving tetracycline only during adulthood, so that the 5-HT1A receptor was expressed only during development, it was found that the mice behaved like wild type animals. By contrast, when 5-HT1A receptor expression was ablated during development, it was not possible to rescue the phenotype in the adult, demonstrating that stimulation of postsynaptic 5-HT1A receptors during a developmental critical period is required to establish normal patterns of anxiety-like behaviour that then persist into adulthood.

The creation of knockouts should not obscure an equally important application of molecular genetic methods in neuroscience: to augment existing functional tools or to create entirely novel ones. The developments can be categorized into visualization tools and, more recently, tools for intervention.

The ability to visualize proteins in cells has transformed cellular neurobiology. Visualization is made possible by attaching a fluorescent tag, usually green fluorescent protein or one of its congeners, to the DNA encoding the relevant protein. The genome projects have made available complete libraries of cloned DNA, so that it is possible to obtain cloned DNA of any gene. By using homologous recombination in bacteria, any gene can be tagged, and then inserted into the mouse genome, either by targeting or random transgenesis.[72,73] This genetic tagging has made it possible to track gene products spatially and temporally at the highest level of resolution (fluorescently tagged genes expressed in the mouse brain can be seen at http://www.gensat.org). One immediate application of this technology is the identification of sequences that confer tissue-specific gene expression, revealed by the expression of the fluorescent protein. Genes expressed in a specific brain region can then be replaced, rather than tagged, making it possible to target proteins to brain regions.[74] This is one of the key technical requirements for mounting an interventionist approach to neurobiology.

Interventionist tools are set to transform neurobiology from a discipline in which function is inferred by observing the connectivity of the nervous system, into one in which a function can be directly tested by activating its component parts. Sensor proteins, that detect changes in the physiological states of neurones through the emission of light, and actuator proteins that effect such changes in response to an exogenous signal, can be genetically engineered and inserted into organisms using genetic targeting technologies.[75,76] The ability to activate specific cell types through genetically encoded sensors responsive to light will undoubtedly facilitate the exploration of neuronal circuits. These techniques, though still in their infancy and currently most useful in invertebrate model organisms, are likely to have broad applications in neurobiology and will be a critical tool for understanding the function of genes involved in psychiatric disease.

2.5.1 Developmental psychology through infancy, childhood, and adolescence

William Yule and Matt Woolgar

Introduction

The child is father to the man. This saying seems so obviously true that it may surprise some people that it needs to be analysed and certain assumptions inherent in it need to be challenged if psychiatric practice across the lifespan is to be properly informed by findings from developmental psychology. This chapter examines different conceptualizations of children and childhood through the ages and the ideas and theoretical models that have shaped popular, as well as professional, views on how children develop. It notes that there are no overarching theories of child development, but rather a pot-pourri of smaller models, most of which address disparate aspects of development.

Developmental psychology is not just about charting the norms of development, although knowledge of such is essential in all clinical practice. Rather, there are many issues that need to be critically examined in trying to understand how individuals develop. Taking a developmental perspective is about integrating this knowledge and understanding the patient's presenting problems within such a framework.

The significance that the clinician will place on a particular piece of behaviour will depend not only on the child's sociocultural background, but also on the child's developmental age. Cox and Rutter[1] note four reasons for taking a developmental perspective:

1 Children behave differently at different ages. The clinician must be familiar with the range of behaviours and their age-appropriateness in separating the normal from the abnormal. For instance, simple consonant substitutions are widespread in the speech of pre-school children, but indicate some delay or deviation in the speech of teenagers.

2 Many aspects of behaviour can be viewed as progressing through a normal sequence. Admittedly, discrete stages are overemphasized by stage theorists such as Freud, Piaget, and Bowlby, whereas the continuities in development are more emphasized by social-learning theorists such as Staats, Bijou, and Baer. Either way, an understanding of the normal sequences and ages permits a judgement as to whether the child has deviated in his or her development.

3 Different stages of development are associated with different stresses and different developmental tasks. Bladder and bowel training are normally achieved between the ages of 2 and 4 years. Major stresses on the child or the family at the time may interfere with the achievement of proper bladder and bowel control. Mood swings are very common in adolescence, making it difficult to diagnose the severity of depression at this stage.[2,3]

4 An understanding of the processes which underlie both normal and abnormal development will help in the understanding of how the problems have arisen.[4] Such an historical perspective can help explain to the parents why a particular problem developed, as well as give possible clues for future programmes for prevention. A major implication of this for clinical practice is that it is always necessary to obtain a good account of the child's developmental history.

5 A better understanding of the *processes* underlying a child's development will lead to far better interventions and prevention.

Once we have a better understanding of the *distal* and *proximal* causes of behaviour, better targeted interventions will follow.

Developmental theories and views

There is a bewildering set of mini-models and mini-theories of developmental processes, each trying to deal with changes in children's functioning either at different periods in their lives or in different psychological functions such as perception, language, and memory. By and large, the different theories seem to ignore each other's work—and many also seem keener on theories than on data that might test the theories.

For example, Piaget's theories predominantly address how children develop a cognitive understanding of their world. His was a biological view of development, and his cross-sectional methodology emphasized the separation between the stages he posited. Staats[5] argued that most of the phenomena described by Piaget and his followers could be interpreted within a social learning theory framework that instead emphasized the continuity of development across stages.

Kohlberg's theory of moral judgement is a stage theory that differs radically from Piaget's in that the different forms of reasoning said to typify different stages can coexist. However, the way in which children (or adults for that matter) judge an ethical dilemma does not necessarily determine how they behave. Most financiers would have little difficulty in providing sophisticated moral judgements on Kohlberg type tasks, but many financiers also present the unacceptable face of capitalism in their ruthless dealings. It is not the case that the older we are, the wiser we behave.

In Freud's theory of psychosexual development, children are seen as passively passing through stages, their development being impeded by obstacles or even regressing in the face of trauma. This view owes more to literature than to science, and the evidence on children's psychosexual development clearly shows that whatever Freud was unaware of during the latency period, children are certainly far from inactive.[6]

Apart from being stage theories, these three sets of influential theories really have very little in common. The psychological mechanisms determining growth of cognitive understanding bear little relationship to any that supposedly underlie socio-emotional behaviour. None of the theories take into account all of the work done in perceptual development, language development, development of memory, development of peer relationships, development during adolescence, and so on. They pay little attention to the work on individual differences in personality or temperament, or to biological development generally.

A totally biological, determinist view of development was anathema to the new theorists of behaviour modification and behaviour therapy in the 1960s. It was seen as too pessimistic, offering little hope of change. By ignoring the biological basis of behaviour and seeking explanations solely in the here-and-now (proximal) influences on behaviour, they undoubtedly broke through to a much more optimistic era of interventions.

Simultaneously, child developmentalists were recognizing the contributions the child brought to all aspects of development. The child has increasingly been seen as an active participant in development. The direction of influence was not all one way: the child helped shape the environment. Thus, parents react to individual differences in children. Different children call out different responses from their social environment. As parents have known all along, children do have different temperaments from birth, and these shape how they develop.[7,8]

The implications of this for child psychiatry are many. For example, it implies that clinicians must take into account a child's temperament when planning treatment.[7,9] Children who are extremely introvert react differently to praise and punishment than children who are extremely extrovert.[9,10] They also respond to different teaching styles in the classroom. Such differences need to be accommodated in setting up individualized treatment programmes.

With young infants, it can be very reassuring to a parent to be told that anyone would find their unpredictable child difficult to rear. It can boost parental self-confidence to be told (when true) that their parenting style is perfectly adequate for most children—just not effective with this particular one. This reassurance should greatly alter the way such a parent participates in parent training programmes that are increasingly part of primary and secondary level child mental health services.[11]

All this is not to say that stage theories carry no implications for child mental health services. Far from it. It is very helpful to remember that young children think and reason about their worlds differently from older children. This has to be borne in mind when interviewing children, when trying to elicit their own understanding of their problem, and, equally, when giving them instructions, feedback, or explanations. However, it must again be emphasized that the stages should only ever be regarded as rough guidelines. We know that there are such wide individual differences in the rate at which children develop that we should never make assumptions about the individual child knowing only his chronological age.

Let us take one example that increasingly confronts clinicians—the issue of helping children deal with bereavement. It is not until around the age of 10 or 11 that *most* children appreciate that death is both universal and irreversible.[11–14] This helps explain why some younger children show an almost casual, matter-of-fact interest in death of a loved one and are less upset by it than adults are.[13] But it would be wrong to assume that all younger children fail to have an adult appreciation of the significance of death, and indeed some children as young as 4 years old have been found to have a mature understanding. Knowledge of the broad outline of the development of the conceptualization of death helps clinicians formulate their questions, but the onus must always be on the clinician to check whether or not the individual child conforms to the average. The adult's task may not be finished when they have helped a young child to understand bereavement at the level the child can cope with. That same child will probably want to revisit the issue when she is older and can understand it in a more mature way.[15] What is true of bereavement also holds true for understanding any other major life event and its effects on the child.

Critical issues in development

When one takes a closer look at how children develop, one cannot help but be amazed at the complexities of the process. Children the world over start using words around their first birthday and within a couple of years more, they are talking in complex sentences using complicated ideas. The contrast between the language development of most children and the minority who suffer a severe mental

handicap is devastating. Likewise, blind children start to smile at the same time as sighted children; deaf children start to use a similar range of phonemes; children in Japan, France, and Britain all start uttering the same range of sounds only to have them narrowed down to those they need in their native language—with the later consequence that they may not even be able to discriminate some of the unused sounds, let alone incorporate them when learning a foreign language. The broad developmental trajectory seems very similar across cultural groups, but particular children do not always follow the average in a smooth, predictable way.

Rutter and Rutter[16] draw attention to a number of issues that need to be considered when trying to understand developmental processes. Clinicians are understandably focused on trying to make sense of cases where something has gone wrong in development. Mostly in child psychiatry, abnormal behaviours of children are quantitatively different from normal rather than being qualitatively different. Disorders following brain damage or genetic/chromosomal abnormalities and many involving very severe degrees of mental handicap, including infantile autism, are increasingly recognized as being qualitatively different. Most of the other disorders seen in child and adolescent mental health services are probably best viewed as deviations lying at the extreme of a continuum. But why do some children break down under stress while others do not? Why are some more resilient than others? What factors protect children against environmental and social stressors? Is it really the case that severe depression in late adolescence is just the extreme end of a continuum ranging from happiness through sadness to suicidality? In order to tackle these issues, it is necessary to clarify some of the concepts of development.

1 One should not assume that the same mechanisms underlie both normal and abnormal development.

2 A biological perspective is necessary to understand human development fully. The brain is clearly the most important organ concerned—the genetic inheritance, insults during critical periods of brain growth, hormonal changes—all these have considerable influence on how children develop.

3 One has to expect both *continuities* and *discontinuities* in development. At times, continuities are intrinsic to the particular process as in language development; at other times, continuities—as in academic attainment—are in large part influenced by continuities imposed by the social environment. Parents concerned about education influence the choice of schools and provide support for learning.

4 The *timing* of an experience is as important as its nature. The brain is most vulnerable to insult when it is developing most rapidly, at and shortly after birth. Severe disruptions in caretaking have their greatest effects from around 9 months to 2 or 3 years. Before then, the infant does not show the same quality of selective attachments; after language is well established, the child can better hold the memory of a loved one, and that may act as a protection against the separation.

5 Children are *active* creatures. Not only do they call out responses from others, but as they develop cognitively and linguistically, they actively seek to make sense of their world. They appraise threat from others, even if they do not always get it right. When they are involved in a major catastrophe, their assumptive world[17] can be literally turned upside down and they take a long time to reconstruct the world as a safe place. The way the child interprets experience will come to determine in part how similar experiences are responded to in the future.

6 'Continuity may be heterotypic as well as homotypic'[16] (p. 8). The brilliant idea developed in the New York Longitudinal Study[18] of temperament was that rather than seeking evidence for predictability and continuity in particular infant behaviours across times when behaviour was developing rapidly, the investigators looked instead at how a variety of topographically different behaviours were expressed and found considerable continuities in such aspects as regularity of functions, strength of response, and predominant reaction to new stimuli. Thus, they adduced evidence of temperamental characteristics that were independent of the specific behaviours shown, and moreover, these temperamental characteristics proved to be predictive of later behaviour and adjustment.[16]

7 Both risk and protective factors, and the interactions between them, must be considered. Not all apparently adverse experiences are necessarily wholly bad for healthy development. In the same way that exposure to a virus or infection can boost resistance to infection, so exposure to mild stressors may boost resistance to other stressful experiences later. In part, this is the basis for stress inoculation therapy.[19] Some would argue that young children should have practice in separating from parents under enjoyable conditions so that in the event of a sudden, unexpected, or traumatic separation being necessary, the effects of experience will be mitigated.

8 As noted earlier, continuities may arise indirectly in that the way parents or society in general support attainment and in turn entry to the job market. The moderately high correlations between early attainment and later earning power are thereby in part determined and supported environmentally.

9 Similarly, the achievement of a particular behaviour may set in motion a chain of events. It is important to understand the processes underlying such a sequence. Too often studies are short-term and cross-sectional in nature and despite being aware of the pitfall of confusing correlation with causality, investigators remain prone to identifying a correlate as being a causal agent. For example, in the early days of studies of reading difficulties, it was noted that poor readers did badly on tests of visual perception. It was assumed that they therefore had a visual-perceptual deficit and generations of poor readers were subjected to hours of mindless tracing of lines and walking along benches. The end result was that they performed better on the particular visual-perceptual test but they were no better at reading! A different experimental design was needed to demonstrate causal relationships between psychological processes and poor reading,[20] and when that was understood, the way was open for better remedial work based on a proper understanding of causal mechanisms.

This can also be viewed as an error in confusing a risk *indicator* with a risk *process*. Forty years ago, studies of the dehumanizing effects of institutionalization on adults and children[21] found that poor living conditions and block treatment of residents were related to a greater risk of behavioural and emotional problems. In one set of studies, a good *indicator* of block treatment was whether patients had their own toothbrushes. Clearly, providing individual

toothbrushes to all would not make much difference if all the other aspects of institutionalization remained in force. A fuller understanding of the *process* of institutionalization is needed in order to be able to develop more humane care that improves development.

These critical issues demonstrate just how complicated the relationship between nature, experience, and development can be. But human beings are indeed very complicated, thank goodness, and so a proper appreciation of all these factors is needed in order to be able to understand how a particular child reached a particular point in development; to be able to predict what the future may hold for a child and to be able to develop rational interventions that have a hope of making a real difference to children's lives.

Developmental psychopathology

Developmental psychopathology emerged in the 1980s to bridge the rift between academic and clinical child psychology.[22,23] 'The developmental psychopathologist is concerned with the time course of a given disorder, its varying manifestations with development, its precursors and sequelae, and its relation to non-disordered patterns of behaviour' (p. 18).[23] Developmental psychopathologists, like social learning theorists, look to normal development to illuminate pathological development. They are interested in continuities and changes in behaviour across time. This fits in well with the tradition of risk research[24] and attempts to answer questions not only about why some children are more vulnerable than others, but also about what protective factors operate to lessen the impact of stressors.

Sroufe and Rutter,[23] following Santostefano,[25] articulated several propositions that are broadly agreed across the many different theories alluded to above:

(a) Holism

'The meaning of behaviour can only be determined within the total psychological context' (p. 20).[23] Thus, behaviour such as crying can only be evaluated according to the age of the child and the circumstances in which it occurs. Crying on separation would be seen as usual for a 3-year-old, but unusual in a 15-year-old. One cannot simply judge the significance of a behaviour simply on the basis of its physical, stimulus properties, but one has to evaluate it within the broader social context.

(b) Directedness

Children are not passive reactors to the demands of the environment. Development consists of a reorganization of previous elements, skills, and behaviour, not just a linear addition of skills.

(c) Differentiation of modes and goals

Over time, children's reactions to their environment become both more flexible and increasingly complex in organization. Thus, one sign of pathology is for children to get stuck in a particular way of trying to solve a problem.

(d) Mobility of behavioural functions

Earlier behaviour becomes integrated into later patterns, and 'the individual does not operate only in terms of behaviours that define a single stage. Especially in periods of stress, early modes of functioning may become manifest' (p. 21).[23] In other words, under stress, those patterns of behaviour that have most recently become integrated into the child's repertoire are most susceptible of disruption. This is very different from the unsatisfactory concept of regression in which all skills achieved remain available in the child's repertoire; some earlier ones also manifest at times of stress.

(e) The problem of continuity and change

Above all, development is seen as lawful, even though we are still far from understanding the processes involved in these laws. Sroufe and Rutter[23] emphasize: 'the continuity lies not in isomorphic behaviours over time but in lawful relations to later behaviour, however complex the links' (p. 21). As noted, Thomas, Chess, and Birch[18] were among the first to demonstrate continuities in the *style* of behaviour (temperament) rather than continuities of behaviour *per se*.

It is now recognized that there are many complex ways in which child behaviour is related to later and even adult adjustment.[26] One of the most powerful predictors of later adult psychopathology is inadequate peer relations. The mechanism by which these work may be due to two interacting processes: (1) Poor peer relations are signs of failure to adapt during childhood, and that failure persists; (2) social support later acts as a buffer against adult stressors.[23]

Clearly, this view of development, with its implications for psychopathology, is far removed from the lessons learned from the Skinner box. Yet what has been learned from the paradigms of classical and operant conditioning must also be integrated into ways that child therapists assess children's problems if we are to provide better treatments. This holistic view manages to incorporate ideas on the biological basis for behaviour and the notion of the child as an active participant interacting with his or her effective social environment within a broad social learning framework.[27,28] Understanding how a problem has arisen may provide useful guidance on what aspects to focus on, but the treatment will still focus on the present. There will be implications for maintaining treatment gains and preventing future problems, as well as implications for preventing such problems arising in other children.

For clinicians more used to working with adult patients, it is worth pointing out that children differ in many ways from their grown up counterparts. This has implications for improving diagnostic classificatory systems in that both DSM and ICD are still too adult oriented and pay insufficient attention to developmental aspects of disorders.[29–31]

Garber[32] makes the point that children differ from adults in cognition, language, physiology, and emotions. Such maturational differences may impact children's abilities to experience or express certain affects, cognitions, or behaviours, and thus the manner in which symptoms are expressed may differ over the course of development (p. 32). Recent work on the effects of major disasters and acute stress on children's adjustment, it became evident that children as young as 8 years old showed most of the symptoms of post-traumatic stress disorder (**PTSD**)—with unpleasant thoughts, poor concentration, and sleep disorders predominating.[33,34] Parents and teachers were often unaware of the nature and extent of the children's subjective distress, and only sympathetic but direct questioning elicited the full spectrum of symptomatology.

The criteria for PTSD are less appropriate for children under 8 years of age. Pre-school children often react with more repetitive play and drawing than older ones. Even the youngest children will report very disturbing, intrusive thoughts about the disaster. Scheeringa *et al.*[35] suggest varying criteria for making the diagnosis

of PTSD in young children. Leaving aside the logical problem of altering criteria but keeping the same name for the supposed underlying condition, this clearly is one aspect of the isomorphism mentioned earlier. It is also interesting to speculate whether the repetitive play seen in 6-year-olds is functionally equivalent to the intrusive thoughts seen in 10 year olds, and when the one changes into the other.

Garber also notes that some disorders, such as mental handicap and autism, first manifest in childhood and persist into adulthood. Others, such as encopresis and enuresis manifest in childhood, but rarely persist into adulthood unless part of a more global developmental delay. Some, such as anorexia and bulimia, are more typical of adolescence. Suicide, although rare before puberty, is rapidly becoming the major cause of death in adolescence, but peaks in old age. Major depression and schizophrenia are rare in childhood, although precursors are being more firmly established. While the wish to treat disorders in childhood so as to prevent them continuing to adulthood is laudable, treating them to improve adjustment during childhood is equally valid.

Linking developmental psychopathology to developing children

These exciting ideas need to be brought out of experimental settings and into clinics—the aim of developmental psychopathology theorists. In the second half of this chapter, some of the key aspects of child development relevant to clinical practice will be highlighted in this framework.

(a) Individual differences

Children differ in their personality, character, or temperament. European psychologists have always emphasized these individual differences and adduced evidence that many were based on biologically determined ways of responding to the world. While the three factor structure of personality developed by Eysenck evolved into the big five structure of today, an issue remained as to how one could demonstrate *continuity* in personality from a very early age. The same issue bedevilled studies seeking to establish continuity in differences in intellectual functioning—simply put, little babies show such a different repertoire of behaviour from mobile, talking pre-school children that it was impossible to test the same behaviours at different ages.

In part, the problem was solved in the New York Longitudinal Study[18] (see Box 2.5.1.1 One) by looking at differences in *style* of behaviour rather than differences in content or topography. By avoiding talking of biologically based personality, the findings reawakened interest in the genetics of individual differences.

In the original sample of 78 babies, the investigators were able to demonstrate considerable individual differences in temperament. There was good inter-rater reliability in making these judgements and direct observations agreed well with reports from parents. The temperamental characteristics were found to be stable over both the short (2 years) and medium term and even predicted reasonably well into late childhood.

Three broad types of temperament were characterized—children who were regular, predictable, and showed generally positive reactions—the easy babies; those who were almost the opposite—whom Chess called the mother killers and a sizeable minority who were slow to warm up to new situations but who adjusted eventually. The difficult children were over represented in those who developed behavioural problems in later childhood.

Box 2.5.1.1 Temperamental characteristics

The repertoire of infant behaviour is so different from that of the pre-school child that it proved very difficult to examine whether there were any continuities of behaviour across the ages. Thomas *et al.*[18] and their collaborators in the New York Longitudinal Study were among the earliest to show continuities across the age, but continuities in *style* of behaviour rather than *content*. Through a mixture of observation and exhaustive interviews with mothers, they originally developed nine different categories of behavioural style or *temperament*.

Mainly

1. Active	1. Passive
2. Regular: (e.g. in feeding and sleeping habits)	2. Irregular
3. Reacts intensely (strongly)	3. Reacts mildly
4. Shows approach behaviour to new people, places, toys, foods, etc.	4. Shows withdrawal behaviour
5. Adaptive—adapts fairly easily to change	5. Non-adaptive
6. Reacts easily to small changes	6. Reactions slow
7. Predominantly good moods—happy, contented disposition	7. Predominantly bad disposition—fretful, hard to please
8. Persistent in what she/he is doing as regards time, and in the face of difficulties	8. Non-persistent
9. Easily distracted from whatever she/he is doing	9. Not easily distracted

(b) Cognitive development

One of the major aspects of development that exercises parents and teachers alike is how best to improve the intellectual functioning of children, be that in language, reading, memory, or general intelligence. To what extent individual differences in these areas are predominantly related to heredity or to environment continues to be a popular, if sterile, source of argument. Clearly, the end result comes from an interaction between genetic predisposition and experience, but there remain issues of how best to manipulate the environment so as to help children gain their maximum potential. To that end, an understanding of modern behavioural genetics is essential. Here, some of the methodological issues in assessing babies' cognitive processes and findings in cognitive development, language, and memory are considered.

(c) Getting inside the baby's head

Until a baby starts to speak, it is difficult to know what they are thinking. Fond parents interpret wind-driven grimaces as smiling; every child is seen as recognizing people and being smart from a young age. But how can one tell what really goes on inside a baby's head?

Robert Fantz[36] studied infants' eye movements and used fixation time as a measure of preference for different stimuli. Film recordings were made of light reflected off the baby's eyes. In a study of 30 infants tested weekly from 1 to 15 weeks of age, it was shown that the infants spent longer looking at complex than simple patterns. This demonstration of a clear perceptual preference in the first few weeks after birth gave the lie to the view that all begins as a big, booming confusion. Infants as young as one week show clear preference for human faces over other shapes presented to them some 10 in. away.

Fantz took advantage of the technology of the day. Since then, others have utilized measures of changes in temperature, in galvanic skin response and in heartbeat to provide behavioural indices of preferences. In addition, investigators have used various indices from learning and conditioning paradigms.

Results from such studies highlight the extent to which infants enter the world ready for social interaction. Infants are highly dependent on their parents because of the cortical developments and increase in brain volume required to allow the special human cognitive characteristics to develop that take place *after* the baby has made its way down the birth canal. Infant's readiness to be part of a social interaction, imbued with intentionality, appears to serve a survival function.

The neonate has remarkable hard-wired skills that can be detected from within moments of birth, while the neonate is in a period of alert inactivity. However, there are limits to the extent of the early ability. Eyesight acuity is about 1/30th of adults at birth and develops over the next 4 years, although significant improvements arise by the second month. Despite problems with visual acuity and focusing, even neonates can track objects, albeit jerkily, and scan for simple, visual features, such as linearity, luminance, and symmetry when stimuli are within about 10 in. of their face.[37] These intrinsic visual abilities combine with preferences for certain spatial forms found in the human face, e.g. a preference for vertical over horizontal symmetry. Fagan[38] tested visual preference in 7-month-old babies and later measured their intelligence when they were 3 and 5 years old. The time spent looking at the novel stimulus when a baby correlated 0.42 with performance on the later Picture Vocabulary Test. Thus, it is getting easier to measure various indices of baby's reactions and some of these are found to be usefully predictive of later development and adjustment.

Hearing is pretty much complete by the 5th or 6th week of foetal life, with sophisticated auditory discrimination abilities along the dimensions of pitch, volume, tone, and duration. Hence neonates may come into the world already familiar with soap opera theme tunes, but so too are they familiar with their mother's voice and are able to orientate towards them from the start. Neonates have a preference for women's voices over men's and unlike the specificity shown towards the mother, appear to show little preference for their father's voice compared with other men.[39]

Bathed in amniotic fluid in the womb, it is unclear whether the foetus has strictly speaking *smelled* the mother before birth, although their olfactory system is well-developed *in utero*. Nonetheless, within hours of birth neonates demonstrate a preference for their mother's smell and, within days, can reliably orient their head towards breast pads worn by their mothers over those worn by other women.[40]

Meltzoff and colleagues have demonstrated that a neonate's social sensitivity is not just a passive turning to stimuli, they can also actively imitate them.[41] Indeed, within moments of birth, neonates are able to mirror adult's facial expressions such as tongue protrusions or mouth openings. Quite how this process operates at a cognitive level is unclear. One can speculate on its function as a way to provide a satisfying contingency for a parent that helps imbue the infant with a sense of communication, agency, and personhood. Overall, neonate's abilities to discriminate between stimuli and their hard-wired preferences for some constellations over others lead them to orient towards their caregivers, as the very beginnings of a selective attachment.

(d) Piaget and cognitive development

Piaget was a biologist who studied amoebas for his doctoral work. Biological models found useful for that purpose clearly influenced the way he regarded cognitive development. He held to a sort of moving homeostasis—children develop a model of the world. New information that challenges that model is gradually assimilated and eventually the model accommodates the new ways of thinking—a bit like an amoeba reaching out to a piece of food, surrounding it and assimilating it.

According to this theory, the child passes through three broad stages of thinking (see Box 2.5.1.2): A sensori-motor stage, a long stage where they think in terms of what he called concrete operations, and finally a stage where they can think logically.

Piaget's stage theory has been very influential and helpfully sparked off a great deal of research which has led to a much better understanding of how children develop cognitively. However, his original models were somewhat simplistic and to have seen only three major stages covering a period of such rapid development

Box 2.5.1.2 Piaget's stages of cognitive development

Birth to 18 months: sensori-motor stage

Cognition is based mainly on the child's actions and six sub-stages were described. A key concept at this stage is that of object permanence—the ability to understand that an object continues to exist even when it is out of sight. Infants of 12 months will continue to look for an object where an experimenter hides it, even when they watch the experimenter move it. It is as if the object belongs only in a particular place.

18 months to 12 years: concrete operations

This is the stage of concrete operations. At the early stage, language develops rapidly. Children begin to demonstrate symbolic play, showing that they have memories and internal representations. Many ingenious little experiments were developed to illustrate how children's thinking about their world develops. Various other conservation tasks—of length, mass, and number for instance—convince teachers that children think differently about the world than adults and this has had a major—if not always beneficial—effect on ways of teaching.

12 years and over: formal operations

From around puberty onwards, the child is able to formulate and test hypotheses about the world. The child realizes that mass and volume can be altered in many ways, but they remain essentially unchanged. Children can examine their own thought processes and can begin to reason more logically.

strikes one as inadequate. Moreover, for the clinician, the question one often wants to raise is how can one use this understanding to bolster the reasoning of a child who is developmentally delayed—what Piaget witheringly dismissed as the American question. Piaget tended to argue that children could not be hurried through the stages. However, critics soon argued that some of the regularities that were apparently replicated in his work owed more to the manner in which the tasks were presented to the child than to any necessary underlying cohesion in types of thinking.

A typical experiment is to give a child two pieces of clay that are identical. Then one is rolled out into a sausage and the child is asked if they remain the same. Alternatively, the child is shown two test tubes of differing diameters. The same amount of liquid is poured into each, but, of course, reaches different heights. Which test tube has more liquid? Not surprisingly, younger children make more errors than older ones and it has been shown that conservation of mass (seeing that the quantity of material remains the same in spite of changes in shape) is acquired around 7 to 8 years, while conservation of *weight* is not achieved until 9 or 10 years. It is not until 11 or 12 that the child typically thinks that each shape also occupies the same amount of space (i.e. achieves conservation of *volume*).

Bruner was one of the earliest to demonstrate that children's judgements could be radically manipulated by small changes in the ways the tasks were presented. For example, in the studies on conservation of volume, a screen was placed between the child and the test tubes so that only the tops showed but not the levels reached by the liquid. This simple change meant that many younger children now understood that by pouring liquid from one container to another—perhaps something done daily in the bath—nothing had changed. Some children as young as 4 years were able to perform the revised task, but once they had to make the judgement again without the screen, they reverted to the more primitive form of reasoning. In other words, young children are more at the mercy of their perceptual impressions, a finding that needs to be taken on board in many circumstances.

(e) Language development

Children communicate from the beginning. They signal their basic needs, often by crying. Parents soon learn to respond to the differing signals. Their own child's crying can be very aversive to most parents and so they quickly learn how to switch the noise off! Autistic and brain damaged children produce grossly abnormal cries, but often parents with little experience do not recognize the unusual nature of the cry. Whilst lower primates and other animals can communicate, none use language in the flexible way that human infants come to do. Language—both spoken and written—is truly the most human of attributes.

Sophisticated social interaction is a precursor to the development of language. Though the infant is hard-wired for social interaction, it is not clear that these behaviours are strictly communicative in the sense of being intentional acts. What appears to be an early communicative competence may be best understood in terms of a *social releaser* model, where caregivers' interactions are triggers that release hard-wired reflexes from the infant, little different from the familiar palmar grasp reflex of the first month that causes an infant to grip an adult's thumb, even in their sleep. In this formulation there is no sense of a two-way communicative interaction being shared between carer and infant.

From approximately 2 months of age, infants appear to be active participants in the interactions that caregivers and their babies regularly play. When carers adjust their speech to the infant's preferences for high-pitched, rhythmic, and repetitive speech, often referred to as *motherese* and hold their face about 12 in. away, within the infants optimal focal range, a dynamic dance of turn-taking between carer and infant can be observed. The infant's attention is held, shared smiling can occur, the pitch and tone of utterances becomes matched and the infant can be observed to make distinctive formations with their lips referred to as 'pre-speech'. Caregiver and infant certainly appear to be experiencing social reciprocity. Some clever experiments based on perturbing the reciprocal nature of the infant caregiver interaction have challenged the notion of a social releaser model and given support to the infant's sophisticated early developing sensitivity to social reciprocity.

The still face paradigm requires the infant's partner to disturb the relationship by substituting their dynamic interaction by holding a still, expressionless face.[42] Presented with this perturbation, infants will initially increase their gesturing, as if to draw the adult back in, but become increasingly distressed, crying, or grimacing as this unnatural state continues. Of course, this is a relatively gross perturbation and technological advances have allowed developmentalists to alter more subtle aspects of the real-time contingency between an infant and its mother using a video link. Murray and colleagues filmed mothers and infants interacting over a video link and then altered the contingency by replaying a segment of the mother's interaction to the infant.[43] Infants as young as 8 weeks were able to detect this perturbation, and initially showed reduced levels of engagement followed by distress and protest. The levels of engagement rose again when the link was switched back to a live interaction. The replay condition demonstrated that simply presenting caregiver behaviours that had been previously adequate to elicit sustained interaction were no longer appropriate when they were taken out of the context of the dynamic flow between infant and caregiver. Thus it was not simply the presentation of maternal signals that triggered the release of infant communicative behaviours, but like a dance or a conversation, it was the to and fro sequence of behaviours between infant and caregiver that set the context of the flow of behaviours.

Language has not been the subject of serious study until the past 50 years. Beginning with simple descriptive studies of the acquisition of words, the complexities of grammar and cross-cultural comparisons, studies of language development now encompass many other dimensions from neuropsychological, brain imaging, and genetics. What stands out is just how difficult it is to affect the onset of language by manipulating the environment. It takes extraordinarily environmental deprivation to interfere with language development and even then, when the environment is normalized, considerable catch up occurs.

The grunts and single syllables of the first couple of months soon give way to the production of the full range of phonemes and babbling between 2 and 4 months. States of feelings are communicated clearly by 3 to 7 months. From 6 months, the baby begins to imitate simple sounds and unreinforced phonemes disappear from the vocabulary. By 8 months, the baby begins to utter two syllable combinations such as ma-ma and da-da—amongst the easiest to produce physically and, perhaps not coincidentally, the most emotionally evocative words parents want to hear. At around 12 months, the first true word appears, usually as the infant takes his first

Box 2.5.1.3 Language development

Vocabulary grows astronomically from 1 to 3 years and beyond. Children's sentences get longer and more complex. A good working approximation is that the average length of sentences is in keeping with the number of years of age:

Average length of sentences—2–5 years

Age in months	24	30	36	42	48	54	60
Average number of words per sentence	1.7	2.4	3.3	4.0	4.3	4.7	4.6

From Smith.[46]

step—girls reaching the milestone slightly ahead of boys. Vocabulary grows astronomically from one to three years and beyond. Children's sentences get longer and more complex. A good working approximation is that the average length of sentences is in keeping with the number of years of age.[46]

Studies in the 1960s and 1970s established that language development followed complicated underlying rules. The idea that children learned language by successive approximations to adult speech being differentially reinforced was quickly laid to rest. Such techniques have an important place in remedial intervention for children with deviant language development, but for ordinary children the sheer inevitability, speed, and beauty of acquisition is overwhelming. This led many to postulate that there is a genetically encoded Language Acquisition Device that guides communication, although not the particular form of language that a particular child will develop. That still depends on what language they are exposed to.

Early sentences are telegraphic with some words acting as pivots on which other words hang to form flexible sentences. Thus, the pivot, 'all-gone' can have 'sock', 'milk', or 'daddy' added to create a whole range of meaningful simple sentences. Children develop rules for expression. A common error is for them to extract a rule and then overgeneralize it to a situation that is an exception in their particular language. For example, the present tense is used before the past tense. Instead of saying 'I went' children often form past participles by adding -ed to a stem and come up with the often heard 'I goed'. This shows they are learning a rule, even though they make some mistakes on the way.

Different ways of describing and classifying language disorders have been proposed in the past few years.[44] Bishop's[45] twin study finds that when language disorder is defined as a discrepancy between non-verbal IQ and language score the heritability is far less than when language delay and disorder are considered without reference to IQ. This is important for clinicians in identifying children with such difficulties .

(f) Memory

One of the most intriguing observations in the current child development literature is the contrast between the ever increasing evidence of just how complicated children's cognitive development is and the phenomenon known as infantile amnesia. Basically, people have very few memories before the age of 3 years. Clearly from all that has been described earlier about the differential reactions of babies to specific stimuli, to their recognizing their mother's voice or holding out their arms to their father rather than to a stranger, children increasingly have some form of central representations that they can work on. Yet, these early memories are not accessible in later life. It is really not until language is well established that people have what is ordinarily termed memory for past events.

Clearly, infantile amnesia poses a major challenge to any theory of child development or personality that tries to link very early experiences with later adjustment. Yet, early experience does affect the way in which relationships are formed, so what are the mechanisms? As the different types of memory (See Box 2.5.1.4) are better understood, so better assessment of these functions is possible.

Some very recent work has looked at implicit and explicit memory as well as attentional processes in children with generalized anxiety disorder, PTSD and depression. Broadly speaking, the preliminary findings are in accord with the voluminous findings with adult patients, namely that depressed children tend to have biases in memory for sad things, while anxious children do not. In contrast, children with anxiety disorders (including PTSD) have biases in attention that make them attend more to threatening cues in their environment—or at least to threatening words projected on computer screens. Studies using these adult-generated paradigms but utilized within a developmental framework should greatly increase our understanding of why some children break down under stress and others do not. Biases in cognitive processing of

Box 2.5.1.4 Memory

Goswami[48] summarizes many ingenious experiments that establish the parameters of children's memory. While parents and teachers often talk about children having problems with memory and even short-term memory, developmental psychologists have worked on much more complex paradigms and identified a number of different memory systems:

Recognition memory is simply the ability to realize that a particular stimulus has been encountered before. Recognition is always easier than recall—as those learning a foreign language can testify. Once established in the first year of life, recognition memory does not change much.

Implicit memory is another term for memory without awareness. Although not able to put it into words, people can act differently to previously exposed stimuli than to novel ones. This seems to be fully developed by around 4 years of age.

Episodic memory involves awareness. It is this memory system that organizes memories into stories or scripts concerning similar activities. These scripts contain both temporal and causal information. The ability to learn sequences in a particular chain of events does develop with age. It is now that one realizes that there needs to be some mechanism to get rid of many of the memories for everyday activities, otherwise the whole memory will get clogged up with non-essential information. In other words, memory processes are seen as being very active with some memory traces remaining in (technically) short-term memory for only a few seconds unless operated upon and stored in long-term store.

Eye witness memory has taken on a special importance as children are expected to testify in court on things they have witnessed happening to themselves or to others. Children can

recall things fairly accurately, as long as deliberate leading questions are not put to them.[49] Three-year olds are more suggestible than 5-year olds. Experienced adults—such as psychiatrists or judges—evaluate children's responses to questioning about a real event using the child's behaviour while giving their answer. Where children gave firm answers with lots of supporting details, they were judged to have clear and accurate memories. Where children were uncertain and hesitant, they were seen as fabrication whereas they were hesitating because the questioner was asking the wrong questions—ones that were in conflict with what had actually happened—they were the ones who were actually telling the truth. The younger, confident children were often telling the adult what they wanted to hear! A great deal more needs to be done in relation to helping children recall what has happened to them without using leading questions.

Working memory was seen by Baddeley and his co-workers as consisting of a central executive processing linked to two separate subsystems: a phonological loop and a visuospatial sketch pad. Information decays in the phonological loop in 1 or 2 s, unless it is actively rehearsed. It is thought that children predominantly use a visuospatial encoding until they switch to the phonological/verbal system around the age of 5 years. Deaf children continue to rely on the visual encoding for much longer.

emotional reactions are implicated and can now be studied more readily.[47]

Social and emotional development

Alongside cognitive development, children are developing both socially and emotionally. It has been recognized for years that children brought up in institutions, away from their natural parents, often develop serious and subtle problems in social interactions and emotional development.

Arising in part from his studies of infants in institutions and his collaborative studies of children's reactions to being in hospital, as well as his dissatisfaction with contemporary psychoanalytic theory, Bowlby turned to ethology for an understanding of early infant relationships. He came to view the intense relationship between the infant and the caretaker, usually but not always the biological mother, as serving a biological survival value and as having been produced by natural selection. Bowlby proposed an attachment system that served to keep the child safe during the extended dependency of human infancy, by ensuring proximity to specific and reliable caregivers.[50]

As memory develops in the first year of life, and as the infant becomes more able to express emotion and to move independently, so there is evidence for selective attachment. This is shown round about 6 to 8 months onwards by the upset at leaving the attachment figure, by seeking comfort when threatened and by a general wariness of strangers.

The idea that attachments were simply associative learning—the baby comes to love the person who feeds him—was quickly dismissed by the evidence from Harlow's studies of infant monkeys. They attached to the cuddly terry-towelling surrogate rather than the wire surrogate where they were fed. Rather, selective attachments in the human served to protect the infant during the prolonged period of helplessness. The function of attachment changes over the years, with children using an attachment figure as a secure base from which to explore. Thus, almost paradoxically, the well attached toddler may move away from the attachment figure more than the insecurely attached counterpart. Attachment is not the same as clinginess.

The attachment system is just one amongst several innate systems proposed to operate in infancy, and it is the interplay between competing behavioural systems that led to the gold standard measure of attachment in infancy. Mary Ainsworth's based her Strange Situation Procedure (**SSP**) around observations of infants in Uganda.[51] The SSP pits the attachment system against the fear and exploration systems, in a structured, unfamiliar situation comprised of increasing levels of stress (e.g. strange room, strange adult, and separation from the caretaker). Observations are focused primarily on proximity seeking and contact maintaining behaviours during reunions with the caregiver. This measure is made possible by the development of stranger fear and mobility around the age of 9 months, and loses its validity by about 18 months as the infant's cognitive development permits different responses to separation, e.g. symbolic representation and language. After this point attachment assessments become less about observed behaviours and more about language and play.[52,53]

The SSP originally suggested three types of infant classification, representing organized responses to the prevailing environment: Insecure Avoidant (A) infants whose behaviour implied an attempt to minimize the importance of the attachment relationship and whose impoverished play and exploration functioned as a distraction from their need of comfort from the caretaker; Secure (B) infants who sought sufficient comfort from the caretaker to be able to quickly return to play and exploration; Insecure-Ambivalent, or Insecure-Resistant (C) infants whose behaviour suggested a maximization of the attachment relationship and an ambivalent

Box 2.5.1.5 Attachment

Ainsworth developed the theory and a method for detecting individual differences in attachment. She introduced the strange situations test in which an infant is left in the care of a stranger for a few minutes. The observer then notes how the infant copes both with the separation and with the reunion. These observations led to a tripartite classification of attachments:

- **Secure attachment:** The infant tends to seek proximity and contact with the attachment figure, shows a preference for the mother over a stranger, and shows very little distress before and after separation.
- **Avoidant insecure:** The baby does not cling when held, avoids the mother (or caretaker) during the reunion, and does not differentiate greatly between the caretaker and a stranger.
- **Resistant insecurity:** The infant resists contact and interaction with the mother. There is great distress at reunion.
- **Disorganized or avoidant insecurity:** This category had to be introduced when it was found that infants of severely depressed and abusive mothers showed a mixed pattern of attachments. The child shows contradictory patterns and unusual patterns of negative emotions.

preoccupation with the caretaker, at the expense of returning to play and exploration. Mary Main's observations of children in high-risk environments, particularly those exposed to maltreatment or parental psychopathology, led to an additional coding category, independent of, but complementing the tripartite Ainsworth system. Main noted a high rate of bizarre infant behaviours in the SSP of some children, which seemed to denote a lack of a clear, organized adaptation to separation from the caregiver. There was also evidence of apprehension and fearful behaviour in the presence of the caregiver, these infants seemed disorganized/disoriented, and were categorized as an Insecure-Disorganized (D) attachment pattern.[54]

A second innovation that Bowlby's attachment theory brought to the study of child development was the notion that the experience of the caregiving environment becomes represented as a cognitive heuristic or *internal working model of attachment* (**IWM**). This model is a dynamic, lifelong *work-in-progress*, which evolves as environmental experience accumulates but which also guides the selection of current behaviour on the basis of past experiences. Thus the infant's model of attachment is shaped by the experience of their caregiving environment, but simultaneously influences interactions with the infant's environment by selecting the behaviours most likely to achieve the goals, of say, proximity, based on what was previously successful. The IWM reflects an adaptation to the current environment, but the flexibility to adapt to changes in the environment is weighted by the accumulation of previous experience. So the possibility of fundamental change in attachment style is always possible but more difficult the longer the old environment prevailed.

Bowlby proposed that as time goes on the IWM becomes less about selecting the appropriate behaviours to protect the dependent infant via maintaining proximity to a safe and reliable caretaker, but moves to a level of representation of the self in relation to others. There is evidence to support the idea that the quality of attachment in infancy has some degree of influence over a range of social and emotional outcomes in early childhood, with peers, teachers and even stretching into later adolescence and early adulthood with partners and, as parents, their own offspring.[55] There is good evidence of some degree of continuity across the lifespan, but as Bowlby's original thesis would predict, expectations of continuity should not be overstated, and the degree of continuity is particularly low in high-risk samples.[56]

By the age of 3 to 4 years, most children show good evidence of having multiple attachment figures. By this age, their memories are so much greater that they are less dependent on the physical presence of the attachment figure to provide security and comfort. Bowlby saw good attachments in infancy as laying the basis for future social and intimate relationships and there is currently an explosion of work re-examining psychiatric conditions from an attachment perspective. Thus, Bowlby saw the child as developing a cognitive model of his effective social world, in keeping with the views of other cognitive theorists such as George Kelly, Aaron Beck, and Ronnie Janoff-Bulmann.

(a) Attachment, psychopathology, and 'reactive attachment disorder'

There is sometimes confusion surrounding the ideas of the relationship between insecure attachment and psychopathology. An organized-insecure attachment is an appropriate response to a particular environment. At most an organized-insecure attachment might be a vulnerability factor for later problems, in the context of other risks, but by no means would it be a major risk factor for pathology in itself. In terms of outcomes such as behaviour problems, the greatest influences still appear to be social risk factors, although attachment may confer some small additional risk.[57] There is stronger evidence for insecure-disorganized attachments predicting psychopathology. Aggressive behaviour problems in preschool are associated with insecure-disorganized classifications in infancy.[58] One study has suggested some degree of homotypic continuity into late adolescence with elevated rates of dissociative phenomena echoing the bizarre stilling and freezing behaviours typical of a insecure disorganized classification in infancy.[59] Of course, disorganized classifications most often occur in high-risk environments, so it is not always obvious if consequent psychopathology is a result of the attachment classification or of the continuing impact of a high-risk environment. Clearer evidence for the enduring impact of disorganized attachment could be collected when the high-risk environment that has led to the disorganization is terminated.

A negative aspect of the focus on attachments has been the emergence of an ill defined disorder described as reactive attachment disorder which seems to be diagnosable by the presence of any or all of a long list of symptoms and signs that haunted previous generations under such labels as Minimal Brain Dysfunction and the like. This has been associated in some countries with the use of assaultative holding therapies intended to break the child's resistance to forming attachments. Clearly, more careful studies need to be undertaken to try to pinpoint the subtle social difficulties presented by children whose early lives have been disrupted in fostering and adoption, but care also needs to be taken to adduce evidence for appropriate interventions.

Having good, supportive social relationships has been shown to be a major protective factor in the aetiology and maintenance of many psychiatric disorders. The ability to make and maintain friends—initially of the same age and later of any age—is often related to the existence of disorders such as personality disorders, social anxiety disorders, depression, and even post-traumatic stress disorders. The emphasis on social skills training for socially inadequate persons points to the early basis for such deficits even though they may have their greatest impact in adulthood. Some children are less sensitive to social cues than others, and some children misinterpret the intentions of other people. Both lead to difficulties, albeit of different sorts.

Boys and girls tend to develop different types of social relationships. It may be inconveniently politically incorrect to note that children tend to prefer playing with others of the same gender when freed from adult influence. Boys tend to play in larger, looser groups in which issues of dominance and play fighting predominate; girls relate in smaller groups of more intense relationships, with best friends often changing.

Concluding comments

Taking a developmental perspective to mental health issues should apply across the lifespan. Psychiatrists working with adults need to understand where their clients are coming from and where they are going to. They need to understand the pleasures and pressures that children bring to their parents, and where appropriate they should be considering the impact of parental illness on the children. The

institutionalized separation of child and adult psychiatry (in terms of service delivery) should not lead to a separation in ways of considering the developmental context of presenting problems.

This chapter has shown that there are many small, focused models of development that deal with discrete areas of development. Stage theories emphasize differences at different stages; social learning theories emphasize continuities on processes of development. As long as practitioners are aware that when they say a child is at a particular stage, this is but a rough guide to describing the child, which may be fine. It is when such models are taken literally, that oversimplification leads to poor practice. There is no one overarching theory of child development and while this may be inconvenient for examiners, it truly reflects the rich diversity of human development. By paying more attention to the interactions between biological, social, and psychological factors, a better understanding of healthy, normal development will emerge. Empirical studies will help identify risk and protective factors which in turn will lead to better mental health promotion and more effective interventions when mental disorders manifest.

2.5.2 Psychology of attention

Elizabeth Coulthard and Masud Husain

Introduction

Attention is generally taken to be the process by which people are able to concentrate on certain information or processes, while ignoring other events. It appears to be a fundamental attribute of human brain processing, although difficult to pin down in terms of mechanism. Psychologists have attempted to fractionate attention in many different ways, using ingenious behavioural paradigms. In this section we, too, will consider different aspects of attention: selective, phasic and sustained, divided and executive control of attention. However, it would be fair to say that all these aspects of attention do not normally operate in isolation. Instead they interact, and deficiencies in one aspect of attention, for example, in a patient population, often to do not occur in isolation. Functional imaging and lesion studies of attention have proliferated in recent years, attempting to place a neurobiological framework to these varied processes. In general, these studies also tend to confirm the view that attention is likely an emergent property of widespread brain networks, with a special emphasis on frontal and parietal regions of the human brain (Fig. 2.5.2.1). In this discussion we illustrate several aspects of attention with examples particularly from literature on visual attention, which is the most widely studied area, but it should be appreciated that many of the concepts discussed here extend to other domains. In fact, there is a good deal of evidence to suggest that several aspects of attention operate at a supra- or cross-modal level allowing integration of information from different sources.

Recent studies suggest there are two fronto-parietal networks: (Fig. 2.5.2.1) a *dorsal* parieto-frontal network involving the superior parietal lobe (SPL) and dorsal frontal regions such as the frontal eye field (FEF); and a *ventral* network involving the inferior parietal lobe (IPL), temporoparietal junction (TPJ) and inferior frontal gyrus (IFG). In addition, dorsomedial frontal areas, including the anterior cingulate cortex (ACC) and pre-supplementary area (pre-SMA) may play a key role in flexible control of attention for strategic behaviour.

Selective attention

Selective attention refers to the processes involved in selecting relevant information and filtering out irrelevant items from the vast array of information we are exposed to. The brain has limited capacity: it simply cannot process everything it is exposed to. Nor would it be sensible for it do so because the majority of sensory input to which it is exposed is not behaviourally relevant. Therefore there is a need for mechanisms to select the

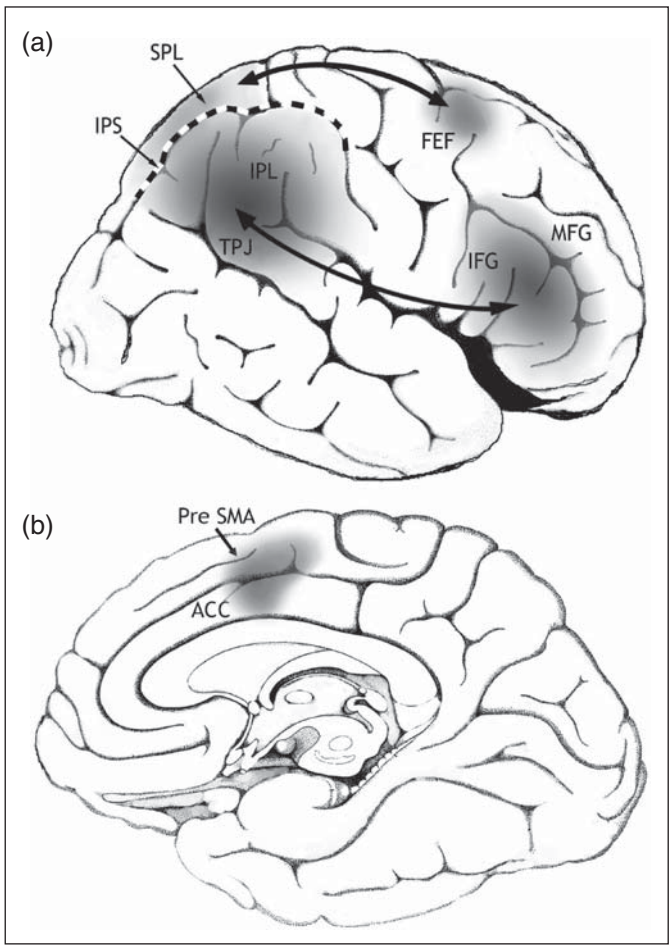

Fig. 2.5.2.1 Lateral (a) and medial (b) regions in the right hemisphere involved in attention. (IPS intraparietal sulcus; MFG, middle frontal gyrus.)

most behaviourally significant and important material, and dispose of trivial, unimportant information. Such selection may occur 'bottom-up', driven by competition between sensory inputs, or 'top-down',
guided by the goals that an individual might have at any moment in time.[1]

Thus if a ball is unexpectedly hurled towards an observer, his attention is likely to be captured—'bottom-up'—by the sensory input of a projectile moving at high velocity towards his head. In this case, selection has been driven by the most perceptually salient item in the external environment. 'Top-down' attention mechanisms, on the other hand, concern selection that is biased by internal goals. For example, consider the processes involved in looking for a friend in a busy, crowded train station. Here the selection process is driven by the features you are searching for: your friend's hair colour, facial features, height all play a role in guiding this search. Importantly, under these circumstances, even perceptually very salient items may be filtered out—or not attended—if they are irrelevant to the task.

But when does selection occur? Is it early or late in the processing of sensory information? This is an issue that dominated attention research for many years. Some investigators proposed that selection occurs early, directly after analysis of the physical characteristics or features of sensory stimuli, but before they are fully identified. According to this view, unattended information receives little or no further processing from this point on. By contrast, others argued that *all* stimuli are analysed up to the point that they are identified. Selection occurs only after this, late in the processing stream. So items that are eventually ignored or unattended, i.e. those that are not selected, actually receive considerable processing before they are discarded. Note that this late selection model allows for the possibility that items which are eventually ignored may nevertheless be processed to a deep level. Thus, even though they may not be attended to, they have the potential to influence our actions subliminally. Most researchers would now agree that there is good evidence for *both* early and late selection systems in the human brain. In fact, whether selection occurs early or late is likely to be influenced by the specific demands of the task.

Two highly influential experimental paradigms used to study selective attention in healthy humans and patients have both focused on *spatial* attention in the visual system. Posner first developed a spatial cueing task in which subjects view a display consisting of a central cross on which they are asked to maintain fixation throughout the trial. On either side of the cross, there are two square boxes. Participants are instructed to ignore a cue which consists of transient illumination of either the left or right box. At varying intervals after the cue, a target stimulus (an asterisk) appears in either left or right box and subjects are required to press a response button as quickly as possible. In 80 per cent of trials the cue is 'valid' in that it occurred at the location of the subsequent target. However, in the remaining 20 per cent of trials the cue is 'invalid', appearing in the box opposite that in which the target subsequently appeared. In healthy volunteers, reaction times to targets appearing where valid cues appear are significantly shorter than when invalid cues are presented.

This critical finding suggests that attention can be spatially localized like a beam or 'spotlight'. Moreover, attention can be captured by the abrupt onset of the cue so that visual processing is selectively oriented towards it, thereby improving responses if a target subsequently appears there. On invalid trials, Posner argued, attention would first have to disengage from the invalidly cued location and then shift to the correct location before engaging it. Note that such shifts occur covertly in the absence of overt eye movements; they represent shifts of visual processing from one location to another across a representation of space in the brain. Subsequent studies have shown that the orienting of attention to a spatial location not only appears to speed up detection of a visual stimulus, as measured by reaction times, but also can improve discrimination of items from non-targets. The neurophysiological mechanisms underlying such boosting of performance are currently the subject of intense scrutiny.[2]

The second experimental task that has proven to be extremely important in selective attention research is the visual search paradigm developed by Treisman. In this task, subjects have to find a target shape embedded among distractors. In simple so-called 'feature search', a target may be defined by a unique feature, e.g. a red circle among green circles is defined uniquely by its colour and therefore 'pops-out' among the distractors. Treisman has considered that such feature searches can occur *pre-attentively* in parallel across the visual scene, without the need for a spotlight of visual attention. She argued that attention needs to be deployed in more complex tasks where a target may share one or more features with distractors, e.g. finding a red circle among green circles and

red squares. In this case, a single feature (colour or shape) is not sufficient to define the target. Instead, the visual system has to find the unique conjunction of red colour and circular shape, and the target does not pop-out to the observer. Such 'conjunction searches', Treisman argued, requires the spotlight of attention to shift serially from one location to the next, inspecting each item in turn. In her model, spatial attention acts to bind or glue together features occupying the same location in space, e.g. the colour, form, luminance, and other attributes that belong to an object at one location in space.

Both the Posner cueing task and Triesman's conjunction task have been used in neuroimaging studies of healthy volunteers and patients with focal lesions on the brain.[3] The results of such studies suggest that regions within the parietal and frontal cortex play a critical role in deploying spatial attention (Fig. 2.5.2.1). In general, dorsal regions of this parieto-frontal network have been implicated in the spatial shifts of processing attention that occupy such a key role in the models of selective attention developed by Posner and Treisman.

Phasic, sustained, and vigilant attention

Several groups have made a distinction between phasic alertness, sustained attention, and vigilance. In general, 'phasic alertness' is used to refer to improvements in performance that follow a warning signal, e.g. an auditory tone or visual cue. The tasks used in such studies are often very simple, comparing the time to respond to a particular stimulus when it is preceded, or not, by a warning tone. Over the course of a few hundred milliseconds after such a warning signal, performance can alter appreciably, with reaction times first declining in the interval from 100 to 500–1000 ms after the tone, and then increasing again thereafter. Thus, this attentional facilitation is limited to a very narrow window in time and refers to the ability of the brain to respond better when warned to expect an upcoming cue to act.

By contrast, 'vigilance' is the term used to refer to the ability to be in a state of readiness to detect small, infrequent changes in the environment which occur at random intervals over *prolonged* periods of time (often hours or tens of minutes). The early studies on vigilance were conducted to assess the ability of radar operators to detect infrequent signals on their screens in the Second World War. Over long 'vigils' the ability to detect rare changes falls—the so-called 'vigilance decrement'—and this may be modulated by the frequency of target and non-target (distractor) stimuli as well as the memory load imposed on observers.

'Sustained attention' is best considered to be at the other end of the continuum from vigilance. Here, too, observers may have to respond over a prolonged period, but the information flow is rapid, with a high frequency of events to monitor and respond to. An everyday, extreme example may be the interpreter who has to give a simultaneous translation of a press conference. In the laboratory, sustained attention may be studied using stimuli presented at a rapid rate, as in many continuous performance tests (CPTs). Such experiments reveal that even healthy subjects may show 'lapses of attention' under such circumstances, with errors of omission (failing to respond to a target stimulus) or errors of commission (responding to a non-target), or increase in mean response time. Another measure that has attracted interest, of late, particularly in patient populations, is the variability of reaction times in such tests.

Functional imaging and lesion studies of patients have emphasized the role of the right lateral frontal lobe in aspects of vigilance and sustained attention. However, it is clear that the inferior parietal lobe of the right hemisphere also has a critical role to play in these functions. The distinction between frontal and parietal contributions remains to be established but, unlike spatial attention studies, investigations of non-spatial vigilance and sustained attention suggest that *ventral*—and not dorsal—frontal and parietal regions of the right hemisphere have a special role in these processes (Fig. 2.5.2.1).[4]

Divided attention

Divided attention is the ability to concentrate on more than one activity at once. Although we often execute two tasks simultaneously ('dual task'), performance on one or both tasks may be impaired compared to doing either alone, e.g. when driving and having a phone conversation. Experimental findings that demonstrate such decrements in performance raise important questions regarding the mechanisms underlying attention. Many investigators have proposed that if a second task leads to deterioration in performance of the first, one may conclude that the two tasks depend on the same brain resources. Because such resources are limited, there will be a decrement in performance once resource limits are reached. Some authors have argued for a single, central resource while others have presented evidence for multiple resources, but the basic concept is the same across these accounts: tasks compete for finite brain resources and if they share those resources, performance suffers.

Other investigators have raised the possibility that it is not just 'resources' that we need to consider but also processing limitations. Two tasks might be difficult to perform simultaneously because they both use a single processing channel or because the tasks interfere with each other. Different paradigms have suggested 'bottlenecks'—mechanisms that are dedicated serially to only one task at a time or have limited resources to spread over two tasks. Such bottlenecks may exist at the level of attentional focus, storage in visual short-term memory (VSTM), and motor preparation.[5] Consider first the issue of processing bottlenecks.

The attentional blink paradigm is used to investigate temporal limitations of attentional processing. Subjects view a stream of individually presented letters and are required to report when they see either of the two target letters (say X and Y). People generally struggle to report a second target if it falls within 360 ms of the first, despite being able to report the second target when not attending to the first. Processing the first object before being free to process the next item appears to require up to 360 ms. Thus speed of attentional processing may act as a limiting factor in dual task processes. Functional imaging studies suggest, once again, that a fronto-parietal network is critical in this regard. Activity in fronto-parietal areas occurs only when the second stimulus is reported. In contrast, even when the second stimulus is undetected, there is still activity in the early visual areas. These findings point to a bottleneck in attentional processes which occurs after basic visual processing has begun, but before conscious perception, consistent with pre-attentive and attentive stages of visual processing as discussed in the section on selective attention above.

The amount of information we can encode at any one time is also limited. The capacity for holding objects in visual short-term memory (VSTM) is around four objects. Diversion of attention

away from an object reduces the accuracy with which it can be encoded suggesting that attention is an important limiting factor in the number of items held in VSTM. Both electrophysiological and functional imaging experiments have suggested that the capacity for storage of objects in VSTM is related to posterior parietal and occipital cortex activity.

As well as these perceptual and memory limitations in capacity, there are limits at the motor selection stage of processing. The psychological refractory period (PRP) refers to the delay in the second response when a subject has to respond to two stimuli one after the other. The shorter the time difference between the two stimuli, the greater the delay in the second response. This bottleneck may be at the level of response selection rather than a pure perceptual or attentional slowing. However, although it is often the case that performing two simultaneous responses with a single effector (e.g. the hand) may be impossible, the PRP cannot simply be explained in terms of a motor selection bottleneck.

When subjects are asked to make two responses to the same attribute of an object (name the colour and press a button for the colour), they can select the appropriate responses at the same time. In addition the PRP is much longer when required to make an incongruent response (e.g. saying 'A' in response visual presentation of the number 1) than a congruent response (e.g. saying 'one' in response to visual presentation of number 1) to the second stimulus. Pashler has proposed that at any time we have a number of response selection rules, with each rule specifying condition-action linkages or associations, i.e. which condition is associated with which action. According to this view, the bottleneck is at the level of rule application, but each rule can specify multiple motor responses.

But how and where rules are selected and maintained? Many studies have suggested a critical role for frontal—so-called 'executive'—control systems when rules need to be applied, as we shall discuss in the next section. Performing two *well learned* or relatively *automatic* tasks together might not lead to performance impairment because these tasks do not require input from such 'executive' control systems to implement rules and select appropriate responses.

In summary, there are multiple possible levels at which processing capacity may be limited. Both the speed of attentional processing and the number of items that can be attended to at once and held in memory are limited. In addition, supervisory or executive control regions may regulate motor output perhaps by implementing goals or strategies. Whether these bottlenecks are due to one resource being serially applied to each stimulus or a limited capacity system shared simultaneously by two processes, but perhaps with a bias toward one, is currently unclear.

Executive control of attention

How are the subtypes of attention mentioned above organized so that they are activated at the appropriate time? Events in our environment reflexively engage attentional networks and this type of stimulus-driven or bottom-up activation may underlie some processes such as rapid shifts in spatial attention to highly salient events. However, everyday experience tells us that rather than always reacting to our surroundings, we are able to generate and implement plans to complete complex tasks and sometimes ignore highly salient events. This has led to the idea of a supervisory or executive attentional control system. Evidence for the presence of such a system comes from patients with brain damage, particularly those with frontal damage.

Patients with frontal lesions have difficulty maintaining attention on a task. They may be highly distractable, or find it difficult to divide attention between competing task demands in an optimal way. Some patients also encounter problems shifting from one task type or task rule to another, often demonstrating perseveration—

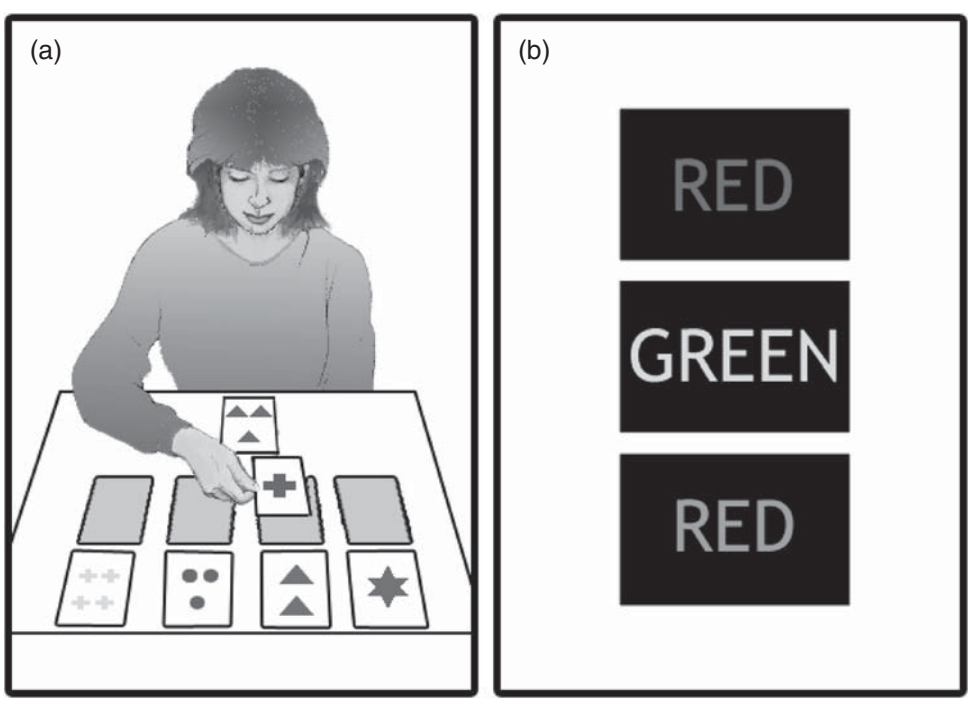

Fig. 2.5.2.2 In the Wisconsin card sorting test (a), the patient has to place a new card alongside one of the visible cards according to a rule to match colour, suit or number. The rule changes during the task and the learning occurs by trial and error. Patients with frontal lobe damage fail to update the new rule. The Stroop task (b) requires subjects to give the colour of the text. In the first box this is easy because the colour of the text and the meaning of the word are congruent (both red). The second and third boxes illustrate the incongruent condition. This is more difficult because the text colour is different from the meaning of the word. Normal individuals are slower to respond in the incongruent than congruent conditions.

applying the 'old' task rule inappropriately when they should be applying the 'new' one. For example, on tasks such as the Wisconsin card sorting task, where subjects establish the criteria for grouping playing cards into sets (according to either colour, or suit, or number) and then have to change to a new grouping rule, such individuals have great difficulty shifting to a new rule (Fig. 2.5.2.2a). Multiple components of executive control including flexible task-switching and response inhibition, as well as vigilance and error monitoring, are required to successfully sort the cards when the rule is switched.

Norman and Shallice developed a model of attention control called the supervisory attention system that conceptualized how this behaviour might be organized. They proposed that routine or well-learned behaviour occurs because perceptual information activates a set of schemas that then triggers appropriate motor output. However, these perceptual-motor associations would no longer be appropriate when the rule changed, for example when one had to sort according to suit rather than number in the Wisconsin card sorting task (Fig. 2.5.2.2a). Under these circumstances, they proposed that the supervisory attention network alters the bias of the schemas so that different motor outputs are triggered by perceptual events. Therefore, rather than processing simple stimulus-response associations such as always signalling the right foot to move from the brake to the accelerator when a green traffic light appears, brain regions within the supervisory network would respond to information at a more abstract level. When driving, for example, one might want to *inhibit* the prepotent response associated with the green traffic light (to press the accelerator) if confronted by a variety of visual inputs such as someone still crossing the road or a car stalled in front. *Response inhibition* in this and other contexts is thought to be one of many abstract functions undertaken by the supervisory control systems.

What are these abstract processes and which regions of the brain perform these supervisory operations? Both lesion studies and functional imaging work have contributed to understanding executive functions. Functional imaging studies provide information about areas activated in association with certain processes while lesion investigations show which regions are critical for normal behaviour. In paradigms such as the Stroop task, subjects are asked to report either the colour of print used to type a word or read the word which can be the same (congruent) or a different (incongruent) colour to the print (Fig. 2.5.2.2b). To avoid making errors in the incongruent condition one is required to focus attention on the target information and suppress the unwanted response. This is usually associated with a reaction time delay in the incongruent compared to the congruent condition. The delay is greater when subjects have to report the colour of the print and inhibit their reading of the word, presumably because word reading is a more hard-wired or automatic than colour naming. Functional imaging and lesion data from subjects performing the Stroop tasks show that medial and lateral frontal as well as parietal areas appear to form a network for executive control of attention.

There is recent evidence that each of these regions has a distinct role within the executive control network. Specifically, the left lateral frontal cortex is thought to maintain and flexibly update task rules, whereas, right lateral prefrontal cortex is critically involved in *inhibiting* the prepotent response associated with a stimulus. Dorsomedial frontal regions (Fig. 2.5.2.1b) reliably activate when executive control is required and are thought perhaps to play a key role in monitoring errors. In addition, part of this area—the anterior cingulate cortex—is considered by some investigators to be important for mediating the physiological autonomic response to demanding circumstances. More posterior regions including parietal cortex, may also contribute to attentional control but, to date, their role has been less well investigated. Research into how areas involved in executive control act and interact to modulate attention is a rapidly expanding area of cognitive neuroscience, likely to yield important insight into mechanisms behind flexible and efficient behaviour.

2.5.3 Psychology and biology of memory

Andreas Meyer-Lindenberg
and Terry E. Goldberg

Memory in psychiatric practice

Memory is the ability to store, retain, and retrieve information. This cognitive function plays a key role in psychiatry. Dementia and the amnesic disorders have memory dysfunction as a defining feature. Intrusive and recurrent emotional memories are one of the most distressing symptoms in post-traumatic stress disorder. Although not as obvious, problems with memory are also commonly revealed on testing in schizophrenia. Remembered episodes are often a focus in psychotherapy, as is the acquisition of new habits and response patterns. An ability to understand and assess memory is therefore important for the practising psychiatrist. In this chapter, basic neurobiological and psychological information

on memory will be reviewed. We have tried to cover a very broad field in a concise manner and give the interested reader a sense of the key memory systems and subsystems that are thought to be important for human information processing in health and in disease. We have emphasized the conceptual over the theoretical and key findings over the experimental details where possible. At times, we have not carefully separated the cognitive and neuroanatomical levels of analysis, both because they are sometimes almost inextricably bound and because it made our explanations clearer not to do so. Necessarily but not happily, we have omitted many important and active areas of investigation.

Forms of memory

One of the key discoveries of cognitive neuroscience is that 'memory' is not an unitary function, but consists of several forms that can be dissociated neurally and are differentially impacted by psychiatric disorders.[1] Several approaches can be taken to subdivide memory. One of the most straightforward is by the duration over which information is retained. In this way, ultrashort-term, short-term, and long-term memory can be distinguished. **Ultrashort-term**, also called **sensoric** or **echoic/iconic** memory, lasts from milliseconds to seconds and consists of a brief and modality-specific retention of sensory information. For example, most people are able to 'replay' the auditory trace of the last second or so of a conversation, or briefly maintain a scene visualized after they close their eyes. In contradistinction, **short-term memory** has been shown to be relevant to a large number of psychiatric disorders. In short-term memory, information is briefly (over a period from seconds to minutes) held in mind, often through a process of rehearsal. A typical example is remembering a phone number from reading it to dialing without writing it down. A key feature of short-term memory is capacity limitation: most people are able to retain about seven items in short-term memory.[2] A specific form of short-term memory that has received considerable interest is **working memory**: the ability to hold information in mind that is necessary for a task at hand, but not present in the environment. This faculty is often regarded as a 'mental workspace' that is critical for information manipulation and goal-directed adaptive behavior, and the association of working memory with specific brain systems and psychiatric disorders has been widely studied. Rehearsal is also one important mechanism by which material is being transferred into **long-term memory**, which refers to the ability to retain information for time periods lasting from minutes up to the life span of the individual. This form of memory, which is also of major clinical importance, is not clearly capacity limited and is thought to depend on more enduring changes in neuronal structure and connectivity, raising the question of where in the brain these enduring memory traces, or 'engrams', are stored, how they are encoded for storage and how they are retrieved from it.

A second important subdivision is whether the content of memory can be consciously and intentionally retrieved (this is called explicit or **declarative** memory) or not (nondeclarative or **implicit** memory) (**Fig. 2.5.3.1**). Declarative memory is further subdivided in memory of facts and memory of events. Memory of events, which often includes recollection of temporal, spatial and emotional circumstances, is called **episodic** memory. Questions such as 'What did you have for breakfast this morning?' or 'Where did you go to school?' access episodic memory. Several features of episodic memory bear mention for their clinical relevance. For example, people can often say that they have seen a specific item before or that it 'feels familiar' without being able to recall the specifics of where and when (the episodic context). As discussed below, some evidence suggests that familiarity and recall may be supported by different brain regions. Intense feelings of familiarity without recall are experienced as *déjà vu* in a psychiatric context. People can also be convinced to remember events that did not, in fact, happen. These so-called **false memories** are also encountered in psychiatry. There has been much work on paradigms that produce false memories in normal individuals that address how they develop and how and why they might be successfully rejected. In one canonical account of episodic memory, the medial temporal lobe system (MTL) stores or indexes contextual markers that serve to bind feature information of a memory into an episodic configuration.

In contradistinction to episodic memory, memory of facts is not connected to specific experience. It is called **semantic** memory, and recollection of facts or vocabulary are examples of information that has become independent of episodic memory. Over time such material is thought to be stored in neocortex and can be retrieved without engagement of medial temporal lobe structures (MTL). Various models of the distinctions between semantic and episodic memory have proposed that while learning in the episodic system is rapid and can be based on a single trial or exposure, storage of information in the semantic system occurs slowly over time and only after multiple exposures or activations [3]. Some accounts suggest that the MTL may also be involved in semantic memory, for example for separation or 'decompression' of stimuli previously learned as a unit.[4,5] We have chosen not to review semantic memory in further detail because of space limitations and its complex overlap with psycholinguistics.

Whereas the subdivision of declarative memory is comparatively simple, implicit memory encompasses quite a heterogeneous group of functions that are supported by different brain systems. Among them are **procedural memory**, which refer to the gradual acquisition of sensorimotor, perceptual or cognitive skills through repeated exposure, **priming** (the facilitation of a response to an item if it was previously encountered), **conditioning** as well as various phenomena wherein a previously acquired response is gradually reduced or lost, such as **extinction**. Since the distinction between declarative and implicit depends on whether or not a memory process supports conscious recollection, clinicians must be careful not to confuse this with the properties of a given neuropsychological test; for example, a test of sentence completion requires conscious

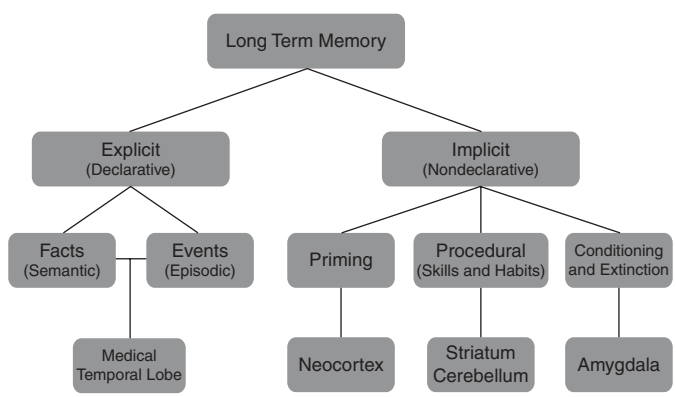

Fig. 2.5.3.1 Classification of memory and associated neural systems

production of words, but performance may strongly depend on implicit processes such as priming.

Although a taxonomy of memory systems is useful, many everyday tasks require functionality from several memory domains, and even relatively subtle changes in task demands may disrupt the balance among those cognitive systems. More refined analysis of learning tasks suggests that a variety of learning systems may mediate performance,[6] and that a given neural system participates in several forms of memory. For example, the hippocampal formation (HF), which is critical for episodic memory, is also thought to play a role in learning sequences so that indirect relations can be specified.[7] Thus, the HF becomes critical not during a>b, b>c, and c>d discriminations, but for the discrimination of the critical indirect b>d probe (e.g. if John is taller than Bill and Bill is taller than Mary and Mary is taller than Ellen, then Bill must be taller than Ellen).

Cellular and molecular mechanisms of memory

Memory is one of the most impressive examples of neural plasticity: the ability of the nervous system for enduring change triggered by external events. Arguably the best-studied cellular mechanisms underlying plasticity are long-term potentiation (LTP) and long-term plasticity (LTD), which mediate enduring changes on the level of the synapse.[8] Both have been best characterized in the hippocampus, one of the key structures for declarative memory.

By stimulating presynaptic fibres in the hippocampus (especially the CA1 section) with a brief pulse of high-frequency electric impulses, a long-lasting increase in responsiveness of the postsynaptic cells to low-frequency stimulation is reliably observed that can last for weeks (**Fig. 2.5.3.2**). This is called LTP. Initiation of this process depends on multiple second messenger mechanisms (**Fig. 2.5.3.2**). One of the best studied pathways starts with calcium influx into the presynapse through a glutamate receptor, NMDA, which activates further molecular cascades involving cAMP and protein kinases such as CamKII (other receptors, such as the glutamate receptors AMPA and mGluR, also play a role). LTP is then maintained by changes in gene transcription factors, such as CREB, and changed patterns of protein synthesis and phosphorylation, probably also dependent on protein kinase cascades. The time course of these processes can be used for a distinction between early phase LTP (the cellular signature of learning that occurs over seconds to minutes) and late phase LTP, which involves protein synthesis and occurs over minutes to hours and is thought to be critical for consolidation of new memoranda and would be linked to memory consolidation.[9,10]

LTD is a closely related process that is triggered when presynaptic stimulation is lower, causing less calcium influx (again through NMDA receptors) and preferential activation of calcineurin, a protein phosphatase. Together, LTP and LTD allow bidirectional enduring modulation of synaptic strength that could underlie formation and reversal of experience-dependent coupling in neural assemblies. Linking these synaptic changes to validated mechanisms underlying the complexities of human memory remains a challenge. However, the active field of neural network modeling has shown that, in principle, such changes in synaptic efficacy can produce efficient mechanisms to encode, store and retrieve information, a proposal first made by the neurophysiologist Donald Hebb.

Declarative/episodic memory

(a) Neural systems

Current evidence indicates that the HF and linked regions of the medial temporal lobe (MTL), in interactions with parts of the prefrontal cortex, play a critical role in the encoding and retrieval of episodic memories, whereas engrams are stored in neocortex[11] (**Fig. 2.5.3.3**). Interactions of the HF with amygdala are important for emotional memories. The HF consists of the hippocampus proper, the entorhinal cortex, which provides the main port of entry for connections with the cortex, and the adjacent perirhinal and parahippocampal cortices, which interact with the entorhinal cortex and in turn receive projections from all other neocortical areas, with parietal, dorsal occipital and prefrontal regions primarily projecting to parahippocampal gyrus and temporal cortex to

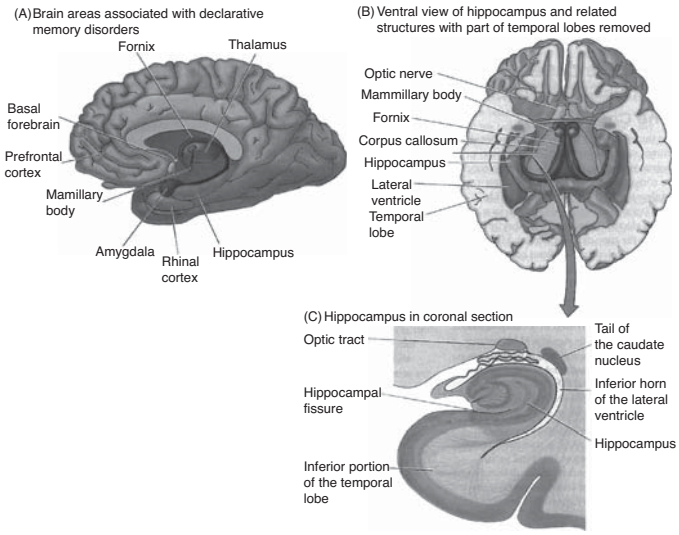

Fig. 2.5.3.3 (A) brain regions associated with dysfunction in episodic memory. (B) the hippocampal formation, view from below. (C) coronal section through the hippocampal formation.

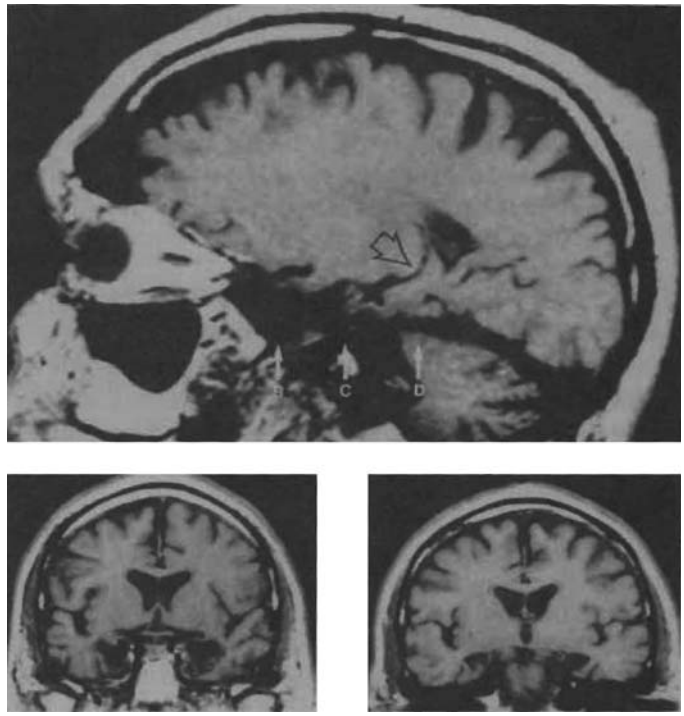

Fig. 2.5.3.4 Hippocampal damage in patient H.M., shown on a sagittal (top) and two coronal slices (below) of the patient's MRI.

perirhinal cortex. In this way, the HF is bidirectionally connected with the rest of the brain. Although pertinent observations were already made at the end of the 19th century by Bechterew, the importance of the hippocampal formation for episodic memory was dramatically shown in 1953 by the case of patient H.M., in whom the HF and amygdala were resected bilaterally as a treatment for drug-resistant epilepsy[12] (**Fig. 2.5.3.4**). This led to complete and enduring **anterograde** amnesia (inability to form new episodic memories). In addition, he has some degree of **retrograde** amnesia (i.e. an inability to retrieve episodic information stored before the operation), while his working and procedural memory, as well as priming, is unimpaired. A similar pattern of memory impairment is observed in Wernicke encephalopathy/Korsakov's syndrome or other neurological processes impacting on diencephalic structures, including the medial thalamus, mamillary body and the fornix, which project to the HF. This indicates that these structures may be viewed as a system that is critical for assigning a spatiotemporal (episodic) context. In rodents, a major role of the HF is indeed to function as a neural map of the environment;[13] it is controversial to what degree this applies to humans. Neuroimaging studies confirm that activation of the HF is observed during successful encoding and retrieval of episodic information.[14]

A neurocognitive model system for examining the computational role of MTL subsystems involved in episodic memory may help the reader gain a sense of the interplay among various subprocessing modules.[15] In this model, the MTL binds memories and their instance-specific context and then stores their code for later retrieval. The model described here is based on studies showing that the bulk of hippocampal (HC) cortical input is segregated over two pathways. One of these may convey spatial information; the other may convey information regarding items and objects. The two streams are interconnected at various levels within entorhinal cortex, which likely contributes to the integration of cortical inputs into a representation of their co-occurrence. The hippocampus proper may quickly associate a code to the conjunction of cortical inputs, such that similar entorhinal patterns come to be separated via their associated hippocampal patterns. These hippocampal patterns are thus not directly associated with individual features, but serve to separate the large number of overlapping entorhinal patterns, which is important to ensure that retrieval will be unambiguous. The representational overlap in entorhinal cortex, combined with the pattern separation system in the hippocampus proper, enormously increases the storage capacity of the memory store and allows accurate recall of episodic memories. In this model, retrieval in this memory system can be sampled using cues, consisting of *partial* input patterns; for instance, part of a context representation from a previously experienced episode. Initially, such a cue may activate only part of an associated entorhinal pattern, but if the set of activated entorhinal nodes sufficiently resembles a stored representation, their combined firing will tend to activate associated hippocampal nodes, through previously strengthened connections with these nodes. The hippocampal nodes, in turn, will recruit missing nodes of the entorhinal representation. This pattern completion process will reinstate the original pattern in the entorhinal layer, which, in turn, can reinstate associated information in the input layers, namely, item representations that have been experienced in that particular context (feature extraction). Thus, all features of an episode can be recalled, even when only part of the input layers is cued.

The model was shown to be sensitive to various types of simulated lesions including reductions of nodes ('neurones'), addition of noise to the system, and perhaps most relevant for the modeling of schizophrenia, marked reductions in connectivity between the various modules. At the network level, this reduced connectivity led to compromised cross-association of episodic features (i.e. item and context) and a superimposed, mild reduction of pattern separation in the system. The latter malfunction made some

patterns irretrievable, affecting all memory tasks including recognition, albeit to a mild degree. The cross-association problem also attenuated 'searching' of the memory store, particularly with single-source cues. This preferentially affected tasks with a large retrieval demand, such as free recall. From an information processing standpoint, what appeared to be disproportionate failures in retrieval were due to compromised encoding.

Recent work has indicated that recollection is predominantly mediated by the hippocampus proper, whereas familiarity has been linked to perirhinal cortex.[16] While this distinction is supported by functional neuroimaging studies of healthy individuals (e.g. Eldridge *et al.*[17]), studies of patients with circumscribed lesions of the hippocampus have nevertheless found severe familiarity-based recognition memory impairments.[18] These results do not necessarily contradict a dual process distinction, but could rather suggest that MTL regions comprise an integrated network that supports both processes.

There has been much interest in the precise role of episodic memory systems in the formation of associations between items that are entering memory. Several new studies suggest that the hippocampus is engaged preferentially when inter-item associations are formed in memory. While there have been several compelling accounts that specific subsystems in the MTL complex play different roles in single item encoding and associative encoding, the distinction between the two may be relative, not absolute.[11,19]

Neuroimaging and lesion studies have suggested that interactions between the HF and the amygdala are relevant for emotional memories, especially if these have a fearful or aversive character.[20] Neuroimaging has also demonstrated that encoding and especially retrieval is associated with activation of the lateral prefrontal cortex, as well as with increased functional interactions of these regions with the HF that are supported by anatomical tracts such as the uncinate fascicle. In some studies, left prefrontal cortex is differentially more involved than right in encoding information into episodic memory, whereas right prefrontal cortex is differentially more involved than left in episodic memory retrieval.[21] Compared to encoding and retrieval, the evidence is much less clear with regard to the storage of the engrams themselves. Cases such as H.M. and the clinical picture of Korsakov's syndrome show that the HF and diencephalic structures cannot be the store, since most episodic and semantic memories laid down before the onset of illness are spared. Current evidence suggests that the neocortex is the ultimate store of memories and that engrams reside in regions that are also specialized in processing stimuli to which they pertain. For example, circumscribed cortical lesions can result in category-specific impairments in retrieving object information, the so-called anomias, which have been described for classes such as people, tools, or living things, and neuroimaging studies show that similar regions are differentially activated during naming of these object classes. In each case, engrams are assumed to be stored in a distributed pattern of synaptic connections over a large group of neurones. It is an open question how the interaction of the HF and cortex accomplishes the encoding, and retrieval of information from these neural assemblies (but see above for a model). On the molecular level, glutamatergic neurotransmission is crucial to support the LTP mechanisms that support the neural plasticity essential for memory formation. In addition, acetylcholine is a neurotransmitter associated with declarative memory function since it is known that muscarinic receptor blockade impairs episodic memory and degeneration of cholinergic neurones in the basal nucleus (of Meynert) is a prominent finding in Alzheimer's disease. It is likely that cholinergic mechanisms act on declarative memory by modulating glutamate-dependent LTP and LTD in MTL regions.

(b) Assessment and neuropsychology

Clinical assessment of memory systems is an important facet of neuropsychiatric and neuropsychologic test batteries. Assessments may vary widely in their depth and breadth and systematic approach. There are numerous tests of episodic memory that can be used for clinical purposes. Well known batteries include the Wechsler Memory Scale-III, which involves verbal memory for stories, verbal paired associates, and word lists, and visual memory for scenes, faces, and designs. Immediate and delayed recall of these tests is assessed. There are also many standardized verbal list learning tests that involve differing degrees of semantic relatedness among words (and perhaps requiring different degrees of strategic encoding) and minor differences in administration. These include the California Verbal Learning Test, the Hopkins Verbal Learning Test, and the Selective Reminding Test. These tests have alternate but equivalent forms that reduce practice effects when tests are administered repeatedly. A comprehensive evaluation of memory should include multiple trials of a word list to assess learning rate or slope; measures of immediate and delayed memory (e.g. recall after 30 minutes); a recognition test in which a subject must decide whether an item had been studied or not (was old or new in order to minimize effortful retrieval); and tests of visual memory and verbal memory that preferentially engage the right or left MTL systems, which are thought to be material specific, at least to some degree.

Cognitively, there are several distinctions or processes in episodic memory that bear special comment. Most are still being actively investigated. One of the earliest and best replicated findings in processing oriented theories of memory suggests that the level at which an item is encoded is an important predictor of later recall.[22] Thus, words that are encoded deeply (for example, after a semantic judgment about animacy) are remembered better than words encoded superficially (for example, after a judgment about whether the word contains a specific orthographic feature). The exact cognitive mechanism by which this occurs is unclear, but could involve the creation of more cue-item associations so that a wider variety of different searches might have yield.

Another important area involves the distinction between a sense of familiarity with an item at recall versus the recollection of an item, which implies knowledge about the spatiotemporal context in which the item was encoded. It is thought that memories may be retrieved through either of these two processes: recollection of a memory that involves adjunctive contextual information; or the feeling of knowing that an item, face, thing, etc. has been encountered before without memory of the surrounding context.[23,24]

Rate of forgetting reflects the degree to which memories that were once successfully retrieved can no longer be retrieved after a delay. For healthy individuals savings (the inverse of rate of forgetting) may be at 80–90 per cent for several hours or more after initial recall. Several amnesic conditions, as well as a form of frontal temporal dementia, have been associated with increased rates of forgetting. In Alzheimer's disease and Korsakov's syndrome, savings may be less than 50 per cent after delays of several minutes. Nevertheless, the situation is undoubtedly more complex psychometrically and cognitively than presented here.[25,26]

Implicit memory

(a) Neural systems

(i) Procedural memory

Clinical experience shows that the acquisition of new visuomotor skills is often unimpaired in patients with deep amnesia due to medial temporal lobe lesions. Conversely, skill learning, but not declarative memory, is often impaired in patients with degenerative or vascular lesions of the basal ganglia (for example in Huntington's) or cerebellum. Neuroimaging has confirmed the importance of basal ganglia and cerebellum for procedural memory[1] and has also demonstrated time-variant activation of primary and secondary motor cortex during skill learning. The basal ganglia receive excitatory glutamatergic projections from the cortex and thalamus, integrate them with monoaminergic inputs and sends them via the globus pallidus and substantia nigra pars reticulata to the thalamus, which projects back to prefrontal cortex.[27] These parallel processing loops are critical for the integration of sensorimotor, cognitive and emotional information.[27] It is usual to distinguish between a dorsal and a ventral subdivision of the striatum, and it is the dorsal striatum (caudate nucleus, putamen and globus pallidus) that is strongly interconnected with cortical areas relevant for motor planning and execution. The learning of repetitive sequence, as well as so-called 'open loop' tasks, in which visual feedback is delayed, especially depends on the integrity of the dorsal striatum and its interactions with cortex.[28] This extends to skills that are not motor, for example the prediction of probabilistic sequences or the planning of complex tasks. Conversely, the importance of the cerebellum lies with 'closed loop' tasks that require continuous visuomotor feedback, as well as fast error control. The cerebellum has also been proposed to play a role in creating new stimulus-response mappings.

(ii) Priming

Neuroimaging suggests that the neural substrate of priming lies in neocortex. Specifically, a reduction of activation to a primed stimulus is consistently found, either in modality-specific regions (such as visual areas for visual repetition priming) or in 'amodal' cortical areas such as lateral temporal cortex for semantic priming. It has been hypothesized that this reduced activation represents neural assemblies that are optimized, by 'pruning' of unnecessary connections, for easier activation, and that this may underlie the facilitated response to a primed stimulus.[29] Clinically, this leads to the prediction that priming should be altered in disorders that impair the integrity of the cortical regions involved, such as semantic priming in Alzheimer's disease.

(iii) Fear conditioning and extinction

Conditioned fear is of high relevance in psychiatry in disorders ranging from simple phobias and generalized anxiety disorder to major depression. In conditioning, a fear response to an unconditional stimulus (for example, an electric shock) is transferred to a conditional stimulus with which it is paired (CS, for example, a tone regularly preceding this shock). A large body of research has established a key role for the amygdala in this memory process.[30] Different subnuclei of this complicated structure are implicated in establishing and storing fear conditioning memory traces. An area of recent research interest concerns extinction, the process in which a conditioned fear response is gradually lost if the conditioned stimulus is repeatedly presented without adverse consequences. It is now clear that extinction is not a passive process, but depends on interactions between amygdala and the cingulate cortex.[31] This circuit has been implicated in depression and anxiety in humans, in which dysphoric mood and affect are abnormally maintained, i.e. not extinguished.[32]

(b) Assessment and neuropsychology

Despite at least 20 years of cognitive science research in implicit memory, procedural memory, or habit formation, there are no commercially available versions of these tests. In part, this may have to do with lack of psychometric evaluation of test-retest reliability, ceiling or floor effects, etc. or unclear relations to functional status or outcome. It might be possible to adapt some instrumentation used experimentally (e.g. rotor pursuit) if there are adequate local normative data for the test. There are several forms of implicit learning, all of which are thought to involve learning or memory without conscious awareness of recall. Various motor skills can be learned incrementally, such as rotor pursuit or mirror tracing. Others involve motor sequences. Probabilistic learning can occur when there is acquisition of information or representations that reflect underlying structural regularities in the input, i.e. when there are statistical regularities between stimuli and responses.[33] This can occur in tasks as seemingly disparate as the so-called weather prediction task (characterized by probabilistic relationships between specific stimulus configurations and a response, in this case 'sunshine' or 'rain') and artificial grammar. Critically, implicit learning can occur even when the episodic system of recollection is dysfunctional.

Other types of implicit memory may be item specific, including some types of priming. Priming is thought to be an instance of memory without awareness. Such priming can be reflected in improvements in accuracy or reaction time during testing. It can be demonstrated in a variety of tasks, some rather rarefied, like word stem completion, and some rather simple and robust, like so-called repetition priming. In the latter paradigm, an item is repeated and access to it (usually measured in reaction time) is speeded at the second presentation, while concomitantly, physiological measures, ranging from single cell activity to BOLD activation, demonstrate reductions in neocortical areas (e.g. for words, inferior prefrontal cortex). Some of these effects may be quite long, lived.

The degree to which episodic memory may also support some types of priming is sometimes unclear and may depend on the paradigm and experimental manipulations. Perhaps the best evidence that priming reflects a dissociable memory system comes from amnesic patients in whom there is little chance that the episodic system is supporting priming (e.g. studies of priming in the amnesic patient HM [34]). Additionally, an important and critical review[35] has proposed that some priming may not reflect changes in the abstract representation of an item, but rather response learning.

Finally, conditioning (especially classical or Pavlovian) has also been considered a type of implicit learning. The neurobiological literature on this phenomenon is quite extensive.[36] The phenomenon itself might be relevant for understanding a wide range of behaviors, including anxiety (as a result of fear conditioning) and preferences.

(c) Working memory

(i) Neural systems

A large body of work has established the importance of dorsolateral prefrontal cortex (DLPFC) for working memory. Both the

simple maintenance of information over a delay and the manipulation of that information require DLPFC function. In the influential model of Baddeley, a 'central executive' component of working memory works together with modality-specific storage systems, the 'visuospatial scratchpad' for visual information and the 'phonological loop' for auditory information.[37] While the details of how this cognitive account reflects neural organization are being debated, it is clear from a multitude of studies that DLPFC activation is usually observed in conjunction with activity of posterior cortical areas that receive input from a variety of specialized sensory cortices.[38] Chief among those is the inferior parietal lobule, a brain region strongly and bidirectionally connected with DLPFC that is likely to be important for item storage during working memory. Within DLPFC proper, some models propose a regional differentiation based on the modality of information stored (with more dorsal activation associated with visual, ventral with semantic items), while others propose a specialization based on cognitive operations (manipulation of memory items being performed more dorsally than pure maintenance). Clinically, large lesions of DLPFC are invariably associated with working memory impairment, however, problems of similar magnitude are also observed in schizophrenia, where only subtle structural abnormalities are found in this (as in any other) brain region.[39] The association of working memory impairment with schizophrenia has driven an extensive programme of research aimed at understanding mechanisms underlying memory impairments in this disorder. One well-validated finding from this work is the importance of the neurotransmitter, dopamine, for DLPFC function, which has been found to exhibit an 'inverted u' shaped relationship with working-memory related activation of DLPFC neurones and dopaminergic, especially D1-receptor, stimulation.[40] It is believed that dopaminergic tone is essential for optimizing signal to noise ratio, or tuning, in DLPFC, an essential network property for working memory maintenance. This is further supported by a modulation of working memory by a functional variant in the COMT gene which alters the protein's thermolability and hence its ability to degrade dopamine in cortex, the impact of dextroamphetamine on N Back driven BOLD activation in fMRI, and the COMT inhibitor tolcapone's impact on N Back RT.[41–43]

Interactions between DLPFC and hippocampus may also be disturbed in schizophrenia and reflect an inability to disengage episodic memory processes during working memory.[44]

(ii) Assessment and neuropsychology

The classic test of simple working memory is digit span, which involves repetition of short sequences of digits. Span is assessed by increasing the length of the sequence that can be recalled. Nonverbal working memory often involves short sequences of locations (as in Visual Span in the WMS-R and the so-called Corsi blocks.) Tests thought to depend on simultaneous storage and manipulation of information are generally considered executive in nature. The Letter-Number Span is a good example of this class of tests. In it, the subject is asked to order a short random sequence of letters or numbers numerically and alphabetically. Interestingly, the test is highly correlated with a nonverbal, formally dissimilar, problem solving task, the Wisconsin Card Sort, providing evidence that both these tests engage executive processes. The Card Sort itself may be the best known executive test administered in clinical test batteries. It calls upon such executive abilities as abstraction, set shifting, and response to examiner feedback.

An exceptionally well validated computerized battery of 'frontal lobe tests' called the CANTAB is based on the comparative and pharmacologic challenge literature, as well as human lesion studies. All tests are nonverbal and may involve problem solving (as in Tower of London), various levels of set shifting (in the ID/ED task), and self-ordered pointing that demands that the subject remember his/her own actions.

A widely used test of cognitive control is the Stroop, for which there are several commercially available versions. In the critical interference condition, the subject must respond to words printed in incongruent colors (e.g. red) by naming the colour of the ink and simultaneously suppressing the prepotent response to read the word.

There are many experimental tests of working memory and executive that could in theory be adapted for clinical purposes provided these have adequate local normative data and adequate validity and psychometric characteristics. In general, many of the paradigms that have interested cognitive neuroscientists have not yet become part of routine clinical assessment.

The working memory (WM) system is thought to be a limited capacity system that holds information on line when the stimulus is no longer present (perhaps up to 40 seconds, as demonstrated in densely amnesic patients). The idea that WM is a capacity limited system comes from the work of G. Miller.[2] Several compelling accounts now suggest that it may under some circumstance be smaller than Miller's canonical '7±2.' For instance, in studies of visual stimuli, Luck *et al.*[45] have suggested that a visual store may hold only four items. Subsystems include a slave system for short term memory of phonological information. This system includes an articulatory rehearsal mechanism and a phonological store. A visual spatial scratchpad processes visual, non-linguistic information. An episodic memory buffer is thought to play a role in the interface between working and episodic memory. A central executive is involved in the allocation of cognitive resources during dual tasks and in the manipulation or transformation of information. The central executive may be involved in cognitive control, such that when there is response conflict (e.g. during response selection in the Stroop task or Eriksen flanker task) more resources can be made available for biasing decisions.[46] More specifically, in this account, cognitive conflict is detected (by the anterior cingulate) and signals are sent to executive areas (in DLPFC) that increase processing resources. The increase in resources is used to bias a response to one or another aspect of the stimulus' features. Importantly, various computational models of this process have shown that a homunculus (i.e. a director or decider) is not necessary for a correct response to be made. There is ongoing interest in how best to characterize operations in the WM system. One view that posits a single algorithm that maintains a stable representation over a delay (although subsystems may be dedicated to spatial, object or verbal information) can be used to characterize the basic function of this system. Goldman Rakic and colleagues provided much neurobiological evidence in favor of this argument. Another view holds that multiple computational algorithms perform a variety of tasks.[47,48] Such functions as attentional set shifting, planning, and monitoring of sequences of responses (self or externally generated) can be brought to bear on a task, depending on its demands and are separable from basic mnemonic maintenance functions.

Updating of information in WM (i.e. registering information and dumping information from a buffer) and suppression of inter-

ference may also engage the executive system and may be critical for refining goal-directed behavior.[49] In one version of a task that makes continual demands for updating and resistance to interference, a restricted set of numbers are displayed successively (and approximately every two seconds) and the subject views one while responding by pressing a button corresponding to a stimulus 'one back'. Thus, the subject must continuously update his/her working memory buffer in that a target-to-be must be shifted in status to a target prior to being 'dumped' from a computational buffer and interference from other similar stimuli must be suppressed. Recent data (see below) suggest that dopaminergic tone at the cortical level may be particularly important in this specific aspect of cognitive control.

Finally, there are several integrative accounts of goal directed behaviour that are dependent on various working and executive functions. In perhaps the best known of these, a 'script' that engages multiple short-term and long-term memories bridges the temporal gap for projects that may be quite long temporally.[50]

Future directions

As our understanding of neural systems involved in memory dysfunction in a variety of psychiatric disorders matures, it will be important to leverage that knowledge to identify new molecular treatment targets. One important recent development in this direction is the identification of genes impacting on memory function. Genetic variation in the neurotrophic factor BDNF, for example, has been shown to impact on hippocampal function and episodic memory,[51] as have several risk genes for schizophrenia.[52] COMT, a gene that impacts on cortical dopamine concentrations, affects working memory performance and prefrontal activation.[41,53] Risk genes for depression and anxiety may affect amygdala-cingulate and amygdala-hippocampal interactions that are important for fear extinction and emotional memory, respectively, providing neural mechanisms for gene by environment interactions mediating the effects of early adverse experience on risk for psychiatric disorders.[32,54] Translational strategies for drug development can arise from these findings. The COMT inhibitor tolcapone has been shown to improve working memory in normals.[43] Data suggesting an impact of stress hormones such as corticosteroids on hippocampal integrity in posttraumatic stress disorder suggest neuroprotective strategies to prevent development of disease before anticipated exposure, for example in battle. Finally, it has become clear that memory impairment is an important predictor for treatment response in psychiatry, schizophrenia being an important example, and neurorehabilitative programs to improve memory are being explored. The study of the neurobiology of memory is therefore a promising avenue towards improved and specific therapies in psychiatry.

2.5.4 The anatomy of human emotion

R. J. Dolan

Introduction

Emotions, uniquely among mental states, are characterized by psychological and somatic referents. The former embody the subjectivity of all psychological states. The latter are evident in objectively measurable stereotyped behavioural patterns of facial expression, comportment, and states of autonomic arousal. These include unique patterns of response associated with discrete emotional states, as for example seen in the primary emotions of fear, anger, or disgust often thought of as emotion proper. Emotional states are also unique among psychological states in exerting global effects on virtually all aspects of cognition including attention, perception, and memory. Emotion also exerts biasing influences on high level cognition including the decision-making processes that guide extended behaviour. An informed neurobiological account of emotion needs to incorporate how these wide ranging effects are mediated.

Although much of what we can infer about emotional processing in the human brain is derived from clinic-pathological correlations, the advent of high resolution, non-invasive functional neuroimaging techniques such as functional magnetic resonance imaging (fMRI) and positron emission tomography (PET) has

greatly expanded this knowledge base. This is particularly the case for emotion, as opposed to other areas of cognition, where normative studies have provided a much richer account of the underlying neurobiology than that available on the basis of observations from pathology as in classical neuropsychology.

Emotion has historically been considered to reflect the product of activity within the limbic system of the brain. The general utility of the concept of a limbic-based emotional system is limited by a lack of a consensus as to its precise anatomical extent and boundaries, coupled with knowledge that emotion-related brain activity is, to a considerable degree, configured by behavioural context. What this means is that brain regions engaged by, for example, an emotion of fear associated with seeing a snake can have both distinct and common features with an emotion of fear associated with a fearful recollection. Consequently, within this framework emotional states are not unique to any single brain region but are expressed in widespread patterns of brain activity, including activity within early sensory cortices, shaped by the emotion eliciting context. This perspective emphasizes a global propagation of emotional signals as opposed to a perspective of circumscribed limbic-mediated emotion-related activity.

The amygdala and emotion

The above considerations aside, the structure most closely affiliated with emotional processing is the amygdala. This structure is an anatomically and functionally heterogeneous, bilateral, collection of nuclei located in anterior medial temporal cortex. The importance of the amygdala in emotional control was first highlighted by reports that rhesus monkeys with bilateral temporal lobe ablations no longer show appropriate fear or anger responses.[1] The role of the amygdala in emotion has been subsequently extended by findings that humans with lesions to this structure have impaired emotional recognition, particularly for fear, and no longer acquire Pavlovian conditioned responses[2] (see below). Finally, functional neuroimaging findings show activation of amygdala in responses to face stimuli that depict a range of emotions, particularly fear but also other primary emotions.[3, 4]

The importance of the amygdala in emotion derives in part from its extensive anatomical connections with all sensory processing cortices, as well as hippocampus, basal ganglia, cingulate cortex and the homeostatic regulatory regions of hypothalamus and brain stem.[5] This widespread anatomical connectivity means that this structure can access information processing in multiple brain regions and, in turn, can exert diffuse modulatory influences, including influences on effector autonomic and motor output systems. In this way activation of the amygdala by a sensory based emotional stimulus influences widespread brain regions including those that mediate homeostatic regulatory responses as expressed in altered autonomic state, such as change in heart rate, blood pressure and respiration.

Learning predictive emotional responses

A central role for emotion is to index value, specifically whether present or future sensory events or states of the environment that are likely to be associated with reward or punishment. From this perspective, all emotions are to a greater or lesser degree valanced. For example, an emotion of joy signals a likelihood of reward while an emotion of fear signals a likelihood of punishment. The fact that signals that predict such emotional occurrences are to some degree arbitrary means that the brain must have some means of associating sensory cues with potential emotional outcomes, an ability that seems crucial for adaptive behaviour.

Associative learning provides a phylogenetically highly conserved means to predict future events of value, such as the likelihood of food or danger, on the basis of predictive sensory cues. The amygdala plays a crucial role in mediating this form of emotional learning as evidenced by deficits seen with animal lesion data and learning-related effects seen in human functional neuroimaging experiments.[6, 7] In its simplest form, Pavlovian conditioning is expressed when a previously neutral sensory stimulus (the conditioned stimulus, or CS+) acquires emotional predictive significance through pairing with a biologically salient reinforcer (the unconditioned stimulus, or UCS). With conditioning, the predictive stimulus (CS+) comes to elicit behaviour previously associated with the UCS, but in the absence of UCS presentation. There is a wealth of animal and human data which now shows that the amygdala has a key role in this form of associative learning, for both appetitive and aversive outcomes.

How the brain updates predictions of emotional outcomes

While contingencies acquired on the basis of associative learning provide a basis for generation of predictions of future event of value in response to sensory cues, this form of learning lacks flexibility in optimizing future behaviour. For example, the value of future states associated with predictive cues may change in the absence of subsequent pairing with these cues. Thus, a cue that is associated with a particular food that is valued when a person is hungry has diminished relevance when the person is sated with that same food. Consequently, it is important for optimal adaptive behaviour to be able to maintain an updated representation of the current value of such sensory-predictive cues that does not slavishly depend on new learning in relation to that cue.

Reinforcer devaluation is a standard experimental methodology for examining how value representations accessed by predictive cues are updated. As indicated, in the case of food, its value can be decreased through what is termed sensory-specific satiety. In this type of manipulation, the reward value of a food eaten to satiety is reduced (devalued) relative to foods that are not eaten to satiety. In humans, functional neuroimaging measured brain responses elicited by predictive stimuli (such as a CS+), that have been subject to devaluation, are associated with significant response decrements in the OFC paralleling the behavioural effects of satiation.[8] This response pattern within OFC indicates that this region is involved in representing reward value of predictive stimuli in a flexible manner, observations that also accord with extensive evidence from animal lesion data.[9, 10]

The observation that neural responses evoked by a food predictive conditioned stimulus (a CS+) in OFC are directly modulated by hunger states can inform an understanding of the behavioural impact of pathologies that impact on orbital-frontal cortex, especially the feeding abnormalities observed in both the Kluver-Bucy syndrome and fronto-temporal dementias. Patients with these conditions frequently show increased appetite, indiscriminate eating, food cramming, and change in food preference, hyperorality, and even attempts to eat non-food items. A dysfunctional network

involving OFC and amygdala would mean that food cues, and other predictive cues, are unable to recruit motivationally appropriate representations of food-based reward value.

A computational account of emotional learning

Learning to predict reward or danger is a basic and highly conserved form of learning, as embodied in Pavlovian or associative learning. However, to be maximally adaptive, it is important that this form of learning is used not only to predict but also to shape optimal actions. The computational principles that underpin what is now referred to as value learning, involving prediction and optimization of action with respect to likely future outcomes, is more than an abstract issue and speaks to the critical issue of optimal control in decision-making.

One classical solution as to how associative learning is implemented is by means of a signal, referred to as a prediction error, which registers a difference between a predicted and actual outcome. This type of solution to predictive learning has been formalized within what is known as the Rescorla-Wagner learning rule. Temporal difference learning (TD) provides a more sophisticated computational extension of this learning rule that accounts in a precise manner for how an organism learns to make predictions, as well as select optimal actions, in response to states of the environment so as to maximize long-term reward or avoid long-term punishment.[11] As in the case of the Rescorla-Wagner model, when a positive (or negative outcome) is not predicted there is a large prediction error which reduces to zero when this same outcome is fully predicted. The function of the prediction error is to act as a teaching signal that can both update future predictions as well as shape optimal policies or action choices. In temporal difference learning (TD), credit is assigned by means of the difference between temporally successive predictions, rather than between a predictive stimulus and an outcome, such that learning occurs whenever there is a change in prediction over time.

The importance of the above theoretical considerations rests upon empirical observations that TD error-like responses have now been demonstrated in the response pattern of dopamine neurones recorded in monkeys during associative learning.[12] Consequently, in a classical conditioning context where a stimulus is followed by an unexpected reward it can be shown that dopamine neurones respond with a burst of action potentials after actual reward receipt. Over the course of learning, with repeated presentations of a predictive stimulus and reward, dopamine neurones no longer respond to receipt of the reward. In this latter case, the reward is accurately predicted because of the occurrence of the preceding predictive stimulus. What is now observed is a prediction error at the time of the earliest predictor of this reward, for example at time of presentation of a predictive CS stimulus. Prediction error type brain responses have also been shown to occur in the human striatum and orbital-prefrontal cortex during both Pavlovian and Instrumental learning in humans, as measured by fMRI.[13,14] Indeed, a crucial link between a dopamine prediction error signal, human striate activity and reward-related choice behaviour in humans has also been shown using fMRI techniques. In this latter case, a reward outcome prediction error signal was enhanced by boosting the impact of dopamine using L-dopa (a precursor of dopamine), while a dopaminergic blocker Haloperidol led to an attenuation of a prediction error signal. Crucially, the former manipulation was associated with enhanced reward learning while the latter was associated with impaired reward learning in a manner that indicates that a reward outcome prediction error is involved in shaping optimal behaviour.[15]

How emotion influences memory

The cognitive domain where the modulatory influences of emotion have been best characterized is with respect to episodic memory, the type of memory that underpins autobiographical experience. Emotion enhances episodic memory function as seen in an enhancement for material that encompasses personal autobiographical, picture, and word based-items, an effect best seen in free recall tasks.[16] The critical role played by the amygdala in this modulation is illustrated by functional neuroimaging experiments where amygdala activity during encoding predicts a benefit in later recall of emotional material relative to neutral material.[17] Thus, enhanced amygdala activity at encoding for both positive and negative stimuli is predictive of later episodic memory function, during free recall tasks.

During encoding of emotional items there are bi-directional interactions between amygdala and hippocampus, the latter structure being a region essential for episodic memory formation. The bi-directional interaction between amygdala and hippocampus is inferred from the fact that an enhanced amygdala response, measured using functional neuroimaging, to presentation of emotional items is dependent on influence from hippocampus. Conversely, an enhanced hippocampal response to emotional items is dependent on influences from the amygdala.[18] While these studies were carried out at encoding it is important to acknowledge a role for the amygdala during retrieval of emotional items and contexts.

How emotion influences perception

Emotion often signals an environmental event of value. From an evolutionary perspective, it is important that such occurrences are amenable to privileged perceptual processing. There appears to be two distinct mechanisms by which emotion can influence perception of such event. One of these is through emotion grabbing attention, leading to enhanced deployment of attention to an emotional eliciting stimulus. This would result in preferential detection of emotional events enabling appropriate adaptive responses to be enacted.

There is also evidence for a second means by which emotion can influence perception that appears to operate independent of attention. For example, in visual backward masking paradigms, a target presented for a brief instance can be rendered invisible if it is immediately followed by a second 'masking stimulus'. In situations where the hidden target stimulus is an emotional item, for example, a conditioned angry face or a spider, there is preserved processing. This is evident in differential skin conductance responses (SCRs) to fear-relevant compared to fear-irrelevant unseen targets.[19] Similar findings are reported using what is referred to as an attentional blink paradigm. The latter refers to a situation where detection of an initial target stimulus, in a stimulus stream, leads to impaired awareness, or inattentional blindness, for a successive second target. Critically, when this second target has emotional content there is an increased probability of its detection as opposed to the default attentional blindness.[20]

In terms of anatomical substrates of these modulatory effects, there is compelling evidence to implicate the amygdala. In functional

neuroimaging experiments, using visual backward masking paradigms, an amygdala response discriminates between unseen emotional and unseen non-emotional target.[19] In other experiments that involve overt stimulus presentation, but where attention is systematically manipulated, such that emotional items are presented out of the window of attention, an amygdala response to emotional stimuli is independent of the concurrent attentional focus.[21] Likewise, in studies of patients with either blindsight (loss of primary visual cortex resulting in visual field blindness) or visual extinction (a situation following a lesion to the right inferior parietal cortex whereby subjects cannot consciously represent stimuli in the contra-lesional visual field) demonstrate an amygdala response to emotional stimuli presented out of awareness in the damaged hemifield.[22]

How pre-attentive processing of emotional events influence, and enhance, perception is an important mechanistic question. One possibility is that inputs from emotional processing regions, in particular the amygdala, modulate the very regions involved in object perceptual processing, specifically when this relates to an emotion eliciting object or event. Anatomically, the amygdala receives visual inputs from ventral visual pathways and sends feedback projections to all levels of this pathway. Neuroimaging data provide evidence for enhancement of the strength of connectivity between amygdala and extra-striate visual regions during processing of an emotional visual input. In patients with amygdala lesions, the enhancement of activity seen in early extra-striate visual areas during encoding of emotional items, for example faces, is no longer expressed. Crucially, neuropsychological data from patients with amygdala damage indicate that a perceptual enhancement seen in extra-striate visual cortex for emotional items is abolished following damage to this structure.[23] This type of evidence is consistent with a proposal that boosting of activity in early sensory cortices, when an emotional stimulus is encountered, reflects a direct modulatory influence from the amygdala.

The neurobiology of subjective feeling states

Human emotion research often conflates the neurobiological mechanisms that index the perception or occurrence of an emotional event (representational aspects of emotion) with their subjective experiential counterparts, usually referred to as feeling states. Feelings can be formally defined as mental representations of physiological changes that characterize, and are consequent upon, processing an emotion eliciting object event or image.[24] This definition assigns an important causal role in the genesis of subjective feeling states to afferent feedback to the brain from the body, both sensory and neurochemical. At a broader level, feeling states can be thought of as reflecting the operation of homeostatic mechanisms that underlie survival of the organism. In a recent theoretical model, based on neurological observations, prime emphasis is given to the cerebral representation of bodily states as providing the substrate for the conscious awareness of feeling states.[25]

A key neurobiological question is whether brain systems supporting emotional perception are distinct from those supporting feelings states. Candidate structures that mediate feeling states encompass those involved in bodily homeostasis and that process information regarding the bodies internal milieu including brain stem peri-acqueductal grey (PAG) and parabrachial nuclei, tegmentum, hypothalamus, insula, somatosensory and cingulate cortices. Functional neuroimaging provides strong evidence that feeling states are mediated by distinct neuronal systems to those that support emotional perception.[26] Thus, functional neuroimaging studies of volunteer subjects have shown that the central generation and re-representation of peripheral autonomic states involve structures such as anterior cingulate and insular cortex. For example, recall of subjective feeling states associated with past emotional experiences engages regions encompassing the upper brainstem nuclei, hypothalamus, somatosensory, insular and orbitofrontal cortices. In subjects with pure autonomic failure (PAF), where there is absence of visceral afferent and information regarding the peripheral body state due to selective acquired peripheral autonomic damage, there is attenuation of subjective emotional feelings as well as emotion evoked neuronal activity in regions implicated in mediating feeling states, such as anterior cingulate and insula cortex.[27]

Among the regions most strongly implicated in mediating subjective feeling states is the insula cortex, an extensive region of cortex enfolded from the cortical surface within temporal lobes. Direct evidence for its role in representing subjective feeling states comes from investigations that tap awareness of internal bodily states, such as that required in performing a heartbeat detection task.[28] In this task, subjects who have the ability to detect and accurately report their own heartbeat, which is seen as evidence of somatic awareness, show enhanced activity in the anterior insula cortex when performing such a task.[29]

The proposal that the insula cortex area mediates subjective feeling states is bolstered by evidence that empathetic awareness of the subjective feeling states of others, for example, that engendered when one observes another person receiving pain, is reflected in enhanced activity within anterior insula and cingulated cortex.[30] These same regions are also engaged when a subject is exposed to a pain eliciting stimulus suggesting the same neural matrix that represents subjective feeling states is engaged when representing the subjective feeling states of another person.

(a) Imaging emotional influences on decision-making

Emotion is frequently invoked as influencing decision-making, often detrimentally, a view that tends to pit a hot 'irrational' emotional decision system in opposition to a cold 'rational' cognitive decision-making system. This dichotomy almost certainly represents a simplification and there are compelling neurobiological reasons to suggest multiple decision-making systems in the human brain with emotion in many instances facilitating optimal decision-making.

Real-life decision-making often involves choices between actions which yield potential rewards or punishments, albeit with some element of uncertainty, for example, as manifest in varying probabilities and magnitudes of outcomes. Adaptive decisions that seek to optimize goal-oriented behaviour require an estimation of expected future reward that will follow from choosing a particular action. This behaviour can be described as utility maximization. As outlined previously, reward prediction based on expected reward value can be studied through classical conditioning, in which an arbitrary cue (or conditioned stimulus) takes on predictive value by association with subsequent delivery of an affectively significant or unconditioned stimulus (which can be a reward or punishment, or strictly speaking, an appetitive or aversive stimulus).

Neuroimaging studies implicate OFC alongside structures such as amygdala and ventral striatum in prediction for reward and punishment.[31] As described above, human neuroimaging studies of classical conditioning for reward have highlighted a prediction error signal in prominent target areas of dopamine neurones, including the striatum and OFC. The finding that a neural reward prediction error signal is expressed, present in OFC and striatum, and indeed throughout the reward network, is consistent with the idea that this signal provides a basis for flexible learning and updating of stimulus-reward associations.[33]

Accounts of human decision-making emphasize rationalistic perspectives which invoke analytic processes mediated by an executive prefrontal cortex. An emotional or value based contribution to high level decision-making is evident following ventromedial prefrontal cortex damage where, despite the absence of intellectual deficits, such patients often make real life decisions that are disadvantageous.[33] The types of deficits seen in these patients have been conceptualized as a myopia for the future, in which current needs (as opposed to an integration of current and future needs) dominate decision-making. Observations from patients with this type of lesion has led to the suggestion that this ventromedial OFC provides access to feeling states evoked by past decisions during contemplation of future decisions of a similar nature. Thus, evocation of past feeling states biases the decision-making process, towards or away from a particular behavioural option.[34] However, alternative frameworks that might explain behavioural deficits seen following damage to this region include an inability to represent the value of competing options for action or extreme discounting of future rewards (a myopia for the future), leading to an overvaluing of current as opposed to future rewards.

It is well recognized that normative human decision-making does not always accord with rationalistic perspectives of utility maximization. An influence of prior emotional experience on decision processes is captured by the consequences of an emotion such as regret. Regret is an emotion generated by counter-factual thinking involved in comparing an obtained and foregone outcome which indicates to the subject that the latter, if chosen, would have been more advantageous. In this sense, regret is also a prototypical example of a secondary or higher order emotion, meaning that it emerges out of cognitive or higher order processing as opposed to being stimulus elicited as in the case of fear or disgust (prototypical exemplars of primary emotions). It is known that subjects who experience regret as a consequence of a choice show a subsequent bias away from a rationalistic imperative that invokes a maximization of expected value when making similar choices, an effect that can be explained as regret minimization. This behavioural bias is associated with engagement of the amygdala and orbitofrontal cortices regions, that are also engaged by the actual experience of regret.[35] This pattern of brain response is consistent with theories that suggest evocation of past emotions in the context of decision-making, providing a biasing influence on rational decision processes.

An additional tenet of rational behaviour is the idea that human decisions should be consistent regardless of how choices are presented. One notable deviation from this axiom is described as a framing effect. In simple terms, the framing effect describes a bias in decision-making observed when choices are presented in terms of gain, leading to choices of a sure as opposed to a risky option, versus the same choices presented in a loss where subjects are biased to choose a risky option. Functional neuroimaging data show that a framing engendered bias in human decision-making, risk aversiveness in the gain and risk seeking in the loss frame, is associated with enhanced amygdala activity at the point of decision-making.[36] The suggestion here is that an emotional heuristic, mediated via key emotion processing brain regions, is invoked when humans make decisions under situations where information is incomplete or overly complex.

Conclusions

The neurobiology of human emotion has now undergone a radical revision with the development of sophisticated neuroimaging technologies. There is a clear evidence that it no longer makes sense to think of the brain in terms of simple dichotomies such as limbic and non-limbic. Emotion engages widespread regions of the brain with the precise regions being dynamically configured as a function of behavioural context. Thus, patterns of brain activity evoked by the seeing a fear eliciting stimulus, such as a snake, are distinct from those evoked when seeing another person in pain. The former situations involve activation of the amygdala and through its modulatory effects it influences widespread interconnected regions, including early sensory cortices. The latter situation results in engagement of distinct structures such as the insula and cingulate cortex. Learning about likely emotional occurrences involves a distinct teaching signal, a prediction error, expressed in widespread brain regions including the striatum and OFC, the latter region mediating a flexible representation of the value of emotional occurrences including reward.

2.5.5 Neuropsychological basis of neuropsychiatry

L. Clark, B. J. Sahakian, and T. W. Robbins

Introduction

Neuropsychology makes an essential contribution to neuropsychiatry. It seeks objectively to characterize mental competence in component cognitive functions such as perception, attention, spatial cognition, memory, learning, language, thinking, and 'executive' function. Executive function is often associated with the functions of the frontal lobes, although these are not at all synonymous; we will pay special attention to this domain below, as it may be crucial to the understanding of several neuropsychiatric disorders. Neuropsychology is often conveniently divided into clinical neuropsychology and cognitive neuropsychology. The former is primarily concerned with the methodology and psychometric theory that lies behind the selection, administration, and interpretation of standardized psychological tests aimed at assessing deviation from the norm and an individual patient's profile of strengths and weaknesses with a view to optimizing functional outcome and quality of life. Cognitive neuropsychology, by contrast is more concerned with the elucidation of cognitive processes through the study of patients, using both classical and newly devised tasks.[1] Neuropsychology also forms part of cognitive neuroscience, which has as its major goal the understanding of normal, as well as abnormal cognitive function, not only through the neuropsychological study of patients and healthy controls, but also using other techniques, including functional neuroimaging and the use of transcranial magnetic stimulation or psychopharmacology. In practical

terms, a neuropsychological assessment is often made together with a psychiatric examination; in addition to contributing to diagnosis it also helps to define the functional status of the patient.

Functions of neuropsychological assessment

These are perhaps easiest to define when there has been an organic brain injury causing a lesion; for example, due to a stroke, removal of a tumour, or a closed or penetrating head injury. It is clearly vital to have an accurate evaluation of a patient's cognitive status so that his or her care can be optimized. This applies equally in neuropsychiatric disorders. In conditions like attention-deficit/hyperactivity disorder (ADHD) or prodromal Alzheimer's disease, the cognitive examination provides essential information for making a diagnosis. Whilst acquired brain damage can lead to neuropsychiatric symptoms (e.g. depression or apathy), it may also be associated with specific patterns of cognitive deficit. However, most neuropsychiatric disorders are not associated with clearly defined brain injuries, but are instead hypothesized to result from the cumulative effects of neurodegenerative disease, neurotransmitter malfunctions, developmental hypoplasias, diffuse white matter lesions, or brain volume gains and losses. This is an important point, as it may require more sensitive new methodologies to characterize deficits produced by regional *overactivity*, or deficits associated with changes in regional *connectivity*, as distinct from brain lesions per se. In these examples, neuropsychology offers the opportunity to examine underlying pathophysiological mechanisms, in combination with other methods such as structural and functional brain imaging and evoked brain potentials.

Cognitive deficits (e.g. of memory) can exist in parallel to, and independently of, psychiatric symptoms (e.g. of melancholia) but they may also be intrinsic to them. For example, part of the psychiatric description of anxiety may emphasize abnormal attentional biases paid to threatening stimuli, which can be objectively assessed using cognitive testing.[2] Furthermore, some psychological factors may influence performance across a number of distinct cognitive domains, producing a broad profile of impairments from a relatively specific form of deficit. For example, patients with depression may show a 'catastrophic response' to receiving error feedback during testing, such that they are then more likely to respond incorrectly on the subsequent trial.[3] This interaction of emotional and social factors with cognitive processes forms an especially important part of neuropsychology as applied to psychiatry. Neuropsychology also enables the impact of neuropsychiatric symptoms to be assessed on functional status—whether the patient will be able to function in everyday life, and return to paid employment, and how rehabilitation may be best achieved. It is becoming clear that the effective treatment of certain symptoms (e.g. psychotic symptoms) can sometimes unmask profound cognitive impairments that are actually the main barrier to rehabilitation, as has recently been shown in schizophrenia.[4,5] Taking into account the corollary finding that cognitive status may be the best predictor of functional outcome and return to paid employment, this has made cognitive disabilities a new target for pharmaceutical treatment. Of course, with schizophrenia again in mind, it is also necessary to ascertain that medication is not associated with significant cognitive toxicity, for example in terms of sedation, distractibility, or impaired judgement. Neuropsychology must play a major role in providing such evidence. Sometimes neuropsychology may substantially contribute to the diagnosis itself of a psychiatric state, for example in dissociative disorders and in the study of fatigue disorders and malingering.

Principles of neuropsychological testing

Neuropsychological scores on most tests are standardized with respect to overall age, IQ, and ideally gender. Parallel forms of tests exist in different languages although cultural and ethnic factors are still difficult to take account of adequately. Testing is generally done in a quiet room without distraction by an experienced clinical neuropsychologist. Most tests have generally been shown to give consistent results when given by different testers and on different occasions to the same patient, when using standardized instructions. These 'inter-tester' and 'test–retest' forms of reliability are often critical factors in situations where testing has to be repeated, for example, in drug trials, or epidemiological studies.[6] Good test–retest reliability (i.e. $r > 0.8$) can be hindered by practice effects that markedly change how subjects approach the tasks. Such factors typically affect measures of executive function, where the subject may evolve strategies for dealing with the task over repeated test sessions. The various cognitive domains are usually tested in one or two sessions that contain an assortment of tests drawn from the types described above to provide a cognitive profile of the patient. The duration of the test sessions should be carefully considered in view of the concentration span and distractibility, or apathy of many patients. Neuropsychological test batteries normally comprise a selection of paper and pencil tests which are being supplemented increasingly with computerized elements. Computerized tasks benefit from the ease and accuracy of recording and analysing complex data (e.g. reaction times), and of standardizing the presentation of the test materials and trial-by-trial feedback. The Cambridge Neuropsychological Test Automated Battery (CANTAB), for example, utilizes a touch sensitive screen that allows the subject to interact directly with the test materials and obviates the need for divided attention between a video monitor screen and keyboard or desktop. Other possible advantages of computerized testing include the removal of the 'confrontational' or 'interrogative' elements of conventional testing, which may be especially advantageous when testing, for example, schizophrenic patients. The construction of batteries may also be affected by other factors such as the need to translate findings, presumably through the use of non-verbal tests, across species, based on the extensive knowledge of underlying neurobiological mechanisms gained through studies of non-human primates. Alternatively, there is a trend to customize neuropsychological batteries so as to focus on typical deficits in a given disorder, as illustrated by the recent derivation of the MATRICS battery for cognitive deficits in schizophrenia.[7]

Domains and neuropsychological tests of cognitive function

Neuropsychological assessment is made generally with respect to the overall profile of cognitive performance. For example, it is difficult to interpret an apparent memory deficit if the subject has a profound impairment in perception or attention. An important index of overall performance is the intelligence quotient, or IQ. The structure of intelligence is still being debated; whether there is a distinction for example between Cattell's fluid and concrete

intelligence, and the possible existence of a general factor, Spearman's *g* versus Thurstone's more specific components.[8] Regardless of these theoretical issues, it is still useful to classify an individual in terms of their overall intelligence with a mean scaled score of 100 and a standard deviation of 15. IQ is often measured using sub-tests from the Wechsler Adult Intelligence Scale (or the child equivalent, the WISC), which broadly subdivides into verbal and non-verbal ('performance') components. The individual sub-tests include such categories as vocabulary, information, comprehension, arithmetic, digit span, similarities, block design, picture arrangement, picture completion, object assembly, and digit symbol, which thus probe a range of abilities from general knowledge and basic language skills to memory span, working memory, visuo-spatial construction, and psychomotor speed. As the time taken to make all these assessments can be prohibitive, a 'prorated' score based on a smaller selection of the tests is often employed, justified by the relatively high inter-correlation of performance among the 12 sub-tests. Intelligence is also measured effectively by the Raven's Matrices, a set of visuo-spatial problems based on analogies.

Frequently, it is useful to be able to gauge the patient's premorbid intelligence level, before the onset of psychiatric symptoms. One way of estimating this is from years of education, as frequently employed in the United States. A second method depends on the National Adult Reading Test (NART), an instrument that depends on the subject's ability to pronounce infrequent words; this correlates with educational level, and its utility was realized when it became apparent that patients with Alzheimer's disease showed relative sparing of reading abilities, thus enabling their premorbid IQ to be captured by this test.[9] Alongside its US analogue, the Wechsler Test of Adult Reading (WTAR), the NART is now widely used to estimate premorbid intelligence in neuropsychiatric disorders including schizophrenia.

Superimposed on this general assessment of IQ is performance on tests of more specific abilities. The Wechsler Memory scale provides a method by which memory can be assessed in the context of overall intelligence. Some of its components, such as the Logical Memory test are still much used. However, with our burgeoning theoretical understanding of the components of cognition has come the introduction of ever more sophisticated instruments for measuring sub-components of cognitive performance. This brief chapter can but summarize some of the consequences of this, and encyclopaedic compilations of the various tests are now available, together with details of their mode of administration and interpretation.[10] However, the main domains of function that are generally evaluated are now outlined.

Over and above basic clinical sensory testing, measures of higher order perception in either the auditory or the visual modalities are available—for example, the Visual Object and Space Perception Battery.[11] Memory function is a controversial and complicated area of assessment. Most rapid batteries include tests of recognition memory, simply deciding whether or not a stimulus is familiar or not. Recent evidence, for example from the animal literature, suggests that such memory is relatively independent of hippocampal function, and depends instead on such regions as the perirhinal cortex.[12] Verbal recall, particularly a free recall, is considered to be a more demanding form of memory, thought to require the coordinated functioning of medial temporal lobe and frontal lobe structures. The frontal lobes are also implicated in retrieval of the temporal sequence or order of events, or the source of a particular memory in the past. Tulving's distinction between episodic and semantic memory is still influential.[13] Episodic memory generally refers to the subjective reminiscence of an event that has 'what, where, and when' qualities, almost invariably associated with a person's autobiographical memory. By contrast, semantic memory reflects memory for facts that may well have a different form of representation within the temporal lobe and is importantly influenced by verbal processes. In addition to these various modalities of memory material, are specific memory processes that have to be evaluated, such as encoding and retrieval. The latter is often assessed efficiently by the so-called verbal fluency tests, in which subjects have to retrieve words from a semantic category (e.g. animals) or beginning with a specific letter (e.g. F) in a set time period, usually of 60 s. Standardized tests of learning of verbal or non-verbal forms of material are provided by the California Verbal Learning Test (CVLT), the Rey Auditory Verbal Learning Test (RAVLT), and the CANTAB Paired Associate Learning (PAL) test. Emotional memory, which almost certainly implicates such structures as the amygdala, is another area of memory research that requires urgent development for application to psychiatry, for such conditions as Post-Traumatic Stress Disorder (PTSD). However, it is difficult to see how the current tests of traditional neuropsychology can be of much assistance here when the problem is to quantify the disruptive effect of a specific memory that has become over-salient rather than inaccessible.

Working memory is another important component of memory that refers to the coordination of various short-term memory stores to provide more permanent representations and aid in the solution of ongoing activities such as planning and discourse. Working memory comprises short-term visuo-spatial and verbal memory stores, with postulated rehearsal processes (e.g. the articulatory 'loop') and a 'central executive' system. Perhaps a simple way of understanding what working memory accomplishes is to contrast digit span in a forward and backward modes (e.g. repeat back the sequence '5 2 3 7 1' in either the same order, or in the reverse order). In the former case, it represents the buffer capacity of the verbal store, whereas in the latter case, the response sequence requires manipulation at output. Working memory reflects the active ('conscious') processing of memory traces whether at the encoding or retrieval stages and is clearly dependent on such factors as attention and arousal level.

Attention is a complex theoretical construct that has gained much in recent years from its analysis in terms of underlying neural systems.[14] Unfortunately, despite the interest in attention from experimental psychology, there are not many standardized tests of attention in general use. A common distinction is between the automatic forms of 'covert' attention mediated by posterior cortical structures and voluntary forms engaged by anterior cortical (cingulate and prefrontal cortices).[15] In practical terms, tests are usually provided of *sustained attention*, which might include detecting infrequent visual or auditory targets in 'continuous performance' tasks over a protracted period of several minutes. *Vigilance*, the capacity to detect rare targets over very long time periods, is rarely assessed, for obvious practical reasons. The capacity for *selective attention* is very important to assess in psychiatry because of the evident distractibility of patients with anxiety, psychosis, or attentional deficit/hyperactivity disorder. Selective

attention can be assessed with a variety of tests including the Stroop task, the Eriksen Flanker paradigm, or the Posner covert spatial attentional task. In the Stroop test, for example, the subject is required to name the ink colour of congruent or incongruent colour words (e.g. the word GREEN prinked in red ink). Resolution of response conflict is a key feature of this test, which has been associated with anterior cortex function through extensive investigation with functional brain imaging.[16] The Stroop test has been much used in psychiatry, both in its standard form and in various adapted forms with disorder-relevant stimuli. In the Alcohol Stroop, for example, alcohol-related stimuli (e.g. BOTTLE in red ink) may also interfere with naming of the ink colour in patients with alcohol-dependency problems.

There is, in fact, considerable overlap between tests of working memory, attention, and what is termed executive function. The notion of a set of control functions that optimize performance is controversial but seemingly necessary in accounting for performance on complex tests involving planning and decision-making. Planning is generally measured by such tests as the 3-disc Tower of London task, which requires subjects to move discs in one array to match the goal arrangement of another. The test is especially useful in its form where the subjects are not allowed to move the discs but are required to visualize and plan the solution in their 'mind's eye'. Validation of this test as being sensitive to frontal lobe function has come from the study of patients with neurosurgical lesions of the frontal lobe and also functional brain imaging.[17] However, it should be realized that there is no such thing as a 'frontal lobe' test; this is evident for example from studies of patients with basal ganglia lesions and also from the demonstration of an extensive neural network that is activated during spatial planning performance. The Tower of London is a planning task where there is one goal only, whereas many real life situations that overwhelm psychiatric patients require the optimization of performance on several task simultaneously. This requires high level planning and scheduling of behaviour, as tapped by the 'Six Elements Test' in which six different tasks have to be completed.

A further cluster of executive tasks tap into higher-level emotional and affective processes, which appear to be associated with the inferior parts of the frontal lobes including the ventromedial prefrontal cortex. Famous neurological case studies like Phineas Gage and EVR displayed profound changes in personality, social behaviour, and judgement after lesions to this brain area. These processes are also often defective in psychiatric disorders such as bipolar disorder and schizophrenia, which resemble in some respects, the problems in everyday life encountered by patients with ventromedial prefrontal cortex lesions. The Iowa Gambling Task is a measure of emotional decision-making that was developed for the assessment of such patients. The Iowa task allows subjects to 'play' with four decks of cards which vary in their pay-offs, such that two risky decks are associated with attractive short-term gains but with heavy occasional penalties over time. Typically, patients with ventromedial frontal lesions persist in selecting from these 'dangerous' decks, despite accruing considerable debt, and comparable neuropsychological deficits have also been seen in neuropsychiatric conditions, particularly drug dependence.[18] These tasks also draw on concepts of inhibitory control over behaviour, as there is a requirement to suppress responses that have either become dominant through repeated practice, or that are superficially attractive by virtue of immediate reinforcement.

Specific applications of neuropsychological tests to psychiatric disorders

(a) Standardization of neuropsychological assessment in schizophrenia

Now that cognitive deficits have been realized to be a core problem in schizophrenia, there is increasing attention being focused on the nature of these cognitive deficits and how to remediate them, for example by novel pharmacological treatments. In order to facilitate this process, NIH funded researchers to perform a meta-analysis of the cognitive deficits in schizophrenia in order to determine a profile of deficits and to construct a battery that would be sensitive to those deficits and to possible remediation.[19] They provided a principal component analysis suggesting cognitive impairments to be present in seven major domains: attention and vigilance, visual long-term memory, verbal long-term memory, working memory, reasoning and problem solving, psychomotor speed, and social cognition.[7] In fact, there was not very much published evidence for prominent deficits in the latter, but the investigators felt that it was justified to include it on the basis of clinical judgement. This led secondarily to the construction of a test battery for those domains, with a major requirement being its test–retest reliability. This battery is being used now in clinical trials and so it is too early to assess its utility. As with many other initiatives to provide a standard battery, this carries with it both advantages and disadvantages. A consensus battery is clearly of enormous value and aids the collection of data across multiple sites. Hard decisions do have to be made about the trade-off of reliability with validity and sensitivity and committees have to make compromises because of the difficulties of addressing these sometimes intangible issues. For example, the Wisconsin Card Sort test is clearly sensitive to deficits in schizophrenia, but it does have relatively poor test–retest reliability because of its intrinsic changes of contingency and requirement for cognitive shifting, and so has been excluded. However, it is possible that performance on such a test would be sensitive to cognitive enhancing drugs. Similarly, all tests using verbal material are problematic because of the need to provide translated versions whose reliability and relationship to the existing test has to be reassessed to determine its validity. Once batteries such as MATRICS are adopted it is sometimes difficult for innovative methods based on other theoretical perspectives, such as contemporary cognitive neuroscience to be developed. However, the recognition of a domain of cognitive function, social cognition, for which there are relatively few standardized instruments available has been useful for motivating new research and test development in that area. The final crucial issue, which has a much more general applicability than the MATRICS battery, is the need to relate the profile of deficits obtained to sensitive and reliable measures of functional outcome.

(b) Early detection of Alzheimer's disease

Alzheimer's Disease (AD) is a chronic and severe form of dementia that is increasing in prevalence as improved health care extends life expectancy. AD patients typically present with deficits in episodic memory; that is, memory for specific events or experiences that can be defined in time and space. AD poses an important challenge to neuropsychologists, to facilitate the early detection of the illness, so that future generations of pharmacological interventions may be administered to patients at the earliest opportunity, so that the

rapid decline may be slowed, or eventually, halted. Individuals in the prodrome of AD often report subjective memory problems but do not fulfil clinical criteria for AD, in that activities of daily living and non-memory cognitive faculties are intact. This condition is referred to as Mild Cognitive Impairment (MCI) or 'Questionable Dementia'. There is accumulating evidence that the Paired Associates Learning test in the CANTAB assessment may be sensitive to the early stages of AD. PAL is a non-verbal test of learning and memory that requires the subject to associate abstract visual patterns with a series of box locations on a computer screen. Successful performance relies on learning the conjunction of shape and location; the task cannot be solved by learning either shape or location alone. The task increases in difficulty from one to eight patterns, and the task is terminated if the subject fails repeatedly at a given stage.

PAL performance was previously shown to be defective in patients with mild Alzheimer's disease, and test scores could discriminate AD from other neuropsychiatric conditions with similar symptom presentation, including Fronto-Temporal Dementia and unipolar depression.[20] Recent studies of 'at risk' older adults with MCI or Questionable Dementia have reliably isolated a subgroup of cases who have an increased likelihood of converting to a full AD diagnosis by the time of a follow-up assessment. PAL performance in the baseline assessment could be used to accurately predict the conversion from Questionable Dementia to an AD diagnosis.[21] Through a combination of age, PAL score, and performance on the Graded Naming test, subjects with Questionable Dementia could be classified with 100 per cent accuracy into those who did or did not convert to probable AD at a 32-month follow-up.[22] These neuropsychological measures display both sensitivity, in reliably detecting the progression to AD in a subclinical sample, as well as specificity, in differentiating AD from depression. A strong programme of translational research with the PAL task suggests this utility may stem from the critical role of medial temporal lobe structures in visuo-spatial associative learning.

(c) Relating neuropsychiatric disorders to specific impairments in executive function: ADHD, OCD, and mania

Recent biological analyses of such disorders as bipolar illness, ADHD, and OCD have focused on the importance of providing objective measures of performance that relate strongly to the clinical symptoms themselves, but that also provide sensitive indices of the underlying pathophysiology. These markers are often referred to as endophenotypes, a term that draws a further link to the putative genetic susceptibility to these conditions. One example is the profound deficit in thinking and decision-making that is a characteristic symptom of mania—a recent study has been able to demonstrate deficits in decision-making in patients with mania in the context of a gambling task.[23] What was especially striking about that study was that one of the main measures of quality of decision-making correlated significantly with symptom ratings on the Young Mania scale.

ADHD is a spectrum disorder with several sub-types that are characterized by the prominence of different clusters of symptoms that may be related to different underlying psychological constructs, neural and neurochemical substrates, and genetic factors.[24] Prominent among these is the so-called hyperactive/impulsive sub-type, which then requires sensitive and reliable measures of behavioural inhibition. One commonly used test is the Go-No-Go type task. In perhaps its most sophisticated form, this task measures the capability to countermand a speeded response (the 'stop signal reaction time (SSRT) task). The speed of the SSRT has been related to the volume of damage in the right inferior frontal gyrus in patients with frontal damage.[25] The task is also robustly impaired in children and adults with ADHD, and this deficit can be remediated by psychostimulant treatment with drugs such as methylphenidate.[26]

OCD may also relate to pathology in executive functions. The compulsive component in particular may arise from the repeated selection of a response option long after that option has ceased to be beneficial or contextually appropriate. This symptom may be operationalized in a neuropsychological setting in two complementary ways. First, there may be a failure to suppress a previously reinforced response, comparable to the deficit reported above in ADHD. Second, there may be a failure to flexibly shift responding to the newly-relevant mode. These processes can be assessed with some further tasks that are frequently employed in the assessment of psychiatric patients. For example, the Wisconsin Card Sorting test requires subjects to learn a rule on the basis of trial-and-error feedback and then to shift that rule according to altered feedback. OCD patients, like neurosurgical patients with frontal lobe lesions, display perseveration where they continue to sort cards according to the previously reinforced rule. Performance on a similar set-shifting test has been shown to be impaired not only in patients with OCD, but also in their first-degree relatives, implying that this capacity for cognitive flexibility may provide a suitable endophenotype for this disorder. Structural and functional neuroimaging data support a neuropsychological account that implicates the orbitofrontal region and interconnected (ventral) striatal circuitry in the pathophysiology of this condition.[27]

Conclusion

Psychiatry is the science of psychopathology, and as such, the measurement of behaviour and cognition is central to its theory and methodology. Neuropsychology provides such measures, which can be used to augment the psychiatric interview and other clinical instruments, as well as to provide an interface with other important approaches including functional brain imaging (see Dolan, this volume), functional genomics, and clinical psychopharmacology. Clinical neuropsychology has developed via the need to assess brain-damaged patients, whereas in most neuropsychiatric disorders, such damage is much less well defined if it is present at all. Thus, whilst there is growing information about specific brain abnormalities in many forms of neuropsychiatric disorder, the lesion model is not necessarily the most appropriate. Moreover, some of the deficits in disorders such as depression and anxiety involve subtle interactions between specific emotional and attentional mechanisms with cognitive function. Therefore, the study of neuropsychiatric patients has also enriched our understanding of clinical neuropsychology. We predict that these aspects of the discipline will develop considerably in the next few years, particularly in combination with data from other domains such as functional brain imaging and pharmacogenetics. Indeed, the specification of specific neural systems implicated in core behavioural or cognitive processes may well aid the enterprise of psychiatric genetics by providing more precise definitions of phenotypes (or endophenotypes)

than are currently feasible in nosology (e.g. as defined by the Diagnostic and Statistical Manual).

A further theme for the future that can readily be envisaged is the development of neuropsychological methods for children and adolescents that are more suitable in a psychiatric context. We can predict that there will be an increasing emphasis on 'lifespan' studies that potentially will enable the origins of many psychiatric disorders and prodromal states to be identified. Thus, it will be necessary to examine cognitive function, including under-researched areas such as 'social cognition', in longitudinal terms with tests that can be administered appropriately at different points in the lifespan. Allied to this will be pressure to make tests less 'laboratory-bound' and more predictive of everyday functioning at school or in the workplace. One technological advance that may facilitate all of these requirements would be through the use of 'virtual reality' software, and also the collection of norms on a massive scale by utilizing web-based data collection. It is to be hoped that psychiatry will encourage and embrace such developments, rather than rely on the traditional methods.

2.6.1 Medical sociology and issues of aetiology

George W. Brown

Introduction

David Mechanic, in his pioneering textbook, *Medical Sociology*,[1] views human activity within an adaptive framework—as a struggle of human beings to control their environment and life situation. While this view informs the research to be outlined, there are a number of ways it differs in emphasis from much medical sociology. First, by its concern with particular disorders defined in medical terms. Second, by its use of the investigator rather than respondent to characterize phenomena—to decide, for example, whether an incident should be classified as a life event. Third, by the importance placed on context. In order, for example, for an investigator to make a judgement about the likely meaning of an event such as a loss of a job it is essential to know whether it cast the person in a bad light; its impact on the person's family; her chance of getting another job, and so on. It is such circumstances surrounding an event that usually give it meaning via the emotion they create. Finally, by recognizing that where appropriate such emotion should be taken into account: 'A world experienced without any affect would be a pallid, meaningless world, and it is what gives us feedback about what is what is good or bad about our lives'.[2]

Context and measurement

Concern with context in the social sciences was central to the problem of meaning discussed widely in Germany in the late nineteenth century; and the ideas were introduced into sociology by Max Weber[3] and into psychiatry by Karl Jaspers,[4] although no one showed how to apply the methods systematically to concrete examples.[5] Jaspers, in his *Allegemeine Psychopathologie*, emphasized the way in which *Verstehen*, or understanding, on the part of an investigator 'depends primarily on the tangible facts' (i.e. verbal contents, cultural factors, people's acts, ways of life, and expressive gestures) in terms of which the connection is understood, and which provides the objective data.[4] While this view influenced the approach to meaning in what follows, there is a critical difference. No attempt has been made to make a judgement about the presence of a causal link between a set of circumstances and a psychiatric episode. The investigator has to judge only the likely meaning of a set of circumstances in the light of 'tangible facts' about a person's past and present. Any link with disorder is explored using established scientific procedures.

As noted by Jaspers, it is possible to take note of cultural factors; for example, when rating the likely implications of a birth, as part of research among women in a black township in Zimbabwe, investigators took into account the cultural importance on a wife producing a male child for her husband and his family.[6]

A second, more limited, use of context deals with the actual observation of emotion. For example, the Camberwell Family Interview, by taking account of vocal (in contrast to verbal) aspects of speech, for example, establishes how far a parent's talk about a child conveys 'criticism' rather than 'dissatisfaction'.[7] The approach can be extended to deal with core sociological concepts such as role commitment. For example, mothers in North London have been shown to differ substantially in commitment to roles such as 'mother' or 'wife' judged by how enthusiastically associated activities are discussed.[8] The relevant context is limited to the interview itself and what this conveys about a person's emotional style. In everyday life we automatically make allowances for the fact, for example, that some people show warmth in a more open way and, by taking this into account, makes it is possible for different expressive styles to be treated as equivalent.

Some methodological considerations

These developments have enabled 'soft' variables to be quantified. It has also been possible to make a reasonably persuasive case that significant bias has not followed the use of the investigator as the measuring instrument. For example, Creed[9] in a study of appendectomy found a relationship between severely threatening events rated contextually and the onset of non-inflamed but not inflamed conditions. This result was persuasive for two reasons. First, on the basis of a detailed description of the event and surrounding circumstances a consensus rating team reached agreement about the likely degree of threat, blind to what the person conveyed she felt and to whether she was a patient. Second, Creed, who provided the team with this edited account, was blind to clinical details. (He consulted medical records after the ratings had been made.) Such flexibility is difficult, if not impossible, with a questionnaire-based instrument which hands over the task of measurement to the respondent.

There are now a number of investigator-based instruments developed to deal with psychiatric issues covering areas ranging from 'expressed emotion' (e.g. critical comments, warmth, etc.), attitudes to self (e.g. self-esteem), plans and concerns (e.g. commitment to various roles), behavioural systems (e.g. styles of attachment), experience of adversity in childhood (e.g. sexual and physical abuse), and characteristics of non-family groups (e.g. restrictiveness of a psychiatric ward regimen). Around each a fair amount of replicable and theoretically relevant findings have emerged. Particularly important was the development in the 1960s of the clinically informed interview-based Present State Examination (**PSE**) by Wing *et al.*[10] later amended to deal with a 12-month period,[11] and psychosocial measures such as that of 'expressed emotion'[12] and the Life Events and Difficulties Schedule.[13] Part of the strength of the resulting research has been due to the levels of inter-rater reliability achieved and the ability of the approach to deal with time order. It is often overlooked that even with longitudinal designs it can be important to be able to establish what has happened between interviews.

Life events and building aetiological models

The characteristic features of the aetiological studies that have emerged can be illustrated by those dealing with life events. The significance of findings concerning depression is enhanced by the fact that most studies have produced broadly consistent findings about the role of events.[14–16] Indeed, for some years the challenge has been not so much to establish the presence of an effect, but to learn more about the nature of the events involved and to integrate findings into a more comprehensive aetiological model.[17]

The role of life events in the aetiology of depression

(a) Measurement and meanings

The original version of the Life Events and Difficulties Schedule was developed to study schizophrenic episodes[18] and there has since been a good deal of research dealing with psychotic patients.[19] An early achievement in the study of depression was to make clear that the amount of change in activity as such appears to be irrelevant and that the impact of events results from their meaning.[13] It has also been clear that attention needs to be given to ongoing difficulties that can either be brought about by an event (e.g. the death of husband leading to financial problems) or lead to an event (e.g. a marital difficulty eventually ending in a separation).

In dealing with meaning, two perspectives have proved productive. The first is summed up by the statement that we cannot fully know the meaning of an event until we relate it in some manner to our concerns. One way of conceiving of these is in terms of the impact of a particular event on plans and purposes that stem from role activity caught up in the crisis: how, for example, being turned down for rehousing by a local authority thwarts a woman's wish to move from an overcrowded and damp flat to give her children 'a better start in life'.

A second perspective concerning meaning assumes the likely presence of evolutionary-based response patterns that help to guide us in terms of what to want or to avoid, and that such systems are sensitive to a particular range of stimuli. The attachment system and fear responses are obvious examples.[20, 21] Of course, such responses will be influenced by individual differences of various kinds and by cultural display rules concerning emotions, but there is good reason to believe that such systems are often involved in the development of psychiatric disorders. For example, the central importance in a number of cultures of 'critical comments' of a close relative rather than 'dissatisfaction' in a schizophrenic relapse probably reflects an evolutionary-based sensitivity to emotionally toned criticism interacting with some constitutional predisposition to the disorder.[22]

The Life Events and Difficulties Schedule deals with both kinds of meaning. Blind consensus ratings usually based on four-point scales, made by several members of a team are employed to rule out reporting artifacts using 'edited' accounts supplied by the person who carried out the interview as discussed earlier in relation to the study of appendectomy. General as well as specific kinds of threat are rated in this way. They are contextual in the sense of taking into account a person's likely concerns of relevance for the event insofar as these can be assessed from a person's current circumstances and biography. In making such ratings no account is taken of reported feelings or whether a disorder followed the event. It deals not only with possible bias on the part of raters, but also with the problem that the cognitive processes involved in the appraisal of an event are not necessarily ones a person is willing or able to report.[23] General guidelines for rating severity of threat are given in an extensive manual containing thousands of examples listed in terms of a number of event categories (such as 'demotion at work' and 'unplanned pregnancy'). A similar procedure is followed for ongoing difficulties.

Some findings concerning depression

The first use of the Life Events and Difficulties Schedule to study depressive conditions took place in the early 1970s and involved a patient series seen at the Maudsley Hospital together with a sample of women from the local Camberwell population. A threshold of 'caseness' reflected what an outpatient psychiatrist would accept as a 'case'.[13] This enquiry, and a number made later, have established that the majority of episodes of clinical relevance are preceded by a severely threatening event.[14–16] These at a minimum had to be judged to continue to convey threat for at least a further 10 to 14 days. Nothing emerged to suggest that events with only short-term threat play a role.

Table 2.6.1.1 gives a typical result from a prospective enquiry of 400 women living in Islington in North London with at least one child at home. The table shows that 29 of the 32 onsets in the first

Table 2.6.1.1 Onset of depression within 6 months of a severe event or a severe difficulty among 303 women in Islington

	Percentage onset
Severe event	22 (29/130)
Severe difficulty and no severe event	5 (1/20)
Neither	1 (2/153)
Total	11 (32/303)

follow-up year were preceded by at least one severe event in the prior 6 months with most occurring within a matter of weeks.[8,23] For example, a woman experiencing a second miscarriage after persistent attempts to have her first child would probably have the event rated severe, but a first miscarriage shortly after marriage would most likely be rated upsetting but not severely so.

This finding emerged despite the use of contextual ratings that, as made clear, are based on a limited amount of information and deliberately designed to be approximate and probabilistic. It was also possible to obtain more direct evidence about the relevance of plans and purposes by a measure of emotional commitment to various roles made at the time of the first interview based on how they were talked about. Where a severe event (e.g. a child's delinquency) in the follow-up year 'matched' an area of high emotional commitment (e.g. to motherhood), risk of an onset was considerably increased when compared with a non-matching severe event.[8]

The contextual approach has also been used to take account of more specific aspects of meaning. Severe events preceding an onset of depression generally involve loss, if this is defined broadly not only in terms of loss of a person but loss of a role or a cherished idea—the latter about oneself or someone close.[24] (In contrast, events preceding the onset of anxiety tend to involve 'danger'—the threat of future loss.[25]) However, although loss is typically present it may not be the factor of central aetiological importance. Table 2.6.1.2 illustrates this by the development of a more comprehensive rating scheme—again carried out by the investigator. Four overall types of meaning are considered, covering in all nine categories. The ratings are hierarchical. Where more than one rating is possible the highest on the scale is taken. The first three categories concern possible types of **humiliation**, i.e. the likelihood of the event provoking a sense of being put down or a marked devaluation of self. The first category, for example, covers separating from a partner or a lover where they either took the initiative or the respondent was 'forced' to leave or break off a relationship because of violence or the discovery of infidelity.

Table 2.6.1.2 Onset by type of severe event over 2-year period in the Islington community series

Hierarchical event classification	No. of onsets	Percentage onset rate
(a) All 'humiliation' events	31/102	30
Humiliation: separation	12/34	35
Humiliation: other's delinquency	7/36	19
Humiliation: put down	12/32	38
(b) All 'trapped' alone events (i.e. not (a))	10/29	34
(c) All 'loss' alone events (i.e. not (a) or (b))	14/157	9
Death	7/24	29
Separation: subject initiated	2/18	11
Other key loss	4/58	7
Lesser loss	1/57	2
(d) All 'danger' alone events (i.e. not (a), (b), or (c))	3/89	3
All severe events	58/377	15

Events associated with **entrapment**, the second main type, had to have failed to meet criteria for one of the three humiliation categories. Such events emphasized the fact of being imprisoned in a punishing situation that had gone on for some time. The third type deals with four kinds of **loss** (in the absence of humiliation or entrapment) with the final type, **danger**, involving threat of a future loss.[24]

The table shows whether a particular severe event (or sequence of closely related events) was followed by an onset of depression, taking the event (or sequence) nearest to the onset when there was more than one event within 6 months of onset. Using a 2-year period for the Islington women, it shows that there were large differences in risk by event type. If events involving humiliation are combined with those of entrapment, risk was increased threefold.[24] The relatively low risk of depression associated with loss alone, except following a severe event involving a death, suggests that while the majority of events involve loss, something more than this is usually involved and that the experience of humiliation or entrapment associated with the loss is often critical.

Diagnostic issues

So far I have discussed only studies dealing with depressive onsets in the general population, almost entirely of a 'neurotic' kind. In the Camberwell enquiry of psychiatric patients, while events were rather less frequent before 'melancholic' than before 'neurotic' depression, there was considerable overlap between the two types. This lack of a clear link between the presence of a provoking life event and type of diagnosis had been reported earlier[26] and also in several subsequent studies.[27,28]

A recent study of North London psychiatric depressive patients has thrown possible light on this somewhat unexpected picture. When episode number was taken into account, those patients with both a melancholic/psychotic diagnosis and a prior episode of depression had a much smaller chance of experiencing a severe event before onset.[29] A patient series from Pittsburgh produced consistent findings.[30] These results, if confirmed, may also help to explain inconsistencies in published results since the proportion with a melancholic/psychotic picture and a prior episode is bound to vary by type of treatment centre. It is also of note that this same London study concluded that, despite detailed questioning, as many as one-tenth of *patients* with a 'neurotic' depressive disorder gave no hint of being provoked by social adversity of any kind.[24]

It is of interest that the smaller number with provoking events as episode number rises has also been found to relate to the course of bipolar conditions where there is some evidence for a sensitization or kindling mechanism.[31] Important research continues to emerge about psychosocial risk factors and bipolar conditions[32] and other psychiatric conditions.[33] However, for this brief review I will continue to focus on common depressive disorders.

Course and remission

Life-event research has also thrown some light on the processes involved in remission from depression. Evidence has begun to emerge that these often involve the reverse of the process leading to onset. A 'positive' event or the reduction in the level of a severe difficulty (with or without an event) is commonly found to have been present in the 20-week period before any remission (or marked improvement). However, it is of interest that although the events involved were rated contextually as likely to have given renewed hope about the future, one-third were at the same time judged as severely threatening.[34]

In the Islington general population series somewhat over half of the remissions of episodes that had lasted 20 weeks or more were preceded by such an event. There was no such link with episodes lasting less than this. In the patient series the result was much the same, although the chances of a positive event or difficulty reduction for those on antidepressant medication was somewhat less.[35]

A different approach to the issue of outcome concerns determinants of the length of a particular episode. Here the presence of severe interpersonal difficulty at the point of onset (but no other difficulty) was an important predictor of whether a depressive episode would go on to last for at least 1 year, and this held for a general population and patient series.[36, 37] Ongoing difficulties therefore need to be taken into account in terms both remission and in terms of whether an episode takes a chronic course.

Psychosocial vulnerability

The part played by severe events in depression has proved to be a particularly effective platform for exploring psychosocial vulnerability. The importance of this question was, in fact, illustrated in Table 2.6.1.1 where, despite the fact that the majority of onsets were preceded by a severe event, only one-fifth of those who experienced a severe event developed depression. While, as already discussed, taking account of event type increases this to one-third, it is still necessary to ask why only a minority go on to develop clinically relevant depression following a severe event.

In the Islington series, two background factors present at the time of the first interview proved highly predictive of onset: a negative environmental factor (negative interaction with others in the home and in addition, for single mothers, lack of a close confidant seen fairly often) and a negative psychological factor (negative evaluation of self). (The presence of chronic anxiety or subclinical depressive symptoms has often been included in the latter index, but findings are broadly similar with only negative evaluation of self.)

Their predictive power can be judged by the fact that, while only 23 per cent of the women without depression at the time of first contact had both, three-quarters of onsets in the 12-month follow-up occurred among these women.[38] The result has recently been confirmed in a second prospective enquiry.[39]

In terms of an overall aetiological model, the predictive power of the two indices appears to be largely a result of relating to a greater chance of a severe event occurring and to a lack of effective emotional support from a close confidant once the event has occurred.[40–43] Consideration of social support, of course, links the research, with social science concepts such as 'social integration', 'social bond', and 'social alienation'.[5] The topic is too complex to pursue in any detail in the present brief review. Research has so far underlined the need to recognize that support at one point in time does not necessarily predict what will occur in a subsequent crisis and, indeed, that a significant aspect of a number of severe events is the fact they involve the withdrawal of social support that up to that point had largely been taken for granted.[43, 44] There is also some indication that the ability of a woman to make supportive ties that can be used in a future crisis, and also to use them in such circumstances, is adversely influenced by the early experience of childhood abuse and neglect.[45, 46]

Figure 2.6.1.1, dealing with the Islington series, sums up research on the issue of vulnerability. It takes into account both event type and vulnerability and it shows that a severe event, however threatening, was not enough to provoke depression without the presence of at least one of the two vulnerability risk factors. Subsequent research has confirmed this general picture.

Gender differences

Most research on depression using the Life Events and Difficulties Schedule has dealt with women, although in the original Camberwell enquiry a small series of men gave similar results, as did a subsequent population enquiry.[24] However, recent research has gone further to suggest that the well recognized greater risk of a depressive onset among women may relate to their greater sensitivity to severe events involving their role as mothers. In a study of couples experiencing a severe event in common, women were twice as likely to develop a depressive episode following events involving procreation, children, and housing; for other events, risk was much the same.[47] While this study requires replication, it does support the increasingly held opinion that the large gender difference in the experience of 'neurotic' depression is likely to have an essentially psychosocial explanation.[48]

A lifespan perspective

So far only current environmental circumstances have been taken into account. The Camberwell research also identified loss of a mother before the age of 11 as a risk factor.[43] While there has been a good deal of controversy about this finding,[49, 50] two further population studies produced equally clear evidence with the added suggestion that such a loss between 11 and 17 may also increase

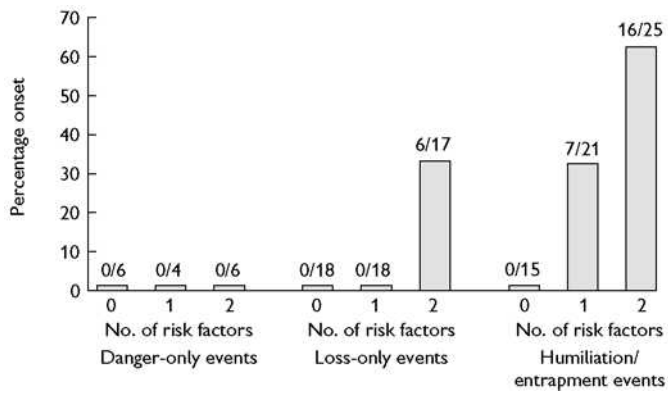

Fig. 2.6.1.1 Onset rate among 130 Islington women with a severe event by type of event and number of background risk factors.

risk.[51,52] The mode of the impact of such an early loss of mother for women is undoubtedly complex, but several studies have now established the critical importance of untoward experiences during childhood *after* the loss and have downplayed the role of loss as such.[51] More important than the loss of the mother itself was the quality of replacement parental care (in terms of an index of parental indifference or lax control). Risk of adult depression was doubled for those positive on the index.In order to understand its link with later adult depression it has been necessary to trace the history of a woman from the loss itself to such depression in a way that makes it possible to gain some sense of a life trajectory. Certain early experiences are particularly associated with the chance of experiencing the kind of adult factors already discussed.[53]

A factor playing a critical mediating role was the experience of a premarital pregnancy, and, like the care index itself, this was found to be associated with the subsequent experience of severe events. What seemed to be crucial about these premarital pregnancies was that they often trapped women in relationships which they might well not otherwise have chosen and which became a source of ongoing problems—such as severe housing and financial difficulties consequent upon a couple starting a family too young to have built up adequate savings, or marital difficulties with undependable partners. These women also emerged as less upwardly mobile, in terms of social class, than their peers without such pregnancies. In interpreting this complex of experiences, a conveyor belt of adversities was outlined, on which some women often appeared to move inexorably from one crisis to another, starting with lack of care in childhood and passing via premarital pregnancy to current working-class status, lack of social support and high rates of severe events.[53]

Although it was often hard to see from the women's accounts of their lives how they could have left this conveyor belt once their childhood had located them on it, a more personal element is likely to have played a role in many instances. Here the work of Quinton and Rutter[54–57] has been particularly significant in developing a lifespan perspective in this regard, and over this issue the results of the two research programmes have largely complemented each other.

The kind of early adverse experience just outlined was subsequently incorporated into a broader index of childhood adversity that included severe physical abuse within the family and also severe sexual abuse in any setting.[58] This index not only relates to a doubling of the risk of a depressive onset in adult life, but also to a number of other adverse outcomes, for example to the quadrupling of risk of an episode taking a chronic course[59] and also to the risk of a depressive condition comorbid with anxiety disorder defined by DSM-IIIR criteria (excluding simple phobias and mild agoraphobia).[60] It can be added that the retrospectives measures of early maltreatment used in these enquiries appear to be sufficiently free of bias to enable the findings to be taken seriously.[61, 62]

A population perspective

It is useful also to consider 'neurotic' conditions that form the bulk of depressive disorders, even in patient series, in terms of a population perspective. Figure 2.6.1.2 summarizes the findings of six population studies of women aged between 18 and 65 carried out in a comparable manner, using the same semi-structured interview-based measures as in the Islington survey, including the Present State Examination. The bottom half of Fig. 2.6.1.2 shows the rate of depressive 'caseness' in a 12-month period. Between the two extreme populations there is a 10-fold difference—3 per cent in a rural Basque-speaking population in Spain[63] and 30 per cent in a black urban population in Zimbabwe.[6, 64] In addition these rates are fairly closely paralleled by differences in the experience of severe events particularly likely to provoke depression (see top half of Fig. 2.6.1.2).

One of the implications of these results becomes clear in the context of a behavioural genetic perspective. A key point about the concept of heritability is that it is specific to a particular population and based on consideration of individual discrepancies from a population mean. While there may well be a genetic contribution in each of the six populations, this would reflect individual variability in risk within each population. Even if large, the genetic contribution would only be likely to be of relevance for explaining the substantial population differences in rates of depression if there were large population differences in the frequency of relevant genes. On present evidence the most plausible interpretation of such differences is that they are the result of psychosocial factors.[65]

There is, however, no inherent conflict between the two perspectives—they refer to different ways of looking at the 'variance' of a condition.[66] The general point is that the study of individual variability within particular populations cannot rule out the possibility that the mean level of disorder is largely under environmental control; that it can be increased or decreased markedly by external changes quite uninfluenced by the genetic make-up of a population.

A population perspective is also concerned with variability in rates of disorder within populations in terms of social categories such as socio-economic status. Thus, the survey in Camberwell in South London in the early 1970s found that, while the rate of severe events was related to social class position, this explained comparatively little of the large class difference in prevalence of depression; of greater importance were background vulnerability factors such as an unsupportive marriage.[13] However, the picture has recently become more complex with the finding that severe events involving

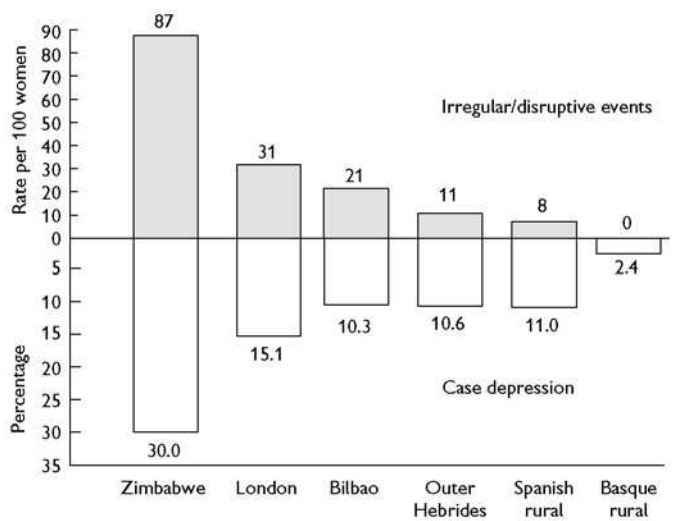

Fig. 2.6.1.2 Yearly rate of irregular or disruptive severe events per 100 women in six populations and prevalence of caseness of depression in year.

humiliation and entrapment are not only especially depressogenic but particularly common in high-risk populations (such as Harare) and within populations in high-risk subgroups (such as working-class women in London). In Islington such events were common among single mothers, a social category that has expanded dramatically in most western populations in recent years and among whom there is a high risk of depression.[67]

Final comments

There are two ways of looking at the findings that have been reviewed. First, that the study of life events has been an effective way of opening up wider issues concerning psychosocial factors and the aetiology of depression. This has been possible because, given the presence of a substantial causal link, a platform is provided for the study of a whole range of other experiences. As research has progressed it has pushed back in time to consider the aetiological role of early experiences of neglect and abuse which can have event-like characteristics. In more general terms the study of events has led to consideration of issues of vulnerability and protection, event production, chronicity, and course of particular episodes, and also issues not covered in this account such as coping and social support. It can be added that the work has also led to a good deal of research on other psychiatric conditions that have not been reviewed.[9,18,68,69]

The second contribution of the findings reviewed involves the stimulation of cross-disciplinary research concerning the depression—event link itself. This is a complex issue because life events correlate with factors ranging from genetic/personality[70] to macrolevel/societal.[65] The growing literature on the role of the serotonin transporter gene in depression is of particular interest as evidence has emerged for an important interplay with life events. A recent study has documented an interaction of the *s* allele variant of 5-HTTLPR polymorphism and life events with young adults. It also reported that childhood maltreatment predicted depression only among those with the *s* allele.[71] A somewhat similar finding with adult twins concerning life events has also been reported.[72] It is intriguing that there is a possibility of an important developmental contribution: that the critical gene-environmental interplay occurs early in life perhaps involving experiences such as parental maltreatment.[73] However, other studies have had more mixed findings with some showing no evidence of an interactive effect.[74,75] It is clearly too soon to review findings with any confidence—for example, some of the mix findings may well relate to the general failure to utilize the kind of detailed investigator-based measure of life events reviewed earlier and a failure to restrict consideration to events occurring not long before onset. In most studies the environmental measures fall a good way short of current best practice, although optimizing such assessments is essential for the detection of gene x environment interaction.[76,77] Nonetheless the research is an exciting development and it seems possible that well-established findings will emerge. But here my earlier comments about the likely critical importance of psychosocial factors in explaining differences in *rates* of disorder across populations should be kept in mind, although here there is some evidence that the genotype for 5-HTTLPR polymorphism may differ across populations.[78] It will also be important to take into account diagnostic issues. For example, it would be interesting to explore the fact, mentioned earlier, that it has been possible to isolate a small group of 'endogenous' neurotic depressive episodes.[24] Also it should be borne in mind that while this short review has largely restricted itself to work on depression, the life-event approach has been successfully employed with a number of other psychiatric and physical conditions and the possibility for collaborative research may well be much wider. For example, the *s* variant of 5-HTTLPR polymorphism also appears to be relevant for other psychiatric conditions.[74] There are other relevant biological considerations. The findings concerning life events involving humiliation and entrapment may need to be viewed from an evolutionary perspective, that is, that in some way a response pattern closely linked to issues surrounding defeat and exclusion, which has developed in group-living animals, may have functioned to promote survival.[78,79] It is possible that clinically relevant depressive conditions are often a complication of essentially non-pathological submission and appeasement responses to defeat in group-living mammals. Therefore, the high rates of clinically relevant depression that appear to be possible in some populations may well be a result of the more highly developed cognitive developments of *Homo sapiens* together with the event-creating potential of many societies experiencing periods of marked social change due to factors such as war, industrialization, technological development, urbanization, changing sexual mores.[80]

2.6.2 Social and cultural anthropology: salience for psychiatry

Arthur Kleinman

Social and cultural anthropology

One of the social sciences (together with history, economics, political science, sociology, and social psychology), social and cultural anthropology is principally concerned with the study of society, in almost all of its aspects. Together with linguistics, archaeology, and biological anthropology, social and cultural anthropology formed the classic (and now considered overly ambitious) four-field base of anthropology, the science of man. Yet still, in many universities, anthropology departments bridge the traditional divisions of the humanities, social sciences, and natural sciences. From the outset, anthropologists defined their subject in holistic terms meant to contextualize women and men in a nested hierarchy of influential environments that ran from the human body to the social body, and that assumed that these levels were related to each other, so that individual and collective processes (biological, psychological, social relational, and cultural) intersected in some way. Social and cultural anthropology, in particular, took as its subject matter studies of communities, ranging from small-scale preliterate groups to neighbourhoods or institutions in megacities. Comparison of different societies, or different structures and processes in those societies, is still seen as a defining approach, as is the analysis of cultural symbol systems (from languages to aesthetics), history of kinship, and other systems of social relationship, as well as research on large-scale social changes such as our era's globalization, ethnonationalism, and resurgence of religious fundamentalism.

Anthropology's chief research methodology is ethnography, the close study of a local world—a village, an urban neighbourhood, an institution, a network. Ethnography privileges local language, conceptual categories, values, and practices. Its procedure is to begin with local definitions and perceptions of reality (sometimes

called 'emics', from phonemics), and only when these experience—near patterns are understood in a particular context of everyday life (with the larger political, economic, and cultural forces that influence it) are comparisons made with other local worlds in the framework of experience-distant scientific definitions of reality (referred to as 'etics', from phonetics). Knowledge is generated by participant observation, informal interviews, and the use of more formal procedures from structured interviews to questionnaires. Cross-cultural comparison is another core mode of knowledge production. Both ethnography and cross-cultural comparisons draw on empirical data to engage larger questions in social theory, which itself is constantly being reorganized in this dialectical engagement.

In this century, social and cultural anthropology's division of labour has spun off at least two subfields that are of particular relevance for psychiatry: psychological anthropology and medical anthropology.

Psychological anthropology

This subfield grew out of the culture and personality school (ca. 1930–1950), when psychoanalysts and anthropologists sought to collaborate to understand how mental processes differed or were similar across greatly different societies. Margaret Mead, Ruth Benedict, and Irving Hallowell are those anthropologists most often associated with this school. Although, most anthropologists became critical of the basis of the field in psychoanalysis and a correlation of individuals with entire cultures, a small group of social and cultural anthropologists continue, none the less, to pursue this direction, and over time they have developed broader ties with psychology, as can be readily seen by their leading research interests in cognition, lifecycle development, and ethnopsychological categories. Anthropologists working in this tradition have studied self-concepts and self-images, emotion terms, interpersonal processes and their relation to personhood, as well as experiences of childhood, child rearing, adolescence, midlife, and ageing. Psychological anthropology has been influential in recent years in psychology, where a sister subdiscipline called cultural psychology has started up in close connection to it.

Medical anthropology

Physicians were among the founders of anthropology, and some, like the British polymath W.H.R. Rivers, combined medicine and anthropology. Another source of medical anthropology was social medicine and public health; indeed the great German pathologist and social medicine advocate, Rudolph Virchow, was one of the first to use the term 'medical anthropology'. Thus, medical anthropology's early roots were applied. After the Second World War, the field took off as anthropologists developed an interest in the theoretical and empirical aspects of non-Western medical traditions, religious healing and its relation to medicine, and increasingly in experiences of suffering. In more recent years, medical anthropologists, of whom there are several thousand worldwide, have developed special interests in infectious diseases (especially diarrhoeal disease, malaria, tuberculosis, and AIDS), female reproductive lifecycle problems, the health problems of children and the aged, substance abuse, cancer, diabetes, disabilities, medical ethics, and the economic and social transformation of health care. One of the earliest and abiding interests has been in psychiatric diagnosis, disorders, and treatments. This subfield of social and cultural anthropology has many ongoing relationships to cultural psychiatry (see Chapter 2.6.1) and has been active in recent years in the effort to introduce mental health concerns into international health (see Chapter 1.3.2 and 7.3). Indeed, the cultural sections of the DSM-IV were contributed by a taskforce that included both medical anthropologists and cultural psychiatrists, in equal numbers.

Major contributions of anthropology to psychiatry

Cultural critique of biomedicine

One of the crucial contributions of anthropology is theoretical, namely a critique of the theoretical biases inherent in psychiatric science and clinical practice. This may seem self-evident because unlike any other branch of medicine, there is no blood test, biopsy, or radiograph to diagnose psychiatric disorder (leaving aside Alzheimer's disease, which is after all a neurological disorder). That means that psychiatric diagnosis is based on the establishment of symptom and syndromal criteria, which are based in turn in language, lay categories, and everyday social experience. Cultural bias can enter this process in several ways. Anthropologists have shown that this can happen when diagnostic criteria that have been developed in one society are applied to another where they lack validity. This is called a 'category fallacy', a term introduced by Kleinman.[1] Classic examples include trance and possession states in many non-Western societies, which are frequently normative and normal experiences. Failure to recognize this phenomenon, and therefore the diagnosis of persons in religious trance as psychotic, creates a category fallacy in the application of the diagnostic criteria of psychosis to normal people. The cultural critique has been applied to personality disorders as well, because this category of disorder models self-processes on a Euro-American, middle-class, and usually male behavioural type and lifestyle. Anthropologists argue for a much more flexible and interactive understanding of subjectivity that changes in basic ways in response to different social circumstances.

In the 1990s, cultural critique has been important in highlighting the influence of institutional racism in psychiatric diagnosis, referral, and treatment. Leading examples are the overdiagnosis of African-Americans and African-Caribbean Britons with schizophrenia, the tendency to perceive them as more dangerous and less amenable to psychotherapy, and differences in the way their discharge and aftercare are organized. Anthropologists have examined how racism is unwittingly built into psychiatric categories and infiltrates the model cases used to illustrate diagnostic criteria, and also the way that psychiatrists are trained to replicate such patterns in the practice of triage.

Cultural critique, informed by the cross-cultural and international data, is the basis for anthropologists' doubts about the validity of many of the psychiatric conditions detailed in DSM-IV and ICD-10. The ethnographic database strongly suggests that, apart from brain tumours and infections, Alzheimer's disease, metabolic encephalopathy, substance abuse, and other well-documented brain-based disorders such as certain sleep disorders, only six psychiatric syndromes of adults can be found cross-culturally; i.e. only these have stability as syndromes outside the cultural mainstream of Euro-American societies. The conditions are schizophrenia, brief

reactive psychoses, major depression, bipolar disease, a range of anxiety disorders from panic states through phobias to obsessive–compulsive disorder, and trauma, whether understood as PTSD or in other categories. Most of the other hundreds of conditions described in DSM-IV, for example, are culture bound to Euro-America.

Related to these contributions of cultural critique, anthropologists have also contributed to the development of culturally informed diagnostic criteria, questionnaires, structured interviews, and guidelines for working with translators. Globalizing and indigenizing psychiatric approaches is an even more general emphasis in anthropology. Anthropology contains numerous concepts and methods that might be tried out, but relatively few have been experimented with or adopted. Besides those described below, several examples of the concepts, methods, and findings from anthropology that await trial in psychiatry are listed in Table 2.6.2.1.

Local moral worlds: interpersonal basis of illness experience

Ethnographies—hundreds of them, including many on psychiatric topics—demonstrate, with great consistency, that most people and most patients are not isolated individuals but rather live their lives as active members of local worlds. By local worlds, ethnographers mean villages, neighbourhoods, networks, and families, as well as particular social institutions, including hospitals and outpatient systems. These local worlds are differentiated by class, ethnicity, gender, age cohort, political faction, religious ties, and still other social differences. In any given local world crucial things are at stake that orient the attention and actions of participants. What is at stake may be shared (status, resources, survival, transcendence), but it also can be as distinctive as the different meanings of ultimacy that make religions distinguishable from each other.

Illness experience and experiences of treatment are as much caught up these stakes as experiences of normality. Thus, for anthropology how a person's illness is encountered, coped with, understood, and lived is crucial for understanding the illness and the treatment. Therefore, anthropologists write about the social course of illness: meaning that local worlds shape the course of illness so thoroughly that the same disease process (diabetes, AIDS, depression, schizophrenia) can take different trajectories. When sick people go for treatment, who they first seek out, whether they comply with the therapeutic regime, how they assess their experience of treatment—all are in one way or another influenced by what is most at stake for communities, families, networks, and individuals. The anthropological contribution here is to highlight the processes through which individuals relate to collectives. Thus, Estroff[2] shows that collective and individual definitions of identity affect how schizophrenic patients live their schizophrenia as an illness identity, which in turn affects their careers as patients and their experiences in other domains (family, workplace, etc.).

Table 2.6.2.1 Anthropological concepts, methods, and findings that await trial in psychiatry

Ethnography Ethnography as a research strategy in clinical and epidemiological research. For example, as a means of studying the clustering of psychiatric conditions with social problems. Ethnography also has uses in evaluation research, in generating categories and questions in epidemiological studies, and in sociosomatic research. It is also a means of training researchers.
Ethnographic database Ethnographic database as a routine source of knowledge about communities (foreign and domestic) for clinicians, mental health planners, and researchers.
Cross-cultural comparisons Cross-cultural comparisons as a routine form of knowledge production. For example, cross-cultural comparisons of psychotherapy might help (a) to clarify what is common among religious, moral, and medical healing, (b) to determine how culture influences psychotherapeutic practice, and (c) to develop psychotherapeutic techniques for use with patients and families from different minority, ethnic, and international populations.
Social theory Systematic reading of social theory as a source of hypotheses for research in social psychiatry and as a means of preparing clinicians to practise community psychiatry. Concepts such as social and symbolic capital, globalization, marginalization. ethnic identity, and institutional racism, among many others, can be used to frame psychiatric research and clinical intervention.

Practical clinical relevance

Immigration processes have so altered national demographic patterns that most nation states today have plural populations representing distinctive ethnic backgrounds. In 1900, the population of the United States, for example, included only 13 per cent categorized as ethnic minority members. By 1990 that figure was greater than 25 per cent. The percentage is projected to be one-third in 2010, and by mid-century to reach an astonishing 50 per cent. In California, the largest American state, non-Hispanic white Americans are already in a minority.

Ethnic background has been shown empirically to influence epidemiological rates of disease, patterns of access to health care, help-seeking, and patient–doctor interactions, often with negative outcomes such as delayed treatment, misdiagnosis, noncompliance, and treatment failure. Taking ethnicity into account in the provision of services means a variety of things, such as making translators available, putting up signs in several languages, holding clinics at times when working-class patients can attend, and paying attention to differences in cultural meanings and practices. The now popular idea of providing culturally informed and sensitive care is premised on anthropological concepts and methods. Several of these have been elaborated in the literature.

1 The distinctions between illness and disease: for medical anthropologists illness is the patient's experience of symptoms in the context of family, work, and community; disease is the practitioner's model of the pathological process. Help-seeking is usually orientated around the illness experience with respect to what is most at stake for the patient and significant others. Care can founder when the patient's primary concerns with the illness experience conflicts with or is entirely different from the physician's focus on disease. Thus, many patients with chronic pain experience interrogation of the disease process by the sceptical physician as delegitimizing their illness experience. This leads to high rates of dissatisfaction with care among this group of patients. When patients and families are from ethnic minority backgrounds, differences in cultural meanings and practices intensify conflicts between patient and physician models.

2 Medical anthropology sponsors a method to reduce this explanatory gap and thereby to improve clinical relationships. Called the explanatory models' methodology, it involves three steps.[3]

(a) Elicitation of patient and family explanatory models of the illness experience and treatment, which can be accomplished by asking the following questions:

- What do you call your problem?
- What do you think caused it?
- Why did it start when it did?
- What course will it take from here on?
- How does it work in your body?
- What do you most fear about the illness?
- What kind of treatment do you desire for this illness?
- What do you most fear about the treatment?

(b) Presentation of the clinician's explanatory model of the disease process.

(c) Negotiation of a mutually acceptable understanding of the clinical problem across patient, family, and physician models.

Closely related to this technique is the development of a mini-ethnography. This is a brief description, based on interviewing the key parties about the impact of family and work context on the illness experience and vice versa. The mini-ethnography and the explanatory models' elicitation generally give rise to patient stories of the illness experience. The influence of cultural categories, values and practices on the illness and treatment can be assessed from this standpoint.[4]

Revised cultural formulation

Appendix I to DSM-IV contains an outline of how psychiatric cases can be culturally formulated. This has recently been updated[6] and includes:

- the ethnic identity of the individual
- what is at stake as patients and their loved ones face an episode of illness
- the illness narrative
- psychosocial stresses and social supports
- cultural elements of the relationship between the individual and the clinician
- an examination of the efficacy of a cultural competency approach in the particular case

This is a feasible approach to routine patient care with members of ethnic minorities and recent immigrants and refugees that has a high likelihood of making that care culturally informed and culturally sensitive. Key to it, as it is to anthropology's core methodology, ethnography, is the display of genuine respect for patients, families, and their meanings and practices. That respect for the person and his or her illness experience is the indispensable condition of anthropologically informed care. It includes, as its first step, the ethical act of acknowledging the suffering of the other in his or her own terms as the basis for diagnosis and treatment. In this sense, it reverses the cultural preoccupation of the biomedical practitioner with the disease process, and establishes the interpersonal relationship as the grounds of knowledge as well as caregiving.

Conclusions

Anthropology's chief contribution to psychiatry is to emphasize the importance of the social world in diagnosis, prognosis, and treatment, and to provide concepts and methods that psychiatrists can apply (the appropriate cross-disciplinary translation first being made, however). But that is not the only contribution that anthropology offers. Ethnographers are aware that knowledge is positioned, facts and values are inseparable, and experience is simply too complex and robust to be easily boxed into tight analytical categories. Hence a sense of the fallibility of understanding, the limitation of practice, and irony and paradox in human conditions is the consequence of ethnography as a method of knowledge production.

Anthropology also complements the idea of psychosomatic relationships with evidence and theorizing about sociosomatic relationships. Here moral processes—namely what is at stake in local worlds—are shown to be closely linked with emotional processes, which are frequently about experiences of loss, fear, vexation, and betrayal of what is collectively and individually at stake in interpersonal relationships. Change in the former can change the latter, and this can at times work in reverse as well. Examples include the way symptoms intensify or even arise in response to fear and vexation concerning threats perceived as serious dangers to what is most at stake.

The relationship of poverty to morbidity and mortality is a different example of sociosomatic processes. Poverty correlates with increased morbidity and mortality. Psychiatrists have often had trouble getting the point that public health and infectious disease experts have long understood. But it is not just diarrhoeal disease, tuberculosis, AIDS, heart disease, and cancer that demonstrate this powerful social epidemiological correlation—so do psychiatric conditions. Depression, substance abuse, violence, and their traumatic consequences not only occur at higher rates in the poorest local worlds, but also cluster together (much as do infectious diseases), and those vicious clusters define a local place, usually a disintegrating inner-city community. Hence the findings of the National Co-Morbidity Study in the United States of America that most psychiatric conditions occur as comorbidity is a step toward this ethnographic knowledge—that in the most vulnerable, dangerous, and broken local worlds, psychiatric diseases are not encountered as separate problems but as part of these sociosomatic clusters.

Finally, anthropology is also salient for policy and programme development in psychiatry. Against an overly narrow neurobiological framing of psychiatric conditions as brain disorders, anthropology in psychiatry draws on cross-national, cross-ethnic, and disintegrating community data to emphasize the relationship of increasing rates of mental health problems, especially among underserved, impoverished populations worldwide, and increasing problems in the organization and delivery of mental health services to fundamental transformations in political economy, institutions, and culture that are remaking our epoch. In so doing, anthropology projects a vision of psychiatry as a discipline central to social welfare and health policy. It argues as well against the profession's ethnocentrism and for the field as a larger component of international health. Anthropology (together with economics, sociology,

and political science) also provides the tools for psychiatry to develop policies and programmes that address the close ties between social conditions and mental health conditions, and social policies and mental health policies.[5] In this sense, anthropology urges psychiatry in a global direction, one in which psychiatric knowledge and practice, once altered to fit in more culturally salient ways in local worlds around the globe, have a more important place at the policy table.[6,7]

2.7

The contribution of epidemiology to psychiatric aetiology

Scott Henderson

Introduction

Epidemiology deals with the overall patterns of disease. On one hand, people are unique with their own genetic endowment and life experiences. This idiographic paradigm is balanced by the nomothetic in which recurrent and predictable patterns are sought in the whole of humankind. It is the business of psychiatric epidemiology to determine the distribution of mental disorders in populations, the factors determining that distribution, and measures that may help in their prevention.

From their undergraduate years onward, clinicians see patients who have a disorder and who at the same time give a history of certain experiences from birth to their present. It may be tempting for both patient and doctor to accept that the patient's recent experiences have some role in the onset of symptoms. But if the principles of epidemiology are brought into play, some questions need to be asked first. Being unwell may itself bias the recall of recent or distant experiences. What proportion of the general population have had the same experiences but not developed the disorder? What proportions have the same disorder but have not had these experiences? What proportions have the same disorder but have not reached health services? A simple two-by-two table is the simplest way to think this through (Table 2.7.1).

The columns are made up of persons in a population who have or do not have a particular disorder. The rows are the numbers who have or have not had a certain exposure. That exposure is being considered as a putative risk factor. It may be biological or psychosocial and may have taken place at any time from conception to the present.

Table 2.7.1 Cases and exposure: a two-by-two table

		Case	
		Yes	**No**
Exposed	Yes	*a*	*b*
	No	*c*	*d*

Letters refer to numbers of persons.

To establish a causal link between some factor and a disorder is a demanding but most engaging exercise. It is well worth reading the classic expositions by Hill[1] and Susser[2] on how a cause can reasonably be inferred from the data.

The uses of epidemiology

In his celebrated monograph bearing this title, Morris[3] described seven uses of epidemiology. It continues to give us a framework for assessing the state of psychiatric epidemiology in relation to the biological and psychosocial conditions of the contemporary world. Morris's list can be reinterpreted for our use as follows.

Completing the clinical picture

This means knowing about all the ways in which a disorder may present and what its usual course is. But it also means relating subclinical cases to fully developed ones. An excellent example here would be the anxiety, depressive, or somatization states seen in general practice or field surveys compared to the more severe syndromes specified in the international criteria and encountered by psychiatrists.

Community diagnosis

Here one obtains estimates of morbidity as it occurs at the general population level, not just in persons who have reached primary care or mental health services. Only by having such estimates of prevalence or incidence for whole populations can the size of the nation's disease burden be determined. This is because community-based measures of morbidity include not only persons with treated conditions but also those who are symptomatic yet have not reached services.

Secular changes in incidence

This refers to the rise and fall of diseases in populations. For example, there is some evidence that schizophrenia has been dropping in incidence and becoming more benign in its clinical course; and it is likely that in many Western countries, depressive disorder has become more frequent in persons born since the Second World

War.[4] The suicide rate of young persons has indisputably increased in many industrialized countries. It is likely that eating disorders have increased in frequency and it is certain that the use of illegal drugs and AIDS are new arrivals and will be a continuing burden.

The search for causes

Here, epidemiology is looking for aetiological clues. It is the substance of this chapter.

Applying population data to individual risk

In this, the focus moves from the population back to the individual. For example, if the annual incidence rate for schizophrenia is known in a population and if this information is age-specific, it is possible to estimate the probability that a person in a given age group will develop the disorder within the next year. This is the base rate, before one starts to consider risk factors such as family history. Next, by aggregating data on the course of schizophrenia, it is possible to estimate the chances of recovery for persons who are currently having their first episode. The common principle is that data based on large numbers of persons are used to make probability estimates for individuals.

Delineation of syndromes

This is done by examining the distribution of clinical phenomena as they occur in the population. It fits well with recent experience of repetitive strain injury, chronic fatigue syndrome, and post-traumatic stress disorder or its congeners.

Health services research

This begins with a determination of needs and of resources, then an analysis of services currently in action, and ends with attempts to evaluate them, including the costs. Research activity in this area has expanded greatly in recent years, driven by the forces of economic rationalism.

Prevention

To Morris's seven uses of epidemiology should be added prevention, which Gruenberg[5] said was its 'ultimate service'. All other uses are subsidiary to this. Examples are the current activity in the prevention of suicide in young persons and of alcohol or drug abuse. In these, the traditional medical approach of targeting high-risk groups should be contrasted with the epidemiological and population-based approach described by Rose.[6] One under-recognized fact is that knowledge about factors that determine the duration of a disorder can lead to prevention. This is because prevalence is the incidence rate times the duration. So shortening the duration will lower the prevalence. For example, if people with depressive disorder were treated earlier in primary care, the prevalence should fall. The prevention of a mental disorder is greatly helped by knowledge about aetiology, but it is not essential. For example, Snow did not know about the cholera vibrio when he had the water supply changed. Prevention is discussed further by Bertolotte in Chapter 7.4, prevention in child psychiatry by Lenroot in Chapter 9.1.4, and in intellectual disability by Kaski in Chapter 10.3.

Research on aetiology: three levels

Epidemiological methods can be applied at any of the three levels: to disorders as these present in hospitals and specialist health services, in primary care, or in the general population. These are represented diagrammatically in Fig. 2.7.1 as a three-dimensional cone, derived from the seminal volume on pathways to care by Goldberg and Huxley.[7] The base of the cone consists of those in the general population who have clinically significant psychological symptoms (Stage 1). When these symptoms become unmanageable to self or to others, people seek help from their doctor or other health practitioners (Stage 2). But only some of them are recognized by the professional to have significant mental health problems (Stage 3). A small proportion may be referred to mental health services (Stage 4), of whom an even smaller fraction are admitted to inpatient care (Stage 5). Note that most teaching and the diagnostic criteria in international use are largely based on their authors' experience in Stages 4 and 5, where patients are more severely ill!

There are two very different ways to express morbidity. The most common, and easiest to obtain, is prevalence, either at the time of assessment (point prevalence), 1-month, 1-year, or lifetime prevalence. The other is incidence, the number of new or fresh onset cases in a given period. For aetiological research, incident cases are emphatically preferable.

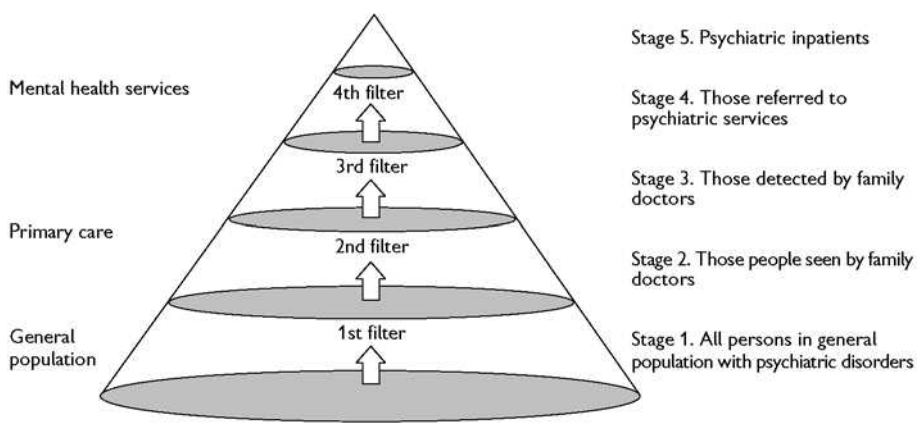

Fig. 2.7.1 Pathways to care. (Reproduced from D.P. Goldberg and P. Huxley, *Mental illness in the community,* Copyright © 1980, The Tavistock Institute.)

Three main designs

At any of these levels, research directed at aetiology uses one of three designs: cross-sectional, prospective longitudinal, or case-control. A cross-sectional study is often an excellent start, because it provides a picture of how much morbidity is present at one point in time and the variables most closely associated with this. But because it is only a 'snapshot', the cross-sectional study can rarely allow much to be said about causes. For example, in a community sample of several thousand adults, the data will show that persons with symptoms of anxiety or depression will tend to report having had more adversities. But it would be unwise to conclude that adversity contributes to the onset of symptoms. First, persons with anxiety or depression may be more inclined to report that they have had many troubles. This may be through selective recall of unpleasant events, because it is known that depressed people are more likely to remember bad times than good times.[8] Another mechanism is effort after meaning, whereby people try to account for feeling psychologically unwell. Next, symptomatic persons may be more likely to have unpleasant things happen to them as a consequence of their mental state. Lastly, persons with anxiety or depression may have certain personality traits or lifestyles that make them more likely to have troubled lives and also be vulnerable to common mental disorders.

Such problems in methodology can be resolved to some extent by using a *prospective longitudinal design* or cohort study. In this, a population sample is assessed at the start when most persons are psychologically well. In one type of cohort study, the sample may deliberately include a group who have had a particular exposure, such as a head injury or disaster, and an equivalent number who have not. At the start, data are obtained on personality, lifestyle, past health, and family history. The cohort is then re-examined at least once after an appropriate interval. Some will have developed symptoms. The research question is whether the putative risk factors that were assessed at the start were more frequently present in those who later developed symptoms. A design of this type yields considerably more information about the causal processes likely to be at work, either those leading to mental disorders or protecting against them. It also overcomes the problem of a putative risk factor really being a consequence rather than an antecedent of a disorder. But it is obviously very demanding in resources—human, administrative, and financial. It also takes a long time. For these reasons, epidemiologists often use the *case-control* method as a more practicable alternative.

Case-control designs have been underused in psychiatric research, but they can be a powerful strategy for identifying risk factors for a specified disorder.[9,10] The essence of the case-control design lies in obtaining data to complete the cells in Table 2.7.1. The aim is to find a sample of all persons in a population who have reached case level for a particular disorder and an equivalent number of persons who are similar in age, gender, and other variables, but who do not have the disorder, at least not yet. The cases should ideally be 'incident' or recent in onset. If instead, the study has to have recourse to all the cases of the disorder known to the service, that is, the prevalent cases, some will be long-standing and some more recent. This could lead to misleading results because a putative risk factor may show up as 'positive' not because it is a cause or true risk factor, but because it is associated with chronicity through prolonging the duration of the disorder. This problem can be avoided only by recruiting recent-onset or incident cases for case-control studies. The cases and controls are then asked about the various possible exposures. If the cases are unable to give information because they are cognitively impaired (as in dementia), at least one informant has to be found for each case, usually a partner or close family member.

In Table 2.7.1, the important question is whether there are more persons in cell *a* than would occur by chance. We do not know the incidence of the disorder in all persons in the population who were exposed to each risk factor, nor do we know the number not exposed. Likewise, we do not know how many people in the population have recently developed the disorder. As a consequence, we cannot compare the incidence in those exposed and not exposed for the whole population. All we have are the data from the cases examined, who are necessarily only a fraction of all incident cases in the population; and data from a fraction of all healthy persons. But we can proceed as follows. First, the relative risk is calculated from Table 2.7.1. The relative risk is $a/(a + b)$ divided by $c/(c + d)$

i.e. $$\frac{a/(a+b)}{c/(c+d)}$$

By simple algebra, this becomes

$$\frac{a(c+d)}{c(a+b)}$$

Then something very helpful can be done. Where a disorder is fairly uncommon in the general population, *a* will be very small compared with *b*, and *c* will be small compared with *d*. If we assume a negligible contribution by *a* in the term $a + b$, and by *c* in the term $c + d$, the relative risk will be nearly equal to

$$\frac{ad}{bc}$$

This is the odds ratio, which is an expression of the strength of a risk factor.

Whom to study: principles of sampling

The essential principle is that everyone in the true denominator (usually the total population within a defined geographical or administrative area) *must have an equal probability* of being included in the numerator. If this is not achieved, there is a likelihood of bias whereby the achieved sample may be systematically different in ways that could be important in the analysis. For example, the sample of cases should not differ from all the incident cases in that population in attributes such as level of education, age, or likelihood of having been exposed to a candidate exposure or risk factor. So in a study of the association between, say, sexual abuse in childhood and depressive disorder in adult life, the cases of depression should ideally be representative of all those with depressive disorder in that community and not just those reaching a particular service. See also Chapter 2.2 by Dunn.

Sample bias

In field surveys, it has long been accepted that not everyone who is in the 'target sample' will agree to be interviewed or will be available at the time the interviewer calls. It is common to find that

only 70 to 90 per cent are actually assessed. Furthermore, those who refuse or are repeatedly not available are known to be more likely to have the mental disorder under investigation. For this reason, the prevalence that is found will often be an underestimate. A putative risk factor may itself increase the chances of a person's not being in a sample in the first place, of dropping out, or of dying during the study. Statistical methods are available for estimating how much error may have occurred due to refusals and how to correct for this in the conclusions drawn.

The other occasion when non-response is a problem is in longitudinal studies, where a sample is followed over several years. If a disorder with an increased mortality is the topic, such as dementia or schizophrenia, it is recognized that some cases will be lost at follow-up. This means that those who are successfully re-examined are a survival élite and are different in important ways from the original cohort. These distortions could lead to mistaken conclusions if the losses are not allowed for. Various techniques have been developed to handle these difficulties, including Bayesian methods which adjust final estimates on the basis of prior knowledge.[11]

Specifying the disorders

Diagnostic categories

The epidemiology of mental disorders could have made no real progress without methods for specifying the disorders to be investigated, then measuring these. Only in this way can research data be comparable between research teams, within and between countries. Having consistency in diagnosis has been made much easier through the development of the diagnostic criteria now in wide international use. The two systems are the International Classification of Diseases (10th Revision) (**ICD-10**) with its *Classification of Mental and Behavioural Disorders*; and the *Diagnostic and Statistical Manual*, fourth edition (**DSM-IV**) of the American Psychiatric Association. These classifications are described further in Chapter 1.9. Both are under revision.

Continuous measures of morbidity

Reliable and valid case ascertainment might be assumed to be the *sine qua non* for any progress in the epidemiology of mental disorders. But to use the traditional expression 'case ascertainment' nicely illustrates the very problem that has to be re-thought, because it implies a categorical structure in the morbidity that we wish to study. In a population, there are traditionally cases and non-cases. But this is not really how morbidity shows itself. As expressed by Pickering,[12] 'Medicine in its present state can count up to two, but not beyond'. He was referring to hypertension, but others have argued that mental disorders also have dimensional properties.[6] The frequency distribution of their component symptoms such as anxiety, depression, or cognitive impairment is usually a reversed J-shape, with most people having none or only a few symptoms and progressively fewer persons having higher counts. A committee of clinicians in Geneva or Washington, whose experience is largely derived from teaching hospitals, has decided by consensus where the cut-point should be placed for persons to be 'cases'. While this is entirely appropriate for some purposes, it may not always be a true representation of the underlying pathology. In statistical terms, it loses information.

It is not disputed that mental disorders exist in categorical states and that these have some utilitarian value: a depressive episode, Alzheimer's disease, anorexia nervosa, or alcohol dependency are clinically realistic entities. What is proposed here is that, in epidemiological studies at the general population level, hypotheses about the aetiology require large numbers of respondents, solely because the base rates for such conditions are not large. But it is possible to identify persons with *some* symptoms of depression, of cognitive impairment, of abnormal eating, or of alcohol misuse. The score on a scale of these symptoms can become the dependent variable in an analysis of candidate risk factors. So it is usually more powerful statistically to look for associations between a putative risk factor and morbidity expressed as a continuous variable, rather than as a dichotomy of cases and non-cases.

When a continuous measure of common psychological symptoms such as the General Health Questionnaire (**GHQ**)[13] (*vide infra*) is applied to a population, a unimodal distribution curve is found, with no break between so-called cases and normals. Rose[6] argued that there are three important consequences from this approach to studying morbidity. First, a characteristic of the community as a whole emerges. This is the mean and standard deviation of its GHQ scores. Second, this collective characteristic may show significant differences between men and women, geographical regions, social strata, and income groups. These differences are based on shifts of the entire distribution. The third consequence is that differences between these groups in the prevalence of probable cases (those with a score above a threshold) are related to different average scores in these groups. As Rose[6] concisely put it, 'The visible part of the iceberg (prevalence) is a function of its total mass (the population average)'.

He suggested that '*Psychiatrists, unlike sociologists, seem generally unaware of the existence and importance of mental health attributes of whole populations, their concern being only with sick individuals*' (emphasis added). It is an appealing notion that populations, while they are made up of individuals, take on properties of their own, much as molecules acquire attributes not found in their constituent atoms. The concept of populations having different frequency distributions of dimensional morbidity, not just different prevalence rates for clinical cases, carries with it the implication that some factors are shifting the overall distribution in some populations but not in others. An example is the societal forces that Durkheim[14] proposed were related to national suicide rates.

Disablement

There is yet a further advantage in considering morbidity as a continuum in a population. Morbidity refers to symptoms, syndromes, or disorders. But there is a universe of discourse closely linked to this, namely disablement. This is the collective noun now used to refer to the impairment, disability, and social role handicap in daily life that disorders bring with them. The main categories of mental disorder, especially the psychoses, affective disorders, and dementias, are almost always associated with substantial disablement. But subclinical levels of mental disorders also carry with them a certain amount of disablement. From the point of view of a whole population, the cumulative amount of disablement from subclinical or milder conditions is considerable because such conditions have a high point prevalence. Therefore, from a public health perspective, the significance of milder mental disorders is not trivial.

Measurement of disablement

The most comprehensive measure is the Disability Assessment Schedule (DAS)[15] that assesses an individual's functioning in daily life. Its short form is suitable for survey use. Self-completion instruments are the Brief Disability Questionnaire (BDQ)[16] and the SF-36[17] or its briefer version, the SF-12.

The measurement of psychiatric symptoms

Instruments for epidemiological research fall into two types: self-completed questionnaires and standardized interviews.

Questionnaires

The more simple type is a symptom scale which can be completed by respondents themselves or administered by an interviewer. The best-known instrument is the GHQ. The briefest version, the GHQ-12, is a highly efficient screening tool. A score of 2 or more indicates that the person is likely to have one of what Goldberg and Huxley[18] have usefully termed common mental disorders. Another screening instrument is the Hopkins Symptom Checklist.[19] For depressive states specifically, examples are the Center for Epidemiologic Studies Depression Scale (**CES-D**)[20] and the Beck Depression Inventory.[21]

The Alcohol Use Disorders Identification Test (**AUDIT**) was developed by the WHO for population screening. This 10-item test has been shown to have satisfactory psychometric and predictive properties. The total score is 40 and a score of 8 or more (7 for women) is recommended for identifying persons likely to have adverse consequences of drinking.[22]

For cognitive impairment, the Mini-Mental State Examination (**MMSE**)[23] gives a score for a person's current cognitive function, or by applying a cut-point to that score, it can be used to identify persons who are likely to have a dementia. Like any other cognitive test, it cannot itself make a diagnosis of dementia. It detects cognitive impairment, not cognitive decline, which requires a history. The MMSE is known to be sensitive to education, in that persons with limited intelligence or education may have low scores without their having had any cognitive decline.

All these instruments can be used in two ways: by applying a cut-point to identify persons who are likely to be clinically significant cases; or by using the score as a continuous variable. When a questionnaire or self-rated instrument is used in research, the investigators have to be confident about its psychometric properties. In addition to validity and reliability, there are two others: its sensitivity and specificity. These refer to its performance when compared with a criterion or 'gold standard', such as a comprehensive psychiatric examination or a consensus diagnosis amongst experts. In Table 2.7.2, a sample of persons has been examined with both the screening instrument and a full examination. We consider the number of persons who are 'cases' according to both assessments (*a*), according to one but not the other (*b* or *c*), and according to neither (*d*).

Sensitivity is the proportion who screen positive and who are indeed cases by the criterion; that is: $a/(a + c)$, while specificity is the number who screen negative and who are indeed not cases: $d/(b + d)$.

The sensitivity and specificity of a test are expressed as a percentage and vary according to where the cut-point is placed on the scores.

Table 2.7.2 Screening a population sample

		Criterion (cases by full psychiatric assessment)		
		Yes	**No**	
Cases by screening test	Yes	*a*	*b*	*a+b*
	No	*c*	*d*	*c+d*
		a+c	*b+d*	

Letters refer to numbers of persons.

As sensitivity increases, specificity tends to decrease, so that an appropriate balance between the two has to be determined. For some purposes, such as in screening for depression, it is more important to identify as many as possible of the true cases, but it does not matter if there are quite a few false-positives because these can be corrected by a more extensive second-stage examination. Under these conditions, one would want a highly sensitive screening test that placed most of the true cases in cell *a* and few in *c*. It matters rather less if quite a few of the true non-cases are incorrectly placed in *b*. See also Chapter 2.2 by Dunn.

Standardized psychiatric interviews

Even the best-designed questionnaires with the best psychometric properties cannot be a substitute for a psychiatric interview. Only it can obtain the information that leads to a diagnosis, reached according to the international criteria. What is termed information variance is reduced by having interviewers ask about symptoms in the same way. Next is the reduction of criterion variance, where the symptoms or signs elicited are, like building bricks, assembled in exactly the same way, both within and across studies. This is achieved by applying to the data an algorithm that is a precise expression of the diagnostic criteria in ICD or DSM. The algorithm can be computerized so that the responses to each item in the interview are assembled automatically and invariably.

There are two types of standardized psychiatric examination. The Schedule for Clinical Assessment in Neuropsychiatry (**SCAN**) is a clinician's instrument, requiring familiarity with the phenomenology of mental disorders. It assumes that interviewers are comfortable in examining persons with a mental disorder. The second type, exemplified by the Composite International Diagnostic Interview (**CIDI**) is fully scripted and has been automated for interviewing on laptop computers so that it can be administered by laypersons after only a few days' training. A very large body of survey data has now been collected using it. These instruments are fully described by Cooper and Oates in Chapter 1.8.1.

Validity issues

The quality of information these instruments obtain is clearly of central importance. We know that they do not obtain the same information as each other, nor do they identify the same persons as cases of a particular diagnostic category in the same sample. Their validity and the practical significance is therefore important for administrators using the data obtained in large surveys to guide planning. But it is also a matter of interest for aetiological research.

Typical prevalence estimates

The above instruments have been used in a large number of surveys of the prevalence of the main mental disorders in the general population. Examples are shown in Table 2.7.3. The rates vary markedly, but little is known about why this is so. The differences may be due to differences in methods of case ascertainment; or they may indicate actual variation between countries. What is important is that they all *attempt* to estimate the prevalence in the community of syndromes familiar to psychiatrists working in clinics and hospitals. Prevalence estimates provide evidence for the public health significance of mental illnesses and their associated disablement. Their administrative impact has been considerable. So far, however, they have brought little to advance knowledge about aetiology.

(a) Possible causes of mental disorders: the domains

Having specified the psychiatric disorder to be studied and having developed methods to measure it, the next task is to identify whatever factors might contribute to its onset or to its course. These lie in the traditional three domains: the biological, social, and psychological. But in epidemiology, any variable is rarely specific to one domain. Some biological, some social, and some psychological factors are often conflated. For example, gender expresses biological differences but also different social experiences in the past, different social contexts in the present, and different psychological or intrapersonal differences in personality traits and behaviour. Likewise, age groups can reflect social role, educational opportunities in the past, marital status, financial concerns, and physical health. It is therefore important not to be misled into thinking that a variable is tapping only what one is primarily interested in. Confounding is ever present.

(b) Sociodemographic variables

The level of psychiatric morbidity in a population may differ significantly between age groups, gender, marital status, ethnic background, and socio-economic or educational level. Depressive disorders are consistently more prevalent in women[24] and dementia has a higher prevalence, not only with increasing age, but also in those with lower education.[25] Furthermore, there may be important interaction effects between variables in their relation to morbidity. For example, the average age of onset in schizophrenia is different in men and in women. This has proved to be a clue to causal processes.

Table 2.7.3 Some 12-month prevalence rates per 100 of population, all by DSM-IV criteria

	Any disorder* (%)	Anxiety disorder	Mood disorder	Alcohol or substance use disorder
Australia	20.3	5.6	6.6	7.9
Canada	10.9	5.2	5.8	_
China (Beijing)	9.1	3.2	2.5	2.6
Colombia	17.8	10.0	6.8	2.8
European countries (six)	9.6	6.4	4.2	1.0 (alcohol only)
Iran†	17.1	8.4	4.3	nil
Lebanon	16.9	11.2	6.6	1.3
New Zealand	20.7	14.8	8.0	3.5
Nigeria	4.7	3.3	0.8	0.8
Ukraine	20.5	7.1	9.1	6.4
USA	26.4	18.2	9.6	3.8

*Includes disorders other than those listed.
†Only lifetime estimates were published.

(c) The social environment

This can be considered in two parts: first is the individual's immediate social environment—what the sociologist Cooley[26] called the primary group—consisting of those around a person with whom there is both interaction and commitment. There is then the wider community with its standard of living, lifestyle, and cultural values. Plausibly, both may have some influence on the incidence of mental disorders and on their course. The hypothesis that social support protects against depression and other common mental disorders has proved hard to investigate.[27, 28] This is because social support is probably influenced by some intrapersonal factors rather than being a product solely of the individual's environment. Here is a good example of confounding: a major variable concerning the social environment of individuals turns out to be determined not solely by environmental factors, but partly by their own personality attributes. The evidence suggests that social support, stripped of these confounding factors, is not a powerful factor in aetiology.[29] A separate issue is whether social support influences the outcome of psychiatric disorders once these have developed.

Societal (macrosocial) variables have long been suspected of playing an important role in aetiology. It was such a hypothesis that was investigated in the celebrated Stirling County Study in Canada by Dorothea and Alexander Leighton *et al.*[30] with their concept of sociocultural disintegration. The current increase in depression and suicide in the young is popularly attributed to such macrosocial variables. On the other hand, work opportunities, diet and use of drugs and alcohol have also changed appreciably over the last 50 years. There is no certain explanation so far.

Experiential variables

'Experiential' is a useful term to refer inclusively to all that individuals have been exposed to, from conception to death. In epidemiological research, it includes intrauterine exposures—such as maternal influenza or malnutrition—and perinatal events. In infancy and childhood, social and interpersonal experiences have been the main focus of research. Maternal deprivation was intensively studied in both clinical and community samples for two decades. The expectation from Bowlby's attachment theory was that loss or separation from the mother would be pathogenic for depression and possibly personality disorders.[31] This hypothesis has proved very hard to test because of confounding by other factors. Rutter[32] concluded that '. . . the residual effects of early experiences on adult behaviour tend to be quite slight because of both the maturational changes that take place during middle and later childhood and also the effects of beneficial and adverse experiences during all the years after infancy . . . '

Migration and schizophrenia

Migration is an excellent example of how epidemiological data lead to aetiological clues, straddling both the biological and social. People who have moved from one country to another have offered opportunities for aetiological research on schizophrenia for a long time, starting with the celebrated study in 1932 by Ödegaard. He found that Norwegian migrants to Minnesota had more mental disorders than those at home. Since then, migration has become increasingly common and some striking findings have been made. An integrative review[33] has found a relative risk of 2.7 for first-generation migrants and 4.5 for the second-generation. While a family history is the largest risk factor for schizophrenia, migration is the next compared with most others. It is not due to an artefact in diagnosis. The effect is unlikely to be due to any single factor. Both biological and social factors are probably implicated. In the latter, perception of social inequality is thought to be a plausible mechanism.

Parental style

Promising findings have been obtained on the association between parenting style and depressive disorders in adulthood. Parker[34] developed the Parental Bonding Instrument (**PBI**) to measure two fundamental dimensions of the manner in which parents behave towards their children: care and affection as one dimension and protectiveness as the other. The PBI is too lengthy for epidemiological research on community samples where the interview is often already extensive. Parker and his colleagues have subsequently developed a briefer instrument, the Measure of Parenting Style (**MOPS**), which includes the experience of physical and sexual abuse.[35] MOPS is likely to prove useful in case-control and prospective studies of psychiatric disorders for systematically obtaining information on exposures of theoretical relevance.

(a) Childhood abuse

It seems intuitively likely that children who have been physically or sexually abused have an increased risk of having anxiety, depression, or other psychiatric disorders in adulthood. The findings from epidemiological studies on unreferred samples (people in the community) point to the many other adverse experiences that accompany childhood sexual abuse, including physical violence, unstable and untrustworthy relationships with parents, and emotional deprivation. This topic is further considered in Chapter 9.3.3.

(b) Recent exposure to adversity

Adverse experiences have been very extensively studied for their contribution to the onset and course of psychiatric disorders. In epidemiological research, much attention has been accorded to issues that arise in the measurement of adversity. Some of these issues are equally relevant in clinical practice. They include the following:

- The duration of the stressor: acute or long-standing.
- Its magnitude and how to determine this independently of the person's reaction to it.
- The independence of the event from the individual: some events are entirely independent while others may have come about because of the individual's own behaviour or psychiatric state.
- The personal context of the experience may augment or reduce its psychological impact.
- Confounding by personality traits that may be independently associated with psychiatric morbidity.
- The additive effect of multiple events, some of which may be causally linked in a chain.
- The quality of the event itself: a loss or a threat.
- Effort after meaning, whereby patients and doctors may attribute symptoms to a particular experience as a way to explain the onset of illness.

These issues are fully discussed in Chapter 2.6.1.

Personality variables

Although personality traits may contribute to how vulnerable individuals are to adverse experiences, it has not often been possible to measure personality traits in general populations, then follow the sample prospectively to demonstrate if the incidence of specific disorders is indeed higher in some types. Many measures of personality are too lengthy to be used in surveys. One exception is the Eysenck Personality Questionnaire (**EPQ-R**) in which the trait of neuroticism has been found to confer increased risk of anxiety, depression or later schizophrenia.[36] The assessment of personality is considered in Chapter 1.8.2.

Molecular genetics and epidemiology

In the next few years, it can be expected that some personality traits will be found to occur more often in people with particular alleles in genes related to brain function. Amongst these, a preferred group of candidates are genes with known polymorphisms that alter the function of neurotransmitter systems, either by affecting the metabolism of a transmitter or some aspect of its function such as transport, receptor binding, or signal transduction. The attraction for psychiatric epidemiology is twofold: the promise of introducing to population studies a biological variable of fundamental significance; and the possibility of looking for interaction between biologically based vulnerability and life experiences. The finding by Caspi *et al.*[37] sparked great interest by reporting an association between a 5-HTT polymorphism and depression, but only on persons who had been exposed to recent adversity. The finding has not been consistently replicated. Furthermore, the relevant polymorphisms may be rather more complicated than at first assumed. What is significant is that it is now feasible to study genotype and environment at the population level.

How epidemiologists think

We can now look back on the strategies used to find causes of mental disorders and how epidemiologists go about the task. To find aetiological clues, they look firstly for associations, some of which may later be shown to have a causal influence. This is often best done by working not with individual patients, nor even with a series of patients in one clinic. Instead it is better to have data that represent *all* cases of a disorder in a defined population. The way in which a candidate risk factor comes to be proposed is itself very interesting. There are three:

Table 2.7.4 The search for causes: a matrix for epidemiological studies

		Child psychiatric disorders	Anxiety disorders	Affective disorders	Schizophrenia	Dementias	Personality disorders	Eating disorders	Alcohol and substance abuse	Suicide	Parasuicide	Intellectual disability	Psychological well being
Sociodemographic factors	Gender Age Marital status Social class Education Employment status Urban/rural World region												
Experiential factors	Season of birth Parental age Childhood separation Parental style Cultural or subcultural beliefs and attitudes Adverse experiences Extreme experiences Bereavement Expressed emotion (for relapse) Social support Secular changes in society Other macrosocial factors (economic depression, war, social cohesion) Migration Climate and daylight Noise Environmental toxins Diet Alcohol and drugs Medication Infections Physical illness												
	Interaction of two or more factors Comorbidity Genetics: major genes quantitative trait loci												

No attempt has been made to be exhaustive in either the classes of morbidity or the putative causal factors.

1 **The inspired hypothesis**. A sharp-eyed clinician develops the idea that some factor—in any of the three domains—is present more often than by chance in a certain disorder; and that factor may contribute to the onset of the disorder. This is exactly what happened to the ophthalmologist Sir Norman Gregg in Sydney when he noticed that many disabled children had mothers who had contracted rubella during the pregnancy. The association was later confirmed and shown to be causal. So here a hypothesis arising in the course of clinical work was taken out of the clinic and tested by epidemiological methods, then the knowledge applied in prevention.

2 **A coarse observation**. A second pathway to a hypothesis starts with a coarse observation of a link between a disorder and, say, some demographic variable. Here are two examples. In the aetiology of schizophrenia, a slight excess in winter birthdates was noticed in persons who later developed schizophrenia. Work on the 1946 birth cohort in Britain showed that persons who later developed schizophrenia had been recorded as children to have had more speech and educational problems, more social anxiety, and a preference for solitary play. Both observations point to a neurodevelopmental hypothesis for schizophrenia.

3 **The enquiry is theory driven**. A good example is what came from attachment theory. In epidemiological research on Alzheimer's disease, it was theory that led to a search for putative risk factors such as a family history of Down syndrome, aluminium in drinking water, maternal age at the patient's birth, and a history of previous head injury. It was also theory that led Jenkinson *et al*. to find an inverse association between Alzheimer's disease and rheumatoid arthritis. This subsequently led to studies of people who had been treated with long-term anti-inflammatory drugs.

4 **The search for causes: a matrix for epidemiological studies**. All these three approaches can be brought together, and then used as the building material to construct a matrix. This can then drive a systematic search. In Table 2.7.4, the main categories of mental disorders are listed across the top to form the columns, while the rows are made up of those variables that may contribute to the onset or course of morbidity. The matrix proves to be a tidy way of organizing what information is already available; but it also acts heuristically by proposing associations that call for investigation but might not otherwise have been considered. The variables can be placed in categories: sociodemographic, experiential, intrapersonal (psychological), and biological. The alert observer will notice that interactions between two or more variables should be considered, because these can be of the greatest importance.

Conclusion

The epidemiology of psychiatric disorders has shown the extent to which these are present in all human populations. It has also provided a large body of knowledge about aetiology. Now that biological including genetic information can be added to data on environmental exposures, opportunities for further advancement carry much promise.

Psychoanalysis: Freud's theories and their contemporary development

Otto F. Kernberg

Psychoanalysis is:

1 A personality theory, and, more generally, a theory of psychological functioning that focuses particularly on unconscious mental processes;

2 A method for the investigation of psychological functions based on the exploration of free associations within a special therapeutic setting;

3 A method for treatment of a broad spectrum of psychopathological conditions, including the symptomatic neuroses (anxiety states, characterological depression, obsessive–compulsive disorder, conversion hysteria, and dissociative hysterical pathology), sexual inhibitions and perversions ('paraphilias'), and the personality disorders.

Psychoanalysis has also been applied, mostly in modified versions, i.e. in psychoanalytic psychotherapies, to the treatment of severe personality disorders, psychosomatic conditions, and certain psychotic conditions, particularly a subgroup of patients with chronic schizophrenic illness.

All three aspects of psychoanalysis were originally developed by Freud[1–3] whose theories of the dynamic unconscious, personality development, personality structure, psychopathology, methodology of psychoanalytic investigation, and method of treatment still largely influence the field, both in the sense that many of his central ideas continue as the basis of contemporary psychoanalytic thinking, and in that corresponding divergencies, controversies, and radical innovations still can be better understood in the light of the overall frame of his contributions. Freud's concepts of dream analysis, mechanisms of defence, and transference have become central aspects of many contemporary psychotherapeutic procedures.

Freud's ideas about personality development and psychopathology, the method of psychoanalytic investigation, and the analytic approach to treatment gradually changed in the course of his dramatically creative lifespan. Moreover, the theory of the structure of the mind that he assumed must underlie the events that he observed clinically changed in major respects, so that an overall summary of his views can hardly be undertaken without tracing the history of his thinking. The present overview will lead up to summaries of his final conclusions as to the structure of the mind and how this is reflected in personality development and psychopathology. Psychoanalysis will then be described as a method of treatment, as seen from the point of view of resolution of conflict between impulse and defence, and from that of object-relations theory. We shall explore significant changes that have occurred in all these domains, and conclude with an overview of contemporary psychoanalysis, with particular emphasis upon the presently converging tendencies of contemporary psychoanalytic approaches, and new developments that remain controversial.

Freud's theory of the mental apparatus: motivation, structure, and functioning

Unconscious mental processes: the topographic theory; defence mechanisms

Freud's starting point[4] was his study of hysterical patients and the discovery that, when he found a way to help these patients piece together a coherent account of the antecedents of their conversion symptoms, dissociative phenomena, and pathological affective dispositions, all these psychopathological phenomena could be traced to traumatic experiences in their past that had become unconscious. That is, these traumatic experiences continued to influence the patients' functioning despite an active defensive mechanism of 'repression' that excluded them from the patient's conscious awareness. In the course of a few years, Freud abandoned his early efforts to recover repressed material by means of hypnosis, and replaced hypnosis with the technique of 'free association', an essential aspect of psychoanalytic technique until the present time. Freud instructed his patients to eliminate as much as possible all 'prepared agendas', and to try to express whatever came to mind, while attempting to exert as little censorship over this material as they could. He provided them with a non-judgemental and stable setting in which to carry out their task, inviting them to recline on a couch while he sat behind it. The sessions lasted for an hour and were conducted five to six times a week. There has been little change in the essentials of this format, except that sessions have been shortened to 45 to 50 min and are carried out three to

five times a week. The method of free association led to the gradual recovery of repressed memories of traumatic events. Originally, Freud thought that the recovery of such events into consciousness would permit their abreaction and elaboration, and thus resolve the patients' symptoms.

Practicing this method led Freud to several lines of discovery. To begin, he conceptualized unconscious mechanisms of defence that opposed the recovery of memories by free association. He described these mechanisms, namely, repression, negation, isolation, projection, introjection, transformation into the opposite, rationalization, intellectualization, and most important, reaction formation. The last of these involves overt chronic patterns of thought and behaviour that serve to disguise and disavow opposite tendencies linked to unconscious traumatic events and the intrapsychic conflicts derived from them. The discovery of reaction formations led Freud to the psychoanalytic study of character pathology and normal character formation, and still constitutes an important aspect of the contemporary psychoanalytic understanding and treatment of personality disorders (for practical purposes, character pathology and personality disorders are synonymous concepts).

A related line of development in Freud's theories was the discovery of the differential characteristics of conscious and unconscious thinking. Freud differentiated conscious thinking, the 'secondary process', invested by 'attention cathexis' and dominated by sensory perception and ordinary logic in relating to the psychosocial environment, from the 'primary process' of the 'dynamic unconscious'. That part of the unconscious mind he referred to as 'dynamic' exerted constant pressure or influence on conscious processes, against the active barrier constituted by the various defensive operations, particularly repression. The dynamic unconscious, Freud proposed, presented a general mobility of affective investments, and was ruled by the 'pleasure principle' in contrast to the 'reality principle' of consciousness. The 'primary process' thinking of the dynamic unconscious was characterized by the absence of the principle of contradiction and of ordinary logical thinking, the absence of negation and of the ordinary sense of time and space, the treatment of a part as if it were equivalent to the whole, and a general tendency towards condensation of thoughts and the displacement of affective investments from one to another mental content.

Finally, Freud proposed a 'preconscious', an intermediate zone between the dynamic unconscious and consciousness. It represented the storehouse for retrievable memories and knowledge and for affective investments in general, and it was the seat of daydreaming, in which the reality principle of consciousness was loosened, and derivatives of the dynamic unconscious might emerge. Free association, in fact, primarily tapped the preconscious as well as the layer of unconscious defensive operations opposing the emergence of material from the dynamic unconscious.

This model of the mind as a 'place' with unconscious, preconscious, and conscious 'regions' constituted Freud's[1] 'topographic theory'. He eventually replaced it with the 'structural theory' namely, the concept of three interacting psychic structures, the ego, the superego, and the id.[5] This tripartite structural theory is still the model of the mind that dominates psychoanalytic thinking. A major determinant of the shift from the topographic to the structural model was Freud's recognition that the 'regions' of conscious, preconscious, and unconscious were fluid, and that the defence mechanisms directed against the emergence in consciousness of the dynamic unconscious were themselves unconscious. Another consideration was Freud's[6] discovery of a specialized unconscious system of infantile morality, the superego. What follows is a summary of the characteristics and contents of these structures, an analysis that will lead us directly into contemporary psychoanalytic formulations.

The structural theory, the dual-drive theory, and the Oedipus complex

The id: infantile sexuality and the Oedipus complex

The id is the mental structure that contains the mental representatives of the 'drives', that is, the ultimate intrapsychic motivations that Freud[7] described in his final, 'dual-drive theory' of libido and aggression, or metaphorically, the sexual or life drive and the destruction or death drive to be examined below. Behind this categorical formulation lies a complex set of discoveries regarding the patients' unconscious experiences that Freud came across in the course of the application of the psychoanalytic method to the treatment of neurotic and characterological symptoms. In exploring unconscious mental processes, what at first appeared to be specific traumatic life experiences turned out to reflect surprisingly consistent, repetitive intrapsychic experiences of a sexual and aggressive nature.

Freud[4] was particularly impressed by the regularity with which his patients reported the emergence of childhood memories reflecting seductive and traumatic sexual experiences on one hand, and intense sexual desires and related guilt feelings, on the other. He discovered a continuity between the earliest wishes for dependency and being taken care of (the psychology, as he saw it, of the baby at the mother's breast) during what he described as the 'oral phase' of development; the pleasure in exercising control and struggles around autonomy in the subsequent 'anal phase' of development (the psychology of toilet training); and, particularly, the sexual desire towards the parent of the opposite gender and the ambivalent rivalry for that parent's exclusive love with the parent of the same gender. He described this latter state as characteristic of the 'infantile genital stage' (from the third or fourth to the sixth year of life) and called its characteristic constellation of wishes and conflicts the positive Oedipus complex. He differentiated it from the negative Oedipus complex, i.e. the love for the parent of the same gender, and the corresponding ambivalent rivalry with the parent of the other gender. Freud proposed that Oedipal wishes came to dominate the infantile hierarchy of oral and anal wishes, becoming the fundamental unconscious realm of desire.

Powerful fears motivated the repression of awareness of infantile desire: the fear of loss of the object, and later of the loss of the object's love was the basic fear of the oral phase, directed against libidinal wishes to possess the breast; the fear of destructive control and annihilation of the self or the object was the dominant fear of the anal phase directed against libidinal wishes of anal expulsion and retentiveness, and the fear of castration, 'castration anxiety', the dominant fear of the Oedipal phase of development, directed against libidinal desire of the Oedipal object. Unconscious guilt was a dominant later fear, originating in the superego and generally directed against drive gratification (see under superego). Unconscious guilt over sexual impulses unconsciously equated with Oedipal desires constitute a major source of many types of pathology, such as sexual inhibition and related character pathology.

Prototypical intrapsychic infantile experiences linked to the Oedipus complex were fantasies and perceptions around the sexual intimacy of the parents (the 'primal scene'), and unconscious fantasies derived from experiences with primary caregivers ('primal seduction'). In all these phases of infantile development of drive motivated wishes and fears, powerful aggressive strivings accompanied the libidinal ones, such as cannibalistic impulses during the oral phase of physical dependency on the breast and psychological dependency on mother, sadistic fantasies linked to the anal phase, and parricidal wishes and phantasies in the Oedipal stage of development.

Freud described the oral phase as essentially coinciding with the infantile stage of breast feeding, the anal phase as coinciding with struggles around sphincter control, and the Oedipal stage as developing gradually during the second and through the fourth years, and culminating in the fourth and the fifth years of life. This latter phase would then be followed by more general repressive processes under the dominance of the installation of the superego, leading to a 'latency phase' roughly corresponding to the school years, and finally, to a transitory reactivation of all unconscious childhood conflicts under the dominance of Oedipal issues during puberty and early adolescence.

The id: drives

The drives represent for human behaviour what the instincts constitute for the animal kingdom, i.e. the ultimate biological motivational system. The drives are constant, highly individualized, developmentally shaped motivational systems. Under the dominance of the drives and guided by the primary process, the id exerts an ongoing pressure towards gratification, operating in accordance with the pleasure principle. Freud initially equated the drives with primitive affects. After discarding various other models of unconscious motivation, he ended up with the dual-drive theory of libido and aggression.

He described the libido or the sexual drive as having an 'origin' in the erotogenic nature of the leading oral, anal, and genital bodily zones; an 'impulse' expressing the quantitative intensity of the drive by the intensity of the corresponding affects; an 'aim' reflected in the particular act of concrete gratification of the drive; and an 'object' consisting of displacements from the dominant parental objects of desire.

The introduction of the idea of an aggressive or 'death' drive, arrived at later in Freud's[7, 8] writing, stemmed from his observations of the profound self-destructive urges particularly manifest in the psychopathology of major depression and suicide, and of the 'repetition compulsion' of impulse-driven behaviour that frequently seemed to run counter to the pleasure principle that supposedly governed unconscious drives. He never spelled out the details of the aggressive drive as to its origins. This issue was taken up later by Klein,[9] Fairbairn,[10] Winnicott,[11] Jacobson,[12] and Mahler and her colleagues.[13] Freud described drives as intermediate between the body and the mind; the only thing we knew about them, Freud suggested,[14] were 'representations and affects'.

The structure and functions of the ego

While the id is the seat of the unconscious drives, and functions according to the 'primary process' of the dynamic unconscious, the ego, Freud[5] proposed, is the seat of consciousness as well as of unconscious defence mechanisms that, in the psychoanalytic treatment, appear as 'resistances' to free association. The ego functions according to the logical and reality-based principles of 'secondary process', negotiating the relations between internal and external reality. Guided by the reality principle, it exerts control over perception and motility; it draws on preconscious material, controls 'attention cathexes' and permits motor delay as well as selection of imagery and perception. The ego is also the seat of basic affects, particularly anxiety as an alarm signal against the danger of emergence of unconscious, repressed impulses. This alarm signal may turn into a disorganized state of panic when the ego is flooded with external perceptions that activate unconscious desire and conflicts, or with overwhelming, traumatic experiences in reality that resonate with such repressed unconscious conflicts, and overwhelm the particularly sensitized ego in the process. The fact that the ego was seen by Freud as the seat of affects, and that affects had previously been described by him as discharge phenomena reflecting drives (together with their mental representations) tended to dissociate affects from drives in psychoanalytic theory, in contrast to their originally being equated in Freud's early formulations. As we shall see, this issue, the centrality of affects in psychic reality and interactions, has gradually re-emerged as a major aspect of contemporary psychoanalytic thinking.

Freud originally equated the 'I', i.e. the categorical self of the philosophers, with consciousness; later, once he established the theory of the ego as an organization of both conscious and unconscious functions, he at times treated the ego as if it were the subjective self, and at other times, as an impersonal organization of functions. Out of this ambiguity evolved the contemporary concept of the self within modern ego psychology as well as in British and American object relations and cultural psychoanalytic contributions.[15] An alternative theory of the self was proposed by Kohut[16] the originator of the self-psychology approach within contemporary psychoanalysis.

Nowadays, an integrated concept of the self as the seat of subjectivity is considered an essential structure of the ego, and the concept of 'ego identity' refers to the integration of the concept of the self: because of developmental processes in early infancy and childhood better understood today, an integrated self-concept usually goes hand-in-hand with the capacity for an integrated concept of significant others. An unconscious tendency towards primitive dissociation or 'splitting' of the self-concept and of the concepts of significant objects runs counter to such integration: we shall return to this process later. Already Freud,[17] in one of his last contributions, described a process of splitting in the ego as a way of dealing with intolerable intrapsychic conflict, thus opening up the road for considering splitting processes of the ego as an alternative, pathological defence against intolerable intrapsychic conflict (alternative, that is, to the repression of that conflict and to drawing important related ego functions into repression as well).

Character, from a psychoanalytic perspective, may be defined as constituting the behavioural aspects of ego identity (the self-concept) and the internal relations with significant others (the internalized world of 'object relations'). The sense of personal identity and of an internal world of object relations, in turn, reflect the subjective side of character. It was particularly the ego psychological approach—one of the dominant contemporary psychoanalytic schools—that developed the analysis of defensive operations of the ego, and of pathological character formation as a stable defensive organization that needed to be explored and resolved in the

psychoanalytic treatment. In the process, ego psychology contributed importantly to the psychoanalytic treatment of personality disorders.

Personality disorders reflect typical constellations of pathological character traits derived from abnormal developmental processes under the influence of unconscious intrapsychic conflicts. The description of 'reaction formation' as one of the defences of the ego led Freud to the description of the 'oral', 'anal', and 'genital' characters, particularly to the description of the obsessive–compulsive personality as a typical manifestation of reaction formations against anal drive derivatives. This was followed by the description by Abraham[18] of the hysterical personality as a consequence of multiple reaction formations against the female castration complex. Over the years, psychoanalytic explorations led to the description of a broad spectrum of pathological character constellations, which today are a part of the spectrum of personality disorders.

Perhaps the most important psychoanalytic contribution to character pathology and the personality disorders is the clinical description of the narcissistic personality disorder. While Freud provided the basic elements that led to its eventual description, psychoanalytic understanding and treatment, it was not he who crystallized the concepts of normal and pathological narcissism. Freud[19] conceptualized narcissism as the libidinal investment of the ego or self, in contrast to the libidinal investment of significant others ('objects'). In proposing the possibility of a withdrawal of libidinal investment from others with an excessive investment in the self as the basic feature of narcissistic pathology, he pointed to a broad spectrum of psychopathology, and thus first stimulated the contribution of Abraham,[20] and later those of Klein,[21] Rosenfeld,[22] Grunberger,[23] Kohut,[16] Jacobson,[12] and Kernberg.[24] Thus, crystallized the description of the narcissistic personality as a disorder derived from a pathological integration of a grandiose self as a defence against unbearable aggressive conflicts, particularly around primitive envy.

The superego in normality and pathology

In his analysis of unconscious intrapsychic conflicts between drive and defence, Freud regularly encountered unconscious feelings of guilt in his patients, reflecting an extremely strict, unconscious infantile morality, which he called the superego. This unconscious morality could lead to severe self-blame and self-attacks, and particularly, to abnormal depressive reactions, which he came to regard as expressing the superego's attacks on the ego. It was particularly in studying normal and pathological mourning, where Freud[6] arrived at the idea of excessive mourning and depression as reflecting the unconscious internalization of the representation of an ambivalently loved and hated lost object. In unconsciously identifying the self with that object introjected into the ego, the individual now attacked his or her own self in replacement of the previous unconscious hatred of the object; and the internalization of aspects of that object into the superego reinforced the strictness of the individual's pre-existing unconscious infantile morality.

Freud traced the origins of the superego to the overcoming of the Oedipus complex via unconscious identification with the parent of the same gender: in internalizing the Oedipal parent's prohibition against the rivalry with him or her and the unconscious death wishes regularly connected with such a rivalry, and against the incestuous desire for the parent of the other gender, this internalization crystallized an unconscious infantile morality. The superego, thus based upon prohibitions against incest and parricide, and a demand for submission to, and identification with the Oedipal rival, became the guarantor of the capacity for identification with moral and ethical values in general. In simple terms, the little boy renounces mother out of fear and love of father, takes father's fantasized prohibition against the little boy's sexuality into the superego as a fundamental prohibition, and establishes an identification with his father in the consolidation of his character structure. The little boy thus enacts the unconscious fantasy that, in identifying with father, he will gradually grow into his role, and satisfy his sexual desire in the distant future, by choosing another woman who, unconsciously and symbolically, will represent mother. The superego thus introduces a new time perspective into the functioning of the psychic apparatus.

Freud also described the internalization of the idealized representations of both parents into the superego in the form of the 'ego ideal'. He suggested that the earliest sources of self-esteem, derived from mother's love, gradually fixated by the baby's and small child's internalizations of the representations of the loving mother into the ego ideal, led to the parental demands becoming internalized as well. In other words, normally self-esteem is maintained both by living up to the expectations of the internalized idealized parental objects, and by submitting to their internalized prohibitions. This consideration of self-esteem regulation leads to the clinical concept of narcissism as normal or pathological self-esteem regulation, in contrast to the theoretical concept of narcissism as the libidinal investment of the self.

The superego, in summary, is a mental structure constituted by the internalized demands and prohibitions from the parental objects of childhood, the 'heir to the Oedipal complex'. This unconscious structure is of fundamental importance in determining unconscious 'fixations' to infantile prohibitions against drive derivatives and the corresponding unconscious motivation for the activation of a broad spectrum of ego defences against them, thus preventing the ego from responsibility-examining and reintegrating unresolved pathogenic conflicts from early childhood. In health, this internal sense of unconscious morality is the underpinning of moral and ethical systems. Excessive superego severity, usually derived from excessive parental strictness, determines excessive repressive mechanisms and ego inhibitions, irrational moralistic behaviour, or pathological activation of depression and loss of self-esteem.

Having thus summarized the basic psychoanalytic theory of motivation (drives), of development (the stages of development from the early oral phase to the dominance of the Oedipal complex), of structure (the tripartite model), and their implications for psychopathology, I shall now describe more specifically the contemporary psychoanalytic theory of psychopathology and of psychoanalytic treatment.

Psychoanalytic treatment

The psychoanalytic theory of psychopathology

The psychoanalytic theory of psychopathology proposes that the clinical manifestations of the symptomatic neuroses, character pathology, perversions, sexual inhibitions, and selected types of psychosomatic and psychotic illness reflect unconscious intrapsychic conflicts between drive derivatives following the pleasure principle,

defensive operations reflecting the reality principle, and the unconscious motivations of the superego. Unconscious conflicts between impulse and defence are expressed in the form of structured conflicts between the agencies of the tripartite structure: there are ego defences against impulses of the id; the superego motivates inhibitions and restrictions in the ego; at times the repetitive, dissociated expression of id impulses ('repetition compulsion') constitutes an effective id defence against superego pressures. The resolution of unconscious conflicts implies the analysis of all these intersystemic conflicts.

All these conflicts are expressed clinically by three types of phenomena:

1 inhibitions of normal ego functions regarding sexuality, intimacy, social relations, work, and affect activation;

2 compromise formations between repressed impulses and the defences directed against them;

3 dissociative expression of impulse and defence.

The last category implies a dominance of the splitting mechanisms referred to before; these have acquired central importance in the understanding of severe character pathology as reflected in contemporary psychoanalytic thinking.

The structural formulation of the psychoanalytic method

Psychoanalytic treatment consists, in essence, in facilitating the reactivation of the pathogenic unconscious conflicts in the treatment situation by means of a systematic analysis of the defensive operations directed against them. This leads to the gradual emergence of repressed impulses, with the possibility of elaborating them in relation to the analyst, and their eventual adaptive integration into the adult ego. Freud[25] had described the concept of 'sublimation' as an adaptive transformation of unconscious drives: drive derivatives, converted into a consciously tolerable form, are permitted gratification in a symbolic way while their origin remains unconscious. The result of this process is an adaptive, non-defensive compromise formation between impulse and defence. In analysis, the gradual integration into the patient's conscious ego of unconscious wishes and desires from the past and the understanding of the phantasized threats and dangers connected with them, facilitates their gradual elaboration and sublimatory expression in the consulting room and in everyday life as well.

The object-relations theory formulation of psychoanalytic treatment

In the light of contemporary object-relations theory, the formulation based upon the structural theory (resolution of unconscious conflicts between impulse and defence) has changed, in the sense that all unconscious conflicts are considered to be imbedded in unconscious internalized object relations. Such internalized object relations determine both the nature of the defensive operations and of the impulses against which they are directed. These internalized object relations constitute, at the same time, the 'building blocks' of the tripartite structure of id, ego, and superego. Object-relations theory proposes that the gradual analysis of intersystemic conflicts between impulse and defence (structured into conflicts between ego, superego, and id) decomposes the tripartite structure into the constituent conflicting internalized object relations. These object relations are reactivated in the treatment situation in the form of an unconscious relation between self and significant others replicated in the relation between patient and analyst, i.e. the 'transference'.

The transference is the unconscious repetition in the 'here and now' of unconscious, conflicting pathogenic relationships from the past. The transference reflects the reactivation of the past conflict not in the form of a memory, but in the form of a repetition. This repetition provides essential information about the past, but constitutes, at the same time, a defence in the sense that the patient repeats instead of remembering. Therefore, transference has important informative features that need to be facilitated in their development, and defensive features that need to be therapeutically resolved once their nature has been clarified. Transference analysis is the fundamental ingredient of the psychoanalytic treatment.

The psychoanalytic treatment process

The psychoanalytic treatment consists of the creation of an atmosphere of safety in which a patient is willing to try to express whatever comes to mind. In 45 to 50 min sessions, three to five times per week, the patient usually reclines on a couch while the analyst, generally sitting behind the patient, helps the patient become aware of his or her defensive operations ('resistances') by means of interpretations. The systematic interpretation of resistances gradually permits an ever-growing freedom of free association, and helps the patient to become aware of his or her unconscious desires and fears, phantasies and terrors, traumatic situations, and unresolved mourning. Defensive operations are usually classified as ego defences (in the form of the mechanisms listed earlier), superego defences in the form of excessive guilt feelings activated during the treatment, id resistances in the form of repetition compulsion, the development of secondary gain from symptoms as a powerful resistance, and, last and most importantly, the transference as the dominant resistance and source of information.

Gill,[26] in a classical definition that is still relevant today, proposed the definition of psychoanalysis as a treatment that facilitates the development of a 'regressive transference neurosis' and its resolution by means of interpretation alone, carried out by the analyst from a position of technical neutrality. Let us define these concepts.

'Regression' refers to the patient's return to earlier experiences (temporal regression), and modes of functioning (structural and formal regression) under the effect of the analysis of resistances, and is an expression of the reactivation of his unconscious conflicts from the past in the transference. In essence, the patient activates or enacts earlier object relations in the transference. Certain past stages of development where particular traumatic experiences occurred act as gathering points ('fixations') that foster regression towards them. The concept of a regressive transference neurosis refers to the gradual gathering into the relationship with the analyst of the patient's most important past pathogenic experiences and unconscious conflicts. The concept of a regressive transference neurosis has been largely abandoned in practice because, particularly in patients with severe character pathology, transference regression occurs so early and consistently that the gradual development of a regressive transference neurosis is no longer a useful concept.

Gill's proposal that the resolution of the transference be achieved 'by interpretation alone', refers to 'interpretation' as a set of the psychoanalyst's interventions that starts with 'clarification' of the

patient's subjective experiences communicated by means of free association, expands with the tactful 'confrontation' of aspects of the patient's patterns of behaviour that are expressed in a dissociated or split-off manner from his subjective awareness, and thus complements the total expression of his intrapsychic life in the treatment situation, and finally evolves into 'interpretation per se'. Interpretation per se implies the formulation of hypotheses regarding the unconscious meanings in the 'here and now' of the patient's material, and the relation of these unconscious meanings with the 'there and then' of the patient's unconscious, past pathogenic experiences. The analysis of the transference is 'systematic', in the sense that all emerging transference dispositions are interpreted, ideally, in the natural sequence of their emergence in the analytic situation. Gill's phrase, 'by interpretation alone', implies that the psychoanalyst abstains from measures other than helping the patient to fully understand the unconscious conflicts activated in the here and now. Thus, providing guidance about life decisions, or attempting to modify the patient's behaviour or state by means of praise, prohibition, or reward is not part of the psychoanalytic method of treatment.

The concept of 'technical neutrality' refers to the analyst's impartiality regarding both impulse and defence, with a concerned objectivity that provides a helpful collaboration with the patient's efforts to come to grips with his intrapsychic conflicts.

This definition of the nature of psychoanalytic treatment needs to be complemented with the contemporary concepts of 'transference', 'countertransference', 'acting out', and 'working through'.

An object-relations theory model of the transference and countertransference

Modern object-relations theory, further explored below, and presented in more detail in terms of particular schools in Chapter 3.2, proposes that, in the case of any particular conflict around sexual or aggressive impulses, the conflict is imbedded in an internalized object relation, i.e. in a repressed or dissociated representation of the self ('self-representation') linked with a particular representation of another who is a significant object of desire or hatred ('object representation'). Such units of self-representation, object representation, and the dominant sexual, dependent or aggressive affect linking them are the basic 'dyadic units', whose consolidation will give rise to the tripartite structure. Internalized dyadic relations dominated by sexual and aggressive impulses will constitute the id; internalized dyadic relations of an idealized or prohibitive nature the superego, and those related to developing psychosocial functioning and the preconscious and conscious experience, together with their unconscious, defensive organization against unconscious impulses, the ego. These internalized object relations are activated in the **transference** with an alternating role distribution, i.e. the patient enacts a self-representation while projecting the corresponding object representation onto the analyst at times, while at other times projecting his self-representation onto the analyst and identifying with the corresponding object representation. The impulse or drive derivative is reflected by a dominant, usually primitive affect disposition linking a particular dyadic object relation; the associated defensive operation is also represented unconsciously by a corresponding dyadic relation between a self-representation and an object representation under the dominance of a certain affect state.

For example, a conflict between unconscious aggression and unconscious guilt feelings, respectively located in id and superego, is clinically represented by manifestations of a guilt-provoking object representation relating to a guilty self (the superego defence), and an enraged self-representation attempting to attack a threatening or frustrating object representation (the id impulse). The development of the transference, therefore, consists of a sequence of activation of such impulsively determined and defensively determined internalized object relations and their systematic clarification, confrontation, and interpretation by the analyst.

The concept of **countertransference**, originally coined by Freud as the unresolved, reactivated transference dispositions of the analyst is currently defined as the total affective disposition of the analyst in response to the patient and his or her transference, shifting from moment to moment, and providing important data of information to the analyst. The countertransference, thus defined, may be partially derived from unresolved problems of the analyst, but stems as well from the impact of the dominant transference reactions of the patient, from reality aspects of the patient's life, and sometimes from aspects of the analyst's life situation that are emotionally activated in the context of the transference developments. In general, the stronger the transference regression, the more the transference determines the countertransference; thus the countertransference becomes an important diagnostic tool. The countertransference includes both the analyst's empathic identification with a patient's central subjective experience ('concordant identification') and the analyst's identification with the reciprocal object or self-representation ('complementary identification') unconsciously activated in the patient as part of a certain dyadic unit, and projected onto the analyst.[27] In other words, the analyst's countertransference implies an identification with what the patient cannot tolerate in him- or herself, and must dissociate, project, or repress.

At this point, it is important to refer to certain primitive defensive operations that were described by Klein[9] and her school in the context of the analysis of severe character pathology. Primitive defensive operations are characteristic of patients with severe personality disorders, and emerge in other cases during periods of regression. They include splitting, projective identification, denial, omnipotence, omnipotent control, primitive idealization, and devaluation (contempt). All these primitive defences centre around splitting, i.e. an active dissociation of contradictory ego (or self) experiences as a defence against unconscious intrapsychic conflict. They represent a regression to the phase of development (the first 2 to 3 years of life) before repression and its related mechanisms mentioned are established.

Primitive defensive operations present important behavioural components that tend to induce behaviours or emotional reactions in the analyst, which, if the analyst manages to 'contain' them, permit him to diagnose in himself projected aspects of the patient's experience. Particularly 'projective identification' is a process in which:

1 the patient unconsciously projects an intolerable aspect of self-experience onto (or 'into') the analyst;

2 the analyst unconsciously enacts the corresponding experience ('complementary identification');

3 the patient tries to control the analyst, who now is under the effect of this projected behaviour;

4 the patient meanwhile maintains empathy with what is projected.

This scenario is in contrast to the more mature mechanism of 'projection', secondary to repression, where there is no longer any conscious emotional contact with what is projected. Such complementary identification in the countertransference permits the analyst to identify him- or herself through his own experience with the aspects of the patient's experience communicated by means of projective identification. This information complements what the analyst has discovered about the patient by means of clarification and confrontation, and permits the analyst to integrate all this information in the form of a 'selected fact' that constitutes the object of interpretation. Interpretation is thus a complex technique that is very much concerned with the systematic analysis of both transference and countertransference.

Contemporary trends of the psychoanalytic method

Contemporary psychoanalytic technique can be seen as having evolved from a 'one person psychology' into a 'two person psychology' and then into a 'three person psychology'. The concept of 'one person psychology' refers to Freud's original analysis of the patient's unconscious intrapsychic conflicts by analysing the intrapsychic defensive operations that oppose free association. The 'two person psychology' refers to the central focus on the analysis of transference and countertransference. In the views of the contemporary intersubjective, interpersonal, and self-psychology psychoanalytic schools, the relationship between transference and countertransference is mutual, in the sense that the transference is at least in part a reaction to reality aspects of the analyst, who therefore must be acutely mindful of his contribution to the activation of the transference. The so-called 'constructivist' position regarding transference analysis assumes that it is impossible for the analyst to achieve a totally objective position outside the transference/countertransference bind.

In contrast, the contemporary 'objectivist' position, represented by the 'three person psychology' approaches of the Kleinian school, the French psychoanalytic mainstream, and significant segments of contemporary ego psychology proposes that the analyst has to divide him- or herself between one part influenced by transference and countertransference developments, and another part that, by means of self-reflection, maintains him- or herself outside this process, as an 'excluded third party', who, symbolically, provides an early triangulation to the dyadic regression that dominates transference developments. This triangulation in the treatment situation becomes particularly important in the treatment of severe personality disorders.

The 'enactment' of pathogenic past internalized object relations in the form of both transference and countertransference developments needs to be differentiated from **acting out**, the replacement of self-awareness by often dramatic, and at times, violent action. It is characteristic of patients with severe character pathology, and may occur in both patient and analyst under the influence of regression. Acting out may occur both during and outside the sessions. While it reflects an intense defensive operation and resistance, it also offers the opportunity for a very fundamental exploration of a primitive conflict, if dealt with by consistent interpretations in as much depth as possible. Acting out may also be considered an extreme, behavioural manifestation of 'enactment' as the usual experience of transference/countertransference manifestations.

The **repetition compulsion** as a resistance of the id is most probably a form of acting out as a defence against emotional containment of an extremely painful or traumatic set of experiences. **Working through** refers to the repeated elaboration of an unconscious conflict in the psychoanalytic situation. It is a major task for the analyst, who has to be alert to the subtle variation in meanings and implications of what on the surface may appear to be an endless repetition of the same conflict in the transference. The patient elaboration of the conflict that presents itself with these repetitive characteristics also implies the function of 'holding' originally described by Winnicott.[11] It consists of the analyst's capacity to withstand the onslaught of primitive transferences without retaliation, abandonment of the patient, or a self-devaluing giving up, and the maintenance of a working relationship (or 'therapeutic alliance') that addresses itself consistently to the healthy part of the patient, even when the latter is under the control of his most conflicting behaviours. Bion's concept[28] of 'containing' is complementary to 'holding', in the sense that holding deals mostly with the affective disposition of the analyst, and containing with his cognitive capacity to maintain a concerned objectivity and focus on the 'selected fact', permitting the integration in the analyst's mind what the patient can only express in violently dispersed or split-off behaviour patterns.

Dream analysis developed in the context of the method of free association, and constituted, in Freud's[29] view, a 'royal road to the unconscious'. Freud's discovery of primary process thinking derived from his method of dream analysis. By now, psychoanalytic thinking has evolved into the view that there are many 'royal roads' to the unconscious. The analysis of character defences, for example, or of particular transference complications, may be equally important avenues of entry into the patient's unconscious mind.

The technique of dream analysis consists, in essence, in asking the patient to free associate to elements of the 'manifest content' of the dream, in order to arrive at its 'latent' content, the unconscious wish defended against and distorted by the unconscious defensive mechanisms that constitute the 'dream work', and have transformed the latent content into the manifest dream. The latent content is revealed with the help of the simultaneous analysis of the way in which the dream is being communicated to the analyst, the 'day residuals' that may have triggered the dream, the unconscious conflicts revealed in it, and the dominant transference dispositions in the context of which the dream evolved. Dreams also provide some residual, universal symbolic meanings that may facilitate the total understanding of the latent content.

The **analysis of character** may be the single most important element of the psychoanalytic method in bringing about fundamental characterological change. Character analysis is facilitated by the patient's use of reaction formations, i.e. his defensively motivated character traits, as transference resistances. Thus, the activation of defensive behaviours in the transference, reflecting the patient's characterological patterns in all interpersonal interactions, facilitates both the analysis of the underlying unconscious conflicts, and in the process, the resolution of pathological character patterns. The result is an increase in the patient's autonomy, flexibility, and capacity for adaptation. Character analysis was originally developed by Reich[30] within an ego-psychology perspective, but has re-emerged in the work of Rosenfeld[31] and Steiner[32] in the analysis of 'pathological organizations' in the transference, within the Kleinian school. Gray[33] and Busch[34] within an ego-psychological perspective, have

enriched further the technique of character analysis by means of detailed exploration of particular characterological defences in the transference.

Character analysis, although not always referred to under this specific heading, constitutes a major focus of contemporary psychoanalytic treatment. In essence, its technique addresses repetitive, ego syntonic behaviour patterns in the transference, raising the patient's curiosity about their function in the relationship with the analyst, and inviting the patient to associate about this behaviour. Gradually, their exploration makes character resistances ego dystonic, and facilitates the discovery of the underlying internalized object relations condensed in these pathological character traits, both in their defensive and impulsive meanings. The question, to what extent such rigid behaviours should be analysed first, in order to free the patient's capacity for analytic work, or to what extent they should be left for later, until more fluid conflicts have been resolved, has been settled in favour of the general psychoanalytic technical principle of focusing interpretations upon what is affectively dominant in each hour.[35] Affective dominance refers once more to the 'selected fact',[36] to be interpreted. All interpretations are usually carried out from surface to depth, which in practice means first analysing the object relation activated by the need for defence before analysing the corresponding object relation activated by impulse.

The overall objective of psychoanalytic treatment is not only the resolution of symptoms and pathological behaviour patterns or characteristics, but fundamental, structural change, that is the expansion and enrichment of ego functions as the consequence of resolution of unconscious conflict and the integration of previously repressed and dynamically active id and superego pressures into ego potentialities. Such change is reflected in the increasing capacity for both adaptation to and autonomy from psychosocial demands and expectations, and an increased capacity for gratifying and successful functioning in love and work.

Derived modalities of treatment

One of the most important contributions of psychoanalytic theory and technique to the contemporary treatment of a broad spectrum of patients with severe psychopathology who, for various reasons, cannot benefit from psychoanalytic treatment proper, is the development of psychoanalytic psychotherapy, also called expressive or exploratory psychotherapy, and of supportive psychotherapy (SP) based on psychoanalytic principles. These treatments are explored below.

Psychoanalytic psychotherapy

Psychoanalytic psychotherapy may be characterized by the same basic techniques as psychoanalysis, but with quantitative modifications that, in combination, result in a qualitative shift in the nature of the treatment. Any given session of psychoanalytic psychotherapy may be indistinguishable from a psychoanalytic session, but over time, the differences emerge quite clearly. Psychoanalytic psychotherapy utilizes interpretation, but with patients with severe psychopathology, a good deal of time must be devoted to clarification and confrontation before interpretation can be effective; and interpretations of unconscious meanings in the 'here and now' occupy the foreground until late in the treatment, when genetic interpretations in the 'there and then' become useful.[15, 37]

In the treatment of patients with severe character pathology, transference analysis is the essential focus of psychoanalytic psychotherapy from the very beginning; it must be modified, however, by active interpretive connection of transference analysis with exploration in depth of the patient's daily life situation, an approach made necessary by the predominance of primitive defence operations in these patients. Splitting operations in particular tend to dissociate the therapeutic situation from the patient's external life, and may lead to severe, dissociated acting out either in the sessions or outside the sessions. Therefore, interpretive linkage between the patient's external reality and transference developments in the hours becomes central.

In order to enable the therapist to analyse transference developments in sufficient depth, psychoanalytic psychotherapy requires a minimum frequency of two sessions per week. It is usually carried out in 'face-to-face' sessions.

Technical neutrality is an essential feature of analysis in general, but in the treatment of patients with severe character pathology, the need to set limits may necessitate abandoning neutrality again and again, in order to control life- or treatment-threatening acting out. The self-perpetuating nature of acting out in these cases may prove impossible to resolve interpretively without such structuring or setting limits. Whenever the analyst has to abandon technical neutrality to protect the patient or the treatment, it is essential to explore the episode immediately. The transference implications of the therapist's structuring behaviour must be laid out, followed by the analysis of the transference implications of the patient's behaviour that necessitated the imposition of limits or the initiation of a new structure in the treatment; this in turn is followed by the gradual resolution of the structure or limit setting by interpretive means, thus restoring technical neutrality. In short, technical neutrality in psychoanalytic psychotherapy is an ideal working state that is again and again preventively abandoned and interpretively reinstated.[15, 37, 38]

Supportive psychotherapy

Supportive psychotherapy based on psychoanalytic theory may also be defined in terms of the three major techniques of interpretation, transference analysis, and technical neutrality. Supportive psychotherapy utilizes the preliminary steps of interpretive technique, i.e. clarification and confrontation, but rarely uses interpretation per se. It seeks to strengthen the ego by bolstering adaptive compromises between impulse and defence through the provision of cognitive support in the form of information, persuasion and advice, and emotional support via suggestion, reassurance, encouragement, and praise. Supportive psychotherapy may call upon direct environmental intervention by the therapist, relatives, or other mental health personnel engaged in auxiliary therapeutic functions.[39]

While the transference is seldom interpreted in supportive psychotherapy, it is not ignored either. Careful attention to transference developments helps the therapist to analyse any maladaptive transference developments, to call the patient's attention to the reproduction with the therapist of pathological interactions the patient generally engages in with significant others, and to encourage the patient to reduce such pathological behaviours. Pointing out the distorted, unproductive, destructive, or confusing nature of the patient's behaviour is accompanied by clarifying the patient's conscious reasons for his behaviour, followed by the transfer or 'export' of the knowledge thus achieved to the patient's relationships outside the treatment. In short, supportive psychotherapy includes the clarification, reduction, and 'export' of the transference, thus contributing to

the re-educative functions of supportive psychotherapy together with the direct cognitive and affective support of adaptive combinations of impulse and defence, and direct supportive environmental interventions.

Technical neutrality is systematically abandoned in supportive psychotherapy, the therapist taking a stance alternatively on the side of the ego, superego, id, or external reality, according to which agency represents, at a certain point, the more adaptive potential for the patient. The main dangers, of course, in supportive psychotherapy are, on the one hand, infantilizing the patient by an excessively supportive stance, and, on the other, countertransference acting out as a consequence of the abandonment of the position of technical neutrality. The therapist carrying out supportive psychotherapy, therefore, needs a heightened awareness of the risk of these complications. Like psychoanalytic psychotherapy, supportive psychotherapy is carried out in 'face-to-face' sessions. It has the advantage of considerable flexibility regarding its frequency, from several sessions per week, to one session a week, or one or two sessions per month, according to the urgency of the patient's present difficulties, the long-range objectives of the treatment, and the patient's ability to tolerate and use the relationship with the therapist.

Indications and contraindications for psychoanalysis and derived psychotherapies

The **indications** for these three modalities of treatment remain controversial: with the recognition of the limitations of psychoanalysis in many cases with severe, chronic, life-threatening self-destructive behaviour, such as chronic suicidal behaviour, severe eating disorders, dependence upon drugs or alcohol, and severely antisocial behaviour, psychoanalytic psychotherapy has proven to be a highly effective treatment for many but by no means all patients with these conditions. The differential diagnosis of a spectrum of severity of antisocial behaviour and those cases of severe self-destructive and antisocial behaviour who are amenable to treatment with psychoanalytic psychotherapy has been one of the important side-products of the psychoanalytic exploration of these cases.[37]

Supportive psychotherapy, originally conceived of as the treatment of choice for patients with severe personality disorders, now may be considered the alternative treatment for those patients with severe personality disorders who are unable to participate in psychoanalytic psychotherapy. The Menninger Foundation Psychotherapy Research Project showed that patients with the least severe psychopathological disturbances tend to respond very positively to all three modalities derived from psychoanalytic theory, although best to standard psychoanalysis.[40]

Standard psychoanalysis is the treatment of choice for patients with neurotic personality organization, that is with good identity integration and a repertoire of defences centring on repression along with sufficient severity of illness to warrant such a major therapeutic intervention. Psychoanalysis has also expanded its scope to some of the severe personality disorders, particularly a broad spectrum of patients with narcissistic personality disorders, patient with mixed hysterical-histrionic features, and selected cases of patients with severe paranoid, schizoid, and sado-masochistic features.

We are still lacking systematic studies of the relationship between particular types of psychopathology and outcome with the various psychotherapeutic treatments derived from psychoanalytic theory. As a tentative generalization it may be stated that there is a definite relationship between outcome and the severity of illness in any diagnostic category. The least severe cases will respond favourably to either brief psychoanalytic psychotherapy, supportive psychotherapy, or psychoanalysis. Psychoanalysis represents the opportunity for most improvement if the severity of the case warrants psychoanalytic treatment. For cases of neurotic personality organization of moderate severity, psychoanalysis is the treatment of choice; definitely less can be expected in these cases from psychoanalytic psychotherapy. For the most severely ill patients (those with severe identity diffusion, predominance of primitive defences centring on splitting, and general 'ego weakness') psychoanalytic psychotherapy is the treatment of choice, with supportive psychotherapy a second choice if psychoanalytic psychotherapy is contraindicated. A few such cases may be able to participate in psychoanalysis and benefit from it.

In all cases, individualized **contraindications** for the respective treatment are important: in the case of psychoanalysis, individual contraindications depend on the questions of ego strength, motivation, introspection or insight, secondary gain of illness, intelligence, and age. In the case of psychoanalytic psychotherapy, secondary gain, the impossibility of control of life- or treatment-threatening acting out, limited intelligence, significant antisocial features, and a desperate life situation may constitute individual contraindications, particularly when they occur in combination. When psychoanalytic psychotherapy is contraindicated for such reasons, supportive psychotherapy becomes the treatment of choice. Participation in supportive psychotherapy requires a sufficient capacity for commitment to an ongoing treatment arrangement, and the absence of severe antisocial features as minimal individual requirements. This is not meant to be a complete list, but an illustration of the kind of criteria that become dominant in the individual decisions regarding the selection of the treatment and its contraindications.

Psychoanalytic object-relations theories: overview and critique

Given the centrality of object-relations theory in practically all contemporary psychoanalytic formulations and treatment approaches, the following summary is included. It should help the reader to further clarify the references made earlier to this theory.

Psychoanalytic object-relations theories may be defined as those that place the internalization, structuralization, and reactivation in the transference and countertransference of the earliest dyadic object relations at the centre of their clinical formulations, and of their thinking about motivation, pathogenesis, development, and psychic structure. Internalization of object relations refers to the concept that, in all interactions of the infant and child with the significant parental figures, what the infant internalizes is not merely an image or representation of the other ('the object' of fear, hatred, or desire), but the relationship between the self and the other, in the form of a self-image or self-representation linked to an object image or object representation by the affect that dominates their interaction. This internal structure replicates in the intrapsychic world both real and phantasied relationships with significant others.

Several major issues separate different object-relations theories, the most important of which is the extent to which the theory is perceived as harmonious with or in opposition to Freud's traditional drive theory: i.e. whether object relations are seen as replacing drives as the motivational system for human behaviour. From this perspective, Klein,[9,21] Mahler *et al.*,[13] and Jacobson[12] occupy one pole.

They combine Freud's dual-drive theory with an object-relations theory. For Fairbairn,[10] and Sullivan,[41] on the other hand, object relations themselves replace Freud's drives as the major motivational system. Here, the establishment of gratifying object relations in itself constitutes the major motivational system. Contemporary interpersonal psychoanalysis as represented by Greenberg and Mitchell,[42] based upon an integration of principally Fairbairnian and Sullivanian concepts, asserts the essential incompatibility between drive- and object relations-based models of psychic motivational systems. Winnicott,[11] Loewald,[43] Sandler,[44] and Sandler and Sandler,[45] (each for different reasons) maintain an intermediate posture; they perceive the affective frame of the infant–mother relationship as a crucial determinant in shaping the development of drives. While adhering to Freud's dual-drive theory, Kernberg[15] considers drives supraordinate motivational systems, while affects are their constituent components.

A related controversy has to do with the origin and role of aggression as motivator of behaviour. Those theoreticians who reject the idea of inborn drives,[41] or equate libido with the search for object relations,[10] conceptualize aggression as secondary to the frustration of libidinal needs, particularly traumatic experiences in the early mother–infant dyad. Theoreticians who adhere to Freud's dual-drive theory, in contrast, believe aggression is inborn and plays an important part in shaping early interactions: this group includes Klein in particular, and to some extent Winnicott, and ego-psychology object-relations theoreticians such as Kernberg.[37] Finally, contrast may be made between object-relations theories and French approaches, both Lacanian and (non-Lacanian) mainstream psychoanalysis. The French psychoanalytic mainstream,[46, 47] has maintained close links with traditional psychoanalysis, including the British object-relations theories. Insofar as Lacan[48] conceptualizes the unconscious as a natural language and focuses on the cognitive aspects of unconscious development, he underemphasizes affect—a dominant element of object-relations theories. At the same time, however, in postulating a very early Oedipal structuralization of all infant–mother interactions, Lacan emphasizes archaic Oedipal developments, which implicitly links his formulations with those of Kleinian object-relations theory in general. French mainstream analysis also focuses on archaic aspects of Oedipal developments, but places a traditional emphasis on Freud's dual-drive theory and on the affective nature of the early ego-id. As neither French mainstream nor Lacanian psychoanalysis spells out specific structural consequences of dyadic internalized object relations, however, neither would fit the definition that frames the field of object-relations theory as proposed in this chapter.

All object-relations theories focus heavily on the enactment of internalized object relations in the transference, and on the analysis of countertransference in the development of interpretive strategies. They are particularly concerned with severe psychopathologies, including those psychotic patients who are approachable with psychoanalytic techniques, borderline conditions, severe narcissistic character pathology, and the perversions ('paraphilias'). Object-relations theories explore primitive defensive operations and object relations both in cases of severe psychopathology and at points of severe regression with all patients, regarding such exploration as essential in facilitating transference analysis and conflict resolution.

The contemporary re-evaluation of Freud's dual-drive theory that has occurred mostly in France is relevant to the relationship between object-relations theory and drive theory. Perhaps particularly the work of Laplanche[49] and Green[46] has emphasized the central importance of unconscious destructive and self-destructive drive manifestations in the form of attacks on object relations, and the central role of unconscious erotization in the mother–infant relationship in libidinal development, all of which tends to link drive theory and object-relations theory in intimate ways.

Another important development within psychoanalytic theory has been the growing emphasis on affects as primary motivators, and the centrality of the communicative functions of affects in early development, particularly the infant–mother relationship.[50] This emphasis has linked affect theory and object-relations theory quite closely, despite the persistent controversy between those who see affect, particularly peak affect states, as essential representatives of the drives,[50] and those who stress the psychophysiological nature of the affective response, and attempt to replace drive theory with an affect theory.[51]

The basic (self-representation–object representation) units of internalized object relations include the representative affects, or else, the constituent affective components of the drives. One might say that the affect of sexual excitement is the central affect of libido, in the same way as the affect of primitive hatred constitutes the central affect of the aggressive or death drive. The id is conceptualized in this object-relations theory model as the sum total of repressed, desired, and feared primitive object relations. The gradual integration of successive layers of persecutory and idealized, prohibitive and demanding, internalized object relations become part of the primitive superego, while internalized object relations activated in the service of defence consolidate as part of an integrated self-structure surrounded by integrated representations of significant others. In short, the id or dynamic unconscious, the superego, and the ego are constituted by different constellations of internalized object relations, so that the development of the drives and the development of the psychic apparatus—the tripartite structure—occur hand in hand.

Perhaps the most important practical implication of object-relations theory is the conception of identification as a series of internalization processes of dyadic units of self-representation and object representation linked by a dominant affect state, ranging from earliest introjections to identifications per se, to the development of complex identity formation. Each step includes the internalizing of both self and object representations and their affective interactions under the conditions that prevail at different developmental levels.

In the transference of healthier patients, with a well-consolidated ego identity, the diverse self-representations are relatively stable in their coherent mutual linkage. This fosters the relatively consistent projection onto the analyst of the object representation aspect of the enacted object relationship. In contrast, patients with severe identity diffusion lack such linkage of self-representations into an integrated self. They tend to alternate rapidly between projection of self and object representations in the transference, so that the analytic situation seems chaotic. Systematic interpretation of how the same internalized object relation is enacted again and again with rapid role reversals between patient and analyst makes it possible to clarify the nature of the unconscious object relation, and the double splitting of self-representation from object representation and idealized from persecutory object relations. This process of interpretation promotes integration of the split representations, which characterize severe psychopathology and account for the marked instability of the emotions, behaviour, and interpersonal relationships of these patients.

Kernberg[37] proposes that affects are the primary motivational system and that, internalized or fixated as the very frame of internalized 'good' and 'bad' object relations, affects are gradually integrated into libidinal and aggressive drives to form hierarchically supraordinate motivational systems. In other words, primitive affects are the 'building blocks' of the drives. He sees unconscious intrapsychic conflicts as always between the following:

1 certain units of self and object representations under the impact of a particular drive derivative (clinically, a certain affect disposition reflecting the drive derivative side of the conflict);
2 contradictory or opposing units of self and object representations and their respective affect dispositions reflecting the defensive structure.

Unconscious intrapsychic conflicts are never simply between impulse and defence; rather, both impulse and defence find expression, respectively, through certain internalized object relations.

In patients with borderline personality organization and severe conflicts around early aggression, splitting mechanisms stabilize such dynamic structures within an ego-id matrix and permit the contradictory aspects of these conflicts to remain at least partially conscious, in the form of primitive, mutually split-off, idealized, and persecutory transferences. In contrast, patients with neurotic personality organization present impulse–defence configurations that contain specific unconscious wishes of an integrated though infantile self, reflecting sexual and aggressive drive derivatives embedded in unconscious phantasies relating to the Oedipal objects. Repressed unconscious wishes, however, always come in the form of corresponding units composed of self-representation and object representation and affect linking them.

Patients with neurotic personality organization present well-integrated superego, ego, and id structures; within the psychoanalytic situation, the analysis of resistances brings about the activation, in the transference, first of relatively global characteristics of these structures, and later, the internalized object relations of which they are composed. Oedipal conflicts dominate the dynamic unconscious of these patients. The analysis of drive derivatives occurs in the context of the analysis of the relation of the patient's infantile self to significant parental objects as projected onto the analyst.

Patients with severe personality disorders or borderline personality organization, in contrast, show a predominance of psychic representations of pre-Oedipal conflicts, with pre-Oedipal aggression, in particular, condensed with representations of the Oedipal phase. Conflicts are not predominantly repressed and therefore unconsciously dynamic: rather, they are avoided by being represented in mutually dissociated ego states reflecting the defence of primitive dissociation or splitting. The activation of primitive object relations that predate the consolidation of ego, superego, and id is manifest in the transference as apparently chaotic affect states, which have to be analysed in sequential steps as follows:

1 the clarification of a dominant primitive object relation in the transference, with its corresponding self and object representation, and the dominant affect linking them;
2 the analysis of the alternative projection of self and object representation onto the therapist, while the patient identifies with a reciprocal self or object representation of this object relationship, leading to the patient's gradual capacity to become aware of his identification with an object in that relationship;
3 the interpretive integration of mutually split-off, idealized and persecutory 'part object' relations with the characteristics mentioned.

This analysis may gradually bring about a transformation of mutually split, ('part object') relations into 'total object' relations, or of primitive transferences (largely reflecting Mahler's stages of development that predate object constancy) into the advanced transferences of the Oedipal phase. In other words, a gradual integration of self-representations into an integrated self-concept, and a parallel integration of significant object representations into integrated concepts of significant others develop first in the transference, and later generalize in the patient's relations with significant others. The analyst's exploration of his or her countertransference, including concordant and complementary identifications in the countertransference,[27] facilitates transference analysis; and the analysis of primitive defensive operations, particularly splitting and projective identification in the transference, also contributes to strengthening the patient's ego.

Treatment results: research on outcome

The psychoanalytic profession has been slow in developing systematic research on treatment process and results, let alone controlled randomized comparison of treatment methods evaluating efficacy and efficiency. The reasons are multiple: the complexity of the psychoanalytic treatment, and the changes in its technique; the long duration of treatment, making systematic research, and controlled comparison with other treatment methods difficult; the private nature of psychoanalytic exploration in the context of patients' regression, and the related concerns over disturbing the therapeutic relationship by recording or direct observation. In addition, the general methodology of psychotherapy research evolved to a degree of sophistication applicable to the evaluation of psychoanalytic treatment only in recent decades. With all these reservations, significant progress has been made, and outcome studies are beginning to be available.

The Menninger Psychotherapy Research Project, a naturalistic study comparing psychoanalysis, psychoanalytic psychotherapy, and SP, showed psychoanalysis to be the most effective of these approaches with patients presenting relatively good ego strength, while patients with severe ego weakness—what nowadays would be described as presenting severe personality disorders or borderline personality organization—improved most with psychoanalytic psychotherapy.[39] This research also showed how important supportive elements were throughout all modalities of treatment.[52] A comprehensive review of outcome studies on psychoanalytic psychotherapy and psychoanalysis by Bachrach *et al.*[53] concluded that the improvement rates are in the 60 to 90 per cent, but it also pointed to limitations and problems in the methodology utilized.

Recently, studies regarding the treatment process and outcome of psychoanalysis and psychoanalytic psychotherapy have become more precise in defining the specific treatment variables of psychotherapeutic and psychoanalytic treatments, and several systematic studies on psychoanalytic psychotherapies and psychoanalysis are in progress.[54] A recent study by the Stockholm Outcome of Psychoanalysis and Psychotherapy Project has found, on the basis of a relatively large patient population, that psychoanalytic treatment, in comparison with psychoanalytic psychotherapy, obtained a significantly higher degree long-range symptomatic improvement.[55] The extent to which the psychotherapist had years of experience linked with

appropriate, long-term supervisory experiences, i.e. an 'experiential learning cluster', was related to treatment outcome, in the sense that those therapists with long experiences in doing teaching or supervision of psychotherapy had a significantly better outcome than therapists who only had been in supervision or personal therapy for long periods. It also appeared that the maintenance of a rigid 'psychoanalytic' attitude as part of a psychoanalytic psychotherapy was not as effective as a more flexible shift in techniques in psychotherapy, but not in analysis proper.[56] A manualized psychoanalytic psychotherapy for a specific patient population, namely, the psychotherapy research project of the Cornell Personality Disorders Institute's manualized treatment for borderline patients has provided evidence for the efficacy of the treatment with severely ill patients. This treatment, called Transference Focused Psychotherapy (TFP) was found to be more effective than treatments as usual (TAU) for borderline patients,[38] and, compared to dialectic behaviour therapy (DBT), and supportive psychotherapy (SP) in a randomized controlled study, proved as effective as DBT and SP in improving depression, anxiety, global functioning, and social adjustment at the end of 1 year of treatment. It also was more effective in reducing aggression than DBT and SP, and the only one to improve reflective function (RF), an index of mentalization, that is the patient's capacity for self-reflection and appropriate assessment of others in depth.[57,58] (Bateman and Fonagy[59,60] have found that mentalization-based therapy (MBT), another form of psychoanalytic psychotherapy was more effective than treatment as usual (TAU) in the treatment of borderline patients in a day hospital setting. Further developments of MBT research will be referred to in Sections 3, 5, and 6.

In summary, process research has predated outcome research on psychoanalysis and derived psychotherapies; major efforts at outcome research are being made, and should contribute to clarify the effects, not only of psychoanalysis proper, but also of the derived psychotherapeutic approaches now being carried out in clinical practice.

3.2

Object relations, attachment theory, self-psychology, and interpersonal psychoanalysis

Jeremy Holmes

Despite many splits and schisms, dating back to Adler and Jung's early break with Freud, there has been an enduring attempt within psychoanalysis to hold to a central psychodynamic vision and to find common ground between differing theoretical and clinical approaches. The aim of this chapter is to describe the work of some of the major figures who have extended and developed Freud's ideas, pointing to areas of both conflict and convergence, and, wherever possible, to relate their concepts to the everyday practice of psychiatry.

From drive theory to object relations

Psychoanalysis started its life as a 'drive theory' or 'dual instinct' theory—the idea that mental life and its pathologies could be understood in terms of the interplay between the erotic and death drives, and the ways in which these were repressed, or expressed either covertly via 'conversion', or directly. As Freud's thought evolved, so new paradigms began to emerge. Drive theory had little to say about relationships: other people appear merely as satisfiers or thwarters of an individual's instinctual needs. Freud began to ask how children, and later adults, reconciled their own wishes and desires—their drives or instincts—with those of their caregivers and peers. Struggling with this problem, while remaining within the confines of drive theory, he now differentiated between self-love, or narcissism, and other, or 'anaclitic', love, directed outwards. In this model, the individual gradually emerges from egg-like self-absorption and healthy narcissism into the world of relationships.

A further push towards a more relational theory came from Abraham, later to become Melanie Klein's analyst, who noticed the parallels between the phenomena of grief and depression. The intense psychic pain and disruption associated with a loss suggested a much more intimate connection between relationships and the architecture of the psyche than drive theory would allow. 'The unconscious' is not so much a repository of drives and desires, but an inner world populated by significant others or 'objects'. The self is forged out of these 'objects' with whom the individual has or has had important relationships: 'the shadow of the object falls on the ego'.[1] A further theoretical move arose from considering the origins of conscience and ideals. It is a matter of observation that much of development depends on processes of imitation and identification. The developing child internalizes, or 'introjects', his or her parent's values and standards. How, and where in the psyche, does this process take place? In Freud's 'tripartite model', the 'superego', alongside the ego (i.e. executive and experienced self) and the id (the locus of desire and dreaming), is the focus for these internalized parental values and aspirations. The inner world now contained not just 'objects', but value-based relations between them: prohibitions, encouragements, injunctions, and gratifications. Much of post-Freudian theory consists of attempts to develop and elaborate these ideas.

Object relations 1: Klein, Fairbairn, and their successors

This was the state of theoretical play in psychoanalysis when **Melanie Klein** first burst on to the scene in the late 1920s. Like Freud, her work can be divided into a number of phases.[2,3]

Psychoanalysis is concerned with early mental life, which it sees as the basis for much adult psychopathology. But how do we gain access to the thought processes of small children, whose verbal and introspective capacities are limited or non-existent? Klein's great technical innovation was the introduction of play therapy. She provided her little patients with play materials—paper and pencils, a doll house with figures, a sandpit, and farmyard animals—and observed the pictures and games which the children set-up, making her interpretations around them. She used the methods of dream interpretation to formulate her ideas. What she observed in play—movement of figures in and out; bringing things together, often violently; separation and disruption—she took to represent the workings of the child's mind. Still deeply influenced by drive theory, and by Freud's insistence on the pre-eminence of sexuality and castration anxiety, she found sexual and aggressive meanings in all that was presented to her. Every vertical line or orifice-shaped circle drawn had a sexual significance; every conjoining or emitted sound stood for parental intercourse, by which the child was both fascinated and frightened. Exploration and the drive to know were seen

as an expression of the desire to possess the mother's body, and inhibitions of learning as manifestations of castration anxiety.

Here Klein began to depart from Freud. For him the Oedipus complex arose around the age of three, when the child begins to observe his or her parents' relationship and to feel such emotions as passionate love, envy, fear, and jealous vengefulness. Klein, by contrast, saw Oedipal phenomena as arising much earlier in development. For example, the infant may experience weaning as a punishment or symbolic castration, and believe that his mother's breast in his mouth has been displaced by the paternal penis in her vagina. Two other aspects of Kleinian thought emerge from this. First, in Klein's schema the infant has an instinctual knowledge of the body and its relationships. There appears to be a reservoir of unconscious phantasy, which she saw as the mental accompaniment of bodily function: phantasies about the breast, the mouth, the penis, the vagina, and their relationships that could not have arisen from direct observation, and therefore must be present from within, as correlates of the child's bodily sensations, which Klein saw as dominating the early years of life. Unconscious phantasies are akin to Jungian archetypes or perhaps the 'language acquisition devise' postulated by linguists: preformed mental constructs unconsciously shaping experience and patterns of relationship.

Second, and closely related to unconscious phantasy, is the idea of internal objects—initially body parts, and later 'whole objects' that are salient to emotional life—the mother and her breast, the father and his penis, bellies and their contents such as unborn babies, faeces, and sphincters. These objects are endowed with motivational properties reflecting the infant's emotional life, which Klein saw as dominated by persecutory fears. The 'death instinct' ensures that the child reacts to frustration with overwhelming feelings of hatred and destructiveness. These feelings are then projected outwards on to the objects in the child's emotional environment, which are in turn reintrojected to populate the inner world. To preserve good feelings from these terrifying bad objects, the child also projects goodness outwards. Thus a radical split arises between good and bad experiences, which are attributed to good and bad objects: 'in the very earliest stage every unpleasant stimulus is related to the 'bad', denying, persecuting breasts, every 'good' experience to the 'good' gratifying breasts'.[2]

Klein depicts early emotional life as dominated by the infant's fears of annihilation from without, and the use of the mechanisms of splitting and projection to reduce these fears. She postulated the onset of a new type of anxiety towards the end of the first year of life. Here the infant is beginning to bring the image of the 'good' and the 'bad' breast together, and to realize that they are one and the same. With weaning, the child experiences his first major loss. Now 'depressive' anxiety comes into the picture. The child believes that he is responsible for the loss, and that he has destroyed the good object with his aggression and sadism. He begins to feel guilt and remorse, and wants to repair the damage he believes he has inflicted on his objects. His attempts at creation, the gifts he offers, and the charm with which he approaches his caregivers are all motivated by this sense of depressive despair and the wish to make reparation.

Klein thus described a developmental sequence: inherent aggression, annihilation anxiety, projection and splitting of the object into good and bad, loss, bringing together the split objects, depressive despair, concern for the object, and finally reparation. For her this was a description of normal development, and she saw pathological states as resulting from developmental arrest along this line. The fulcrum of this sequence is the movement from what, drawing on Fairbairn's term (see below) Klein now called the '**paranoid–schizoid' position** (**PSP**) to the '**depressive' position**' (**DP**), a movement from splitting, blaming, and avoidance, to integration, responsibility, and concern for the object (see Hobson *et al.*[4] for objective evidence of the validity of the PSP–DP distinction). Klein saw the struggle between PSP and DP as a lifelong process, an equilibrium driven one way or the other depending on life experience and constitutional endowment.

Klein was generally rather unconcerned about the impact of external reality on psychological development (a point which, as we shall see, stimulated Bowlby's divergence from her ideas). To the extent that she did consider the real as opposed to the phantasized role of the parents, it was as benign figures whose job it is to mitigate the strength of the infant's need to hate, project, and split. An important late theoretical contribution, however, concerned the role of envy in psychic life. One of the strengths of a psychoanalytical approach to psychotherapy is that it takes seriously the phenomenon of resistance, and the fact that psychic growth is usually hard-won, often with much backsliding and self-defeatingness. With her emphasis on the dark side of human nature, Klein realized that the infant may feel persecuted not just by frustration and separation, but also by the very capacity of the caregiver to satisfy his needs. The breast upon which the baby depends for satisfaction and pleasure can also be a source of envy and hatred in its plenitude and ability to create dependency. This **envy** then becomes a basis for destructiveness within psychotherapy, and more generally: an explanation, perhaps, for the graffiti which inevitably appear on beautiful buildings, or, at times, the fact that patients attack and seem to want to destroy the very help that is offered to them.

Another key Kleinian concept is that of **projective identification** (**PI**), a difficult and perhaps misnamed concept, coined almost casually by Klein in an attempt to describe how parts of the ego may be split-off and projected not just *on to* objects in the environment as visualized in Freud's notion of projection, but *into* them. As originally conceived by Klein PI referred to the solipsistic world of the infant described above, in which unbearable feelings of rage and hatred are split-off, projected into the breast, which is then perceived by the child as 'having' properties that in fact originated in the self. Projective identification here is a form of misperception or delusional perception, which can be used both to explain the fact that normal adults' experience of the world is inevitably coloured by their emotional state (the gloomy or rose-tinted spectacles with which we view the world), and to account for delusional ideas in psychosis, such as paranoid feelings of persecution which, it is hypothesized, originate in the subject's own aggressive phantasies but are attributed, via projective identification, to persecutors.

Projective identification differs from simple projection in that the objects of PI are induced or controlled by the projection in such a way that they then *enact* the phantasy, which has been transferred into them. Paranoid people have the capacity to make those around them behave in suspicious or hostile ways, and thus projective identification can be thought of as a form of communication in which the recipient of the projection is induced to think or feel in ways that properly 'belong' to the projector. Post-Kleinian authors, notably Bion,[5] Heimann,[6] and Ogden,[7] have extended the concept of projective identification, with an emphasis on this communicative aspect, in that PI requires a recipient as well as a projector.

Bion, an analysand of Klein, realized that projective identification also underlies normal empathy and fellow feeling. PI is 'primitive' in the sense that preverbal children rely on it almost exclusively to communicate their feelings, but this denotes immaturity rather than pathology. Bion went on to develop his **container-contained** theory of early emotional communication. Here the mother, or 'breast', acts, via PI, as a recipient or container for the infant's unmanageable feelings of fear, hatred, annihilation, etc. These feelings are contained or held by the mother, and 'detoxified' before they are 'returned' to the infant through her understanding and empathic handling. She knows intuitively—through projective identification—when her child cries whether it is hungry or cold, or bored or wet, etc., and responds appropriately. In this way the infant begins to build-up a sense of himself through the **reflective awareness** of the mother. Disruptions of this process, for example through maternal depression or the violent use by the parent of the infant as a container (**role reversal**) as occurs in child abuse, may sow the seeds of disorders of identity found in borderline personality disorder in later life.

PI is important in the contemporary understanding of **counter-transference**. Paula Heimann pointed out that the therapist's reactions to the patient, while no doubt coloured to some extent by her own conflicts (Freud's classical conceptualization of counter-transference), also represent feelings induced by contact with the patient, that is to say they are a manifestation of projective identification. By attending to these thoughts and feelings the therapist gains clues about the patient's state of mind, which can then be put into words as interpretations. Here the therapist's mind is the container for the patient's split-off feelings. Sometimes this container-contained relationship fails, and the therapist is induced to enact some aspect of the patient's inner world, for instance by forgetting an appointment with a patient who has felt neglected and overlooked as a child, or by expressing anger or boredom in his tone of voice, being himself moved by feelings which properly belong to the patient.

The firm boundaries of psychotherapy are, in part, designed to minimize these occurrences (although they are unavoidable, and often, if reflected on, can be put to good use in the form of deepened understanding), but in the much more uncontained setting of general psychiatric wards or community mental health centres such enactments are widespread. A common example would be the polarization which disturbed people with borderline personality disorder can induce in their carers, some seeing the patient as manipulative and demanding, others feeling intense sympathy, and the wish to repair past hurts on the patient's behalf. Each perspective represents a split-off aspect of the patient's inner world that has been picked up via PI by different staff members. This is an essentially interactive process, since, no doubt, what determines which aspect depends on the carers' own developmental history and defensive strategies.

Working in the relative isolation of Scotland, and coming to essentially similar conclusions to Klein about the importance of splitting, W.R.D. Fairbairn[8] further developed this interpersonal perspective. For him drives were 'a signpost to the object', the glue that held human beings together. Sex is what gets us close to those who matter, rather than vice versa, as originally conceived by Freud. Like Bion later, Fairbairn also placed great emphasis on the role of the mother and of environmental failure as a source of psychopathology. Frustration plays a central part in his schema. With a perfectly responsive mother, the child has no need to think or develop an inner world. When separation and frustration come into play, the child then builds up an image of the object, which is split into three parts: the **ideal object** (one that would never cause frustration), the **libidinal object** (one that could satisfy the child's drive-related needs), and the **anti-libidinal object** (the one that frustrates). This in turn sets up a split of the self into three corresponding parts—ideal self, libidinal self, and anti-libidinal self. The Fairbairnian model provides clarity in understanding some typical phenomena found in severe personality disturbance: the swing between idealization and denigration of therapists and partners (who become the anti-libidinal withholding object at that point), the self-destructiveness of the anti-libidinal self, or 'internal saboteur', and the split-off search for pure libidinal satisfaction unrelated to persons represented by substance abuse and promiscuity.

Fairbairn's notion of schizoid withdrawal was conceptualized as a typical interpersonal strategy in the face of frustration. John Steiner[9] has developed a similar idea in his notion of the psychic retreat, an inner place to which individuals with borderline personality may repair in the face of environmental trauma, and which may make them relatively inaccessible in therapy. Another important neo-Kleinian development has been Ronald Britton's[10] attempt to link the Oedipus complex with the tolerance of separateness and loss implicit in the depressive position. Britton sees the ability, at times, to let go of the mother as the Oedipal stage is successfully negotiated—in which the child comes to see that his mother and father are sexually involved with one another and he is necessarily excluded—as an important developmental step towards the establishment of an inner world and the ability to see things from varying perspectives. This can be linked with Bion's idea of creative thought in which ideas are brought together to create 'conceptions', in contrast to the destructiveness of schizoid thinking in which, as a way of reducing anxiety, the links between things and ideas are attacked, and the world emptied of meaning. The restoration of meaning is a central task of psychotherapy. The dialectic of close involvement and repeated separation inherent in the therapeutic relationship fosters this capacity, enabling disturbed patients first to **find their experience mirrored** by the responsive therapist, then gradually to **tolerate loss and envy**, and so to gain the capacity to think and to feel more autonomously.

Object relations 2: Balint and Winnicott

The 'Object relations' school of psychoanalysis is a broad church. Klein's view of the mind and of psychopathology was essentially a **conflictual** model: difficulty arises out of the inherent conflict in an immature mind between love and hate, and attempts to avoid the inevitability of loss. For her, such conflict was characteristic of normal development, and pathology merely an exaggeration of normal conflict in which the environment has failed to mitigate its potentially destructive effects. By contrast, the non-Kleinian members of the 'object relations' school tend to espouse some variety of a **deficit** model, in which normal and abnormal development are more sharply differentiated, and the basis for psychopathology is a failure of the environment to provide the conditions needed for healthy psychic growth.

Michael Balint[11] is perhaps best known for his work in raising psychological awareness among general practitioners through the

use of 'Balint groups', but he was also a significant figure in psychoanalysis, introducing a number of key terms and concepts. In contrast to Klein, who saw the newborn infant as wracked with fear and conflict, Balint proposed a state of **primary love** characterizing the early mother–infant relationship—which he described as a 'harmonious interpenetrative mix-up'. Where, however, parenting was inadequate, due to neglect, overintrusiveness, aggression, or abuse he claimed that the child would be permanently scarred at the level of the '**basic fault**'. His model of therapy implied a **remedial**, rather than purely **interpretative** approach, with the therapist's role including both quiet acceptance, and on occasion therapeutic 'acting in': Balint would sometimes gently hold the patient's hand, and, famously, once encouraged a patient who stated that she had never had the courage to do a somersault to try one out in the consulting room then and there (behaviour therapy meets psychoanalysis!).

Donald Winnicott,[12] visualized an intermediate zone in the early years of life that was neither the realm of pure phantasy (as described by Klein), nor that of reality (to which adaptation by the ego was required, as described by Freud), although it partakes of both. In this intermediate, or **transitional** zone the infant learns, with the help of the mother, to play (another key Winnicottian theme). Here phantasies can become reality, at least for the duration of the interactive play. In this transitional space Winnicott saw the origins of creativity and culture generally, and of a nascent sense of self. He suggested that the mother's face is a kind of mirror in which the child sees his own feelings reflected, and through this recognition begins to gain a sense of who he is. This process is disrupted if the mother is depressed or abusive, and here perhaps are the germs of borderline personality disorder, characterized by a deficient sense of self, and feelings of inner emptiness and sterility. Winnicott saw 'learning to play' as a key task in therapy in helping patients to regain their sense of self.

A related phenomenon is that of the **transitional object**—the special handkerchiefs, teddy bears, and precious playthings that toddlers often need for comfort and to help them sleep. Winnicott saw these as buffers against loss, objects that are invested with the properties of the primary object (the mother and her breast) but remain under the control of the child. They are 'transitional' in the sense that they lie between the ideal object of phantasy and the real, but potentially unreliable, objects of external reality.

The subtlety of Winnicott's thought is exemplified by his notion of the **good-enough mother**. Unlike some psychoanalytical writers he did not attribute all the evils of mankind to parental failure. Winnicott realized that a 'perfect' mother, intrusively aware of her infant's needs could inhibit rather than foster the development of a sense of oneself as a separate and autonomous being. Mothers (and presumably fathers) should be 'good enough', not perfect, not least because through healthy protest about parental failure the child learns his own strength and finds limits, which reassure him that his parents can withstand his aggression and still love him.

Winnicott realized that developmental deficit does not always take the form of neglect or overt violence. He noticed the ways in which parents, driven by their own unconscious needs, may subtly impose their will on a compliant child, thereby inhibiting the growth of a robust and distinct sense of self. The **false-self-real-self** distinction tries to capture the ways in which children, and later personality disordered adults, may present an acceptable face to the world that is radically at variance with inner feelings of terror, emptiness, or rage. In his seminal, but today largely forgotten, classic *The Divided Self*, R.D. Laing[13] took Winnicott's false-self-real-self distinction as a central theme in his psychodynamic account of schizophrenia, seeing delusions as representing a way of holding together, albeit 'falsely', a disintegrating 'real' self and its inner world.

John Bowlby and attachment theory

Winnicott's contemporary John Bowlby[14] life's work was an attempt to bring logical and scientific rigour to psychoanalytical thought. Attachment theory, an empirically validated version of object relations theory, starts from Freud's[15] revised theory of anxiety, in which, rather than viewing it as the result of incomplete repression of incestual wishes, **anxiety is conceptualized in interpersonal terms as a response to the threat of the loss of a loved one**. Based on his observations of delinquent youths, many of whom had suffered the loss of a parent during early childhood, and the depressive reactions of small children to separation from their parents on entering hospital, Bowlby saw that protection from danger was a key component of the parent–child relationship, and that there were built-in psychological mechanisms to ensure the maintenance of attachment bonds.

Attachment theory[16] postulates that, when faced with threat, illness, or exhaustion, children will seek proximity to their caregivers, or '**secure base**'. A protective response from the caregiver assuages the child's attachment needs, who can then return to play or exploratory behaviour, secure in the knowledge that help will once more be at hand if needed. This provides the conditions for **secure attachment**, and the child builds up an **internal working model** (Bowlby's preferred term for the inner world) of a secure robust self and responsive others.

Secure attachment arises out of **responsive and sensitive parenting** and is contrasted with **insecure attachment**, which Bowlby saw as a factor predisposing to adult neurosis. Bowlby's collaborator, Mary Ainsworth, and her students, have researched different patterns of insecure attachment and the conditions under which they arise.[17] They delineate three main types of insecure attachment: **insecure-avoidant, insecure-ambivalent, and insecure-disorganized**. The avoidant child has experienced brusque or aggressive parenting, and tends to avoid close contact with people, hovering near caregivers rather than openly expressing need when faced with threat. The ambivalent child clings to his inconsistent parents, and finds exploratory play difficult, even when the danger has past. Disorganized children behave in bizarre ways when threatened, and tend to have parents who are either emotionally intrusive or absent, often in the context of a parental history of abuse in their childhood. Disorganization is thought to be a severe form of insecure attachment and a possible precursor of severe personality disorder and dissociative phenomena in adolescence and early adulthood.

Mary Main[18] has developed a psychodynamic interview schedule, the Adult Attachment Interview (**AAI**), which is rated for the interviewee's narrative style, and, in long-term follow-up studies of children whose attachment patterns have been classified in infancy, yields significant links with these earlier patterns of attachment. As with response to threat in childhood, adults' ways of talking about themselves and their lives vary enormously. Some, in

the **secure-autonomous** style, talk freely about themselves and their past pain in a coherent and apposite way. The **insecure-dismissive** style minimizes problems and is characterized by unelaborated speech lacking in metaphor or vividness. The **insecure-preoccupied** style is rambling and emotionally laden, while an **insecure-unresolved** pattern has evident breaks in continuity and logical flow. These insecure speech patterns are, it is suggested, manifestations of the underlying psychobiological relational dispositions, which the various theories of object relations attempt to capture. The way we speak about ourselves reveals the state of our inner world. Peter Fonagy[19] has suggested that the capacity to represent experience, which he calls **reflexive function**, (a contemporary version of the classical psychoanalytic notion of 'insight'), is a buffer against psychiatric disturbance. Once pain is represented in the mind the sufferer can distance himself from it, and consider alternative ways of responding. Enhancement of reflexive function is a generic psychotherapeutic strategy and applies as much to cognitive therapy (becoming aware of negative cognitions and automatic thoughts) as psychodynamic therapies.

Bowlby objected to what he saw as the hijacking of the term 'biological' by organic psychiatry, since he believed the attachment relationship and its vicissitudes, adaptively shaped by evolutionary pressures, was no less 'biological' than the neurochemistry which presumably mediates it. For him human psychology was fundamentally relational. He saw attachment needs as existing throughout the life cycle, and put separation and loss as central to his view of the origins of psychiatric disturbance. In the attachment model, separation from a caregiver is a threat: we are biologically programmed to respond with shock, denial, anger, and searching behaviours when separated from a loved person or object. Loss is an irrevocable separation, and the early phases of the bereavement response are all vain attempts to restore the status quo. Despair and depression come with the recognition that separation is final, and, beyond that, reorganization of internal working models, the recognition that although the loved one is lost in reality, good memories live on in the inner world.

The attachment perspective has implications for the day-to-day practice of psychiatry. One function of the psychiatric facilities and of mental health workers is to provide the patient with a 'secure base', which in itself goes some way to reducing anxiety. Appropriate dependency is integral to the supportive psychotherapeutic relationship, which is such a key part of the psychotherapeutic dimension of psychiatry. Short-term, unresponsive, or rejecting relationships with psychiatrists and other mental health workers reinforce insecure attachment and may lead patients to redouble their efforts to cling on to the psychiatric institution—an all too familiar vicious circle.

The ego and its defences: Anna Freud, Hartmann, and Lacan

The role of the ego and of defence mechanisms was a particular concern of Anna Freud,[20] who represented a parallel tendency to the object relations school. She elaborated a taxonomy of defences used by the ego to maintain its integrity in the face of both internal threat from the id, and the demands and impingements of external reality. Valliant[21] groups Anna Freud's defences into those that are **immature** (like projective identification and splitting), **neurotic defences** (which include intellectualization, reaction formation, and identification with the aggressor), and **mature** ones (such as humour and sublimation).

Reaction formation describes the ways in which the ego counteracts unconscious desires or impulses that threaten its equilibrium by consciously held views directly contrary to these: the militant pacifist who is out of touch with any feelings of aggression for example. **Identification with the aggressor** is frequently invoked in discussions of the psychological effects of childhood abuse. One way of dealing with the horror of abuse is to 'dis-identify' with oneself (a form of dissociation), and to put oneself in the place of the person who is attacking, thereby reducing feelings of pain and helplessness. This idea helps to explain how those who have been abused in childhood may become abusers themselves in adult life. A frequent experience in working with severely disturbed patients, many of whom are abuse survivors, is that health care workers may themselves feel attacked or symbolically 'abused' by these patients—seeing how the patient may have unconsciously identified with their aggressor can help carers to a greater understanding of their patients' problems and to respond less defensively to these attacks.

Valliant has found that men who use more mature defence mechanisms are less vulnerable to physical and psychological illness, and an important aim of psychotherapy would be to help the patient move from the use of more- to less-primitive defence mechanisms. Defences are therefore legitimately seen as adaptive, and, from a developmental perspective, the earlier the presumed psychic trauma, the more likely are primitive defence mechanisms to be employed.

David Malan's[22] **triangular model** of anxiety, defence, and 'hidden impulse' is another variety of ego psychology, which has found favour in psychiatric circles. It provides a clear formula for thinking about neurotic difficulties: for example people suffering from agoraphobia commonly defend against anxiety by avoidance and dependency; underlying this there may be hidden feelings of dissatisfaction and aggression, immediately towards a spouse, and in the past towards a controlling but unaffectionate mother. For Malan, the task of therapy is to allow the ego to tolerate and express the hidden feelings; note that cognitive therapy (q.v.) similarly helps the patient to become aware of and then counteract the automatic thoughts (equivalent to hidden feelings) that undermine the ego's attempts to achieve conflict-free functioning.

The self, meaning, and interpersonal psychoanalysis: Sullivan, Horney, and Kohut

Freud's models of the mind were essentially intrapsychic, and couched in quasi-scientific language. Object relations retained this perspective but introduced a relational dimension never fully developed by Freud. **Interpersonal psychoanalysis** in the United States was even more radically interpersonal than object relations. Harry Stack Sullivan[23] was a free thinker who emphasized this existential aspect of psychotherapy, while remaining within the psychoanalytical tradition. He worked particularly with people suffering from schizophrenia. Sullivan believed in close involvement with his psychotic patients. His mission was always to find meaning in their experience, rather than dismiss it as an unintelligible manifestation of organic illness. He was a major influence on a generation of psychoanalytically informed psychiatrists including Harold **Searles**, Freida **Fromm-Reichman**, and Karen Horney.[24]

The latter, like Sullivan, was critical of the patriarchal bias of psychoanalysis. For her, castration complex and penis envy were social rather than biological phenomena, manifestations of social relations that subjugated women, and from which, by appropriate action, including psychotherapy, they could be liberated. Horney's contemporary, Eric **Fromm**, brought a Marxist influence into psychoanalysis, emphasizing the part played by capitalist production methods in contributing to isolation and anomie of modern men and women and their psychological troubles.

Although conventional psychoanalytical treatment for schizophrenia is now largely discredited, there is increasing interest in the role of psychosocial interventions in psychosis. Here the Sullivanian principles of respect for the patient's experience and its meaning, the need for a long-term supportive psychotherapeutic relationship, attention to the social precipitants of psychosis, and a focus on the ways in which the therapist may, through countertransference, foster recovery or reinforce pathology, are all highly relevant to contemporary psychiatry.

Heinz Kohut[25] was concerned not so much with schizophrenia, but with that intermediate world between neurosis and psychosis which psychoanalysts call 'borderline' pathology, and which has entered the DSM as Borderline Personality Disorder. Like Sullivan, Kohut puts **self-esteem and its disorders** at the centre of his psychology, seeing the origins of self-esteem in the empathic responsiveness of caregivers in the early years of life. For him there is a core of **healthy narcissism**, which is based on the grandiosity and omnipotence of the young child ('his majesty the baby', as Freud put it), which is both accepted and fostered by effective parenting. Parents at this stage are '**self-objects**', a concept akin to Winnicott's transitional objects, who partake both of the self and of the responsive environment, and which the infant believes, in his state of healthy delusion, to be there exclusively for his benefit.

Like Winnicott, Kohut emphasizes 'mirroring' as a key interpersonal theme. For Winnicott parental mirroring helps the child to own his emotions and begin to know who he is. Kohut, by contrast, takes up the narcissistic aspect of the mirror: the child sees his reflected glory in the eyes of his admiring parents, and this contributes towards his own positive self-regard. As development proceeds there is a process of 'optimal disillusionment', similar to the resolution of the Oedipus complex, in which the child gradually learns that his objects have a life of their own. By this time, however, his sense of a valued and effective self will be sufficiently developed, and residual narcissism will serve the useful functions of ambition, aspiration to success and admiration, a sense of duty and concern for others, and the capacity to invest in ones offspring.

Where the environment is unempathic, mirroring is deficient, fragile grandiosity squashed, or disillusionment traumatic, the stage is set for borderline pathology, in which self-absorption, and the use of others as self-objects, appropriate to the infantile years, persists into adult life. Self-injurious behaviour such as drug abuse, eating disorders, and deliberate self-harm are 'breakdown products' of a disintegrated self, trying to use the environment as a self-object that will provide momentary and illusory satisfaction and self-affirmation.

A therapeutic implication of Kohut's approach is that the therapist is more supportive than in classical analysis, tolerant of the patient's grandiose designs, especially in the early stages of treatment. This contrasts with the approach of Otto Kernberg[26] who synthesizes classical and Kleinian concepts, and advocates rigorous interpretation, especially of destructive and self-defeating behaviour in borderline patients. Kohut's and Kernberg's theories reflect the typical polarization that such patients evoke in clinical settings, perhaps mirroring an inner world rigidly split into good and bad objects. Effective treatment requires a synthesis: empathy and tolerance is needed to form a working alliance, but firm limit-setting and confrontation of destructiveness is also essential. Another interpersonal synthesis is to be found in the work of Stephen Mitchell[27] whose approach reminds the therapist of the reciprocity of the therapeutic relationship in what Robert Lang calls the 'bipersonal field': patient and therapist form a system of mutual influence, the job of the therapist being both to participate in this, and at the same time to be sufficiently detached to be able to reflect upon it.

The shift in interpersonal psychoanalysis away from the analyst as an objective and privileged observer to a co-participant has given rise to a contemporary interest in narrative or hermeneutic explanations in psychotherapy,[28] in contrast to the scientific psychology, which Freud originally hoped to establish. These authors argue the case for psychoanalysis as a hermeneutic discipline whose aim is to explore meaning rather than objective truth. If Freud is one of the intellectual founding fathers of modernism, their approach is 'postmodern' in the sense that it stresses the relativism of values and meanings, and the importance of power in determining one's view of the world. Here is a link—albeit so far rather distant—with the emerging 'user' movement in psychiatry, and the importance of giving as much weight to the client's voice as to that of the professional. Psychological truths are inherently contextual, and without awareness of the social context they can be obfuscatory.

Conclusions

Many new perspectives have emerged in the century since psychoanalysis was conceived. Emphasis has shifted from the intrapsychic to the interpersonal. Kleinian psychoanalysis offers a unique vision of the ways in which interpersonal reality is inescapably coloured by the emotional state of the participants. Attachment theory provides an account of human psychological development that both takes account of meaning and is empirically based. Psychoanalysis is emerging from its isolation and bridges have begun to be built with cognitive science: the inner world of phantasy is not unlike the world of schemata and assumptions that are the focus of cognitive therapy. There are, through modern neuroimaging techniques links to be forged with neurobiology: the impact of effective therapeutic interventions on brain architecture can now be visualized. Progress will depend on further theoretical syntheses and technological advances, while holding firm to the humanistic emphasis on personal meaning and inner experience that is the fundamental contribution of psychoanalysis to contemporary psychiatry.

3.3

Current psychodynamic approaches to psychiatry

Glen O. Gabbard

Psychodynamic psychiatry is broadly defined today. In fact, the term psychodynamic is now used almost synonymously with psychoanalytical. Freud originally used the term psychodynamic to emphasize the conflict between opposing intrapsychic forces: a wish was opposed by a defence, and different intrapsychic agencies, such as ego, id, and superego, were in conflict with one another. Indeed, for much of the twentieth century psychoanalytical theory was dominated by the drive-defence model, often referred to as ego psychology.

In the last decades of the twentieth century, however, psychoanalytical theory expanded beyond the notion of conflict among intrapsychic agencies. Internal object relations became paramount in models deriving from these sources. In addition, a deficit model of symptomatology arose from the work of the British object-relation theorists, such as Balint and Winnicott. In the United States, Kohut's self-psychology also developed a model based on developmental deficits. In other words, disturbed patients who came to treatment were seen as suffering from absent or weakened psychic structures based on developmental failures by parents or caretakers in the early childhood environment. (See Chapter 3.1 for an account of the development and modern practice of psychoanalysis.)

The typical psychodynamic psychiatrist then uses multiple models to assist in the understanding of a particular patient. Developments in neuroscience must also be taken into account. Moreover, the diagnostic and treatment approach to an individual patient is psychodynamically informed even when a decision has been made to forego psychodynamic psychotherapy. Psychodynamic thinking provides a conceptual framework within which all treatments are prescribed, including pharmacotherapy, psychotherapy, inpatient or partial hospital treatment, and group or family modalities. Psychodynamic psychiatry is not synonymous with psychodynamic psychotherapy.

A comprehensive definition of current psychodynamic psychiatry is the following:[1]

Psychodynamic psychiatry is an approach to diagnosis and treatment characterized by a way of thinking about both patient and clinician that includes unconscious conflict, deficits, and distortions of intrapsychic structures, and internal object relations, and that integrates these element with contemporary findings from the neurosciences.

Basic principles

A set of time-honoured basic principles, all derived from psychoanalytical technique and theory, define the overall approach of the dynamic psychiatrists (Table 3.3.1).

The unconscious

A fundamental premise of psychodynamic psychiatry is that mental activity going on outside our awareness can be profoundly influential. Freud saw signs of the unconscious in two major types of clinical evidence: parapraxes and dreams. Parapraxes, commonly referred to as slips of the tongue or 'Freudian slips', involve substituting one word for another. For example, a patient who intends to say 'Protestant', may unwittingly say 'prostitute'. Parapraxes may also involve actions, such as forgetting, or executing one action when intending to do another.

Freud regarded dreams as the 'Royal Road' to the understanding of the unconscious. Another primary way that the unconscious manifests itself in the clinical setting is the patient's behaviour toward the clinician. Certain characteristic patterns of relatedness to others set in childhood become internalized and are manifested automatically and unconsciously as part of the patient's character. Hence certain patients may consistently act deferentially toward the clinician, while others will behave in a highly rebellious way. This type of procedural memory is closely linked to Squire's[2] notion of implicit memory, which occurs outside the realm of verbal narrative memory.

While declarative or autobiographical memory involves remembered events and narratives of one's life, procedural memory

Resistance

stores the 'how' of executing sequences of actions, such as motor skills. Once guitar-playing or bicycle-riding has been mastered, no conscious recall is necessary when one sits down with a guitar or jumps on a bicycle. The schema referred to as unconscious internal object relations are to some extent procedural memories repeated again and again in a variety of interpersonal situations. They are non-conscious, but not dynamically unconscious, in the sense of being defensively banished from conscious awareness.

The notion that much of mental life is unconscious is one that is often challenged by psychoanalytical critics, but it is also one that is extensively validated by literature from experimental psychology.[3] Repression of memory has even been demonstrated in fMRI research.[4] The active effort to 'forget' unwanted past experiences involves a novel form of reciprocal interaction between the prefrontal cortex and the hippocampus. When subjects control unwanted memories, there is increased dorsolateral prefrontal activation associated with reduced hippocampal activation. The magnitude of forgetting is predicted by prefrontal, cortical, and right hippocampal activations.

Psychic determinism

The notion of psychic determinism is intimately linked with the construct of the unconscious. Freud felt that behaviour and mental life were related to multiple and complex causation.[5] The term overdetermination implies that a variety of intrapsychic and unconscious factors come together to produce specific symptoms or behaviours. The notion of multiple causation implies that there can be alternate sets of sufficient conditions, some involving primarily unconscious conflicting forces, others stemming from biological and environmental influences that ultimately produce similar symptoms or behaviours.

Developmental orientation

Regardless of which psychoanalytical theory seems to fit best with a particular patient, the dynamic psychiatrist always thinks in terms of developmental models. Patterns of relatedness established in childhood are repeated in adult relationships. Modern dynamic psychiatrists avoid the early psychoanalytical reductionism that attempted to link an adult psychopathological syndrome to a specific developmental arrest or fixation in childhood. Today, full account is taken of genetic contributions to personality and to psychiatric disorders. Environmental influences and genetic factors interact with one another reciprocally to shape the human being in health and illness. Still, the wisdom of the psychodynamic approach is that within each of us is a child yearning to complete some unfinished business from earlier in life.

Emphasis on the uniqueness of the individual

In much of descriptive psychiatry the major focus is on taxonomy—specifically: How do groups of patients fit together under one classification? In psychodynamic psychiatry, by contrast, there is great interest in how a particular patient is unique—in other words, different from others. The subjective experience of the individual has been forged through an idiosyncratic narrative that is different from all other life stories and involves a specific interaction between genetic predisposition, intrapsychic factors, and environmental influence.

Transference

Intrinsic to the developmental model of mental organization is that adults are constantly repeating childhood patterns in the present. Transference is the best-known example of this phenomenon. The patient unconsciously experiences the doctor as a significant figure from the past and reacts to the doctor based on a set of unconscious attributions based on those past experiences. Transference has undergone considerable revision in more recent writings, so that today much more emphasis is placed on the clinician's contributions to the patient's transference. In other words, if a clinician is silent and remote, the patient may experience that clinician as disengaged and cold. While an internal template of past experiences with authority figures may correlate with that perception, we would also recognize that the clinician's real behaviour contributes to that precise transference paradigm. In that regard, a more contemporary view of transference would be that every treatment relationship is a mixture of new features based on real characteristics of the clinician and old experiences from the patient's past. Psychodynamic clinicians also recognize a bidimensional quality to transference: while one dimension involves repetition of the past, another dimension is seeking an experience with a new object to facilitate further emotional growth.

Countertransference

Central to the psychodynamic viewpoint is that the clinician and the patient bring their own separate subjectivities to an encounter, and mutually influence one another. Countertransference, in this respect, is the counterpart of transference. In other words, as Freud originally used the term, it referred to the analyst's attribution of certain qualities to the patient based on the analyst's past experiences with similar figures. This perspective, often referred to as the narrow view of countertransference, regarded the phenomenon as an obstacle to be removed because it interfered with the analyst's objectivity.

Subsequent contributors to the literature on countertransference[6, 7] noted that countertransference with severely disturbed patients often involves an objective component. The patient behaves in such a provocative manner that virtually anyone would respond with a certain set of emotional reactions to that patient. This way of looking at countertransference is often regarded as the broad or totalistic view. Inherent in this perspective is that the clinician's reaction has much less to do with his or her own individual past than with the specific characteristics of the patient and that patient's capacity to induce strong reactions in others.

As the definition has continued to evolve, countertransference is now generally regarded as involving both the narrow and the broad characteristics. In other words, most theoretical perspectives view countertransference as entailing a jointly created reaction in the clinician that stems, in part, from contributions of the clinician's past and, in part, from feelings induced by the patient's behaviour.[8] In some cases the emphasis may be more on the contributions of the clinician than the patient, while in other cases the reverse may be true. This model also regards countertransference as something of a unique construction that varies depending on the two subjectivities involved (see Box 3.3.1). In this contemporary perspective, countertransference is both a source of valuable information about the patient's internal world and something of an interference with the treatment.

Box 3.3.1 Changing views of countertransference

Narrow The original Freudian view connoting the analyst's transference to the patient: an obstacle to be removed through careful analysis of the clinician.

Broad or totalistic All the feelings experienced towards the patient, some of which are induced by the patient's behaviour.

Joint creation The contemporary perspective that emphasizes mutual contributions from the patient's behaviour toward the clinician and the clinician's past experiences with similar figures. This perspective emphasizes countertransference as a source of valuable information in addition to being an interference.

Resistance

In 1912 Freud[9] wrote, 'The resistance accompanies the treatment step by step. Every single association, every act of the person under treatment must reckon with the resistance and represents a compromise between the forces that are striving towards recovery and the opposing ones'. The patient's resistance defends the patient's illness from the clinician's attempt to treat it and change it. Resistance may be conscious, preconscious, or unconscious. It may take many forms, including not taking medication as prescribed, forgetting appointments with the psychiatrist, changing the subject in the middle of an appointment to something trivial, and discounting every insight the psychiatrist offers. The patient's characteristic defence mechanisms are often transformed into resistances in the treatment situation. The dynamic psychiatrist knows that all progress will be accompanied by some degree of resistance, and the exploration of resistance is a major part of therapeutic work. Resistance is intimately related to transference because the patient often rebels against the doctor resulting from unconscious transference configurations that lead the patient to oppose the doctor's help.

The mind–brain interface

The psychodynamic psychiatrist eschews reductionism. Recognizing that mental life and psychiatric symptoms are both overdetermined and multiply caused, psychodynamic clinicians are always interested in the interface between the biological and the psychosocial. Psychodynamic psychiatry is not antibiological. The psychodynamic psychiatrist is the integrator par excellence. Avoiding Cartesian dualism, the mind is seen as the expression of the activity of the brain.[10] Subjective experience affects the brain just as mental phenomena arise from the brain. Every treatment intervention is seen as being biopsychosocial in nature. Medications have psychological effects. Psychotherapeutic interpretations affect the brain. Moreover, psychodynamic psychotherapy and medications may work synergistically to provide better outcomes for patients. For example, a patient with a bipolar disorder who is denying that he has an illness and refusing to take lithium may ultimately have better compliance with the medication if the clinician explores the meaning of his denial and his reluctance to consider himself as someone requiring treatment.

The comprehensive mind–brain strategy of the contemporary psychodynamic psychiatrist fits well with our growing knowledge of the interaction between genes and the environment. In an inspired series of experiments with the marine snail *Aplysia*, Kandel[11,12] has demonstrated that synaptic connections are strengthened and permanently altered through regulation of gene expression connected with learning from the environment. In *Aplysia* the number of synapses actually double or triple as a result of learning. Kandel has suggested that psychotherapy might make similar neuroanatomical changes in the synapses. He argues that just as representations of self and others are malleable, the brain itself is a dynamic and plastic structure. He postulates that psychotherapy is a form of learning that produces alteration of gene expression and thereby alters the strength of synaptic connections. While the template function or the sequence of the gene is not affected by environmental experience, the transcriptional function of the gene (namely the ability of a given gene to direct the manufacture of specific proteins) is highly regulated and responsive to environmental factors.

Antisocial personality disorder may be a model disorder with which to examine the interaction of genes and environment. In a perspective study based in Dunedin,[13] a birth cohort of 1037 children was followed prospectively. By the age of 26, 96 per cent of the sample was contacted and evaluated. Between the ages of 3 and 11 years, 8 per cent experienced 'severe' maltreatment, 28 per cent experienced 'probable' maltreatment, and 64 per cent experienced no maltreatment. The investigators determined that a functional polymorphism in the gene responsible for the neurotransmitter metabolizing enzyme monoamine oxidase-A (MAO-A) was found to moderate the effect of maltreatment. Males with low MAO-A activity genotype who were maltreated in childhood had elevated antisocial scores. Males with high MAO-A activity did not have elevated antisocial scores, even when they had experienced childhood maltreatment. Of males with both low MAO-A activity genotype and severe maltreatment, 85 per cent developed antisocial behaviour.[13]

The research summarized here points to the dynamic interplay between genetic expression and the environment. Gene expression cannot be considered static. It is a dynamic phenomenon that interacts with and reacts to environmental experiences. Heritable characteristics of children actually shape their relationships with their parents and siblings.[14] In turn, the response of family members to the child affect the genetic expression. Hence genetic influences on some types of psychopathology may be dependent on the mediation of social processes. A child's genetic endowment will influence the way parents relate to a child, and the way the parents treat the child will then influence that child's developing brain. Biological and psychosocial processes are constantly intertwined, and neither is prior.

In many major psychiatric disorders, such as depression, genetic factors appear to influence whether a stressor produces an episode of illness.[15] From a psychodynamic perspective, the meaning of stressors must also be incorporated. Some stressors that may seem mild to one individual are overwhelming to another because of their idiosyncratic conscious or unconscious meaning. In addition, the presence of biologically generated symptoms in no way diminishes the importance of meaning. Pre-existing psychodynamic conflicts may attach themselves to biologically driven symptoms, and the symptoms then function as a vehicle for the expression of the conflicts.[16] Auditory hallucinations are generated by alterations in neurotransmitters in persons with schizophrenia, but

the content of the hallucination often has specific meanings based on the patient's psychodynamic conflicts. Hence a patient who is being told that he is a failure and should kill himself by a hallucinated voice may be tormented by a sense that his life is shattered by his illness and that he no longer has any purpose in living.

Development of personality

Another key component of the psychodynamic approach is that the clinician treats the person and not just the illness. In practice, that perspective means taking the personality into account in every case. The interface of the biological and the psychosocial is particularly apparent in the area of personality. The psychobiological model of personality developed by Cloninger *et al.*[17] recognizes an equal contribution of biological and environmental factors (see Table 3.3.2). The four dimensions of temperament are roughly 50 to 60 per cent heritable independently of one another. They all manifest themselves early in life, and they involve preconceptual biases, habit formation, and perceptual memory. They include the following:

1 novelty-seeking: characterized by active avoidance of frustration, quick loss of temper, impulsive decision-making, frequent exploratory activity in response to novelty, and extravagance in the approach to cues and rewards
2 harm-avoidance: which involves pessimistic worry about the future, passive avoidant behaviour such as fear of uncertainty, shyness regarding strangers, and rapid fatiguability
3 reward-dependence: characterized by sentimentality, social attachment, and dependence on the approval of others
4 persistence: which refers to the capacity to persevere despite fatigue and frustration

Certain of these temperament dimensions appear to correlate with specific types of personality disorders. The cluster A personalities in DSM-IV, for example, are strongly associated with low reward-dependence. Cluster B personality disorders have been shown to be high in novelty-seeking, while cluster C personality disorder patients tend to rate high in harm-avoidance.

The other component of personality in this model is character. While temperament is genetically based, character is shaped by environmental experiences, such as family relationships, peer relationships, trauma, and neglect. These dimensions appear to make up about 50 per cent of personality. There have been three dimensions of character identified that appear to mature in adulthood. These dimensions influence social and personal effectiveness by insight-learning about self-concepts. The three character dimensions are self-directedness, cooperativeness, and self-transcendence.

Low self-directedness and low cooperativeness are associated with all categories of personality disorder in the DSM-IV system.[17] Self-transcendence, on the other hand, does not differentiate patients with personality disorders from those without personality disorders.

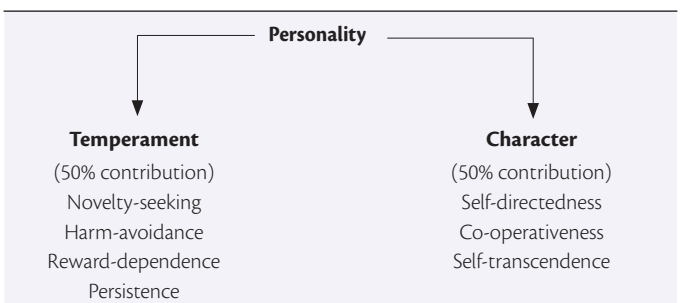
Self-directedness and cooperativeness reflect two fundamental tasks in personality development as defined by Blatt *et al.*[18]: the achievement of a stable, differential, realistic, and positive identity, and the establishment of enduring, mutually gratifying relationships with others. These two dimensions evolve in a dialectical and synergistic relationship to one another throughout the life cycle. Patients with character pathology tend to divide into two groups: introjective types, who are primarily focused on self-definition; and anaclitic types, who are more concerned about relatedness.

The character dimensions readily lend themselves to typical psychodynamic constructs. The self-directedness dimension is closely linked to what are often called ego functions or self-structures. The dimension of cooperativeness is a direct measure of a person's characteristic pattern of internal object relations as they are externalized in relationships with others. In one's assessment of a patient's personality, the transference–countertransference dimensions of the clinical interaction provide a privileged glimpse of the typical patterns of relatedness that cause difficulties in the patient's outside relationships.[19] The patient is involved in an ongoing attempt to actualize certain patterns of relatedness that reflect various wishes in the patient's unconscious. Through the patient's behaviour, he or she subtly tries to impose on the clinician a certain way of responding and experiencing.[20]

An individual internalizes a self-representation in interaction with an object representation connected by an affect through a series of repetitive interactions in childhood. This pattern ultimately leads to an internalized set of self- and object representations in interaction with one another. The adult individual repeats these patterns again and again as an effort to fulfill an unconscious wish. Even abusive or painful relationships involving a 'bad' or tormenting object may be wished for because of the safety and affirmation such relationships provide. In other words, a child who has been abused has internalized a highly conflictual abusive relationship as a predictable and familiar pattern. Having an abusive object may be preferable to having no object at all or being abandoned. Many patients with histories of an abusive childhood become convinced that the only way to remain connected to a significant person is to maintain an abuser–victim relationship.

The repetitive interactions seen in patients with personality disorder may reflect actual relationships with real objects in the past, but they may also involve wished-for relationships, such as those often seen in patients with childhood trauma who seek a rescuer. Clinicians who are influenced by the patient's interpersonal pressure to respond in a particular way may unconsciously accept the role in which they have been cast. When this phenomenon occurs, it is often referred to as projective identification.[8] In other words, the patient may 'nudge' the therapist into assuming the role of an abuser in response to the patient's 'victim' role, and the therapist may feel countertransference hate or anger and begin to make sarcastic or demeaning comments to the patient.

Table 3.3.2 Development of personality



Reproduced from Cloniger, C.R., Svarik, D.M. and Pryzbeck, T.R. (1993). A Psychobiological model of temperament and character. *Archives of General Psychiatry*, **50**, 975–90. Copyright 2003, The American Medical Association.

In addition to this pattern of object relations, the other major component of character, from a psychodynamic perspective, is the particular constellation of defence mechanisms that characterizes the individual patient.[21] While defences were traditionally regarded as intrapsychic mechanisms designed to prevent awareness of unconscious aggressive or sexual wishes, the current understanding of defence mechanisms has been expanded far beyond Freud's dual-drive theory. We now understand that defences also preserve a sense of self-esteem in the face of narcissistic vulnerability, assure safety when one feels dangerously threatened by abandonment, and serve to insulate one from external dangers through, for example, denial or minimization.

Different personality types or disorders use characteristic sets of defence mechanisms. For example, the paranoid personality may typically use projection as a way of disavowing unacknowledged feelings and attributing them to others. Patients with obsessive–compulsive personality disorder may use defensive operations such as isolation of affect, intellectualization, and reaction formation to control affective states that are highly threatening. In the relationship with the clinician, as noted previously, these defences will manifest themselves as resistances. Hence, if a patient with an obsessive–compulsive personality disorder uses intellectualization as a defence against painful affects, when the patient comes to treatment, intellectualization will be used as a resistance to avoid getting at feelings in psychotherapy.

Dynamic pharmacotherapy

The commonly used psychodynamic constructs, such as therapeutic alliance, transference, countertransference, and resistance apply to all modalities of psychiatric treatment, even though their usage is generally associated with psychodynamic psychotherapy. In a study of the relationship between the therapeutic alliance and the outcome of 250 depressed outpatients in the National Institute of Mental Health Treatment of Depression Study,[22] the therapeutic alliance was found to be of extraordinary importance. The patients had been randomly assigned to one of four conditions: brief interpersonal therapy, brief cognitive behavioural therapy, imipramine plus clinical management, or placebo plus clinical management. The researchers found that the therapeutic alliance was just as important for drug therapy as for psychotherapy. In all four treatment cells, the therapeutic alliance counted for more of the variance of treatment outcome than the treatment method itself. This was the first empirical study to show the importance of the therapeutic alliance in psychotherapy, pharmacotherapy, and placebo outcome.

Non-compliance is one of the most challenging problems facing psychiatric practitioners. Many factors go into compliance. Although many patients blame side effects, they often unconsciously undermine the treatment plan. The patient may have a negative transference to the prescribing clinician related to attitudes toward parents and other authority figures that lead the patient to rebel and defy the doctor's orders. Some clinicians may have countertransference reactions to specific patients that lead them to prescribe in a highly authoritarian manner or a tentative and ambivalent manner, giving unconscious messages to the patient that reflect the doctor's attitude about the medication. Patients who feel the doctor is bullying them to take the medication may not comply. Similarly, patients who sense their doctor is ambivalent about the value of the medication may also choose not to fill the prescription. Unconscious resistance is frequently a major factor in non-compliance. Medications may have idiosyncratic meanings to patients based on unconscious identifications with family members who have taken the same medication, views of psychiatric illness as moral weakness, or fears about the effects of the medication. Sometimes a pill or capsule may serve as a transitional object that substitutes for the person of the prescriber when the physician is unavailable. The colour or shape of a tablet may take on special significance for some patients, making them reluctant to change dosage or switch to another medication.

Multiple-treater settings

In inpatient units and partial hospital settings, psychodynamic concepts are of considerable value in understanding the patient's psychopathology as it unfolds in a group setting. Patients re-create their internal object relations in the inpatient or partial hospital milieu.[23] The conflicts that occur in their family context will re-emerge in their relationships with hospital staff members. Through projective identification the patient subtly pressures various staff members to play the roles that are in keeping with the patient's internal world. Hence a patient who has been physically and/or sexually abused by a parent will behave in such a way toward a certain nurse, for example, that the nurse begins to feel abusive toward the patient. The same patient may treat another nurse as an idealized rescuer figure, eliciting loving and protective feelings from that nurse. This form of splitting[23] may create extraordinary conflicts between staff members over the best treatment approach to the patient. Therefore failure to attend to the transference–countertransference dimensions of the milieu treatment may lead to a total disruption of the staff members' capacity to be effective with certain patients.

Moreover, individual patients often act out covert staff conflicts. Psychodynamically informed hospital treatment may help to identify these conflicts and allow staff to process them in such a way that the patients no longer need to enact them. When covert conflicts between staff members become overt and open to discussion, the patient's disruptive behaviour often settles down.[23] This observation reflects how the dynamics of the patient group and staff group often parallel each other. The psychodynamic clinician also understands that individuals behave differently in groups than they do alone or in a one-to-one context. Powerful group forces, such as scapegoating, can be recognized and processed so they do not become destructive to treatment. Similarly, the patient's recurrent problems in groups can be diagnosed, in part, by a careful study of the transference and countertransference responses.

Two-person context of treatment

One of the major shifts in psychodynamic thinking in recent years has been a greater acknowledgement of the influence of the clinician's perspective on the observations about the patient. Postmodern contributions from intersubjectivity and social constructivism have challenged the view that the clinician assesses the patient from a detached and objective frame of reference. Fundamental to this perspective is that clinicians can never transcend their irreducible subjectivity.[24] The psychiatrist in this context can never fully know how his or her subjectivity is influencing the diagnostic

assessment or the treatment process. Countertransference is viewed as both unconscious and continuous, so that a therapist cannot possibly be capable of keeping up with every emotional reaction of the patient.[25]

This two-person model of the treatment situation has contributed to the demise of the classical psychoanalytical view of the therapist or analyst as a blank screen or a dispassionate observer. The influence of the clinician's biases and unconscious feelings toward the patient may have far-reaching implications for a variety of situations in psychiatry. Frustration about a patient's nonresponsiveness to treatment, for example, can lead a clinician to recommend electroconvulsive therapy as a reaction to despair, rather than as a result of systematic decision trees or algorithms about refractory depression. Even in the case of physician-assisted suicide, countertransference may play a major, though hidden, role.[26] Within this context the patient's wish to die may stem from a self-concept as worthless and a burden to others that is, in part, a reflection of what the physician brings to the encounter. Similarly, the doctor's death-anxiety might underlie an omnipotent need to triumph over death through the prescription of physician-assisted suicide that strives to preserve an illusion of control and mastery. In the worst scenario, a clinician's intense countertransference hate toward a patient may lead to a wish to kill that is transposed into a recommendation for physician-assisted suicide.

Psychodynamic psychotherapy for specific disorders

A psychodynamic approach is relevant to the treatment of the vast majority of psychiatric disorders encountered in clinical practice. Depending on the nature of the illness, the setting in which the illness is treated, and the psychological mindedness of the patient, psychodynamic strategies may be the major emphasis in the treatment plan or a relatively minor contribution. Psychodynamic psychotherapy per se is generally divided into short-term psychodynamic psychotherapy (STPP) and long-term psychodynamic psychotherapy (LTPP). The former is generally regarded as involving fewer than 24 sessions or 6 months' duration, while the latter is viewed as a therapy lasting more than 6 months.[27] Psychodynamic psychotherapy, whether long-term or short-term, is often defined as 'a therapy that involves careful attention to the therapist–patient interaction, with thoughtfully timed interpretation of transference and resistance embedded in the sophisticated appreciation of the therapist's contribution to the two-person field'.[28] This form of psychotherapy is also conceptualized as operating on an expressive-supportive continuum. The highly expressive forms of psychodynamic psychotherapy offer more interpretation of unconscious conflict, while the forms that are more supportive focus on bolstering adaptive defences and building self-esteem. The continuum of interventions from the most expressive to the most supportive (see Table 3.3.3) guide the psychotherapist in how to intervene with any given patient.

Short-term psychodynamic psychotherapy

A recent meta-analysis of STPP[29] found that this modality made significant changes in general psychiatric symptoms, target problem, and social functioning. The treatment also yielded significant and large pre-treatment—post-treatment effect sizes. The effect sizes were stable and tended to increase at follow-up. No significant differences were found between STPP and other forms of psychotherapy. Evidence from randomized controlled trials supports the use of STPP for major depressive disorder, panic disorder, social phobia, and post-traumatic stress disorder. In addition, the treatment has also been efficacious in somatoform disorders, bulimia nervosa, and substance-related disorders in association with drug counseling.

Long-term psychodynamic psychotherapy

Research on LTPP has been more limited than for STPP because the gold standard of the randomized controlled trial is more difficult to implement when studying LTPP. One must find a suitable control group where an alternative extended treatment or a placebo condition can be implemented. The most rigorous controlled condition is an alternative extended treatment, although some investigations have used treatment as usual as well.[30] The dropout rate can also be problematic in long-term studies. In addition, intervening life events, Axis I conditions, and medication shifts can influence outcome. Nevertheless, despite the obstacles to designing and implementing rigorous research on LTPP, there are a number of studies that have appeared in recent years that suggest that LTPP is an efficacious treatment.

Two randomized controlled trials have shown LTPP to be efficacious with Cluster C personality disorders. Included in this group are avoidant, dependent, and obsessive–compulsive personality disorders. One study compared 40 sessions of psychodynamic therapy to control patients on a waiting list and found substantially better outcomes than those who received the dynamic therapy.[31] In a more rigorously designed study,[32] 40 sessions of dynamic psychotherapy were compared to 40 sessions of cognitive behaviour therapy. While both treatments were effective, the dynamic therapy resulted in continued improvement after termination of treatment, suggesting that patients internalized the therapeutic dialogue and used it to deal with problems as they arose.

Borderline personality disorder has also been subjected to rigorous trials of long-term psychodynamic psychotherapy. In one head-to-head comparison between a form of LTPP known as transference-focused psychotherapy (TFP), dialectical behaviour therapy (DBT), and supportive psychotherapy (SPT),[33,34] all three modalities

Table 3.3.3 An expressive–supportive continuum of interventions

Expressive						Supportive
Interpretation	Confrontation Observation	Clarification	Encouragement to Elaborate	Empathic Validation	Advice and Praise	

(Data modified from Gabbard, G.O. (2004), *Long-term psychodynamic psychotherapy: a basic text*, American Psychiatric Publishing, Arlington, VA.)

showed general improvement. However, TFP showed improvements that were not demonstrated by either SPT or DBT. Participants in the study who received TFP were more likely to move from an insecure attachment classification to a secure one, show greater changes in mentalizing capacity, and have more extensive symptomatic improvement than the other two groups. Only TFP made significant changes in impulsivity, irritability, verbal assault, and direct assault. Suicidality was reduced to an equal extent by TFP and DBT.

A psychoanalytically oriented partial hospitalization treatment for patients with borderline personality disorder was compared to a treatment-as-usual approach.[35,36] In the treatment group, the major difference was the provision of individual and group psychotherapy compared to the control condition. The treatment lasted a maximum of 18 months, and was significantly superior to standard psychiatric care, both at the end of therapy and at the 18-month follow-up.

A randomized controlled trial for children with learning disabilities[37] compared intensive psychodynamic therapy (four times a week) to once-a-week sessions. This trial on featured treatments had lasted longer than 1 year. In the follow-up assessment, children who had sessions four times a week showed much greater improvement.

Future directions

The psychodynamic model continues to enrich the patient's understanding and the psychiatrist's practice. The time-honoured principles elaborated here serve as windows into the murky recesses of the unconscious and illuminate human motivation. They also provide the clinician with a 'second sight' that helps make sense out of bewildering and complex clinical situations.

The evidence regarding the impact of psychotherapy on the brain opens up new lines of investigation to enhance our understanding of psychopathology and treatment. These include the following:

1 the mechanisms of action of psychotherapy

2 the interrelationships between the mechanisms of action of psychotherapy and medication

3 a clearer understanding of pathogenesis itself and the malleability of some components of the pathogenetic mechanisms of major psychiatric disorder

Research is sorely needed on psychodynamic treatments because there is only a modest empirical base for psychodynamic therapy. Many more studies are needed, especially those with a randomized controlled design targeted at specific disorders. Studies investigating extended dynamic therapy of a year or more are needed to demonstrate which patients benefit from the additional investment of time and money. In the current climate of cost containment, practitioners of psychodynamic therapy must take cost-effectiveness into account.

The optimal treatment for many psychiatric patients involves a combination of medication and psychotherapy, but research support for this view is also rather modest. Controlled studies of combined treatment versus single modalities are needed for personality disorders and anxiety disorders. In addition, the role of psychodynamic thinking in compliance problems needs rigorous investigation.

In the meantime, the psychodynamic model continues to focus on the uniqueness of the individual patient. Psychodynamic psychiatry, above all, is interested in the person with illness rather than the illness alone.

4.1

Delirium, dementia, amnesia, and other cognitive disorders

Contents

4.1.1 Delirium

David Meagher and Paula Trzepacz

Introduction

Delirium is an acute or subacute, usually reversible syndrome of impaired higher cortical functions hallmarked by generalized cognitive disturbance and caused by one or more aetiologies. It is most common in medical-surgical patients, especially in intensive care units, and those in hospice and nursing homes. The term 'delirium' derives from the Latin '*lira*' meaning literally to wander from the furrow. Prior to DSM-III (1980) such disturbances were described by a plethora of labels (acute organic brain syndrome, acute confusional state, brain failure, toxic encephalopathy, intensive care psychosis), before Lipowski advocated for the umbrella term delirium to subsume these multiple synonyms. This engendered a more scientific research effort and consistent approach to detection and management. Though delirium has been recognized for at least two millenia, it is only now beginning to receive the attention that it warrants, with increasing appreciation of the considerable impact upon outcomes and independent need for treatment as a brain disorder beyond only treating its underlying aetiological precipitants.

Inattention is the cardinal disturbance, including distractibility, reduced vigilance or concentration, and impaired environmental awareness. This contrasts with dementia, another disorder of generalized cognitive deficits, where memory deficits are cardinal. While full-blown episodes are easier to diagnose, its prodrome, subclinical presentation, and potential persistence present unresolved dilemmas regarding diagnostic boundaries of delirium. Further, comorbidity with dementia presents challenges for detection and attribution of progressive impairments in the elderly. Though delirium occurs at any age, there is a dearth of research in younger age groups such that it is unclear whether research findings from geriatric studies can be generalized to other age groups (e.g. regarding risk factors and outcomes). Studies that clarify common features such as phenomenology, neural circuitry or electrophysiology are thus critical.

Clinical features

Delirium is a complex neuropsychiatric syndrome with a broad range of cognitive and neurobehavioural symptoms which is why it can be misattributed to other psychiatric disorders by nonspecialists. Symptoms involve cognition, thought, language, sleep-wake cycle, perception, affect, and motor behaviour. The constellation of symptoms—along with the cardinal symptom of inattention and acute onset and fluctuating temporal course—are characteristic of delirium and when comorbid with dementia, delirium dominates the clinical presentation.[1] Phenomenology studies (mostly cross-sectional) suggest that 'core' symptoms occur with greater frequency while other less consistent 'associated' symptoms may reflect the biochemical influence of particular aetiologies or genetic, neuronal or physiological vulnerabilities (see Table 4.1.1.1). Accumulating evidence indicates three core domains of delirium phenomenology: 'Cognition' comprising of inattention and other cognitive deficits; 'Higher Level Thinking Processes' including impaired executive function, semantic expression, and comprehension; and 'Circadian Rhythm' including fragmented sleep-wake cycle.[2] The underlying neural support for these domains is consistent with neuroanatomical findings in lesion and functional neuroimaging studies that implicate certain brain regions and neural circuitry.

Table 4.1.1.1 Symptoms of delirium

Diffuse cognitive deficits
Attention
Orientation (time, place, person)
Memory (short- and long-term; verbal and visual)
Visuoconstructional ability
Executive functions
Temporal course
Acute/abrupt onset
Fluctuating severity of symptoms over 24-hr period
Usually reversible
Subclinical syndrome may precede and/or follow the episode
Psychosis
Perceptual disturbances (especially visual), including illusions, hallucinations, metamorphosias
Delusions (usually paranoid and poorly formed)
Thought disorder (tangentiality, circumstantiality, loose associations)
Sleep-wake disturbance
Fragmented throughout 24-hr period
Reversal of normal cycle
Sleeplessness
Psychomotor behavior
Hyperactive
Hypoactive
Mixed
Language impairment
Word-finding difficulty/dysnomia/paraphasia
Dysgraphia
Altered semantic content
Severe forms can mimic expressive or receptive aphasia
Altered or labile affect
Any mood can occur, usually incongruent to context
Anger or increased irritability common
Hypoactive delirium often mislabeled as depression
Lability (rapid shifts) common
Unrelated to mood preceding delirium

(Reproduced from Trzepacz, P. T., Meagher, D.J. *Delirium, Chapter 11 in American Psychiatric Publishing Textbook of Neuropsychiatry*, (5th edn) eds. S. Yudofsky and R. Hales, copyright 2007, American Psychiatric Publishing, Inc., Washington DC.)

Delirium occurs as a stage of consciousness in the continuum between normal awakeness/alertness and stupor or coma. During the 20th century, delirium was described as a 'clouding of consciousness' but this rather nebulous concept has been replaced by a better understanding of the components of phenomenology that culminate in severely impaired higher order brain functions. Specifically, a disproportionate disturbance of attentional processes, including environmental awareness difficulties, along with impaired higher level thinking reflected in irrelevant, unfocused or illogical thought processes and impaired abstraction and comprehension (i.e. executive cognition and semantic language function) typifies the delirious state. Sleep-wake cycle fragmentation belies a circadian disturbance that may contribute to the abnormal level of consciousness and alterations in motor behaviour, where hypoactivity contributes to difficulties in differential diagnosis of delirium from stupor. Delirium is distinguished from stuporose states by the presence of arousability. The majority of intensive care unit patients emerging from comatose states experience a period of diagnosable delirium.[3]

Inattention is the cardinal and required symptom to diagnose delirium and is noticeable on interview by distractibility, spatial inattention, and inability to sustain attention. More formal testing can be assessed using months of the year backwards or digit span. The Cognitive Test for Delirium (CTD)[4] allows for separate visual digit span and vigilance testing. Memory impairment—of both short and long term—can be affected by inattention but appears to be independently impaired. Visuospatial impairment can be assessed by observing patient behaviour in their immediate environment e.g. losing their way or getting lost. Constructional ability can be tested formally by copying figures; clock face drawing assesses not only proportions and details but also involves prefrontal executive functions for placing the minute hand correctly. Delirious patients have executive dysfunction affecting abstraction, initiation/perseveration, switching mental sets, working memory, temporal sequencing and organization, insight and judgment. Poor performance on the Trailmaking Part B test distinguishes delirious from nondelirious patients and requires not only spatial attention and concentration but also switching mental sets. Though none of these cognitive deficits is specific to delirium, the array and pattern is highly suggestive.

Thought process abnormalities in delirium range from circumstantiality and tangentiality to frank loose associations in more severe cases. Naming impairment is common though more severe cases can mimic fluent dysphasia with semantic deficits being characteristic such that communication is wrought with deficits of meaningfulness. Interestingly, the dysphasia can be mistaken for Wernicke's aphasia and possible stroke but is reversible when the delirium clears. Careful assessment can usually distinguish between semantic deficits (language impairment) and loose associations (thought process disorder) except with word salad.

Disruption of sleep-wake cycle is essentially ubiquitous in delirium except in the briefest episodes (e.g. concussion) and often predates the appearance of a full-blown episode. Minor disturbances with insomnia or excessive daytime somnolence may be hard to

distinguish from other medically ill patients without delirium, but more substantial alterations involve sleep fragmentation or even complete sleep-wake cycle reversal that reflect disturbed circadian rhythm regulation. The relationship of circadian disturbances to the characteristic fluctuating severity of delirium symptoms over a 24 hr period or to motor disturbance is unknown.

Motor activity alterations are very common in delirium. They have been used to define clinical subtypes (hypoactive, hyperactive, mixed) though studies are inconsistent as to the prevalence of these subtypes and often include nonmotor symptoms in descriptions. Cognitive impairments and EEG slowing are comparable in hyperactive and hypoactive patients though other symptoms may vary. Psychotic symptoms occur in both although the prevailing stereotype suggests that they only occur in hyperactive cases. Hypoactive cases are prone to non detection or misdiagnosis as depression. A range of studies suggest that motor subtypes differ regarding underlying pathophysiology, treatment needs, and prognosis for function and mortality though inconsistent subtype definitions and delayed/poorer detection of hypoactives impacts interpretation of these findings.

Psychotic symptoms occur in up to 50 per cent of patients with delirium. Thought content abnormalities include suspiciousness, overvalued ideation and frank delusions. Delusions are typically poorly-formed and less stereotyped than in schizophrenia or Alzheimer's disease. They usually relate to persecutory themes of impending danger or threat in the immediate environment (e.g. being poisoned by nurses), and less commonly to grandiose themes. Misperceptions include depersonalization, delusional misidentifications, illusions and hallucinations. Hallucinations and illusions are primarily visual though they can be tactile and auditory whereas auditory modalities tend to dominate in psychosis in mood and primary psychotic disorders. Formications suggest dopamine or anticholinergic toxicity.

Delirium may be abrupt as with concussion, drug intoxication or stroke, or can be preceded by a prodromal period characterized by anxiety, sleep disturbance, cognitive impairments and increased levels of perceived distress. Symptom profile appears similar across age groups[5] but delirium is understudied in pediatric patients. The propensity for particular aetiologies to shape clinical presentation is also understudied. Unfortunately, delirium tremens (with florid psychosis and agitation) is the dominant clinical stereotype even though many cases present with relative hypoactivity especially in the elderly, those with concomitant dementia, or where delirium is related to metabolic causes or organ failure. This misleading stereotype is one of the reasons for the poor recognition of delirium where typically 50 per cent of cases are missed in routine clinical practice.

Diagnosis and differential diagnosis

ICD-10 and DSM-IV share key features used to diagnose delirium (i.e. acute onset, fluctuating course, inattention, and disorganized thinking) although the ICD-10 description gives better account of the breadth of symptoms that can occur (e.g. disturbances of sleep and motor activity). DSM IV is more inclusive and preferred in research studies, though may be less rigorous than ICD-10 when used by less skilled clinicians. DSM-IV classifies cases according to presumed aetiological cause, though a single aetiology occurs in less than half of cases and no aetiology is identified in around 10 per cent. Delirium is also subclassified according to its relationship to dementia.

Delirium is poorly detected in clinical practice by nonpsychiatrists with more than 50 per cent of cases missed, misdiagnosed, or diagnosed late. This is due to multiple factors: the complex and fluctuating nature of delirium symptoms, inadequate education and interview skills of nonpsychiatrists, underappreciation of the prognostic significance of delirium, and inadequate routine cognitive screening in real world practice. Delirium can be the first indicator of serious physical morbidity (e.g. stroke) and represents a medical emergency. It is not surprising therefore that nondetection is associated with poorer outcomes that include elevated mortality.[6] Poor outcomes in hypoactive patients may be in part due to nondetection.

The course of delirium is highly variable reflecting the heterogeneity of aetiology and patient populations in which delirium occurs, with recent studies emphasizing that it is frequently not the benign and transient condition that was previously thought. While in many cases, delirium is brief (hours to days), represents a transitional state from unconsciousness or is a benign reaction to treatment exposures, in other cases it can be more prolonged (e.g. after traumatic brain injury) or associated with serious complications and persistent cognitive difficulties where differentiation from dementia becomes difficult. Rudberg *et al.*[7] studied elderly medical-surgical inpatients with delirium and found that episode duration was 24 hrs or less in over two-thirds of patients. Conversely, Sylvestre *et al.*[8] studied elderly medical admissions over two-month follow-up and identified five separate patterns of recovery, with fast improvement in only 11 per cent of patients. Greater clarity regarding the factors that shape these varying courses is needed.

Delirium diagnosis is complicated by *comorbidity* where over 50 per cent of cases are superimposed on dementia or other pre-existing cognitive impairments. Distinguishing delirium from the neuropsychiatric symptoms of dementia can be challenging but acute onset, fluctuating course, temporal relationship to an identifiable physical precipitant, prominent inattention and altered level of consciousness usually allow differentiation. Third party informants and previous medical charts can be crucial in clarifying the trajectory of cognitive impairment. Studies comparing symptoms of delirium and dementia indicate that where they coexist, delirium symptoms dominate the clinical picture. Given the poor prognostic implications of delirium, a management hierarchy applies with delirium taking diagnostic precedence over other neuropsychiatric disorders so that any acute alteration in mental state is presumed to be delirium until otherwise established.

Some symptoms of delirium also *overlap with primary psychiatric disorders*. Major depressive disorder can be misdiagnosed in hypoactive presentations or when affective lability includes tearfulness and sad mood. Agitated depression or severe mania ('Bell's mania') can mimic hyperactive delirium but the affective lability and incongruent moods of delirium contrast with more sustained alterations in mood and effect in major mood disorders. The character of psychotic symptoms in delirium differs from primary psychotic illness (see above). Acute schizophrenic psychosis involves disorganized thoughts with delusions and hallucinations but inattention is less prominent. Acute schizophrenia can include marked cognitive impairment with perplexity that can mask or be mistaken for comorbid delirium and in such cases the EEG can be helpful. Table 4.1.1.2 describes key clinical features for differentiating delirium from other neuropsychiatric conditions.

Table 4.1.1.2 Differential diagnosis of delirium vs other common neuropsychiatric conditions

	Delirium	Dementia	Depression	Schizophrenia
Onset	Acute	Insidious[a]	Variable	Variable
Course	Fluctuating	Often progressive	Diurnal variation	Variable
Reversibility	Frequently[b]	Not usually	Usually but can be recurrent	Chronic relapsing and remitting course typical
Level of consciousness	Impaired	Unimpaired until late stages	Generally unimpaired	Unimpaired (perplexity in acute stage)
Attention/memory	Inattention is primary with poor memory	Poor memory without marked inattention except in end-stage illness	Mild attention problems, inconsistent pattern – depressive pseudodementia, memory intact with formal testing	Poor attention, inconsistent pattern, memory intact
Affect	Lability	No clear pattern	Flattening	Incongruity
Hallucinations	Usually visual; can be auditory, tactile, gustatory, olfactory	Can be visual or auditory	Usually auditory	Usually auditory
Delusions	Fleeting, fragmented, and usually persecutory often relate to immediate environment or impending danger	Paranoid, often fixed, relate to misconceptions	Complex and mood congruent e.g. themes of guilt or nihilism	Frequent, complex, systematized, and often paranoid

[a]Except for large strokes that can be abrupt and Lewy Body Dementia which can be subacute.

[b]Can be chronic (paraneoplastic syndrome, central nervous system adverse events of medications, severe brain damage).

Nondetection of delirium is particularly common in older patients with comorbid dementia, multiple medical problems and hypoactive motor presentations. Chronic subsyndromal delirium in the elderly is commonly related to low grade infections or medication adverse effects, where adjusting medications can significantly improve cognition. Monitoring for any acute deterioration from baseline function coupled with regular formal assessment with simple cognitive tests such as the digit span, months of year backwards, serial sevens or clock drawing enables delirium detection. Unfortunately, over-reliance on orientation as a measure of cognition precludes more accurate detection. The emphasis on orientation, inconsistent administration, and ceiling effects limit the usefulness of the (MMSE) in measuring delirium. The Cognitive Test for Delirium was designed specifically for delirium and emphasizes attention, semantic comprehension, and nonverbal, right hemisphere cognitive functions. It is particularly useful in critically medically ill persons.

The *Confusion Assessment Method* (CAM)[9] is a screening tool to assess the presence or absence of four items from DSM-III-R delirium criteria to make a provisional diagnosis of delirium. It is especially suited to epidemiological studies and screening in high risk populations where neuropsychiatric differential diagnosis or broad phenomenological measurements are not needed. Its accuracy is enhanced if ratings are anchored by formal testing as in the CAM-ICU[10] but is substantially reduced when used by nurses because they frequently miss inattention when it is present.

Psychiatrists and delirium specialists use *more detailed instruments* for more specific and sensitive detection of a broader range of symptoms. The Delirium Rating Scale-Revised-98 (DRS-R98)[11] and the Memorial Delirium Rating Scale (MDAS)[12] are the most widely used rating scales, and include measures of a wide breadth of symptoms. The MDAS is a severity scale used in conjunction with a DSM or ICD diagnosis whereas the DRS-R98 is both a diagnostic and severity instrument where each item rating is anchored by phenomenological descriptions.

In clinically challenging situations, an *EEG* can be used to help differentiate delirium from other neuropsychiatric disorders where generalized slowing of the dominant posterior rhythm is characteristic. Additionally, clues for specific disorders like complex partial status epilepticus can be identified.

Epidemiology and outcomes

Epidemiological studies have focused on elderly hospitalized populations with far less research in younger age groups or the general population. Delirium occurs in all age groups but those at age extremes, with pre-existing cognitive impairment, cancer, and the critically ill have especially high rates. It is estimated that around 10 per cent to–15 per cent of general hospital patients have delirium upon admission with a further 10–40 per cent developing delirium during hospitalization. Overall frequency is estimated at 11 per cent to–42 per cent[13] with the clinical rule of thumb that one in five general hospital inpatients experience delirium at some time during hospitalization. Delirium incidence is expected to increase as demographics of the general population shift toward older ages and with higher prevalence of dementia and cerebrovascular and cardiovascular disorders, although improved medical care for elderly persons may offset this pattern. Presence of APOE-4 alleles may confer increased risk for poorer recovery from delirium, reflecting vascular and neurodegenerative influences.

Delirium episodes are associated with elevated morbidity, longer hospital stays, greater costs of care, and higher frequency of complications.[14] Moreover, in the elderly, reduced post hospital independence and elevated one year mortality rates occur. Although the latter is partly due to the effects of age, frailty, comorbid dementia, severity of medical comorbidities, and medication exposure, some

epidemiological studies identify delirium as an independent predictor of poorer outcomes in the elderly. However, most studies have not adequately accounted for premorbid vulnerability and cognition, burden of medical problems, and pharmacological effects such that delirium may simply be a marker of underlying pathology causing poor outcomes. Delirium incidence or severity in the elderly can be improved by earlier specialist intervention including the judicious use of haloperidol and more comprehensive delirium care, though the magnitude of this effect remains unclear.

Many report a new diagnosis of *dementia after an episode of delirium*. Some evidence suggests that persistent cognitive impairment can occur after delirium even in those thought to be premorbidly cognitively intact[15,16], while others find that baseline status or medical burden predicts outcome and follow-up reveals progression of an incipient dementing process. Contributors to post delirium cognitive decline include baseline CNS vascular or neurodegenerative pathology, physical problems that also caused the delirium, toxic effects of or inability to comply and benefit from treatments, unresolved delirium, an accelerating effect of delirium on cognitive decline, or possibly a direct neurotoxic effect of the delirious state itself. However, it is still unclear whether delirium plays a causal role or is simply a marker of medical morbidity and preexisting baseline vulnerabilities both of which are associated with delirium. Pharmacological effects (beneficial or adverse effects) are unaccounted for in most studies. The possibility that delirium itself is neurotoxic remains unproven, though could theoretically involve the effects of neurochemical abnormalities associated with delirium (e.g. dysfunctional cellular metabolism or glutamatergic surges). Studies in younger age groups are needed to disentangle confounds from aging.

Elevated mortality rates (ranging from 4 per cent to–65 per cent) during the index admission may reflect a variety of factors including the impact of underlying physical causes of delirium, the consequences of reduced ability to cooperate with medical care, the complications that occur due to the delirium symptoms (e.g. pressure sores, infections, falls). Critical review of methodology suggests that delirium mostly carries an associated increased mortality risk during the year following an episode. Mortality risk is related to agedness, severity of underlying physical illness, presence of dementia, timing of diagnosis, motor presentation and delirium symptom severity. Mortality is elevated even when the confounding effects of age, medical morbidity, and medication exposure are accounted for.[17,18] Mortality is also elevated in hospitalized patients with up to four selected delirium symptoms ('subsyndromal') but without meeting syndromal criteria,[19] highlighting the need for careful assessment and monitoring of patients at risk.

Risk factors

Delirium is a multifactorial condition. A typical episode reflects the cumulative effects of predisposing risk factors, individual patient vulnerabilities (including genetic), and precipitating aetiological insults. A wide range of patient, illness, and treatment variables increase the likelihood of developing delirium but preexisting cognitive impairment, any CNS disorder, age extremes, low serum albumin, and exposure to particular medications are particularly robust predictors of delirium across populations. Geriatric and paediatric medically ill patients may share risk factors such as more vulnerable cholinergic neurotransmission—related to aging effects and developmental immaturity, respectively. Some risk factors are also considered aetiologies (e.g. UTI, anticholinergic medications). Table 4.1.1.3 lists a variety of reported risk factors across a number of reports.

Table 4.1.1.3 Factors associated with an increased risk for delirium

1. Patient vulnerabilities
Age extremes
Pre-existing cognitive impairment e.g. dementia
CNS disorder
Genetic factors e.g. APOE genotype
Visual deficit
Hearing deficits
Poor nutritional status
Previous episode of delirium
2. Environmental
Social isolation
Sensory extremes
Immobility
Novel environment
Stress
Use of restraints
ICU stay
3. Medical
Severe medical illness
Burns
HIV / AIDS
Organ insufficiency
Infection (e.g. UTI)
Hypoxemia
Fracture
Hypothermia / fever
Metabolic disturbances
Dehydration
Elevated BUN
Low serum albumin
Nicotine withdrawal
Increased blood-brain barrier permeability
Uncontrolled pain
4. Procedure-related
Peri-operative
Type of surgery (e.g. hip)
Emergency procedure
Duration of operation
Urinary Catheterization
Artificial respiration
5. Drug-related
Polypharmacy
Drug / alcohol dependence
Psychoactive drug use
Specific agents (e.g. anticholinergics / opiates/ benzodiazepines)

The interaction between predisposition (baseline vulnerability) and precipitating insults account for delirium incidence. Inouye and Charpentier[20] developed a model of four common predisposing and five precipitating factors that predicted a 17-fold variation in delirium risk in elderly medical patients, which has been replicated in post-operative elderly patients.[21] To date most genetic studies have focussed on genotyes related to increased risk of alcohol withdrawal delirium, though APOE-4 allele genotype has been linked to longer duration of delirium in ICU patients.[22]

Aetiology

Single-aetiology delirium is the exception with typically 3–4 significant causative factors relevant during any single episode which interact and overlap sequentially to produce or sustain delirium symptoms. It is crucial that potential aetiologies are constantly reevaluated throughout a delirium episode and even after a single cause is identified, efforts to unearth other factors should continue. Categories of delirium aetiologies include drug intoxication, drug withdrawal, metabolic/endocrine, traumatic brain injury, seizures, intracranial infection, systemic infection, intracranial neoplasm, extracranial neoplasm, cerebrovascular disorder, organ insufficiency, other CNS disorder, and other systemic factors (heat stroke, radiation, hypothermia, etc). Table 4.1.1.4 lists clinical investigations recommended in routine evaluation of delirium and additional tests indicated in particular cases.

Among the most common causes are infections and those related to illicit and prescribed drugs and alcohol, either in toxicity or withdrawal. Additionally, when serum albumin levels are low, more unbound drug is available to cause adverse events. Increased blood-brain barrier permeability (e.g. uremia, sepsis) can allow passage of drugs that ordinarily do not cross into the brain and delirium can result.

Neuropathogenesis

Delirium reflects a generalized disturbance of brain function as evidenced by the broad range of neuropsychiatric symptoms, diffuse slowing on EEG, and widespread alterations in cerebral blood flow.[23] Despite the range of underlying aetiologies, delirium presents with a relatively consistent clinical profile and is thus considered a unitary syndrome reflecting a final common neural pathway for multiple diverse causes and pathophysiologies.[24,25] When studying delirium pathophysiology, it is important to distinguish between physiological mechanisms of aetiologies and neural pathology in the CNS that leads to characteristic delirium symptoms. Figure 4.1.1.1 offers examples of areas to distinguish.

Many functions are typically not disturbed in delirium (e.g. primary motor or sensory functions) and certain neuropsychological functions are disproportionately impaired (e.g. attention) suggesting that particular neurobiological underpinnings are relevant to delirium neuropathogenesis. Neuroimaging and neuropsychological studies suggest involvement of prefrontal cortex, thalamus, nondominant posterior parietal and fusiform cortices, and subcortical regions, especially right-sided pathways.[24] Additionally, anterior and posterior portions of cingulate cortex may be involved in Cognition and Higher Level Thinking domains, while subcortical regions including thalamus, hypothalamus, basal forebrain and brainstem may be involved in the Circadian Rhythm domain. Other features may be related indirectly to the underlying brain disturbances that cause domain abnormalities.

Evidence from preclinical studies, causation (e.g. exposure to anticholinergic and dopaminergic deliriogenic agents), direct studies of pathophysiology, and treatment with dopamine blockers point to a relative cholinergic deficit and dopaminergic excess as the principal neurochemical disturbances underpinning delirium although other neurochemical systems (e.g. serotonergic, glutamateric, GABAergic, noradrenergic) are clearly implicated in delirium due to particular aetiologies, perhaps through their interactions with dopaminergic and cholinergic systems. Synaptic, axonal and glial abnormalities are implicated.

Altered oxidative metabolism, stress axis activation, and neuroinflammatory mechanisms may acutely impact neurotransmission. Further, neurostructural derangements previously thought to occur in chronic neurodegenerative disorders can occur acutely and transiently, and may underlie delirium. These include traumatic hyperphosphorylation during anaesthesia or traumatic elevations of Abeta inducing synaptic morphological and functional alterations.

Table 4.1.1.4 Clinical investigations recommended for delirium

1. Mandatory (recommended for all patients)
Full blood count and differential
Urea and electrolytes to include Mg, Ca, Po4
Renal function
Liver function tests to include serum albumin
Urinalysis
Random blood glucose
Electrocardiogram
Chest X-Ray
2. As indicated (according to particular clinical circumstances—list not exhaustive)
Drug screen (therapeutic and illicit)
Blood alcohol concentration
Blood cultures
Cardiac enzymes
Arterial blood gases
Serum Folate / B12
Thyroid function tests
Erythrocyte sedimentation rate
Cerebrospinal fluid examination
Syphilis serology
CT brain
MRI brain
Electroencephalography (with nasopharyngeal leads)
Polysomnography
Prothrombin time
Urinary porphyrins
Screen for heavy metals and insecticides

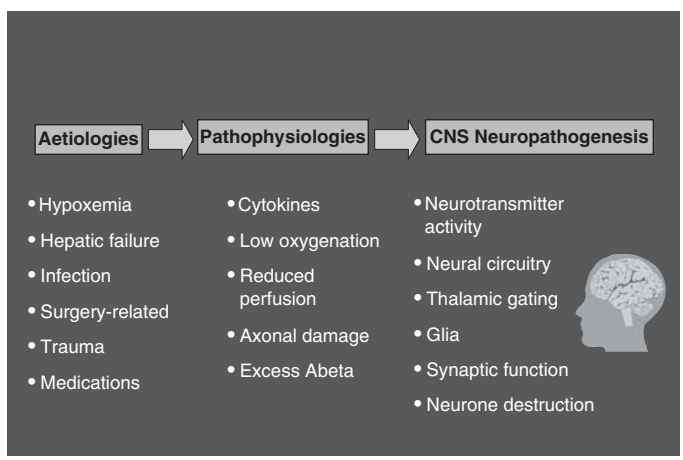

Fig. 4.1.1.1. Examples of different aetiologies for delirium and a variety of pathophysiological mechanisms that can then alter brain function. The neuropathogenesis of delirium involves dysfunction of brain regions and circuitry which may ultimately result in characteristic symptoms of delirium despite a wide variety of aetiologies and pathophysiological insults to the brain.

The broad disturbance of CNS function that occurs in delirium inevitably involves alterations to many cortical and subcortical regions and their neural circuitry, via both direct and indirect (diaschesis) effects.

Management

Delirium is a medical urgency, yet the value of timely intervention in limiting the many deleterious effects of a delirium episode is underappreciated. Optimal management requires the collaborative efforts of primary treating physicians and nursing staff with delirium specialists. Both the underlying causes and the brain disorder need simultaneous assessment and treatment. Careful attention to reorientation strategies (e.g. clearly visible clock/calendar), safety in immediate surroundings and optimal level of environmental stimulation (e.g. natural levels of diurnal lighting) are fundamental to the management of delirium across treatment settings and populations.[26] Relatives / loved ones can report changes in behaviour and mental state ('not themselves') and provide collateral information about baseline cognitive and independent functioning and risk factor exposure.

Delirium prevention using multicomponent interventions to address modifiable risk factors can reduce the frequency and severity of delirium in elderly medical and post-operative populations.[27,28] Common elements include elimination of unnecessary medications, careful attention to hydration and nutritional status, pain relief, correction of sensory deficits, sleep enhancement, early mobilization, and cognitive stimulation. Careful attention to reorientation strategies (e.g. clearly visible clock/calendar), safety in immediate surroiundings and optimal level of environmental stimulation (e.g. natural levels of diurnal lighting) are key elements of delirium care.[26]

Recent studies of pharmacological prophylaxis of delirium in high-risk populations have been encouraging. Controlled studies using haloperidol,[29] olanzapine,[30] donepezil[31] and rivastigmine[32] report significant reductions in delirium incidence, severity and/or duration.

(a) Pharmacological management

Pharmacological management of delirium addresses the brain dysfunction itself while the underlying medical problems are being separately considered. This is akin to acute heart failure where treatment of cardiac function is concurrent with management of the aetiologies for the organ failure. Pharmacological management of delirium is based on empirical knowledge drawn from case reports, open label prospective studies and a small number of randomized trials some of which are comparator studies. Adequately powered double blind randomized placebo-controlled efficacy trials are needed because there is currently no medication with an indication for delirium treatment by any regulatory authority. The inherent fluctuating nature, varying duration, spontaneous recovery rate, and impact of medical treatments upon underlying causes render placebo-controlled studies especially important in evaluating therapeutic interventions. Nevertheless, there are over 20 well-conducted prospective studies of antipsychotic agents used in acute treatment of delirium where more than two-thirds of treated delirious patients experience clinical improvement, typically within a week.[33] A randomized controlled trial of haloperidol vs olanzapine vs non-drug treatment in elderly patients indicated similar response rates in those receiving haloperidol (87.5 per cent) and Olanzapine (82 per cent), which was significantly greater than those in the non-drug treatment group (31 per cent).[34] Treatment response includes improved cognitive and noncognitive symptoms of delirium and does not appear to be closely linked to antipsychotic effect or sedative action. Younger patients with hyperactive presentations and patients without comorbid dementia respond more robustly to antipsychotics, but hypoactive patients also improve and deserve treatment given that delirium comprises many serious symptoms besides challenging motor behaviour.[35,36]

Most pharmacological strategies are based upon the prevailing notion of a relative dopaminergic excess and cholinergic deficiency as the principal neurochemical aberrations underlying delirium, and agents with either procholinergic or antidopaminergic effects are favoured. *Haloperidol* remains the standard agent used to treat delirium and is available in oral, intramuscular, and intravenous preparations. However, intravenous haloperidol does not have any indicated use by a regulatory agency and carries a high risk for QTc prolongation and torsades de pointes tachyarrhythmia that can lead to sudden death. Suggested haloperidol doses are 1–2 mg every four hours as needed but with lower doses (e.g. 0.25–0.5 mg every four hours) in the elderly, very frail, or populations with neuroleptic sensitivity—APA guidelines, 1999.[37] Uncontrolled agitated delirium can be life threatening especially in critically ill intensive care unit patients where substantially higher doses have been reported without major adverse effects. Careful monitoring of ECG (telemetry with intravenous haloperidol), and maintaining normal serum potassium, calcium, and magnesium levels are recommended.

Accumulating evidence supports the use of *atypical antipsychotic agents* in delirium (risperidone, olanzapine, quetiapine, aripirazole, ziprasidone, amisulpiride). Comparison studies suggest similar response rates to haloperidol for both risperidone and olanzapine but with reduced extrapyramidal side effects. In highly agitated patients where sedation is desirable, more sedative agents or combination with lorazepam may be considered. Given the importance of sleep-wake cycle disturbances in delirium, dose scheduling should encourage recovery of normal sleeping patterns.
