Benzodiazepines can act as either an alleviating or as a risk factor for delirium depending on the circumstances of exposure. Benzodiazepines can be associated with worsening of mental state[38] and increase delirium risk in ICU[39] and cancer patients.[40] Moreover, therapeutic effects vary from anxiolytic to sedative to hypnotic with ascending doses. Conversely, benzodiazepines are first line treatment for delirium related to sedative and alcohol-withdrawal or seizures. Benzodiazepines can allow for lower neuroleptic doses where intolerance is a problem or where extra sedation is desired. Lorazepam is preferred due to its short acting nature and relatively predictable bioavailability when given intramuscularly. Lower doses are required in the elderly and those with respiratory or hepatic compromise or receiving drugs that undergo extensive hepatic oxidative metabolism. Unwanted effects of benzodiazepines can be rapidly reversed with flumazenil.

The use of *procholinergic agents* such as intravenous physostigmine has long been advocated for delirium due to toxicity with anticholinergic drugs, but routine delirium use is limited by gastrointestinal side effects, cardiac arrythmia and seizures. To date there has been limited study of newer procholinergics in part because their long half-lives preclude reaching steady state for use

in acute conditions, in contrast to parenteral physostigmine's fast onset of action.

Anecdotal evidence also exists for the use of mianserin, trazadone, melatonin, psychostimulants, and even ECT in the treatment of delirium but these strategies are not well-studied or applied in routine clinical practice.

(b) Risks, benefits, and dosing

Adequate drug treatment of delirium is limited by concerns over potential toxic effects in highly morbid, frail elderly whose delirium may actually herald bad outcome from medical illness. In assessing the risk-benefit ratio of medication use one must consider the risk of nontreatment of delirium given its grave consequences. Dosing needs to take into account structural degenerative changes, reduced neurochemical flexibility, less robust counter-regulatory homeostatic mechanisms, reduced renal and hepatic function, lower water to fat ratio with reduced muscle mass, and reduced plasma esterase activity. In hypoactive or mechanically ventilated patients careful dose titration can be assisted by regular monitoring of sedation. With sedation, a beneficial effect of catching up from sleep deprivation also needs to be considered. Adverse events such as Parkinsonism or akathisia can be misattributed to agitation of delirium, though are uncommon in treatment studies perhaps reflecting a protective effect of the hypocholinergic state that frequently underpins delirium. The potential for cardiac arrythmias can be reduced with ECG monitoring in high dose or intravenous haloperidol use or where patients have a cardiac history or baseline ECG shows QTc interval >450 mSec.

(c) Patients with concomitant dementia

Both pharmacological[35] and non-pharmacological strategies[28] appear less effective in patients with concomitant dementia perhaps reflecting the inherently poor outcome of elderly demented populations with high physical comorbidity. There are concerns regarding the small but increased risk of cerebrovascular events in demented patients chronically receiving neuroleptics, but the relative risks of short-term use in delirium must be proportionalized against potential benefits. Lower doses should be used with careful monitoring for adverse effects and more prolonged use should not occur in the absence of clear benefits.

(d) Management after recovery

Depending on the degree of memory imprinting during an episode, patients experience significant emotional distress after recovery[41] and many continue to have distressing recollections of delirium six months later, especially where the episode has involved psychotic symptoms. For families, disturbing recollections of final contacts with loved ones can be enduringly distressing and associated with complicated bereavement reactions. Some patients minimize their experiences fearing that they represent emerging senility or loss of competence. Explicit recognition allows clarification of the causes of delirium and reduction of future risk factors.

Conclusion

Delirium is a complex neuropsychiatric syndrome that occurs commonly across all age groups and healthcare settings. Significant adverse outcomes of delirium are increasingly recognized and can be reduced by a more consistent approach to detection that emphasizes disturbances of attention. Optimal management requires the collaborative efforts of carers and healthcare staff and judicious use of pharmacological and nonpharmacological strategies that concurrently manage underlying physical causes and the delirium itself. Greater clarity is needed regarding the prognostic relationship to dementia, phenomenology of prodromal, subsyndromal and syndromal delirium, and how risk factors, vulnerabilities, and treatment may vary across populations and treatment settings.

Further information

The *European Delirium Association* advocates for better research and aims to foster research activity across all disciplines. Annual meeting details, educational materials and a discussion forum are available at www.europeandeliriumassociation.com

A US-based delirium organization aims to foster delirium care and research in critically ill patients and includes various teaching resources including protocols for assessment and treatment at www.icudelirium.org

The American Psychiatric Association website includes detailed delirium treatment guidelines, a quick reference guide as well as a patient and family guide (see www.psych.org/psych_pract/treatg/quick_ref_guide/DeliriumQRG_4-15-05.pdf)

4.1.2 Dementia: Alzheimer's disease

Simon Lovestone

Introduction

Alzheimer's disease (**AD**) and other dementias incur huge costs to society, to the families of those affected, and to the individuals themselves. Costs to society include both direct costs to health and social services and indirect economic costs in terms of lost productivity, as carers are taken out of the workplace, and the economic costs to those families caring for or funding the care of their relative. Increasingly, as treatments become available, these costs are targets for change and are part of the cost–benefit analysis of new compounds, especially the largest single direct cost, that of the provision of nursing and other forms of continuing care. Apart from the financial cost to families there is the emotional impact resulting in distress and psychiatric morbidity.

As the population ages, these costs pose substantial social and economic problems. Although lifespan itself has remained static, the numbers of elderly in both developed and developing societies is increasing rapidly. In the developed world the sharpest projected growth is in the very elderly cohort—precisely the one that is at most risk of AD. Within the developing world, the total number of elderly people is projected to rise substantially, reflecting to a large part better child health and nutrition. For countries in South America and Asia, with large and growing populations, the costs involved in caring for people with dementia in the future will become an increasing burden on health and social services budgets. In the absence of such services families will inevitably shoulder the main part of providing care, although the very process of development is associated with increasing urbanization and, to some

degree, a diminution of the security provided by extended family structures.

From discovery towards understanding

In the early part of the twentieth century, Alois Alzheimer described his eponymous disorder in a middle-aged woman who suffered not only cognitive deterioration and functional decline but psychotic experiences, including delusions and auditory hallucinations. Neuropathology included gross atrophy and plaques and tangles on microscopy. Although all the important features of AD were described at this stage, two important developments came much later. First, in the 1960s with the studies of Roth and colleagues in Newcastle[1] and others elsewhere, it was appreciated that much dementia in the elderly has an identical neuropathological appearance to that of AD in younger people. The other development was the rediscovery that AD has a rich phenomenology. The non-cognitive symptomatology of AD is integral to the clinical manifestation of this disease, and is a major cause of carer burden and medical intervention. This second phase of research—the recognition that both the neuropathology and clinical phenomenology described by Alzheimer occur in what had previously been though of as senile dementia or, worse, just ageing, was accompanied by a growing understanding of the neurotransmitter deficits in AD. The cholinergic hypothesis provided the first glimpse of possible interventions, and remains the most important finding from this period of AD investigations. The third phase of AD research encompasses the use of molecular approaches to understanding pathogenesis. The techniques of molecular biology have been applied to understanding the formation of plaques and tangles, to a growing understanding of the genetic aetiology of much of AD, and, through the use of transgenic approaches, to developing animal and cellular models of pathogenesis.

Just as research can broadly be seen to have three phases—discovery, neuropathology, and molecular aspects—so too does the clinical response to AD. For many years cognitive impairment in the elderly was perceived as senility. As a process thought to be an inevitable consequence of ageing it was difficulty to establish medical-care models. Hence the needs of the elderly with AD were not seen as requiring specialist intervention, carers needs were not realized, and public appreciation of the impact of dementia on the elderly themselves or on the family was negligible. The change in perception of AD from 'just ageing' to a disease was accompanied, and to some degree led, by the development of 'old-age psychiatry' as a specialism on the one hand and by the rapid growth of the AD societies on the other. During this second phase of AD treatment, the goals have been to ensure that the care needs of patients are met, that families' concerns are addressed, and that behavioural disturbance is minimized. The third phase of AD treatment began with the arrival of specifically designed interventions. Compounds have been introduced that were designed to ameliorate some of the deficits incurred by the disease process, and other approaches are being developed to treat those disease processes themselves.

Clinical features

Cognitive impairment

Dementia is acquired cognitive decline in multiple areas resulting in functional impairment; AD is one cause of dementia and the core clinical symptom of AD is cognitive loss. However, as noted above, AD is clinically heterogeneous and includes diverse non-cognitive symptoms. Cognitive decline is manifested as **a**mnesia, **a**phasia, **a**gnosia, and **a**praxia (the 4As).

(a) Amnesia

Memory loss in AD is early and inevitable. Characteristically, recent memories are lost before remote memories. However, there is considerable individual variation, with some patients able to recall specific and detailed events of childhood and others apparently having few distant memories accessible. With disease progression, even remote and emotionally charged memories are lost. The discrepancy between recent and remote memory loss suggests that the primary problem is of acquisition or retrieval of memory rather than a destruction of memory, and this is confirmed in early AD,[2] although as the disease progresses it is likely that all memory processes are impaired. Retrieval of remote memory is assumed to be preserved for longer because of rehearsal over life.

(b) Aphasia

Language problems are found in many patients at presentation, although the language deficits in AD are not as severe as those of the fronto-temporal degenerations[3] and may only be apparent on detailed examination. Word-finding difficulties (nominal dysphasia) are the earliest phenomena observed and are accompanied by circumlocutions and other responses, for example repetitions and alternative wordings. As the disorder progresses, syntax is affected and speech becomes increasingly paraphasic. Although harder to assess, receptive aphasia, or comprehension of speech, is almost certainly affected. In the final stages of the disorder, speech is grossly deteriorated with decreased fluency, preservation, echolalia, and abnormal non-speech utterances.

(c) Agnosia

Patients with AD may have difficulty in recognizing as well as naming objects. This can have implications for care needs and safety if the unrecognized objects are important for daily functioning. One particular agnosia encountered in AD is the loss of recognition of one's own face (autoprosopagnosia). This distressing symptom is the underlying cause of perhaps the only clinical sign in AD—the mirror sign. Patients exhibiting this will interpret the face in the mirror as some other individual and respond by talking to it or by apparent fearfulness. Autoprosopagnosia can present as an apparent hallucinatory experience, until it is realized that the 'hallucination' is fixed in both content and space, occurring only when self-reflection can be seen.

(d) Apraxia

Difficulties with complex tasks that are not due to motor impairment become apparent in the moderate stages of AD. Typically, difficulties with dressing or tasks in the kitchen are noticed first, but these are inevitably preceded by loss of ability for more difficult tasks. Strategies to avoid such tasks are often acquired as the disease progresses, and it is only when these fail that the dyspraxia becomes apparent.

Other cognitive impairment

There appear to be no cognitive functions that are truly preserved in AD. Visuospatial difficulties commonly occur in the middle stages of the disorder and may result in topographical disorientation,

wandering, and becoming lost. Difficulties with calculation, attention, and cognitive planning all occur.

Functional impairment

Although the cognitive decline in AD is the core symptom, it is the functional deterioration that has the most impact on the person themselves and it is the functional loss that necessitates most of the care needs of patients with AD, including nursing-home residency.[4] Increasingly, abilities to function in ordinary life (activities of daily living (**ADLs**)) are lost, starting with the most subtle and easily avoided and progressing to the most basic and essential. In general, functional abilities decline alongside cognitive abilities. However, the precise correlation between these functions is not perfect, suggesting that factors other than disease severity account for part of the variance between patients.[5] Functional abilities are related to gender; for example, cooking abilities are rehearsed more frequently in women, and home-improvement skills in men. However, the overall pattern shows some similarities between groups of patients with similar disease severity. This is exploited in the Functional Assessment Staging (**FAST**) Scale;[6] in the original form, this is a seven-point scale of functional impairment, with stage 1 as no impairment and stage 7 as severe AD. A sequential decline is mapped by descriptions of the abilities that are lost: stage 2, difficulties with language and finding objects; stage 4, difficulties with finances; stage 6, incontinence and inability to dress or wash oneself.

ADLs are divided into those that relate to self-care and those that concern instrumental activities. Instrumental ADLs, those related to the use of objects or the outside world, are lost first and can be subtle.[7] A change in the ability to use the telephone properly or to handle finances accurately may not be apparent. Self-care ADLs include dressing and personal hygiene and are also lost gradually; for example, untidiness in clothing progresses to difficulties in dressing. Personal hygiene becomes poor as dentures are not cleaned and baths taken less often, before finally assistance is required with all self-care tasks.

Neuropsychiatric symptoms

(a) Mood

The relationship between AD and depression is complex. Depression is a risk factor for AD, depression can be confused with dementia (pseudodementia), depression occurs as part of dementia, and cognitive impairments are found in depression. Depression occurring as a symptom of dementia will be considered here. Assessing the mood of a person with dementia is difficult for obvious reasons. However, psychomotor retardation, apathy, crying, poor appetite, disturbed sleep, and expressions of unhappiness all occur frequently. The rates of depression found in cohorts of patients with AD vary widely, reflecting changes in prevalence at different levels of severity and difficulties in the classification of symptoms suggestive of depression in those with cognitive loss. A major depressive episode is found in approximately 10 per cent of patients, minor depressive episode in 25 per cent, some features of depression in 50 per cent, and an assessment of depression by a carer in up to 85 per cent.[8–12] It is commonly believed that depression is more common in the early than in the later stages of AD, although this may reflect the difficulties of assessing depression in the more severely affected and least communicative patients. Indeed, severely affected patients in nursing homes may be particularly prone to depression.[13] Elation, disinhibition, and hypomania all occur in AD but are relatively infrequent, elevated mood being found in only 3.5 per cent of patients by Burns *et al.*[10]

The underlying cause of mood change in AD is not known. However, loss of serotonergic and noradrenergic markers accompanies cholinergic loss; some studies have found a greater loss of these markers at post-mortem in AD patients with depression than in non-depressed patients.[14–16]

(b) Psychosis

Psychotic symptoms occur in many patients, although, as with depression, there is an inherent difficulty in determining the presence of delusions or hallucinatory experiences in the moderately to severely demented. In community-based surveys, between 20 and 70 per cent are reported to suffer from some form of psychotic symptom with delusions being more common than hallucinations.[11,17,18] Delusions are frequently paranoid and the most common delusion is one of theft. In the context of the confusion and amnesia of dementia, it is easy to appreciate how the experience of mislaying an object becomes translated into conviction of a theft. Other patients become convinced that someone, often a family member, is trying to harm them.

Hallucinations are only somewhat less frequent than delusions—the median of one series of studies being 28 per cent.[19] Visual hallucinations are reported more commonly than auditory ones, and other modalities are rare. Most studies of the non-cognitive symptomatology of AD precede the wide recognition and accepted criteria of dementia with Lewy bodies, one of the cardinal symptoms of which is visual hallucinations. It is probable that a large number of those AD patients experiencing visual hallucinations reported in the studies would now be classified as having dementia with Lewy bodies.

Phenomena falling short of delusions or hallucinations, such as persecutory ideas or intrusive illusionary experiences, are common in AD as are misidentification syndromes. Capgras' syndrome may occur, but frequently the symptom is less fully evolved with the patient mistaking one person for another. Failure to recognize one's own face may be due to visuospatial difficulties or to a true misidentification syndrome—distinguishing between the two is difficult.

Various factors have been associated with psychosis in AD, but few have been substantiated in multiple studies. Burns *et al.*[20] found that more men than women suffered delusions of theft, although others find that psychosis occurs more often or earlier in women. An association with polymorphic variation in serotonin receptors has been reported.[21–23] The relationship between psychosis and dementia severity is not as clear cut as that between functional ability and dementia severity. Psychosis can occur at any stage of the disease process, although most studies find the maximal rate of psychosis in those with at least moderate dementia.

Although the biological basis of psychosis within AD is not fully understood,[14] it is clear that psychosis symptoms impact upon carers causing increased distress,[24,25] and that underlying psychosis accounts for much of the behavioural disturbance and aggression encountered in AD.[26]

(c) Personality

Changes in personality are an almost inevitable concomitant of AD. Indeed, it is difficult to envisage how profound cognitive impairment resulting in the loss of recognition of loved ones, and

an understanding of and ability to react with the outside world, could not result in a change in personality. Family members have described the loss of personality as a 'living bereavement'—the body remains, but the person once known has gone. Personality change is most frequently one of loss of awareness and normal responsiveness to the environment. Individuals may become more anxious or fearful, there is a flattening of affect, and a withdrawal from challenging situations. Catastrophic reactions are short-lived emotional reactions that occur when the patient is confronted, and cannot avoid, such a challenging situation. Less commonly, personality changes may be of disinhibition with inappropriate sexual behaviours or inappropriate affect. Aggressiveness is, as noted above, often accompanied by psychosis, but it may be part of a more general personality change.

(d) Other behavioural manifestations

Behavioural complications in AD have become a target of therapy. However, the term encompasses a wide range of behaviours, some of which include neuropsychiatric syndromes, some caused by neuropsychiatric syndromes, and some of which have little apparent relationship to mood or to thought content. Behavioural complication is itself a largely subjective term that relies to a great extent on informer evaluation: but behaviour may be a complication in one context, although not in another.

Behaviours exhibited in AD include wandering, changes in eating habit, altered sleep or circadian rhythms, and incontinence. These behaviours are closely linked to disease severity and occur to some extent in the majority of patients with AD. Wandering may be a manifestation of topographical confusion, a need for the toilet, or it may reflect hunger, boredom, or anxiety. Sleep is frequently disturbed, with many patients exhibiting altered sleep–wake cycles and others experiencing increased confusion towards evening ('sundowning'). A central defect in the regulation of circadian rhythms underlying these phenomena is postulated.[27] Excessive or inappropriate vocalizations (grunting and screaming) occur in the late stages.

Classification

Alzheimer's disease is classified, as with all other disorders, by DSM-IV and by ICD-10. In addition, it also has a specialized classification system resulting from the National Institute of Neurological and Communicative Disorders and Stroke–AD and Related Disorders Association (**NINCDS–ADRDA**).[28] This clinical diagnostic system is internationally accepted and widely observed. There are also classification systems for neuropathological diagnosis, most notably the Consortium to Establish a Registry for AD (**CERAD**) criteria.[29]

DSM-IV stipulates that a dementia syndrome is characterized by deterioration in multiple cognitive deficits, including amnesia, resulting in functional impairment. A gradual onset and decline in the absence of other conditions sufficient to cause dementia indicates AD. ICD-10 shares with DSM-IV the definition of a dementia syndrome and notes that an insidious onset and slow decline in the absence of other disorders sufficient to cause dementia indicates AD. The NINCDS–ADRDA criteria defines possible, probable, and definite categories; the latter being restricted to neuropathological confirmation of a clinical diagnosis.[28] It is important to note that both clinical and neuropathological data are required—no single neuropathological lesion is pathognomonic of AD, and it is still uncertain how often or to what extent the neuropathological lesions of AD also occur in normal ageing.[30] Probable AD, according to NINCDS–ADRDA, requires a dementia with progressive decline in memory and other cognitive areas, cognitive impairment established by formal testing, no disturbance of consciousness, and absence of other disorders sufficient to cause dementia. Supporting features include decline in function, change in behaviour, positive family history, and decline in specific cognitive areas including aphasia, apraxia, and agnosia. Non-specific change on electroencephalography (**EEG**) and progressive changes on CT are supporting, but not necessary, features. Possible AD should be diagnosed if there are variations in the clinical presentation, another disorder sufficient to cause a dementia (even if it is not thought to do so in this case), or a restricted cognitive decline.

A number of studies have attempted to determine the accuracy of diagnostic criteria against post-mortem diagnosis. One of the difficulties in these studies is that because AD is the most common dementia (by some way), such studies are very likely to find a high-positive predicative value. Kukull *et al.*[31] found the specificity of DSM-III to be higher than NINCDS–ADRDA (0.8 versus 0.65), but NINCDS–ADRDA had a higher sensitivity (0.92 versus 0.76), Mok *et al.* find broadly similar findings for both primary care physicians and for neurologists;[32] some others find an even lower specificity.[33]

Diagnosis

Alzheimer's disease is the most common of the dementias, occurring in some 60 to 70 per cent of cases. However, this oft-stated figure must be treated with some caution for two reasons. First, cases that come to post-mortem represent a biased sample and in the community a large proportion (up to a third) of non-demented individuals have pathological signs of AD such as neuritic plaques.[30] Second, even at post-mortem the distinction between different dementias is not clear cut—many AD brains show the presence of Lewy bodies and others have considerable evidence of vascular damage. The proportion of mixed pathologies is actually rather high, between 15 and 30 per cent of all dementias. Thirdly, even the gold-standard of neuropathological diagnosis is not infallible. Neuropathologists show a very high degree of inter-rater agreement on the diagnosis of probable AD and Dementia with Lewy Bodies (DLB) but a rather lower rate of agreement when there is vascular damage, when the diagnosis is of fronto-temporal dementia (FTD) and on the more equivocal cases of AD.[34]

History

Making a clinical diagnosis of AD is a positive process and not one of exclusion. The most valuable diagnostic assessment is a careful informant history, paying attention to the pattern and timing of onset and progression. In the research context, a family history interview conducted by telephone provides a degree of accuracy compatible with a full clinical assessment.[35] Detailed semi-structured family informant diagnostic schedules are available, such as Cambridge Mental Disorders of the Elderly Examination (CAMDEX).[36] A history should be taken for the presence of risk factors for AD (e.g. a positive family history) and vascular and other risk factors (e.g. hypertension and head injury). Taking a family history for late-onset disorders such as AD requires special

attention. Because of attrition due to other illness, many elderly people have had too few relatives reach the age of onset of dementia to make a pedigree analysis informative. The ages at death of all relatives should be established, together with cause of death and the presence or absence of dementia or memory problems in late life. The term 'sporadic' dementia should be avoided, and is misleading when applied to an individual with a dementia where one parent died young and where no sibling reached the age of 65 to 70 years. The history should also screen for the presence of other illnesses sufficient to cause a dementia and for systemic health in general. The presence of any significant physical illness, from chronic pain to delirium, may significantly alter cognitive abilities in the elderly, and especially so in those with AD.

A careful history should also establish the presence of any behavioural disturbance that has occurred. The relationship of aggression, wandering, agitation, or other behaviours to care tasks and other recent changes in the provision of the care package should be established. As the mainstay of the management of behavioural disturbance in all dementias is behavioural, establishing the antecedents to behaviour is an absolute prerequisite to effective management.

Examination

In addition to an examination of the mental state to establish the presence of disorders of mood and thought content, the examination will establish the specific pattern of cognitive impairment and the degree of impairment. Screening tests used to establish the presence of cognitive impairments include the Mini Mental State Examination;[37] this is a 30-point scale routinely used in all clinical trials of drugs for the treatment of AD, which is also a useful proxy measure for severity. It should be accompanied by other cognitive testing, including supplementary examination for aphasia and apraxias. Other cognitive and physical examinations will be necessary where the differential diagnosis is between a lobar dementia (e.g. FTD) or a subcortical dementia (e.g. that accompanying Huntington's disease).

In addition to the cognitive examination, a physical examination should be conducted in all patients with AD, although this might not be most effectively and conveniently performed at the initial assessment. Physical illness, including chronic pain, infection, cardiac insufficiency, or anaemia are all common in the elderly and can both complicate the diagnosis of AD and increase confusion in those known to have AD.

Assessment of function

Clinical assessment of function can be performed by informant history and by direct observation. Key to an assessment of function is a careful informant history seeking to establish where there has been a functional decline and remembering that instrumental ADLs are lost before basic activities. Instrumental ADLs are highly individual and require careful interviewing to assess—one patient may have a modest decline in their ability to use information technology whilst another may have trouble using all the appropriate settings on the central heating. The occupational therapist fulfils an invaluable role in establishing the detailed functional ability of those with AD, in addition to implementing changes in the home designed to maximize function. The FAST Scale[6] is based on the premise that the pattern of decline in function is relatively uniform in AD, and hence establishes a staging of severity on function rather than cognition. As in most instances functional severity is of more relevance for the provision of services, there is much to recommend such an approach. Scales used in research that can also be usefully employed in the clinic include the Bristol ADL Scale[38] and the Disability Assessment for Dementia.[39]

Global assessment

Driven largely by the United States Food and Drugs Administration, global assessment has become part of the assessment of all patients with AD in clinical trials and is finding its way into clinical practice. The underlying premise is that an assessment by a clinician, often supplemented by an informant history, provides information on severity that neither a cognitive assessment nor a functional assessment alone can provide. Two scales, the Clinicians Interview of Change,[40] and the Clinical Dementia Rating,[41] have become widely used in this context.

Investigations

At the initial assessment, patients with dementia should be investigated for other disorders that could complicate, exacerbate, or be confused with AD. A dementia screen might include routine biochemistry, thyroid function tests, vitamin B_{12} and folate estimations, and a full blood count; many would also include syphilis serology, although the frequency of abnormal findings is low. Neuroimaging is recommended in all cases by expert guidelines,[42] and serves two purposes—to exclude reversible causes of dementia and to contribute towards a definitive diagnosis. Thus using structural imaging with CT or, increasingly, with magnetic resonance imaging (MRI), the hippocampal atrophy of AD, the frontal predominant atrophy of FTD and the lesions of vascular dementia can be identified, adding to the specificity of diagnosis. In practice, neuroimaging is often omitted particularly when patients present with a typical history of a slowly progressive dementia of many years standing. Functional scanning (single-photon emission CT (SPECT) in particular) can be useful where regional dementias are suspected, and MRI should be the imaging modality of first choice where vascular dementia is a possibility. An EEG is nearly always non-specifically abnormal even in the early stages of AD, in contrast with fronto-temporal degenerations where an EEG remains unaffected at a broadly equivalent severity. This can help to distinguish the conditions, particularly where there is neuroimaging evidence of regional insufficiency.

Aetiology and molecular neurobiology

Alzheimer's disease is the most common dementia, affecting more than 20 per cent of the population over the age of 85 years. Epidemiological evidence has suggested risk factors and putative protective factors, but the greatest advances in understanding its pathogenesis have come from the combination of molecular and epidemiological approaches.

Neuropathology

At post-mortem, the brain in AD is lighter than aged-unaffected controls with more prominent sulci and a larger ventricular volume. Microscopic examination reveals the most prominent lesions described by Alzheimer—the extracellular plaque and intracellular neurofibrillary tangle. No consensus has developed regarding which of these lesions is responsible for the cognitive impairment

of AD. Plaques, or more precisely amyloid load, might correlate with the degree of cognitive impairment,[43] although a significant amyloid deposition is also found in normal, unimpaired, aged individuals.[30] However, there is a high degree of correlation between dementia severity and neurofibrillary tangle formation,[44] although it is possible that some of the features of AD are more stable than others; for example, extracellular neurofibrillary tangles persist after the neurone has died, whereas extracellular Lewy bodies are not found.

The plaque consists of an amyloid core surrounded by dystrophic neurites, which are themselves filled with highly phosphorylated tau protein. Studies of Down syndrome brains have suggested a temporal course to plaque formation. First, peptides derived from the amyloid precursor protein (**APP**) are deposited in a diffuse plaque.[45] Over time this becomes organized as the amyloid peptides become fibrillar and form the amyloid deposit, neuritic change then occurs, and the plaque becomes fully mature.

Neurofibrillary tangles are composed of paired helical filaments, structures which are also found in the dystrophic neurites around mature plaques, and together with straight filaments, in neuropil threads. These filaments are themselves composed of the microtubule-associated protein, tau, which is present in a stably and highly phosphorylated state.[46,47] Tau is a neuronal-specific protein, found predominantly in the axon that functions to stabilize microtubules, a property that is regulated by phosphorylation. Phosphorylated tau is less effective in promoting tubulin polymerization into microtubules; normal adult brain a proportion of tau is highly phosphorylated, but this proportion is considerably greater in AD. Tau deposits are a feature of other disorders, such as progressive supranuclear palsy and some fronto-temporal degenerations[48] and together these tau-related disorders have been grouped together as the 'tauopathies'. Mutations have been found in fronto-temporal degenerations with parkinsonism (FTDP-17), and in other tauopathies thereby emphasizing the importance of this molecule to neurodegeneration.[49]

Braak and Braak[50] studied large numbers of brains from individuals who died at various ages and at different stages of dementia severity, which has resulted in the wide acceptance of the neuropathological staging of AD. The very earliest stages, before the clinical manifestation of dementia, are characterized by the appearance of highly phosphorylated tau in the hippocampus. In later stages, neurofibrillary tangles appear in the same brain regions and then become more widely distributed.

(a) The cholinergic hypothesis

The pathological changes in AD are localized both structurally and functionally. Plaques and tangles first occur in the hippocampus before spreading to involve other regions. Some areas of the brain are relatively preserved—the occipital lobe is affected relatively late and the cerebellum appears to be spared from neuritic change (neurofibrillary tangles and the fully matured plaques, although diffuse amyloid deposits do occur). Functional localization was demonstrated by evidence of the relatively greater and earlier loss of cholinergic neurotransmission. At post-mortem there is evidence of significantly greater neuronal loss in the cholinergic nucleus basalis of Meynert and loss of cholinergic markers.[51] These observations led to the cholinergic hypothesis, which stated that the cognitive impairment of AD was due to a disorder predominantly affecting cholinergic neurones. It was this hypothesis that led to the development of pharmacological strategies to rectify cholinergic loss and the introduction of the first compounds specifically designed for and efficacious in AD. However, the cholinergic hypothesis was something of a simplification as other neurotransmitter systems (e.g. serotonergic and noradrenergic) are also affected in AD.

(b) The amyloid cascade hypothesis

In 1984, the protein deposited in blood vessels (congophilic angiopathy) in AD was shown to be a 4-kDa peptide known as β-amyloid. This peptide, which is identical to the amyloid in plaques, is derived from a larger peptide, APP, the gene for which is coded on chromosome 21. Subsequently, mutations in the *APP* gene were found in a family with autosomal dominant early onset AD. These two discoveries—the identification of β-amyloid and the discovery of mutations in the parent *APP* gene—led the way to the amyloid cascade hypothesis, which has remained the dominant molecular model of the disorder (reviewed in Refs[52–54]). Many subsequent molecular observations have been consistent with this model, which posits the formation of β-amyloid as the initiating, or at least early event, leading to all the other changes observed including tau aggregation and phosphorylation, neuronal loss, cholinergic deficits, and clinical symptoms. Perhaps the most convincing evidence that there is such a unidirectional cascade comes from the observation that mutations in the *APP* gene give rise to plaque formation and also to neurofibrillary tangle pathology, whereas mutations in the tau gene give rise to tangle formation but not to plaque formation in the tauopathies.

Much subsequent research has concentrated upon understanding the metabolism of APP and the formation of β-amyloid peptide. APP is a ubiquitous single-pass cell-membrane protein expressed in many cell lines with a high degree of evolutionary conservation. At least three putative secretases cleave APP[55] and the metabolic products can be detected in individuals unaffected by AD; the processing is not pathological in AD, but the balance between different metabolic routes may be shifted in the disease state. α-Secretase cleaves APP at the outer cell-membrane surface at a site within the β;-amyloid moiety itself. Clearly, α-secretase cannot therefore yield intact β-amyloid, and this metabolic route, resulting in a secreted product, APPs, and other fragments, is termed non-amyloidogenic. On the other hand, amyloidogenic metabolism is the result of β-secretase (also known as Beta Amyloid Cleaving Enzyme or BACE) cleaving APP beyond the amino terminus of β-amyloid and of γ-secretase cleaving the resulting peptides at the carboxy terminus in the cell. The β-amyloid products vary in length, with predominant species having a length of 40 or 42 amino acids. The longer peptides are somewhat more prone to forming aggregates *in vitro* and it is probable that a relative increase in the longer peptides is critical in pathogenesis, and that mutations in the *APP* gene increase these longer amyloid peptides. Transgenic mice overexpressing the mutated *APP* gene also produce more β-amyloid peptide and have amyloid deposits in brain.[56] Interestingly, these animals do not develop other aspects of AD pathology, in particular they lack tangle formation. The nature of the toxicity of β-amyloid peptide is not fully understood but increasingly it appears that it is small aggregates (oligomers) that damage neurones rather than the longer fibrils that form the core of the plaque.[57]

(c) The presenilin genes

Mutations in *presenilin-1 (PS-1)* and *presenilin-2 (PS-2)*, two very similar genes on chromosome 14 and chromosome 1 respectively, also cause early onset autosomal dominant AD. The proteins encoded by these genes are part of the γ-secretase complex that metabolizes APP to β-amyloid. In fact these unique proteins turn out to have very many substrates and function in relation to many of these to release an intracellular component of a membrane bound protein that then translocates to the nucleus and triggers gene transcription events.[58] This is certainly the case for APP and also for Notch protein, which is also implicated in some other neurodegenerative conditions, for example. Mutations in the presenilin genes result in an increase in the production of β-amyloid probably through interfering with the normal γ-secretase complex.

Tangle formation and tau phosphorylation

Tangles are composed of paired helical filaments, themselves composed of aggregated and highly phosphorylated tau.[59–62] There are other post-translational modifications in tau, including truncation, and it is not fully determined which of these are primary events. However, in post-mortem studies, neuropathological evidence does suggest that highly phosphorylated tau accumulates in the brain before the formation of tangles, and before the clinical manifestation of AD suggesting that it is a early change in the pathological process.[63]

Protein phosphorylation is a product of kinase and phosphatase activity. It is likely that many such enzymes may participate in the regulation of tau phosphorylation in the brain, but two have been shown to be predominant. In cells, and *in vitro*, glycogen synthase kinase-3 and cyclin-dependent kinase 5 (CDK5) seem to be the predominant tau-kinases and protein phosphatase 2A is probably the predominant tau phosphatase.[64,65]

Molecular genetics

Mutations in three genes have been found to cause early onset familial AD, which is inherited in an autosomal dominant fashion.[66,67] Mutations in the *APP* gene (on chromosome 21) are the least common, only affecting perhaps 20 families worldwide. Mutations in *PS-1* (on chromosome 14) are somewhat more frequent, although are still a rare cause of AD. Mutations in *PS-2* (on chromosome 1) appear to be largely restricted to an ethnic German people residing in the United States, suggesting an individual founder effect. Individuals with Down's syndrome are at extremely high risk of AD, with neuropathological evidence being present in virtually all individuals living to middle age, probably because of trisomy APP (on chromosome 21). Mutations in other genes gives rise to disorders showing similarities to AD and much has been learnt from these findings about the overlap between neurodegenerative disorders. These genes include *tau* and *progranulin*, mutations in which give rise to FTD and related disorders.

The genetic component of late-onset AD has been demonstrated by epidemiological studies, showing that a family history of dementia is the largest single risk factor for AD.[68] However many, perhaps most, patients with AD do not have a positive family history, thus giving rise to the idea of 'sporadic' AD with a separate aetiology to 'familial' AD. For late-onset AD this concept is outmoded and redundant. Many patients with AD do not have a family history because of attrition of family members due to death by other causes. For the cohort currently suffering from AD their parents were born in the latter part of the nineteenth century or early years of the twentieth, lived through two major world wars, and reached adulthood before the discovery of antibiotics. It is not surprising that few patients with late-onset AD have two parents and more than one sibling living to the age of onset of AD, and if one parent died young and there are no elderly siblings then the family history is non-informative. Risk figures for relatives of probands with late-onset AD have been calculated and can be useful in counselling families.[69]

One gene has been unequivocally associated with late-onset AD, although even this gene accounts for only something like 50 per cent of the genetic variance.[70] The *apolipoprotein E* gene (*APOE*, gene; apoE, protein) on chromosome 19 has three common alleles, coding for three protein isoforms that differ by the substitution of an amino acid at just two positions. Of the three alleles ε3 is the most frequent and ε2 the least; following linkage to chromosome 18 it was demonstrated that the ε4 allele confers risk, whilst the ε2 may be protective.[71,72]

The mechanism of action of the *APOE* gene in increasing the risk of AD is not known. As *APOE* variation is a major genetic influence on serum cholesterol (people with the *APOE* ε4/* genotype have higher serum cholesterol levels), it is possible that an altered lipid metabolism—either peripherally or locally—might affect the pathogenesis of AD.[73,74] Alternative theories arise from *in vitro* studies, which show a differential binding of APOE protein isoforms both to amyloid protein and to tau protein.

Other genes have been associated with AD, but none have been replicated in as many studies as *APOE*. It is likely that a combination of linkage and association studies using large populations will identify the other genes that influence AD, either alone or in interactions with other genes or the environment.

Treatment

For many conditions the goals of treatment or intervention are self-evident—cure, prevention of relapse, and resolution of symptoms. For AD, however, the goals of treatment can be less obvious and differ between patients and for individual patients over time. Ultimately, the quality of life of the patient should be improved, but assessing quality of life is difficult in those with dementia, and given the early loss of insight who is to judge such issues?[75] Quality of life may appear poor—patients may have diminished emotional repertoires, few pleasurable activities, and considerable handicap—but they may share none of the negative cognitions experienced by others with a similarly questionable quality of life induced by different illnesses. Other patients may appear content or happy, despite the loss of the autonomy and self-awareness normally considered an essential component of a good quality life. The needs of the patient can be difficult to ascertain.[76] Equally, the treatment unit in AD includes carers, and there are times when the patient's quality of life is in conflict with the quality of life for other members of the family.[77] Resolving such conflicts of interest and other moral and ethical issues is part of the treatment process in AD. With the arrival of specific treatments for AD and the prospect of disease-modifying therapies, an even harder question arises regarding prolonging life for those with dementia: if quality of life appears poor to observers, is it right to prolong the process, can quality of life in those with dementia truly be assessed, or should carers and families be allowed to assess for themselves the benefits and costs of treatment?

There is no single model of management of patients with AD. In many countries management is the role of the gerontologist or neurologist. In others, as in the United Kingdom, the old-age psychiatry team provides the core specialist services. Many, perhaps even the majority, of those with AD are managed within primary care with the support of social services. Referral from primary care to specialist services will be according to local agreements, but most would concur that behavioural disturbance or the use of specific drugs to treat AD warrant referral to secondary care. Interventions for AD, whether provided in primary or secondary care, can be thought of as directed towards the patient, the patient's family, and the patient's environment. Guidelines on the identification and management of patients with dementia have been produced and may be a constructive approach to ensuring best clinical practice.[78]

Managing the patient

Management of the patient with dementia is discussed in greater detail in Chapter 4.1.13. Management starts with the assessment and diagnosis, and perhaps the difficult dilemma is how much of the diagnosis and prognosis to discuss with the patient.[79–81] Most practitioners do not discuss the diagnosis with the patient themselves, although practice is changing and especially in the early stages a frank consultation can be beneficial.

A large part of managing the patient is directed towards managing mood and behavioural disturbance. Accurate assessment of the disturbance is critical, and includes determining the antecedents and responses to the behaviour as well as a full description of the behaviour and any associated abnormalities in the mental state. Treatments of behavioural disturbance in AD are most often behavioural and sometimes restricted to giving information to carers. Evidence overwhelmingly suggests that anti-psychotic medication is relatively ineffective and has frequent adverse effects in dementia.[82,83] They should be a treatment of last resort, if at all.

Specific treatments for AD have been developed, concentrating in clinical trials on ameliorating the core symptom of cognitive impairment. The first to be licensed were the cholinesterase inhibitors followed by memantine. Drug treatments for AD are described in Chapter 6.2.7.

Managing the family

Although patients may not appreciate or be able to follow a detailed discussion of the diagnosis and prognosis, their relatives, spouses, and other carers will. This is an important part of the treatment process; as the carer provides the main interventions for much of the period of the disease process, care should be taken to ensure that appropriate and sufficiently complete information is given.

Caring for a patient with AD can be difficult and stressful and some carers suffer accordingly and need, and may benefit from support.[84] The characteristics of both carers and patients influence the impact that this 'burden' of caring has on the carers themselves. Men in general, and husbands in particular, seem to be less vulnerable to the adverse effects of caring, possibly because of the response seen in many male carers of rapidly and effectively recruiting outside help.[85] Women may be socialized into accepting more caring roles themselves and therefore seek less help. Non-white carers appear to suffer from less adverse consequences of caring, perhaps because of cultural differences in the perception of family bonds.[86] Patient characteristics that increase the burden of caring include behavioural disturbances,[25] depression, and unawareness of cognitive impairment but not the cognitive impairment itself. Although the core outcome variable in clinical trials of AD drugs is the severity of cognitive impairment, it is not the variable that induces most stress in relatives nor is it the variable that predicts entry to residential care. Other variables are almost certainly protective, and caring for a loved one with dementia is not a universally negative experience. Much caring is done willingly, effectively, with love, and without complaint.

Carer support groups offer much to a person with a relative afflicted by AD. Through support groups, and especially through the national AD societies and the umbrella group—AD International—carers can obtain up-to-date and useful information regarding all aspects of AD. A support group can help individuals practically and emotionally through difficult times. Many carers talk of the support group as a lifeline, although little empirical evidence exists as to the impact on carer well being.

One particular intervention for the family is that of genetic counselling. Many relatives are worried about inheriting AD. This concern might arise from two sources—the frequent discussion of genes 'for' AD in the media and the observation of familial occurrence of AD in many individual families. For families with clinically apparent familial AD, advice, information, and where appropriate, genetic testing can be arranged through a genetics centre. Where predictive testing is contemplated for genes causing autosomal dominant, early onset AD this will adhere to guidelines established for Huntington's disease. Genetic testing in late-onset AD is not recommended at the present time but is the subject of an ongoing research programme.[87]

Managing the environment

The mainstay of interventions for AD are provided by social services. The goal of the provision of social care in people with AD is to provide an environment that is comfortable, stimulating, and, above all, safe. For most patients, and for all patients in the early stages, this means care at home, perhaps with the support of home-meal delivery and home-helps to provide shopping and cleaning assistance. Further home care may become necessary as the patient requires assistance with basic self-care tasks such as washing and dressing. The carer may require a sitting service, either for periods during the day to allow them time to themselves or in the evening to allow them to attend a carers group or for socializing. Safety issues are especially important for those with dementia living alone. There are inherent risks to the patient themselves if they wander out of the home and risks to others if the gas can be left on or fires started.

Day care is appropriate for many patients, ideally in a specialist unit. In a generic facility for elderly people those with early dementia can receive little input and those with moderate or advanced dementia can necessitate too much input from the day-centre staff. A good dementia specialist day-care facility will provide the staffing ratio appropriate to patients with a range of 70s, in addition to providing a varied programme of group and recreational facilities to maintain interest and stimulation. Day centres, where patients are arrayed around the edge of the room with a television as a focal point, are, or should be, consigned to history. Day care provides essential respite to many carers, and longer periods of occasional or regular respite can prolong the period a patient can remain in their own home.

The multidisciplinary team consisting of care workers, social services, community psychiatric nurse occupational therapist, and psychologist can maintain patients at home more effectively and for longer periods than can clinicians alone. However, long-term care becomes a necessity for many patients at some point. The costs of providing nursing-home care are huge and far outweigh the costs of providing relatively intensive community care or relatively costly drugs. If treatments were shown to reduce the total length of stay in nursing homes then this would affect the cost–benefit ratio of these compounds considerably.

Translational research in AD

The rapid and comprehensive advances in understanding the molecular basis of AD has led to the promise of advances in health care—translational or bench to bedside research. Most importantly are potential disease modifying therapies. These are distinguished from symptomatic therapies in that they are designed to halt or slow down the disease process itself. Designing trials to assess efficacy of a potential treatment that might only slow down deterioration, and differentiating symptomatic effects from disease-modifying effects is not easy.[88] Two broad approaches are suggested—either a comparison of slopes of decline in which case a disease-modifying therapy would result in divergent slopes whereas a symptomatic therapy would result in parallel slopes, or strategies such as delayed start where in the case of a disease-modifying therapy the treatment arm of the delayed group never do quite as well as the early start group.[89]

Many approaches to disease modification are being pursued including therapeutics designed to alter APP processing—BACE inhibitors and γ-secretase inhibitors for example—or therapeutics designed to prevent β-amyloid from aggregating or for increasing the clearance of β-amyloid.[90] Many such compounds are in early stages of development and some were in phase III trials in 2007. Other potential therapies attempt to reduce tau phosphorylation or aggregation and yet other approaches are predicated on epidemiological findings such as the observation that non-steroidal anti-inflammatory drugs reduce risk of AD or that diabetes increases risk. Primary preventative therapies are probably even further away than disease-modification therapies but modifying cardiovascular risk or other approaches have been suggested. Secondary prevention, possibly in those with memory impairments not amounting to dementia (minimal cognitive impairment), is a more realistic prospect rendering the determination of the very earliest signs of disease or evidence of a prodromal state a high priority.

A second significant translational target in AD research close to clinical utility is that of biomarkers.[91,92] A marker is sought that might help in diagnosis, prediction or disease monitoring. For diagnosis a biomarker is sought that would make early or differential diagnosis more accurate, for prediction a biomarker that would help in predicting which elderly people were more likely to suffer from dementia or, more likely, which of those with mild cognitive impairment are more likely to convert to dementia. A marker of disease progression is sought that could supplement clinical assessments of deterioration. Of the many approaches to biomarkers, biochemical assays of tau and β-amyloid in CSF[91,93] and serial quantitative MRI[94] are the most promising although markers in plasma appear promising.[95,96]

Conclusions

For the foreseeable future, AD will remain a disorder afflicting a large proportion of the world's elderly. The impact on developing countries especially will be considerable. Care for these patients will continue to be provided from many sources, with specialist services being necessary to compliment primary and generic services, particularly for those patients exhibiting the complex psychiatric phenomenology described by Alzheimer and for those patients where specific drugs are indicated. As the molecular pathogenesis of AD is increasingly understood it is to be hoped that this is translated into treatments ever more effective in modifying or preventing the disease process itself.

4.1.3 Frontotemporal dementias

Lars Gustafson and Arne Brun

Introduction

Nosological classification of organic dementia is based on current knowledge and theories of aetiology, including genetics, clinical picture, the pathological substrate, and the predominant location of brain damage. This chapter is concerned with dementia syndromes caused by a degenerative disease primarily affecting the frontal and temporal lobes, named frontal-lobe dementia[1] or frontotemporal dementia (**FTD**).[2] The terminology should be viewed from a historical perspective. The relationship between localized cortical atrophy in dementia and symptoms of aphasia was first reported by Pick in 1892.[3] The pathological account of this lobar degeneration by Alzheimer in 1911 described 'ballooned' neurones (Pick cells) and argentophilic globes (Pick bodies),[4] and the clinicopathological entity was named **Pick's disease**.

In the 1980s, attention was drawn to a larger group of frontal-lobe dementias associated with frontotemporal cortical degeneration.[5–7] The Lund–Manchester consensus of 1994 delineated the prototypical clinical syndrome of FTD with three neuropathological constituents, frontal lobe degeneration of non-Alzheimer type (**FLD**),[5] (alternatively designated '**dementia lacking distinctive histology**'),[8] Pick's disease, and motor neurone disease (**MND**) with dementia (**FTD-MND**).[2] The 1998 consensus on clinical diagnostic criteria for frontotemporal lobar degeneration (**FTLD**)[9] encompassed two additional dementia syndromes; progressive non-fluent aphasia (**PA**),[10,11] and **semantic dementia**.[12] Corticobasal degeneration (**CBD**) and progressive supranuclear palsy (**PSP**) have also been associated with FTLD.[13] A changing clinical classification is shown in Fig. 4.1.3.1. The addition of important genetic and histochemical characteristics has further added to the complex classification of FTD and FTLD with a risk of developing numerous and partly competing definitions. FTLD may be further subclassified into forms positive or negative for tau and ubiquitin. The ubiquitinated form will be referred to as **FTD-U**, which is synonymous to **FLTD-U**.[14]

Neuropathology

On a neuropathological basis about two-thirds of the FTLD cases are of the type with ubiquitinated inclusions (FTD-U) or of FTD type without such inclusions (FLD), both lacking tau pathology.[14,15] In an attempt to classify FTD forms from a structural point of view, FLD might be appointed as a basic form, showing type and distribution of main pathological changes common to the majority of FTLD forms. To this set of alterations are added further features proceeding in the description of frontotemporal degenerative disorders (Table 4.1.3.1).

In FLD, the cortex is the site of a *simple* degenerative process resulting in a cortical atrophy which is frontotemporal with or without asymmetries, moderate or even at times mild. It involves cortical layers 1–3, showing neuronal loss, gliosis, and microvacuolation, seen also in the striatum in a small proportion of cases as well as a mild-to-moderate degeneration of the substantia nigra.[5] DLDH has essentially the same pathology as FLD.[8]

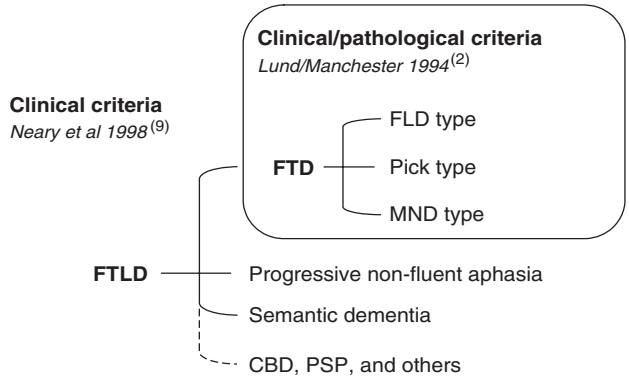

Fig. 4.1.3.1 Clinical classification of frontotemporal dementias.

In FTD-U the ubiquitin-positive inclusions and dystrophic neurites supplement the picture of FLD, as also described in FTD, linked to chromosome 3.[16] The inclusions contain a ubiquitinated protein, also identified in some other varieties of FTD such as FTD-MND.[17] Here there is also a degeneration of motor neurones and paths. The language variants of FTLD show a mainly temporal degeneration in semantic dementia and an asymmetric frontotemporal degeneration with left-sided predominance in PA.

With a mainly frontal or frontotemporal including anterior cingulate gyrus involvement FTD differs markedly from Alzheimer's disease (AD) with its posterior temporal parietal, posterior cingulate, and severe hippocampal involvement and also with Lewy bodies, amyloid, and plaque pathology not seen in FTD. So far mentioned FTD forms belong in the same histopathological group of non-tauopathies and further share a frequent and individually varyingly severe white-matter sclerosis, which is often predominantly frontal and may be primary or secondary.[18] It is also seen in the tauopathy group and in forms of vascular dementia.

The remaining, less common forms comprise the FTD-tau group. In Pick's disease the degenerative process is more intense and partly involves all cortical layers, creating a severe circumscribed or lobar frontotemporal atrophy referred to as 'knife blade atrophy'. Microscopically there are tau-positive neuronal inclusions and sometimes glial tangles and often ballooned nerve cells. The FTD with Parkinsonism (FTDP-17) group with a number of familial disorders shares basic pathological features with the FLD but is

Table 4.1.3.1 Organic dementia with frontotemporal lobar degeneration (FTLD)

Frontal lobe degeneration of non-Alzheimer type (FLD) (Dementia lacking distinctive histology) without ubiquitinated inclusions
FTD with ubiquitin-positive inclusions (FTD-U)
Familial FTD with chromosome 3 mutation (FTD-3)
FTD with motor neurone disease (FTD-MND)
Progressive non-fluent aphasia (PA)
Semantic dementia
Pick's disease
FTD with Parkinsonism (FTDP-17)
Corticobasal degeneration (CBD)
Progressive supranuclear palsy (PSP)

regularly more severe in the basal ganglia and substantia nigra.[19] Glial cells and neurones contain various types of tau-positive inclusions. CBD is structurally and clinically heterogeneous, resulting in overlap with other diseases, especially PSP.[20] These two may represent varieties of the same pathological process, less obviously belonging in the FTD group even if a similar laminar frontal cortical degeneration and related symptoms are part of the presentation. In CBD ballooned neurones, tau-positive inclusions in neuronal and glial cells, white-matter rarefaction and nigral degeneration may be found. For PSP different forms and patterns are noted but it basically affects more widely the striatum, basal ganglia, and hypothalamus. It also involves the brain stem including the substantia nigra as well as the cerebellum, again with silver- or tau-positive inclusions and tangles in neurones and glial cells.[21]

Epidemiology

Most demographic data concern the grouping of FTD, not separating FLD and Pick's disease. Pick's disease is rare, estimated at 24–60/100 000 in Minnesota and 30–60 in Switzerland.[22] The calculated prevalence of FTD in the Netherlands is 10.7 per million between 50 and 60 years of age and 28 between 60 and 70 years.[23] The prevalence of FTD in the province Zuid-Holland in the Netherlands was 3.6/100 000 at age 50–59, 9.4 at age 60–69 years, and 3.8 at age 70–79 years.[24] Pasquier *et al.*[25] diagnosed FTD in 4.8 per cent of all types of dementia. The marked geographic variation of the prevalence might be due to genetic and environmental factors, but also influenced by differences in the diagnostic process and the age group studied. In a clinical study of a total catchments area of 20 million people in Germany the relative proportion of FTLD was 1.9 per cent.[26] The prevalence of dementia in motor neurone disease has been estimated to 2–6 per cent.[27] The proportion of FTD in relation to all types of dementia in different clinicopathological studies varies between 5 and 18.9 per cent.[7, 8, 28–30]

Clinical features

The first clinical manifestations of FTD usually appear in the presenium, in some cases as early as 35 and seldom after 70 years of age. The mean age at onset in post-mortem verified FLD cases is 56 ± 7.6 years with a mean duration of 8 ± 3.4 years (range 3–17 years).[31] The mean age of onset in Pick's disease is similar, 62 years, with a range of 40–80 years and a mean survival of 9.8 years with a range of 4.8–21.2 years.[22] The large variations of the duration of FLD and Pick's disease are similar to that of early-onset AD. The clinical onset of MND dementia is usually in the sixth decade and the mean duration is about 30 months. Age at onset is similar in familial and sporadic cases of FTD and sometimes past 80 years.[32] The Lund–Manchester consensus on clinical criteria for FTD is summarized in Table 4.1.3.2.

Table 4.1.3.2 The Lund–Manchester consensus (1994) on clinical criteria for frontotemporal dementia (slightly modified)[2]

Core diagnostic features
Behavioural disorder
Insidious onset and slow progression
Early loss of insight into changes of own mental state
Early loss of personal and social awareness
Early signs of disinhibition and lack of judgement
Mental rigidity and inflexibility
Stereotyped, repetitive, and imitating behaviour
Hyperorality, oral/dietary changes
Utilization behaviour
Distractibility, impulsivity, and impersistence
Affective symptoms
Depression, anxiety, excessive sentimentality
Hypochondriasis, bizarre somatic complaints
Emotional bluntness, apathy, and lack of empathy
Amimia
Speech disorder
Progressive reduction of speech output
Stereotypy of speech, perseveration
Echolalia
Late mutism
Spatial orientation, receptive speech, and praxis preserved
Physical signs
Early primitive reflexes
Early incontinence
Late akinesia, rigidity, and tremor
Low and labile blood pressure
Investigations
Normal EEG despite clinically evident dementia
Brain imaging (structural and/or functional): predominant frontal and/or anterior temporal abnormality
Neuropsychology: profound failure on 'frontal-lobe' tests in the absence of severe amnesia, or perceptual spatial disorder
Supportive diagnostic features
Onset before 65
Positive family history of similar disorder in a first-degree relative
Bulbar palsy, muscular weakness and wasting, fasciculations (motor neurone disease)

(Reproduced from A. Brun, E. Englund, L. Gustafson, *et al.* Consensus statement—clinical and neuropathological criteria for frontotemporal dementia, *Journal of Neurology, Neurosurgery, and Psychiatry*, **57**, 416–18, copyright 1994, BMJ Publishing Group Ltd.)

Disordered behaviour

The early stage of FLD and Pick's disease is characterized by changes of personality and behaviour, affective symptoms, and a progressive reduction of expressive speech. The clinical onset is insidious with slow progression without ictal events. The changes of personality and behaviour are rather non-specific and easily misinterpreted as a non-organic mental disease such as mood disorder, stress reaction, schizophrenia, or other psychotic reaction. Loss of insight concerning the mental changes is an early and alarming manifestation of the disease. FTD patients may, however, consult a doctor referring to symptoms such as anxiety, tiredness, and strange somatic complaints combined with bizarre hypochondriacal ideas.

The early loss of personal and social awareness is seen as neglect of personal hygiene and grooming, and tactlessness and antisocial behaviour.[6, 9] The impaired control of behaviour is seen as increased sentimentality, inadequate smiling, inappropriate joking, irritability, and acts of aggressiveness, leading to conflicts at home and work. Craving for affection and sexual contact may be easily provoked, but usually expressions of sexual disinhibition are possible to divert. Impulse buying, shoplifting, indecency, and other disinhibited behaviour may, however, lead to rejection by the family and society. Such unpredictable and pseudopsychopathic

behaviour imposes severe strain on the patient's family, leading in some cases to economic problems, divorce, and even suicide in the family.[33] Complications of this type are uncommon in families with an AD patient. FTD patients tend to become inattentive and careless and a danger to traffic. Changes in drinking behaviour are sometimes reported. The patient starts to drink more frequently and in larger quantities than before. The changes of behaviour, which may lead to misdiagnosis of alcohol-induced dementia, can often be controlled by a firm attitude from relatives.

Affective symptoms

The FTD patient becomes emotionally shallow and blunt, showing less concern about family and friends. The patient is described as egocentric, rigid, and lacking empathy. The early emotional changes may be difficult to differentiate from non-organic personality disorders and affective disorder. Mood changes towards euphoria, especially when associated with press of speech and overactivity, may at first be mistaken for a hypomanic or manic state. Slowly developing apathy, in combination with sparse mimical movements and verbal aspontaneity, may be misdiagnosed as depression. During the depressive reactions, which are mostly of short duration, the patient may become dysphoric, and dwell on suicidal thoughts. FTD patients are often diagnosed as depressed and treated with antidepressant medication during the early stage of the disease.[32]

Early symptoms of dementia must be judged against information about the patient's premorbid personality, education, and social background. The vast majority of cases show normal premorbid personality although a few have previously manifested anxiety and restlessness. The emotional features in FTD do not seem primarily related to premorbid personality traits but rather to the distribution of brain pathology as shown at autopsy and brain imaging.[34]

Other symptoms

A striking feature of FTD is the **stereotyped and perseverative behaviour** seen as wandering, clapping, humming, dancing, and hoarding of objects, as well as complex rituals involving washing and dressing. Such behaviour sometimes reaches psychotic intensity. Imitative behaviour is frequent in FTD and occurs more often than in AD.

Hallucinations and delusions are reported in about 20 per cent of FTD and early-onset AD cases. The psychotic symptoms in FTD are often bizarre and the combination with emotional changes and stereotypy of speech and behaviour gives the impression of functional psychosis with schizophrenia as an early tentative diagnosis.[6–8] The psychotic symptoms in early-onset AD seem more strongly related to the cognitive failure with memory failure, impaired recognition, and disorientation, and the degeneration of the temporoparietal association cortex.[6]

The **human counterpart of the Klüver–Bucy syndrome** has been reported in FLD and in Pick's disease. The hyperorality and changes of oral/dietary behaviour are seen as overeating, food fads, excessive smoking, and alcohol consumption. Utilization behaviour, defined as an irresistible impulse to explore and use objects in the visual environmental, shows important similarity to the hypermetamorphosis and distractibility of the Klüver–Bucy syndrome.[35] The Klüver–Bucy syndrome in AD is usually less complete than in FTD with less hypersexuality and utilization behaviour, supporting the suggestion that frontal as well as temporal limbic involvement is needed to produce the syndrome in humans.[6]

Dissolution of language

A core feature of FTLD is progressive impairment of speech and language. In FTD, this has been described as *dissolution du langage* or *Sprachverödung*.[6] Speech becomes aspontaneous with word-finding difficulties and frequent use of stereotyped comments and set phrases. During the early stage there may also be increased pressure of speech. The language dysfunction in FTD is dominated by dynamic expressive failure, which is in agreement with damage in the frontal cortex especially premotor areas. Echolalia is observed in about 50 per cent of FTD and Pick cases.[31] Finally the patients become mute which in combination with the amimia makes communication extremely difficult. The ability to understand information and instructions usually remains until comparatively late in the course of FTD, as does the ability to write. The handwriting may, however, change in magnitude, spelling, and speed of writing. These disturbances are unlike the temporoparietal type of dysgraphia and global dysphasia observed in AD. The symptom constellation of palilalia (stereotypy of speech), echolalia, mutism, and amimia (PEMA syndrome of Guiraud) is typical of FTD and seldom found in AD.

There are important similarities between the speech disorder of early FTD and the clinical spectrum of PA,[10] characterized by effortful speech production in the context of preserved word comprehension and relative preservation of memory and practical abilities. Dementia often develops later in the course, and the underlying degenerative process may be similar to that of FLD, with a predominant and early involvement of the speech-dominant hemisphere. Semantic dementia, the fluent language variant of FTLD is characterized by progressive loss of word retrieval and understanding, and recognition of sensory stimuli.[36] The pathological substrate is bilateral, often asymmetric temporal lobe degeneration.

Physical signs

Few pathological somatic findings including neurological symptom are reported early in FTD. However, primitive reflexes may appear early, while akinesia, rigidity, and tremor may emerge later in the course. Increased muscular tension is, however, significantly more common in AD.[6] The spectrum of FTLD also includes the syndrome of the disinhibition–dementia–parkinsonism–amyotrophy complex linked to chromosome 17 also named FTD-17.[37]

Generalized epileptic seizures may appear in FTD although less prevalent than in AD, and myoclonic twitchings and logoclonia which are prevalent in early-onset Alzheimer's cases are rare in FTD. Urinary incontinence, which is reported early in about 50 per cent of FTD cases, is a comparatively late feature in uncomplicated early-onset AD.

FTD patients in general have low and labile blood pressure with a high prevalence (50 per cent) of orthostatic blood pressure drops and syncopal attacks. These symptoms are, however, also reported in early-onset AD (40 per cent) and late in the course of vascular dementia (50 per cent). The relationship between blood pressure changes and brain damage especially the white-matter changes in FTD is still unclear.[18]

Dementia in motor neurone disease

The clinical picture of the dementia in motor neurone disease is similar to that in FLD with early changes of personality and behaviour, emotional changes such as euphoria and apathy, and signs of disinhibition and hyperorality.[38] Speech becomes stereotyped and perseverative, later developing into mutism. Receptive speech function, orientation, and practicable abilities remain relatively untouched by the degenerative process. The mental changes may appear early and even precede development of typical neurological features.

Investigations

EEG

The EEG may be normal or only slightly pathological in FTD at a stage when dementia is strongly suspected or clinically evident, but it is usually pathological late in the course. This has been shown in FLD, Pick's disease, and FTD-MND.[39] By contrast, EEG is almost always pathological in AD even at an early stage. Quantitative EEG mapping and repeated recordings may strongly improve the differential diagnosis between FTD and AD.[32]

Brain imaging and other investigations

Structural and functional brain imaging has strongly improved the diagnosis and differential diagnosis of FTD, AD, and other dementias. Cortical atrophy with more or less frontal focal accentuation, sometimes asymmetrical, is shown with CT and magnetic resonance imaging (**MRI**).[8,40] MRI may show significantly more prevalent and severe frontal periventricular white-matter lesions in FTD patients than in matched normal controls. The anterior–posterior gradient of the atrophic changes may, however, contribute to the differentiation from AD.[18,40] The differential diagnosis from vascular dementia with frontal subcortical lesions, but lacking large cortical infarctions, may be difficult.

Functional brain imaging measuring regional cerebral blood flow (rCBF) and metabolism with SPECT, PET, and other techniques show frontal and frontotemporal flow pathology in FTD with better preserved perfusion in posterior areas.[41,42] PET studies have indicated the ventromedial frontal cortex as the earliest site of imaging pathology.[43] These changes may at an early stage be mild and asymmetric in accordance with the clinical picture.

Recently several biomarkers in the cerebrospinal fluid (CSF) have been developed for differential diagnosis of dementia. Riemenschneider *et al.*[44] reported significantly higher CSF tau concentrations in FTD compared to healthy controls, but significantly lower than in AD, while CSF Abeta42 levels were significantly lower in FTD than in controls, but significantly higher than in AD. Early diagnosis of FTD might in the future be based on a combination of profile and levels of CSF biomarkers such as tau, β-amyloid, and neurofilaments.[45] Interestingly tau levels are dependent on lobar localization but independent of the degree of cerebral atrophy.[44,46]

Assessment of cognitive impairment

The cognitive changes, which appear early in FTD, may be difficult to evaluate due to the patient's emotional and behavioural changes. Distractibility and slightly reduced recent memory are common findings and remote memory is also impaired although to a lesser extent than in AD. The patients show significant impairment on 'frontal-lobe' tests such as the Wisconsin card sorting test, word fluency test, and the Stroop and trail-making tests. The early test profile is characterized by slow verbal production and relatively intact visuospatial ability, reasoning, and memory, while intellectual and motor speed are reduced.[10,47] Early AD usually shows a relatively preserved verbal ability and simultaneous impairment of reasoning ability, verbal and spatial memory dysfunction, dysphasia, and dyspraxia.[10,48,49] Difficulties in understanding instructions are found early only in a minority of FTD cases. Misspelling and dyscalculia are sometimes reported early in FTD.

Discrimination between FTD and AD can be based on a short test-battery (verbal ability, visuospatial ability, and verbal memory), when used in the context of a neuropsychological evaluation of qualitative as well as quantitative aspects of test performance.[47,49,50] Using a screening instrument based on frontal release signs, awareness of social/ethical dilemma in a short story, and the number of preservation errors, FTD was classified correctly in 83 per cent, validated against clinical diagnosis.[51] The Mini-Mental State Examination does not reflect the FTD patient's true competence because of influence of motivational and behavioural factors.[52]

Differential diagnosis

Differential diagnosis between FTD and AD and other dementias is often possible based on a careful clinical history and examination, supported by diagnostic tests and brain imaging. Detailed neuropathology remains a gold standard for definite diagnosis of FTD and other disorders presenting with FTD-like clinic (Table 4.1.3.3).

The clinical differences between FTD and AD are often obvious at an early stage. The initial stages of FTD are dominated by emotional and personality changes, and progressive reduction of speech. Consequently severe dyspraxia, memory failure, and spatial disorientation develop comparatively late with the relative sparing of the temporoparietal occipital cortical areas. In contrast, early-onset AD is characterized by memory failure, dyspraxia, dysgnosia, and impaired sense of locality, whereas habitual personality traits, social competence, and insight are better preserved in agreement with the consistent pattern of cortical involvement.[6] A minority of AD cases, about 5 per cent, show a marked frontal-lobe involvement at an early stage and consequently also present a frontal-lobe clinical pattern in addition to the temporoparietal symptoms.

The Lund–Manchester consensus[2] is recommended as a guideline for clinical recognition and differential diagnosis of FTD.[53–55]

Table 4.1.3.3 Clinical diagnostic alternatives to FTD

Alzheimer's disease (AD) with frontal emphasis
Vascular dementia with frontal emphasis
Selective white-matter infarction
Binswanger's disease
Multiinfarct dementia with frontal emphasis
Strategic infarct dementia (striatal, thalamic)
Huntington's disease
Creutzfeldt–Jacob disease
General paresis

The NINCDS–ADRDA criteria for AD were originally formulated with the aim to differentiate between AD and vascular dementia. Varma *et al.*[56] found a high sensitivity for probable AD, but also a low specificity since 77 per cent of pathologically confirmed FTD cases fulfilled the NINCDS–ADRDA criteria for AD.

Vascular dementia with frontal emphasis may be caused by selective incomplete white-matter infarction, Binswanger's disease, and frontal and strategic thalamic infarctions. The frontal-lobe dysfunction caused by vascular lesions may closely mimic the course of FTD, when developing gradually without dramatic onset or fluctuations.

The clinical distinction between FTD and Huntington's disease may be difficult when personality changes and psychotic features dominate, and when neurological characteristics are less obvious or appear late in the course. Brain imaging showing striatal involvement and genetic analysis may contribute to the diagnosis.

PSP and the rare progressive subcortical gliosis may also show a frontal-lobe clinical and imaging pathology. CBD may also present with a dementia of frontal-lobe type in addition to the typical asymmetric akinetic-rigid dystonic syndrome.[20] These three diseases have grown increasingly important because of studies suggesting a linkage to chromosome 17.[19]

Dementia of the frontal and frontal subcortical type is also found in Creutzfeldt–Jakob disease, in the AIDS dementia complex, and in general paresis.

Classification dilemma

Classification of frontotemporal dementias must be viewed in a historical perspective. The various clinicopathological entities have been identified by presence of certain and absence of other clinical and pathological features. The current classification and terminology of FTD illustrates, however, the difficulties of most one-dimensional diagnostic systems. A classification on pure clinical grounds is unsatisfactory since symptoms depend more on the starting point in the brain or topography than type of changes, and also on the progression pattern of the disease among brain areas, factors which may vary between cases with structurally identical disorders. A diagnostic classification should be clinically useful and valid, flexible and open to new ideas. There is a need for combination of classifications such as one based on phenomenological syndrome kept apart from, and combined with, aetiological including genotypical classification. Hopefully new generations of classifications and new diagnostic techniques and treatment strategies will further increase the awareness of FTD in clinical practice and research.

DSM-IV[1] and ICD-10[57] do not introduce the concepts of frontal-lobe dementia or FTD. DSM-IV presents Pick's disease as 'One of the pathologically distinct aetiologies among the heterogeneous group of dementing processes that are associated with frontotemporal brain atrophy'. ICD-10 describes 'dementia in Pick's disease' as an early-onset non-Alzheimer degenerative brain disease.

Aetiology and pathogenesis

The FTD is a heterogeneous disease group, but with important clinical features and probably also aetiological factors in common. The clinical and pathological similarities between familial and sporadic cases are, however, striking. About 40–50 per cent of patients with FLD have a history of similar disorder in a first-degree relative.[23,31] A family history study on 478 first-degree relatives of 74 index patients suffering from FTD reported a 10-fold increase in the incidence of FTD compared with the incidence of FTD in a population study.[58] A Swedish pedigree with FTD in 10 out of 21 family members in three generations has been described.[59]

Several genetic loci for FTD have been identified at human chromosomes 3, 9, and 17 in familial forms of the disease. One FTDP-17 locus has been mapped to a region of chromosome 17 where the tau gene is located. So far 35 different mutations in around 100 families have been identified.[36] However, tau mutations seem to be a rare cause of FTD. Dementia of frontal-lobe type has also been linked to chromosome 3p11–12 in a Danish family.[16] Conflicting results exist concerning the relation of FTD-MND to a locus on chromosome 9[60] and to chromosome 19 and the ApoE-allele pattern.[61] There is no solid proof of an autosomal-dominant inheritance in the majority of studies with Pick disease.

Several research groups have recently found mutations in the progranulin (PGRN) gene close to the tau gene to result in a loss of function of the growth or maintenance factor PGRN. This leads to a shortage of PRGN and degenerative dementia of the FTD type, including autosomal-dominant FTLD-U linked to chromosome 17 as well as further tau-positive and tau-negative forms.[17,62] Further research has shown that this mechanism may operate also in other neurodegenerative brain disorders including CBD and MND. MND is often linked to FTD-U by a common ubiquitinated protein[17] and by a frequent concurrence. This protein TDP-43 forms inclusions in a wide variety of functional brain areas in close correspondence to the symptomatology in the FTD spectrum, the clinical expression of which depends on the individual anatomical starting point and spread of the degeneration. The identification of mutations in PGRN explains why multiple families linked to chromosome 17 lack tau mutations.[62]

The pattern of degeneration in FTD may be related to a selective vulnerability of different brain regions to factors such as oxidative stress, environmental toxins, neurotransmitter dysfunction, and certain mutations. A retrospective study of risk for sporadic FTD reported a significantly higher prevalence of head trauma and thyroid disease.[63] A prion aetiology has been excluded in FLD and also in FTDP-17.

Neurochemical post-mortem studies of FTD have indicated abnormalities in serotonin metabolism but no alterations in cholinergic markers have been found.[64,65]

Treatment and care

Early diagnosis is a prerequisite for adequate treatment and care of the patient and support for the family and other carers involved. It is essential to explain the nature of the patients' changed behaviour and current problems. It is important not to forget the children who may still be at school age. It is especially in the social interaction that the earliest signs of the brain disease emerge.[33] Alternative optimal placements must be arranged when the patient can no longer be taken care of at home because of disturbing

symptoms and lack of insight. Temporary and prolonged hospital admissions may be needed to make it possible for the family to cope with the situation. Being a spouse is both physically and emotionally exhausting, causing ill health and socio-economic problems for the family. FTD patients are often restless and stereotyped with a strong need for physical activity such as walking long distances, which, as well as the comparatively preserved memory, spatial and practical abilities should be channeled in a meaningful way rather than restricted. A well-structured programme for daily activities considering the patients premorbid personality and interests, 'routinizing therapy'[66] may be rewarding and minimize the need for pharmacological treatment. Prevailing psychotic features and unpredictable aggressive behaviour should be managed by a special psychiatric or psychogeriatric services[33] also responsible for support to the spouse and family members who often suffer from social isolation and loneliness.

There is presently no specific pharmacological treatment for the underlying degenerative disease in FTD but symptomatic treatment with serotonin-boosting antidepressants may be effective in treating some behavioural disturbances.[67] There are no reports that acetylcholinesterase inhibitors improve cognition or behaviour in FTD, and clinical experience is that the FTD patient may be extremely sensitive to psychotropic medication with disturbing side effects and paradoxical reactions. Various ways to improve progranulin levels may offer future pharmacological treatment for the FTD disorders.

4.1.4 Prion disease

John Collinge

Introduction

The human prion diseases, also known as the subacute spongiform encephalopathies, have been traditionally classified into Creutzfeldt–Jakob disease (**CJD**), Gerstmann–Sträussler syndrome (**GSS**) (also known as Gerstmann–Sträussler–Scheinker disease), and **kuru**. Although rare, affecting about 1–2 per million worldwide per annum, remarkable attention has been recently focused on these diseases. This is because of the unique biology of the transmissible agent or prion, and also because bovine spongiform encephalopathy (**BSE**), an epidemic bovine prion disease, appears to have transmitted to humans as variant CJD (**vCJD**), opening the possibility of a significant threat to public health through dietary exposure to infected tissues.

The transmissibility of the human diseases was demonstrated with the transmission, by intracerebral inoculation with brain homogenates into chimpanzees, of first kuru and then CJD in 1966 and 1968, respectively.[1,2] Transmission of GSS followed in 1981. The prototypic prion disease is **scrapie**, a naturally occurring disease of sheep and goats, which has been recognized in Europe for over 200 years and which is present in the sheep flocks of many countries. Scrapie was demonstrated to be transmissible by inoculation in 1936[3] and the recognition that kuru, and then CJD, resembled scrapie in its histopathological appearances led to the suggestion that these diseases may also be transmissible.[4] Kuru reached epidemic proportions amongst the Fore linguistic group in the Eastern Highlands of Papua New Guinea and was transmitted by ritual cannibalism. Since the cessation of cannibalism in the 1950s the disease has declined but a few cases still occur as a result of the long incubation periods in this condition, which may exceed 50 years.[5] The term Creutzfeldt–Jakob disease was introduced by Spielmeyer in 1922 bringing together the case reports published by Creutzfeldt and Jakob. Several of these cases would not meet modern diagnostic criteria for CJD and indeed it was not until the demonstration of transmissibility allowed diagnostic criteria to be reassessed and refined that a clear diagnostic entity developed. All these diseases share common histopathological features; the classical triad of spongiform vacuolation (affecting any part of the cerebral grey matter), astrocytic proliferation, and neuronal loss, may be accompanied by the deposition of amyloid plaques.

Aetiology

Prion diseases of both humans and animals are associated with the accumulation in the brain of an abnormal, partially protease-resistant, isoform of a host-encoded glycoprotein known as prion protein (PrP). The disease-related isoform, PrP^{Sc}, is derived from its normal cellular precursor, PrP^{C}, by a post-translational process that involves a conformational change. PrP^{C} is rich in α-helical structure while PrP^{Sc} appears to be predominantly composed of β-sheet structure. According to the 'protein-only' hypothesis,[6] an abnormal PrP isoform[7] is the principal, and possibly the sole, constituent of the transmissible agent or prion. PrP^{Sc} is hypothesized to act as a conformational template, promoting the conversion of PrP^{C} to further PrP^{Sc}. PrP^{C} appears to be poised between two radically different folding states, and α- and β-forms of PrP can be inter-converted in suitable conditions.[8] Soluble β-PrP aggregates in physiological salt concentrations to form fibrils with morphological and biochemical characteristics closely similar to PrP^{Sc}. A molecular mechanism for prion propagation can now be proposed.[8] Prion replication, with recruitment of PrP^{C} into the aggregated PrP^{Sc} isoform, may be initiated by a pathogenic mutation (resulting in a PrP^{C} predisposed to form β-PrP) in inherited prion diseases, by exposure to a 'seed' of PrP^{Sc} in acquired cases, or as a result of the spontaneous conversion of PrP^{C} to β-PrP (and subsequent formation of aggregated material) as a rare stochastic event in sporadic prion disease.

The human PrP gene (*PRNP*) is a single copy gene located on the short arm of chromosome 20 and was an obvious candidate for genetic linkage studies in the familial forms of CJD and GSS, which both showed an autosomal dominant pattern of disease segregation. A turning point in understanding the human prion diseases was the identification of mutations in the prion protein *gene* in familial CJD and GSS in 1989. The first mutation to be identified in *PRNP* was in a family with CJD and constituted a 144 bp insertion into the coding sequence.[9] A second mutation was reported in two families with GSS and genetic linkage was confirmed between this missense variant at codon 102 and GSS, confirming that GSS was an autosomal dominant Mendelian disorder.[10] Uniquely, these diseases are therefore both inherited and transmissible. Current evidence suggests that around 15 per cent of prion diseases are inherited and over 30 coding mutations in *PRNP* are now recognized.

With the exception of the rare iatrogenic CJD cases mentioned above, most prion disease occurs as sporadic CJD. While, by definition, there will not be a family history in sporadic cases, mutations are seen in occasional apparently sporadic cases, as with a late-onset disease the family history may not be apparent or non-paternity may occur. However, in the majority of sporadic CJD cases there is neither a coding mutation nor a history of iatrogenic exposure. Human prion diseases can therefore be subdivided into inherited, sporadic, and acquired forms. However, a common PrP polymorphism at residue 129, where either methionine or valine can be encoded, is a key determinant of genetic susceptibility to acquired and sporadic prion diseases, the large majority of which occur in homozygous individuals.[11,12] This protective effect of *PRNP* codon 129 heterozygosity is also seen in some of the inherited prion diseases.

The aetiology of sporadic CJD remains unclear. It has been speculated that these cases might arise from somatic mutation of *PRNP* or spontaneous conversion of PrP^{C} to PrP^{Sc} as a rare stochastic event. The alternative hypothesis, in which such cases arise as a result of exposure to an environmental source of either human or animal prions, is not supported by epidemiological evidence.[13]

A major problem for the 'protein-only' hypothesis of prion propagation has been how to explain the existence of multiple isolates or strains of prions, with distinct biological properties. Understanding how a protein-only infectious agent could encode such phenotypic information has been of considerable biological interest. However, it is now clear that prion strains can be distinguished by differences in the biochemical properties of PrP^{Sc}. Prion strain diversity appears to be encoded by differences in PrP conformation and pattern of glycosylation.[14] A molecular strain

typing approach based on these characteristics has allowed the identification of four main types amongst CJD cases, sporadic and iatrogenic CJD being of PrP^{Sc} types 1–3, while all vCJD cases are associated with a distinctive type 4 PrP^{Sc} type.[14,15] A similar PrP^{Sc} type to that seen in vCJD is seen in BSE and BSE when transmitted to several other species. Such molecular strain typing strongly supported the hypothesis that vCJD was human BSE. This conclusion was strengthened by subsequent transmission studies of vCJD into both transgenic and conventional mice which argued that cattle BSE and vCJD were caused by the same strain.[16,17] Such studies are allowing a molecular classification of human prion diseases. Two such classifications are in use: no internationally agreed classification has yet emerged and it is likely that additional PrP^{Sc} types or strains will be identified.[15,18] Molecular classification may well open new avenues of epidemiological investigation and offer insights into causes of 'sporadic' CJD. The ability of a protein to encode a disease phenotype has important implications in biology, as it represents a non-Mendelian form of transmission. It would be surprising if this mechanism had not been used more widely during evolution such that prion biology may prove to be of far wider relevance.

Transmission of prion diseases between different mammalian species is limited by a so-called 'species barrier'. Early studies of the molecular basis of the species barrier argued that it principally resided in differences in PrP primary structure between the species from which the inoculum was derived and the inoculated host. Transgenic mice expressing hamster PrP were, unlike wild-type mice, highly susceptible to infection with hamster prions.[19] That most sporadic and acquired CJD occurred in individuals homozygous at *PRNP* polymorphic codon 129 supported the view that prion propagation proceeded most efficiently when the interacting PrP^{Sc} and PrP^{C} were of identical primary structure.[12] However, it has been long recognized that prion strain type affects ease of transmission to another species. Interestingly, with BSE prions the strain component to the barrier seems to predominate, with BSE not only transmitting efficiently to a range of species, but maintaining its transmission characteristics even when passaged through an intermediate species with a distinct PrP gene.[20] The term 'species-strain barrier' or simply 'transmission barrier' may be preferable.[21] Both PrP amino acid sequence and strain type affect the 3D structure of glycosylated PrP which will presumably, in turn, affect the efficiency of the protein–protein interactions thought to determine prion propagation.

Mammalian PrP genes are highly conserved. Presumably only a restricted number of different PrP^{Sc} conformations (that are highly stable and can therefore be serially propagated) will be permissible thermodynamically and will constitute the range of prion strains seen in mammals. While a significant number of different such PrP^{Sc} conformations may be possible amongst the range of mammalian PrPs, only a subset of these would be allowable for a given single mammalian PrP. Substantial overlap between the favoured conformations for PrP^{Sc} derived from species A and species B might therefore result in relatively easy transmission of prion diseases between these two species, while two species with no preferred PrP^{Sc} conformations in common would have a large barrier to transmission (and indeed transmission would necessitate a change of strain type). According to such a *conformational selection model*[21] of a prion transmission barrier, BSE may represent a thermodynamically highly favoured PrP^{Sc} conformation that is permissive for PrP expressed in a wide range of different species, accounting for the remarkable promiscuity of this strain in mammals. Contribution of other components to the species barrier are possible and may involve interacting co-factors which mediate the efficiency of prion propagation, although no such factors have yet been identified.

Additional data has further challenged our understanding of transmission barriers.[22] The assessment of species barriers has relied on the development of a clinical disease in inoculated animals. However, it is now clear that *subclinical prion infections* are sometimes established on prion inoculation of a second species.[23] Such animals harbour high levels of prion infectivity but do not develop clinical disease during a normal lifespan. The existence of such subclinical carrier states of prion infection has important potential animal and public health implications and argues against direct neurotoxicity of prions.

The transmission barrier between cattle BSE and humans cannot be directly measured but can be modelled in transgenic mice expressing human PrP^{C}, which produce human PrP^{Sc} when challenged with human prions. Long-term transmission studies have been carried out using such 'humanized' mice to both to characterize the distinct prion strains causing human disease and to model human susceptibility to infection with BSE and other prions.[24] While these transgenic mouse models have been able to faithfully propagate human prion strains[14,16,25] and recapitulate the characteristic neuropathology of vCJD,[26] there are important caveats in extrapolating from such animal models to human susceptibility. However, these studies have found a much higher infection rate in transgenic mice expressing human PrP M129 than mice expressing human PrP V129 when challenged with either BSE or vCJD prions, and demonstrated that BSE prion infection can produce disease phenotypes resembling sporadic CJD infection of these mice and also novel prion strain phenotypes. Most recently, these studies have argued that the vCJD phenotype may only be expressed in the presence of the M form of human PrP.[27] While this would imply that only those humans expressing human PrP M129 may develop the vCJD phenotype, this does not mean that VV individuals are completely resistant to BSE prion infection—but rather that if infected they would show a different phenotype.[27] Modelling of susceptibility of the MV genotype suggests that several different phenotypes, all distinct from vCJD, may be possible when infected with BSE or vCJD prions.[28]

Clinical features and diagnosis

The human prion diseases can be divided aetiologically into inherited, sporadic, and acquired forms with CJD, GSS, and kuru now seen as clinicopathological syndromes within a wider spectrum of disease. Kindreds with inherited prion disease have been described with phenotypes of classical CJD, GSS, and also with other neurodegenerative syndromes including fatal familial insomnia. Some kindreds show remarkable phenotypic variability which can encompass both CJD- and GSS-like cases as well as other cases which do not conform to either CJD or GSS phenotypes and which indeed readily mimic, and are frequently misdiagnosed as, many other neurodegenerative conditions. Inherited prion diseases are a frequent cause of pre-senile dementia and a family history is not always apparent: *PRNP* should be analysed in all suspected cases of CJD, and considered in all early-onset dementia and ataxias. Cases diagnosed by *PRNP* analysis have been reported which are not only

clinically atypical but which lack the classical histological features entirely. Significant clinical overlap exists with familial Alzheimer's disease, Pick's disease, frontal lobe degeneration of non-Alzheimer type, and amyotrophic lateral sclerosis with dementia. Although classical GSS is described below it now seems more sensible to designate the familial illnesses as inherited prion diseases and then to subclassify these according to mutation. Acquired prion diseases include iatrogenic CJD, kuru, and now vCJD. Sporadic prion diseases at present consist of CJD and atypical variants of CJD. Cases lacking the characteristic histological features of CJD have been transmitted. As there are at present no equivalent aetiological diagnostic markers for sporadic prion diseases to those for the inherited diseases, it cannot yet be excluded that more diverse phenotypic variants of sporadic prion disease exist. The key clinical features and investigations for the diagnosis of prion disease are given in the Table 4.1.4.1.

Table 4.1.4.1 Diagnosis of prion disease

Sporadic (classical) CJD
- Rapidly progressive* dementia with two or more of myoclonus, cortical blindness, pyramidal signs, cerebellar signs, extrapyramidal signs, akinetic mutism
- Most cases age 45–75
- Serial EEG shows pseudoperiodic complexes in most cases
- CSF 14-3-3 protein usually positive
- CT normal or atrophy, MRI may show high signal in the striatum and/or cerebral cortex in FLAIR or diffusion-weighted images
- *PRNP* analysis: no pathogenic mutations, most are 129 MM (VV and MV may be longer duration, clinically atypical and EEG less often positive)
- Brain biopsy in highly selected cases (to exclude treatable alternative diagnoses): PrP immunocytochemistry or Western blot for PrP^{Sc} types 1–3

Iatrogenic CJD
- Progressive cerebellar syndrome and behavioural disturbance or classical CJD-like syndrome with history of iatrogenic exposure to human prions (pituitary-derived hormones, tissue grafting, or neurosurgery)
- May be young
- EEG, CSF, and MRI generally less helpful than in sporadic cases
- *PRNP* analysis: no pathogenic mutations, most are 129 homozygotes
- Brain biopsy in highly selected cases (to exclude treatable alternative diagnoses): PrP immunocytochemistry or Western blot for PrP^{Sc} types 1–3

Variant CJD
- Early features: depression, anxiety, social withdrawal, peripheral sensory symptoms
- Cerebellar ataxia, chorea, or athetosis often precedes dementia, advanced disease as sporadic CJD
- Most in young adults; however, age at onset 12–74 years seen
- EEG non-specific slow waves, CSF 14-3-3 may be elevated or normal
- MRI: pulvinar sign usually present (particularly using FLAIR sequence) but may be late feature
- *PRNP* analysis: no mutations, all 129 MM to date
- Tonsil biopsy: characteristic PrP immunostaining and PrP^{Sc} on Western blot (type 4τ)

Iatrogenic vCJD
- Has occurred in recipients of blood transfusion from a donor who subsequently developed clinical vCJD
- Known recipients of implicated blood or blood products in the UK have been notified of their risk status
- Clinical features and investigations as for primary vCJD

Inherited prion disease
- Varied clinical syndromes between and within kindreds: should consider in all pre-senile dementias and ataxias irrespective of family history
- *PRNP* analysis: diagnostic, codon 129 genotype may predict age at onset in pre-symptomatic testing

*Clinical duration typically 6 months or less but high variability: type 1 PrP^{Sc} associated with short duration (~8 weeks); ~10% have duration >2 years.

Sporadic prion disease

CJD

The core clinical syndrome of classic CJD is of a rapidly progressive multifocal dementia usually with myoclonus. The onset is usually in the 45–75-year age group with peak onset between 60 and 65 years. The clinical progression is typically over weeks progressing to akinetic mutism and death often in 2–3 months. Around 70 per cent of cases die in under 6 months. Prodromal features, present in around a third of cases, include fatigue, insomnia, depression, weight loss, headaches, general malaise, and ill-defined pain sensations. In addition to mental deterioration and myoclonus, frequent additional neurological features include extrapyramidal signs, cerebellar ataxia, pyramidal signs, and cortical blindness. About 10 per cent of cases present initially with cerebellar ataxia.

Routine haematological and biochemical investigations are normal although occasional cases have been noted to have raised serum transaminases or alkaline phosphatase. There are no immunological markers and acute phase proteins are not elevated. Examination of the cerebrospinal fluid is normal 14-3-3 protein is usually elevated in CJD and is a useful adjunct to diagnosis in the appropriate clinical context.[29] It is also positive in recent cerebral infarction or haemorrhage and in viral encephalitis, although these conditions do not usually present diagnostic confusion with CJD. It may also be elevated in rapidly progressive Alzheimer's disease, which may be difficult to clinically distinguish from CJD. Neuronal specific enolase (NSE) and S-100b may be also elevated although also are not specific for CJD and represent markers of neuronal injury[30,31] Neuroimaging with CT or MRI is crucial to exclude other causes of subacute neurological illness but MRI has become increasingly useful in diagnosis of sporadic CJD, showing high signal in the striatum and/or cerebral cortex in FLAIR or diffusion-weighted images.[32] Cerebral and cerebellar atrophy may be present in longer duration cases. The electroencephalogram (EEG) may show characteristic pseudoperiodic sharp wave activity, which is very helpful in diagnosis but present only in around 70 per cent of cases. To some extent demonstration of a typical EEG is dependent on the number of EEGs performed and serial EEG is indicated to try and demonstrate this appearance.

Prospective epidemiological studies have demonstrated that cases with a progressive dementia, and two or more of the following: myoclonus; cortical blindness; pyramidal, cerebellar, or extrapyramidal signs; or akinetic mutism in the setting of a typical EEG nearly always turn out to be confirmed as histologically definite CJD if neuropathological examination is performed.

Neuropathological confirmation of CJD is by demonstration of spongiform change, neuronal loss, and astrocytosis. PrP amyloid plaques are usually not present in CJD although PrP immunohistochemistry, using appropriate pre-treatments, will nearly always be positive. Protease resistant PrP, seen in all the currently recognized

prion diseases, can be demonstrated by immunoblotting of brain homogenates. *PRNP* analysis is important to exclude pathogenic mutations. Genetic susceptibility to CJD has been demonstrated in that most cases of classical CJD are homozygous with respect to the common 129 polymorphism of PrP (see aetiology).

Atypical forms of CJD

Atypical forms of CJD are well recognized. Around 10 per cent of cases of CJD have a much more prolonged clinical course with a disease duration of over 2 years. These cases may represent the occasional occurrence of CJD in individuals heterozygous for PrP polymorphisms. Around 10 per cent of CJD cases present with cerebellar ataxia rather than cognitive impairment, so-called ataxic CJD. Heidenhain's variant of CJD refers to cases in which cortical blindness predominates with severe involvement of the occipital lobes. The panencephalopathic type of CJD refers to cases with extensive degeneration of the cerebral white matter in addition to spongiform vacuolation of the grey matter and has been predominately reported from Japan.

Amyotrophic variants of CJD have been described with prominent early muscle wasting. However, most cases of dementia with amyotrophy are not experimentally transmissible and their relationship with CJD is unclear. Most cases are probably variants of motor neurone disease with associated dementia. Amyotrophic features in CJD are usually seen in late disease when other features are well established.

Acquired prion diseases

While human prion diseases can be transmitted to experimental animals by inoculation, they are not contagious in humans. Documented case to case spread has only occurred during ritual cannibalistic practices (kuru) or following accidental inoculation with prions during medical or surgical procedures (iatrogenic CJD).

Kuru

Kuru reached epidemic proportions amongst a defined population living in the Eastern Highlands of Papua New Guinea.[33] The earliest cases are thought to date back to the early part of the century. Kuru affected the people of the Fore linguistic group and their neighbours with whom they intermarried. Kuru predominantly affected women and children (of both sexes), with only 2 per cent of cases in adult males and was the commonest cause of death amongst women in affected villages. It was the practice in these communities to engage in consumption of dead relatives as a mark of respect and mourning. Women and children predominantly ate the brain and internal organs, which is thought to explain the differential age and sex incidence. Preparation of the cadaver for consumption was performed by the women and children such that other routes of exposure may also have been relevant. It is thought that the epidemic related to a single sporadic CJD case occurring in the region some decades earlier. Epidemiological studies provided no evidence for vertical transmission, since most of the children born after 1956 (when cannibalism had effectively ceased) and all of those born after 1959 of mothers affected with or incubating kuru were unaffected. From the age of the youngest affected patient, the shortest incubation period is estimated as 4.5 years, although may have been shorter, since time of infection was usually unknown. The disease has gradually declined in incidence although a small number of cases have been documented in recent years with incubation periods which may exceed 50 years.[5]

Kuru affects both sexes and onset of disease has ranged from age 5 to over 60. The mean clinical duration of illness is 12 months with a range of 3 months to 3 years; the course tends to be shorter in children. The central clinical feature is progressive cerebellar ataxia. In sharp contrast to CJD, dementia is usually absent, even in the latter stages, although in the terminal stages many patients have their faculties obtunded. The occasional case in which gross dementia occurs is in marked contrast to the clinical norm. Detailed clinical descriptions have been given by a number of observers and the disease does not appear to have changed in features at different stages of the epidemic. A prodrome and three clinical stages are recognized:

(a) Prodromal stage

Kuru typically begins with prodromal symptoms consisting of headache, aching of limbs, and joint pains, which can last for several months.

(b) Ambulatory stage

Kuru was frequently self-diagnosed by patients at the earliest onset of unsteadiness in standing or walking, or of dysarthria or diplopia. At this stage there may be no objective signs of disease. Gait ataxia however worsens and patients develop a broad-based gait, truncal instability, and titubation. A coarse postural tremor is usually present and accentuated by movement; patients characteristically hold their hands together in the midline to suppress this. Standing with feet together reveals clawing of toes to maintain posture. This marked clawing response is regarded as pathognomonic of kuru. Patients often become withdrawn at this stage and occasionally develop a severe reactive depression. Prodromal symptoms tend to disappear. Astasia and gait ataxia worsen and the patient requires a stick for walking. Intention tremor, dysmetria, hypotonia, and dysdiadochokinesis develop. Although eye movements are ataxic and jerky, nystagmus is rarely seen. Strabismus, usually convergent, may occur particularly in children. This strabismus does not appear to be concomitant or paralytic and may fluctuate in both extent and type sometimes disappearing later in the clinical course. Photophobia is common and there may be an abnormal cold sensitivity with shivering and piloerection even in a warm environment. Tendon reflexes are reduced or normal and plantar responses are flexor. Dysarthria usually occurs. As ataxia progresses the patient passes from the first (ambulatory) stage to the second (sedentary) stage. The mean clinical duration of the first stage is around 8 months and correlates closely with total duration.

(c) Sedentary stage

At this stage patients are able to sit unsupported but cannot walk. Attempted walking with support leads to a high steppage, wide-based gait with reeling instability, and flinging arm movements in an attempt to maintain posture. Hyperreflexia is seen although plantar responses usually remain flexor with intact abdominal reflexes. Clonus is characteristically short-lived. Athetoid and choreiform movements and Parkinsonian tremors may occur. There is no paralysis, although muscle power is reduced. Obesity is common at this stage but may be present in early disease associated with bulimia. Characteristically, there is emotional lability and bizarre uncontrollable laughter, which has led to the disease being

referred to as 'laughing death'. There is no sensory impairment. In sharp contrast to CJD, myoclonic jerking is rarely seen. EEG is usually normal or may show non-specific changes. This stage lasts around 2–3 months. When truncal ataxia reaches the point where the patient is unable to sit unsupported, the third or tertiary stage is reached.

(d) Tertiary stage

Hypotonia and hyporeflexia develop and the terminal state is marked by flaccid muscle weakness. Plantar responses remain flexor and abdominal reflexes intact. Progressive dysphagia occurs and patients become incontinent of urine and faeces. Inanition and emaciation develop. Transient conjugate eye signs and dementia may occur. Primitive reflexes develop in occasional cases. Brainstem involvement and both bulbar and pseudobulbar signs occur. Respiratory failure and bronchopneumonia eventually lead to death. The tertiary stage lasts 1–2 months.

Iatrogenic CJD

Iatrogenic transmission of CJD has occurred by accidental inoculation with human prions as a result of medical procedures. Such iatrogenic routes include the use of inadequately sterilized neurosurgical instruments, dura mater and corneal grafting, and use of human cadaveric pituitary-derived growth hormone or gonadotrophin. It is of considerable interest that cases arising from intracerebral or optic inoculation manifest clinically as classical CJD, with a rapidly progressive dementia, while those resulting from peripheral inoculation, most notably following pituitary-derived growth hormone exposure, typically present with a progressive cerebellar syndrome, and are in that respect somewhat reminiscent of kuru. Unsurprisingly the incubation period in intracerebral cases is short (19–46 months for dura mater grafts) as compared to peripheral cases (typically 15 years or more). There is evidence for genetic susceptibility to iatrogenic CJD with an excess of codon 129 homozygotes[11] (see aetiology).

Epidemiological studies have not shown increased risks of particular occupations that may be exposed to human or animal prions, although individual CJD cases in two histopathology technicians, a neuropathologist, and a neurosurgeon have been documented. While there have been concerns that CJD may be transmissible by blood transfusion, extensive epidemiological analysis in the UK has found that the frequency of blood transfusion and donation was no different in over 200 cases of CJD and a matched control population.[34] Recipients of blood transfusions who developed CJD had clinical presentations similar to those of sporadic CJD patients and not to the more kuru-like iatrogenic cases arising from peripheral exposure to human prions. Furthermore, experimental transmission studies have shown only weak evidence for infectivity in blood, even when inoculated via the most efficient (intracerebral) route. Iatrogenic (secondary) vCJD related to blood transfusion has however been recognized (see below).

Variant CJD

In late 1995, two cases of sporadic CJD were reported in the UK in teenagers.[35] Only four cases of sporadic CJD had previously been recorded in teenagers, and none of these cases occurred in the UK. In addition, both cases were unusual in having kuru-type plaques, a finding seen in only around 5 per cent of CJD cases. Soon afterwards a third very young sporadic CJD case occurred. These cases caused considerable concern and the possibility was raised that they might suggest a link with BSE. By March 1996, further extremely young onset cases were apparent and review of the histology of these cases showed a remarkably consistent and unique pattern. These cases were named 'new variant' CJD although it was clear that they were also rather atypical in their clinical presentation; in fact most cases did not meet the accepted clinical diagnostic criteria for probable CJD. Extensive studies of archival cases of CJD or other prion diseases failed to show this picture and it seemed that it did represent the arrival of a new form of prion disease in the UK. The statistical probability of such cases occurring by chance was vanishingly small and ascertainment bias seemed most unlikely as an explanation. It was clear that a new risk factor for CJD had emerged and appeared to be specific to the UK. The UK Government advisory committee on spongiform encephalopathy (SEAC) concluded that, while there was no direct evidence for a link with BSE, exposure to specified bovine offal (SBO) prior to the ban on its inclusion in human foodstuffs in 1989, was the most likely explanation. A case of vCJD was soon after reported in France. Direct experimental evidence that vCJD is caused by BSE was provided by molecular analysis of human prion strains and transmission studies in transgenic and wild-type mice (see aetiology). While it is now clear that vCJD is caused by infection with BSE prions, it is unclear why this particular age group should be affected and why none of these cases had a pattern of unusual occupational or dietary exposure to BSE. However, very little is known of which foodstuffs contained high-titre bovine offal. It is possible that certain foods containing particularly high titres were eaten predominately by younger people. An alternative is that young people are more susceptible to BSE following dietary exposure or that they have shorter incubation periods. A possible age-related co-factor could be coexistent infection involving lymphoid tissue, for example tonsillar infection. It is important to appreciate that BSE contaminated feed was fed to sheep, pigs, and poultry and that although there is no evidence of natural transmission to these species, it would be prudent to remain open minded about other dietary exposure to novel animal prions.

vCJD has an insidious clinical onset and its early features are highly non-specific. The clinical presentation is often with behavioural and psychiatric disturbances and in some cases with sensory disturbance. Initial referral has frequently been to a psychiatrist and the most prominent feature is depression but anxiety, social withdrawal, and behavioural change is frequent. Suicidal ideation is infrequent and response to antidepressants poor. Delusions, which are complex and unsustained, are common. Other features include emotional lability, aggression, insomnia, and auditory and visual hallucinations. A prominent early feature in some is dysaesthesiae or pain in the limbs or face or pain, which is persistent rather than intermittent and unrelated to anxiety levels. A minority of cases have been noted to have forgetfulness or mild gait ataxia from an early stage but in most cases overt neurological features are not apparent until some months into the clinical course. In most patients a progressive cerebellar syndrome develops with gait and limb ataxia. Overt dementia then occurs with inevitable progression to akinetic mutism. Myoclonus is seen in most patients, and chorea is often present which may be severe in some patients. Cortical blindness develops in a minority of patients in the late

stages of disease. Upgaze paresis, an uncommon feature of classical CJD, has been noted in some patients. The age at onset in the initial 14 cases reported ranged from 16 to 48 years (mean 29 years) and the clinical course was unusually prolonged (9–35 months, median 14 months). The age range of cases has since broadened, with ages at onset ranging from 12 to 74 years, although the mean remains around 28 years. The EEG is abnormal, most frequently showing generalized slow wave activity, but without the pseudoperiodic pattern seen in most sporadic CJD cases. Neuroimaging by CT is either normal or shows only mild atrophy. The most useful non-invasive investigation in advanced cases is MR neuroimaging, particularly the FLAIR sequence.[36] Early case reports noted bilateral increased signal in the posterior thalamus (pulvinar) on T2-weighted images.[37] A retrospective review of 36 histologically confirmed cases of vCJD suggested that the 'pulvinar sign' occurred frequently in advanced cases of vCJD[38] with a sensitivity and specificity of up to 86 and 96 per cent, respectively. However, this sign appears a late feature of the disease process. Histologically confirmed cases of vCJD with minimal or absent pulvinar changes at a mean 10.5 months during an illness of mean 15 months duration were identified in this series. Figures of 81 per cent sensitivity and 94 per cent specificity have also been reported in a series including 27 cases of vCJD diagnosed by tonsil biopsy.[39] As these studies suggest, the pulvinar sign is not specific for vCJD. These MRI appearances are described in sporadic CJD and paraneoplastic limbic encephalitis, both of which are important considerations in the differential diagnosis of patients with suspected vCJD. Pulvinar signal change on MRI is also reported in a number of rare conditions, which might otherwise be distinguished from vCJD on clinical grounds such as benign intracranial hypertension, status epilepticus associated with cat scratch disease, Alpers' disease, and post-infectious encephalitis. The absence of pulvinar sign does not exclude a diagnosis of vCJD.

Tonsillar biopsy remains the most sensitive and specific diagnostic procedure for vCJD.[39–43] Tonsillar PrP^{Sc} is uniformly present in clinically affected cases of vCJD but not in other forms of human prion disease, including iatrogenic CJD associated with use of human cadaveric-derived pituitary hormones, arguing that this distinctive pathogenesis relates to effect of prion strain rather than to a peripheral route of infection.[41–43] As infection of lymphoreticular tissues is thought to precede neuroinvasion, and indeed has been detected in archived surgical samples removed prior to development of vCJD,[44,45] it is likely to allow firm diagnosis at the early clinical stage or indeed pre-clinically.[46] The PrP^{Sc} type detected on Western blot in vCJD tonsil has a characteristic pattern designated type 4t. A positive tonsil biopsy obviates the need for brain biopsy, which may otherwise be considered in such a clinical context to exclude alternative, potentially treatable diagnoses. CSF 14-3-3 protein may be elevated or normal. *PRNP* analysis is essential to rule out pathogenic mutations, as the inherited prion diseases present in younger patients and may clinically mimic vCJD. It is particularly important to exclude mutations prior to tonsil biopsy. Remarkably, to date all clinical cases of vCJD have been of the *PRNP* codon 129 MM genotype (see aetiology).

The neuropathological appearances of vCJD are striking and relatively consistent, generally allowing differentiation from other forms of prion disease. While there is widespread spongiform change, gliosis and neuronal loss, most severe in the basal ganglia and thalamus, the most remarkable feature is abundant PrP amyloid plaques in cerebral and cerebellar cortex. These consist of kuru-like, 'florid' (surrounded by spongiform vacuoles) and multicentric plaque types. The 'florid' plaques, seen previously only in scrapie, are a consistent feature. There is also abundant pericellular PrP deposition in the cerebral and cerebellar cortex. A further unusual feature is extensive PrP deposition in the molecular layer of the cerebellum. Western blot analysis (molecular strain typing, see aetiology) of brain tissue demonstrates PrP^{Sc} type 4, which is pathognomonic of vCJD.

Some of the features of vCJD are reminiscent of kuru, in which behavioural changes and progressive ataxia predominate. In addition, peripheral sensory disturbances are well recognized in the kuru prodrome. Kuru plaques are seen in around 70 per cent of cases and are especially abundant in younger kuru cases. The observation that iatrogenic prion disease related to peripheral exposure to human prions has a more kuru-like than CJD-like clinical picture may well be relevant and would be consistent with a peripheral prion exposure.

The relatively stereotyped clinical presentation and neuropathology of vCJD contrasts sharply with sporadic CJD. This may be because vCJD is caused by a single prion strain and may also suggest that a relatively homogeneous genetically susceptible subgroup of the population with short incubation periods to BSE has been selected to date.

Secondary (iatrogenic) vCJD

The prominent lymphoreticular involvement raised early concerns that vCJD may be transmissible by blood transfusion. Indeed the tissue distribution is similar to that of ovine scrapie where prionaemia has been demonstrated experimentally. In 2004, two transfusion-associated cases of vCJD prion infection were reported amongst a small cohort of patients identified as having received blood from a donor who subsequently developed vCJD. One patient had a typical clinical course of vCJD although the diagnosis was not made until autopsy, and had the *PRNP* codon 129 MM genotype. The second, who died of an unrelated condition, was found to have prion infection at autopsy. This patient had the *PRNP* codon 129 MV genotype which is associated with relative resistance to prion disease. Subsequently two further patients have been diagnosed with vCJD during life from this group of 23 known surviving recipients of implicated blood. That 4/23 patients have been infected, three dying of vCJD, in each case following transfusion with a single unit of implicated red cells, suggests the risk to recipients of blood from a silently infected donor is very substantial. The incubation period in the clinical cases was 6–7 years. Since 2003, all known recipients of implicated blood have been notified of their status. Over 6000 individuals in the UK have been exposed to blood products prepared from large donor pools containing blood from a donor who went on to develop vCJD. None of these individuals, predominantly haemophiliacs, have yet developed vCJD.

Inherited prion diseases

Gerstmann–Sträussler–Scheinker disease

The first case was described by Gerstmann in 1928 and was followed by a more detailed report on seven other affected members of the same family in 1936. The classical presentation of GSS is with a chronic cerebellar ataxia accompanied by pyramidal features, with dementia occurring later in a much more prolonged clinical course than that seen in CJD. The mean duration is around 5 years, with

onset usually in either the third or fourth decades. Histologically, the hallmark is the presence of multicentric amyloid plaques. Spongiform change, neuronal loss, astrocytosis, and white matter loss are also usually present. Numerous GSS kindreds from several countries (including the original Austrian family described by Gerstmann, Sträussler, and Scheinker in 1936) have now been demonstrated to have mutations in the PrP gene. GSS is an autosomal dominant disorder which can now be classified within the spectrum of inherited prion disease.

Inherited prion diseases

The identification of one of the pathogenic PrP gene mutations in a case with neurodegenerative disease allows not only molecular diagnosis of an inherited prion disease but also its subclassification according to mutation (see Fig. 4.1.4.1). Over 30 pathogenic mutations are reported in the human PrP gene and consist of two groups: (1) point mutations within the coding sequence resulting in amino acid substitutions in PrP or production of a stop codon resulting in expression of a truncated PrP; (2) insertions encoding additional integral copies of an octapeptide repeat present in a tandem array of five copies in the normal protein (octapeptide repeat insertion [OPRI]). A suggested notation for these diseases is 'Inherited prion disease (PrP mutation)', for instance: Inherited prion disease (PrP 6 OPRI) or Inherited prion disease (PrP P102L). Brief details of the more commonly seen types are given below, for a more comprehensive review see Ref.[47] *PRNP* analysis should be considered in all early-onset dementing or ataxic disorders and is available from the UK National Prion Clinic (see websites).

(a) PrP P102L

This mutation was first reported in 1989 in a UK and US family and has now been demonstrated in many other kindreds worldwide. Progressive ataxia is the dominant clinical feature, with dementia and pyramidal features. However, marked variability both at the clinical and neuropathological level is apparent in some families. A family with marked amyotrophic features has also been reported and cases with severe dementia in the absence of prominent ataxia are also recognized.

(b) PrP A117V

This mutation has been described in families from France, United States, and UK. The clinical features are pre-senile dementia associated with pyramidal signs, parkinsonism, pseudobulbar features, and cerebellar signs. Parkinsonian features may predominate in the early stages and mimic Parkinson's disease.

(c) PrP D178N

This mutation was originally described in two Finnish families with a CJD-like phenotype and has since been demonstrated in families in Hungary, the Netherlands, Canada, Finland, France, and the UK. This mutation was also reported in two unrelated families with fatal familial insomnia (FFI).[48] The first case described had a rapidly progressive disease characterized clinically by untreatable insomnia, dysautonomia and motor signs, and neuropathologically by selective atrophy of the anterior-ventral and medio-dorsal thalamic nuclei. Proteinase K treatment of extracted PrP^{Sc} from FFI cases has shown a different sized PrP band on Western blots than PrP^{Sc} from CJD cases suggesting that FFI may be caused by a distinct prion strain type. Goldfarb *et al.*[49] reported that in all the codon 178 families they studied with a CJD-like disease the codon 178 mutation was encoded on a valine 129 allele while all FFI kindreds encode the same codon 178 mutation on a methionine 129 allele. They suggested that the genotype at codon 129 determines phenotype. Insomnia is not uncommon in CJD patients and FFI and CJD may represent extremes of a spectrum of related disease phenotypes. An inherited case with the E200K

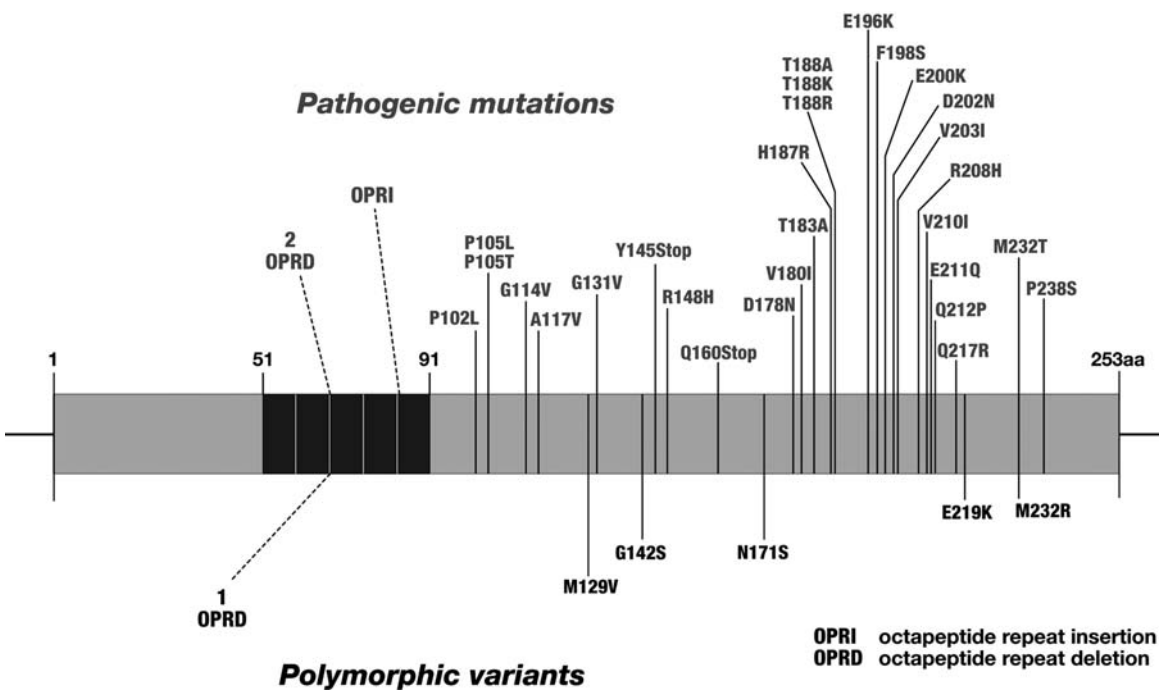

Fig. 4.1.4.1 Pathogenic mutations (above) and polymorphic variants of the human prion protein gene.

mutation, which is normally associated with a CJD-like phenotype, has been reported with an FFI phenotype. An Australian family has also been reported with the FFI genotype but in which affected family members have a range of phenotypes encompassing typical CJD, FFI, and an autosomal dominant cerebellar ataxia-like illness.

(d) PrP E200K

This mutation was first described in families with CJD. Affected individuals develop a rapidly progressive dementia with myoclonus and pyramidal, cerebellar or extrapyramidal signs, and a duration of illness usually less than 12 months. In marked contrast to other variants of inherited prion disease, the EEG usually shows the characteristic pseudoperiodic sharp wave activity seen in sporadic CJD. Interestingly, this mutation accounts for the three reported ethnogeographic clusters of CJD where the local incidence of CJD is around 100-fold higher than elsewhere (amongst Libyan Jews and in regions of Slovakia and Chile).[50,51] Now that cases can be diagnosed by PrP gene analysis, atypical forms of this condition are being detected with phenotypes other than that of classical CJD. Of interest also are reports that peripheral neuropathy can occur in this disease. Elderly unaffected carriers of the mutation have been reported. Patients with this condition have now been reported in several other countries outside the well-recognized clusters, including the UK. At least one of the UK cases does not appear to related to the ethnogeographic clusters mentioned above suggesting a separate UK focus for this type of inherited prion disease.

(e) PrP 6 OPRI

This was the first PrP mutation to be reported and was found in a small UK family with familial CJD[9] now known to form part of a the largest known kindred with an inherited prion disease caused by an OPRI mutation. The diagnosis in the family had been based on an individual who died in the 1940s with a rapidly progressive illness characteristic of CJD. The reported duration of illness was 6 months. Pathologically there was gross status spongiosis and astrocytosis affecting the entire cerebral cortex, and this case is used to illustrate classic CJD histology in Greenfield's *Neuropathology*. However, other family members had a much longer duration GSS-like illness. Histological features were also extremely variable. This observation led to screening of various case of neurodegenerative disease and to the identification of a case classified on clinical grounds as familial Alzheimer's disease.[52] More extensive screening work identified further families with the same mutation which were then demonstrated by genealogical studies to form part of an extremely large kindred.[53–55] Clinical information has been collected on over 80 affected individuals over seven generations. Affected individuals develop in the third to fourth decade onset of a progressive dementia associated with a varying combination of cerebellar ataxia and dysarthria, pyramidal signs, myoclonus and occasionally extrapyramidal signs, chorea and seizures. The dementia is often preceded by depression and aggressive behaviour. A number of cases have a long-standing personality disorder, characterized by aggression, irritability, antisocial and criminal activity, and hypersexuality, which may be present from early childhood, long before overt neurodegenerative disease develops. The histological features vary from those of classical spongiform encephalopathy (with or without PrP amyloid plaques) to cases lacking any specific features of these conditions.[56] Age at onset in this condition can be predicted according to genotype at polymorphic codon 129. Since this pathogenic insertional mutation occurs on a methionine 129 PrP allele, there are two possible codon 129 genotypes for affected individuals, methionine 129 homozygotes or methionine 129/valine 129 heterozygotes. Heterozygotes have an age at onset which is about a decade later than homozygotes.[53]

Pre-symptomatic and antenatal testing

Direct gene testing allows unequivocal diagnosis in patients with inherited forms of the disease and pre-symptomatic testing of unaffected but at-risk family members, as well as antenatal testing.[57] Because of the effect of *PRNP* codon 129 genotype on the age of onset of disease associated with some mutations it is possible to determine within a family whether a carrier of a mutation will have an early or late onset of disease. Most of the mutations appear to be fully penetrant, however experience with some is extremely limited. In some families, for example with E200K or D178N (fatal familial insomnia), there are examples of elderly unaffected gene carriers who appear to have escaped the disease. Genetic counselling is essential prior to pre-symptomatic testing and follows a protocol similar to that established for Huntington's disease. A positive PrP gene analysis has important consequences for other family members, and it is preferable to have discussed these issues with others in the immediate family before testing. Following the identification of a mutation the wider family should be referred for genetic counselling. It is vital to counsel both those testing positive for mutations and those untested but at-risk that they should not be blood or organ donors and should inform surgeons, including dentists, of their risk status prior to significant procedures as precautions may be necessary to minimize risk of iatrogenic transmission.

Prevention

While prion diseases can be transmitted to experimental animals by inoculation, it is important to appreciate that they are not contagious in humans. Documented case-to-case spread has only occurred by cannibalism (kuru) or following accidental inoculation with prions. Such iatrogenic routes include the use of inadequately sterilized intracerebral electrodes, dura mater, and corneal grafting, and from the use of human cadaveric pituitary-derived growth hormone or gonadotrophin. As discussed above, there is now evidence that vCJD prion infection is transmissible by blood transfusion. UK policy for some time has been to leucodeplete all whole blood and to source plasma for plasma products from outside the UK. A further possible route of transmission of vCJD is via contaminated surgical and medical instruments. Prions resist conventional sterilization methods and neurosurgical instruments are known to be able to act as a vector for prion transmission: several cases of iatrogenic transmission of sporadic CJD prions via neurosurgical instruments are documented.[58,59] Recent evidence suggests that classical CJD may also be transmitted by other surgical procedures.[60] The wider tissue distribution of prions in vCJD[42] together with the potential that significant numbers in the population may be silently infected has considerably increased these concerns.

Certain occupational groups are at risk of exposure to human prions, for instance neurosurgeons and other operating theatre staff, pathologists and morticians, histology technicians, as well as

an increasing number of laboratory workers. Because of the prolonged incubation periods to prions following administration to sites other than the central nervous system (CNS), which is associated with clinically silent prion replication in the lymphoreticular tissue, treatments inhibiting prion replication in lymphoid organs may represent a viable strategy for rational secondary prophylaxis after accidental exposure. A preliminary suggested regimen is a short course of immunosuppression with oral corticosteroids in individuals with significant accidental exposure to human prions.[61]

Prognosis and treatment

All recognized prion diseases are invariably fatal following a progressive course.

The duration of illness in sporadic patients is very short with a mean duration of 3–4 months. However, in some of the inherited cases the duration can be 20 years or more. However, there have been significant recent advances in understanding prion propagation and neurotoxicity and clear proof of principle studies of several therapeutic or secondary prophylactic approaches in animal models suggesting effective therapeutics for human disease is realistic.[62]

A variety of drugs have been tried in individual or small numbers of patients over many years. There is no clear evidence of efficacy of any agent, and controlled clinical trials are needed. Such trials are highly challenging. Prion diseases are rare, often rapidly progressive and always fatal which may make randomization to placebo unacceptable. Patterns of disease overall extremely variable with clinical durations varying from weeks to more than 2 years in sporadic CJD, and more than 20 years in some inherited prion diseases. As 'first generation' treatments proposed for prion disease are likely, at best, to have only a modest effect on disease progression, even using survival duration as an outcome measure requires study of large numbers to reliably assess efficacy. There is a lack of systematic natural history studies of disease progression and an absence of biological markers of disease activity. In the United Kingdom, at the request of the Government's Chief Medical Officer, a clinical trial protocol (http://www.controlled-trials.com/ISRCTN06722585/prion1) and infrastructure has been developed to rigorously assess the drug quinacrine[63] and to provide a framework for assessment of novel therapeutics as these become available: the MRC PRION-1 trial. Importantly under these circumstances, a formal consultation with patient's representatives was organized to refine the protocol so that it would be acceptable to the majority of potential participants http://www.mrc.ac.uk/prn/pdf-cjd_workshop.pdf). Pentosan polyphosphate is another candidate anti-prion drug and has shown some efficacy in animal models. Unlike quinacrine, it does not enter the CNS readily and has been administered by intraventricular infusion in several patients. Major toxicity has been reported by this route in animal studies and such treatment was not supported by the UK's Committee of Safety on Medicines or CJD Therapy Advisory Group. A report summarizing clinical experience to date with this treatment has been produced (http://www.mrc.ac.uk/Utilities/Documentrecord/index.htm?d=MRC003453).

While the precise molecular events in prion propagation are not clear, it is clear that PrP^C is the essential substrate. Interference with PrP^C expression in adult brain is without serious effect and blocks onset of neurological disease in animal models.[61] It should be possible to identify small molecules, which penetrate the CNS to bind to PrP^C and to prevent its recruitment into prions, or to use one of a number of emerging technologies to reduce PrP^C expression in brain. If such methods are able to reduce prion propagation rates to below those of natural clearance mechanisms it ought to be possible to cure prion infection. New methods for early diagnosis—and their timely use—will be crucial, as such methods will not reverse neuronal cell loss which is appreciable or severe by the time clinical diagnosis is typically reached. Proof of principle studies in animal models suggest that humanized anti-PrP monoclonal antibodies could be used for passive immunization in the early pathogenesis to block neuroinvasion. This treatment could be considered for known iatrogenically infected individuals.[64]

4.1.5 Dementia with Lewy bodies

I. G. McKeith

Introduction

Lewy bodies are spherical neuronal inclusions, first described by the German neuropathologist Friederich Lewy while working in Alzheimer's laboratory in Munich in 1912. In 1961, Okazaki published case reports about two elderly men who presented with dementia and died shortly after with severe extrapyramidal rigidity. Autopsy showed Lewy bodies in their cerebral cortex.[1] Over the next 20 years, 34 similar cases were reported, all by Japanese workers. Lewy body disease was thus considered to be a rare cause of dementia, until a series of studies in Europe and North America, in the late 1980s, identified Lewy bodies in the brains of between 15 and 20 per cent of elderly demented cases reaching autopsy.[2,3] Dementia with Lewy bodies (DLB) is unlikely to be a newly occurring disorder, since re-examination of autopsy material collected from elderly demented patients in Newcastle during the 1960s, reveals cortical Lewy bodies in 17 per cent of cases. The recent recognition of DLB as the second most common form of degenerative dementia in old age is largely due to the widespread use of improved neuropathological techniques, initially antiubiquitin immunocytochemistry, and more recently specific staining for alpha-synuclein which is a core constituent of Lewy bodies and related lesions.

The spectrum of Lewy body disease

The presence of Lewy bodies probably indicates neuronal dysfunction which is usually indicative of neurological disease. The clinical presentation varies according to the site of Lewy body formation and associated neuronal loss. Three main clinicopathological syndromes have been described.

- Parkinson's disease, an extrapyramidal movement disorder—associated with degeneration of subcortical neurones, particularly in substantia nigra.
- Dementia with Lewy bodies, a dementing disorder with prominent neuropsychiatric features—associated with degeneration of cortical neurones, particularly in frontal, anterior cingulate, insular, and temporal regions.
- Autonomic failure with syncope and orthostatic hypotension—associated with degeneration of sympathetic neurones in spinal cord.

In clinical practice, elderly patients often have heterogenous combinations of parkinsonism, dementia, and autonomic failure, reflecting pathological involvement at multiple locations.

Clinical features

Dementia is usually, but not always, the presenting feature of DLB. A minority of patients present with parkinsonism alone, some with psychiatric disorder in the absence of dementia, and others with orthostatic hypotension, falls, or transient disturbances of consciousness. Episodes of confusion, progressive cognitive decline, and dementia follow in due course. Fluctuation in cognitive performance and functional abilities, which is based in variations in attention and level of consciousness, is the most characteristic feature of DLB and the one which causes greatest diagnostic difficulties. It is usually evident on a day-to-day basis, and often apparent within much shorter periods. The marked amplitude between best and worst performance distinguishes it from the minor day-to-day variations that commonly occur in dementia of any aetiology. Transient disturbances of consciousness, in which patients are found mute and unresponsive for periods of several minutes, may represent the extreme of fluctuation in attention and arousal and are often mistaken for transient ischaemic attacks despite a lack of focal neurological signs. Repeated visual hallucinations are present in about two-thirds of patients. They take the form of vivid, colourful, and sometimes fragmented figures of people and animals, which are usually described in great detail. Emotional responses vary from intense fear to indifference or even amusement. Although patients may respond to their hallucinations, for example, trying to feed an imaginary dog, they later often have good insight into their unreality. Others develop elaborate systematized delusions, usually persecutory or of a phantom boarder. Auditory hallucinations are much less frequent, and only a minority of patients have olfactory or tactile experiences. Depressive symptoms are common and about 40 per cent of patients will have a major depressive episode, similar to the rate in Parkinson's disease and significantly greater than in Alzheimer's disease (AD). The frequency and severity of spontaneous motor features of parkinsonism varies from one clinical setting to another due to referral biases. Postural instability and gait difficulty are the most common manifestations, tremor dominant symptoms occurring in only 20 per cent or less.[4] Less than half of DLB cases have parkinsonism at presentation and a quarter continue to have no evidence at any point in their illness. Clinicians must therefore be prepared to make the diagnosis of DLB in the absence of extrapyramidal motor features. If they do not, their case detection rates will be unacceptably low. Severe neuroleptic sensitivity reactions can precipitate irreversible parkinsonism, further impair consciousness level, and induce autonomic disturbances reminiscent of neuroleptic malignant syndrome. They occur in 40 to 50 per cent of neuroleptic-treated DLB cases and are associated with a two- to threefold

increased mortality.[5] Acute D_2 receptor blockade is thought to mediate these effects; and, despite initial reports, atypical antipsychotics seem to be as likely to cause neuroleptic sensitivity reactions as older drugs.[6] Sleep disorders have more recently been recognized as common in DLB with daytime somnolence and rapid eye movement sleep behaviour disorder as prodromal features.[7] Recurrent falls and syncope occur in up to a third of DLB cases, reflecting autonomic nervous system involvement which may also be evident as early urinary incontinence, constipation, and sexual dysfunction.

Pathological classification

Lewy bodies are composed of intermediate neurofilament proteins, which are abnormally truncated and phosphorylated. Their presence indicates that a neurone is attempting to eliminate damaged proteins from its cytoplasm, a process which is usually followed by cell death. Ubiquitin, α-synuclein, α- and β-crystalin, and associated enzymes are the main chemical constituents. Subcortical Lewy bodies have a dense hyaline core surrounded by a halo of radiating filaments, and are easily seen with conventional histopathological techniques. Cortical Lewy bodies are more easily visualized using antiubiquitin staining but this lacks specificity and immunohistochemical staining for alpha-synuclein, is now the most sensitive and specific method currently available for detecting Lewy bodies and Lewy-related pathology. Current thinking is that Lewy bodies form within neurones as a cytoprotective response in an attempt to sequester toxic alpha-synuclein oligomers. Widely distributed aggregates of alpha-synuclein (Lewy neurites) probably represent an earlier stage in the neurodegenerative process than Lewy body formation itself. Lewy neurites are seen in the substantia nigra, hippocampal region CA2/3, dorsal vagal nucleus, basal nucleus of Meynert, and transentorhinal cortex. Ubiquitin immunocytochemistry and α-synuclein-specific monoclonal antibody stains are beginning to reveal the extensive nature of these neuritic changes, which are probably more relevant for symptom formation than the relatively sparsely distributed Lewy bodies. The presence of Lewy neurites in presynaptic terminals is thought to have a particularly severe impact on synaptic function.[8]

Recommendations have been made[9] about which brain regions to examine for the presence of Lewy bodies and Lewy neurites and a simple semi-quantitative scoring system devised. These scores are added to generate three pathological categories:

1 Brainstem-predominant DLB: predilection sites are substantia nigra, locus coeruleus, and dorsal nucleus of vagus.

2 Limbic (or transitional) DLB: predilection sites are anterior cingulate and transtentorhinal cortex.

3 Neocortical DLB: predilection sites are frontal, temporal, and parietal cortex.

Of DLB cases presenting via psychiatric clinics, 69 per cent have extensive neocortical Lewy body pathology,[10] but this is not essential for the development of dementia or other psychiatric symptoms, both of which may occur in the presence of disease limited to limbic structures (24 per cent of cases) or the brainstem (7 per cent).

Interpretation of the significance of coexistent Alzheimer-type pathology is a major issue in the pathological assessment of DLB cases. High senile plaque counts are found in 80 to 90 per cent of DLB cases, diffuse and neuritic β-amyloid plaques occurring in similar proportions as in pure AD. Significant tau pathology is absent, however, in 80 to 90 per cent whether measured biochemically or by counting neocortical neurofibrillary tangles. Most DLB cases are therefore classified as 'the Lewy body variant of AD'[2] if AD is defined by increased plaque density. Conversely, if AD is defined by frequent neocortical neurofibrillary tangles, equivalent to Braak stages 5 and 6, then 85 to 90 per cent of DLB cases will not fulfil such criteria.[11] (The pathological classification of AD is also discussed in Chapter 4.1.2.) The most recent revision of pathological diagnostic criteria for DLB suggests that both Lewy and Alzheimer pathologies should be fully reported. A probability matrix (see Table 4.1.5.1) is then used to predict the likelihood of the patient having presented with a DLB clinical syndrome, this being directly related to the severity of Lewy-related pathology, and inversely related to the severity of concurrent AD-type pathology.[9] Minor vascular pathology is additionally present in 30 per cent of DLB cases[10] and this is also likely to impact upon the clinical manifestations.

Table 4.1.5.1 Pathological criteria for DLB taking into account the relative contributions of Lewy body and Alzheimer type pathology as predictors of a probable DLB clinical presentation–high, intermediate, or low probability.

		Alzheimer type pathology		
		NIA–Reagan Low (Braak stage 0-II)	**NIA–Reagan Intermediate (Braak stage III-IV)**	**NIA–Reagan High (Braak stage V-VI)**
Lewy Body type pathology	**Brainstem-predominant**	Low	Low	Low
	Limbic (transitional)	High	Intermediate	Low
	Diffuse neocortical	High	High	Intermediate

The relationship between DLB and Parkinson's disease dementia

There has been extended debate about the classification of patients who present with motor symptoms of Parkinson's disease and later develop the typical features of DLB, sometimes after many years of severe motor disability. This is a common outcome reported in up to 78 per cent of PD patients followed over an 8-year period. No major differences between DLB and Parkinson's disease dementia have been found in any variable examined including cognitive profile, neuropsychiatric features, sleep disorders, autonomic dysfunction, type and severity of parkinsonism, neuroleptic sensitivity, and responsiveness to cholinesterase inhibitors. It has been suggested that DLB should be diagnosed when dementia occurs before or concurrently with parkinsonism and Parkinson's disease dementia should be used to describe dementia that occurs in the context of well-established Parkinson's disease.[9,12] This distinction between DLB and Parkinson's disease dementia has two distinct clinical phenotypes, based solely on the temporal sequence of appearance of symptoms that has been criticized by those who regard the different clinical presentations as simply representing

different points on a common spectrum of LB disease, itself underpinned by abnormalities in alpha-synuclein metabolism.

The neurobiological basis of dementia in Parkinson's disease is discussed in detail in Chapter 4.1.6.

Clinical diagnosis of DLB

Patients with DLB may present to psychiatric services (cognitive impairment, psychosis, or behavioural disturbance), internal medicine (acute confusional states or syncope), or neurology (movement disorder or disturbed consciousness). The details of clinical assessment and differential diagnoses will, to a large extent, be shaped by these symptom and specialty biases. In all cases, a detailed history from the patient and reliable informants should document the time of onset of relevant key symptoms, the nature of their progression, and their effects on social, occupational, and personal function.

The recent consensus criteria for the clinical diagnosis of DLB are shown in Table 4.1.5.2. Particular emphasis needs to be given to recognizing the characteristic dementia syndrome. Attentional deficits and prominent frontosubcortical and visuo-perceptual dysfunction are the main features—symptoms of persistent or prominent memory impairment are not always present early in the course of illness, although they are likely to develop in most patients with disease progression. Patients with DLB perform better than Alzheimer's disease on tests of verbal recall, but relatively worse on tests of copying and drawing. With the progression of dementia, the selective pattern of cognitive deficits may be lost, making differential diagnosis based on clinical examination difficult during the later stages.

It is the evaluation of fluctuation which causes greatest difficulty in clinical practice.[13] Questions such as, 'are there episodes when his/her thinking seems quite clear and then becomes muddled?' were previously suggested as useful probes, but two recent studies found 75 per cent of both AD and DLB carers to respond positively.[14,15] More detailed questioning and qualitative analysis of carers' replies is therefore needed. The Clinician Assessment of Fluctuation Scale[16] requires an experienced clinician to judge the severity and frequency of 'fluctuating confusion' or 'impaired consciousness' over the previous month. The semi-structured One Day Fluctuation Assessment Scale[16] can be administered by less experienced raters and generates a cut-off score to distinguish DLB from AD or VaD. The Mayo Fluctuations Composite Scale[15] requires three or more 'yes' responses from caregivers to structured questions about the presence of daytime drowsiness and lethargy, daytime sleep >2 h, staring into space for long periods or episodes of disorganized speech, as suggestive of DLB rather than AD. Recording variations in attentional performance using a computer-based test system offers an independent method of measuring fluctuation, which is also sensitive to drug treatment effects.[17] The assessment of extrapyramidal motor features may be complicated by the presence of cognitive impairment. A simple, five-item subscale of the Unified PD Rating Scale[18] contains only those items that can reliably be assessed in DLB independent of severity of dementia (tremor at rest, action tremor, body bradykinesia, facial expression, rigidity). Standardized methods of assessing visual hallucinations and other visual pathologies in DLB are under development.[19]

(a) Consensus criteria for DLB

Probable DLB can be diagnosed (Table 4.1.5.2) if any two of the three core features (fluctuation, visual hallucinations, spontaneous

Table 4.1.5.2 Consensus criteria for the clinical diagnosis of probable and possible dementia with Lewy bodies (DLB) (Reproduced from McKeith I., Dickson, D., Emre, M., *et al.* Dementia with Lewy bodies, 3rd report of the dementia consortium, *Neurology*, **65**, 1863–72, copyright 2005, AAN Enterprises, Inc.)

1	**Central feature** (*essential for a diagnosis of possible or probable DLB*) Dementia defined as progressive cognitive decline of sufficient magnitude to interfere with normal social or occupational function. Prominent or persistent memory impairment may not necessarily occur in the early stages but is usually evident with progression. Deficits on tests of attention, executive function and visuo-spatial ability may be especially prominent.
2	**Core features** (*two core features are sufficient for a diagnosis of probable DLB, one for possible DLB*) Fluctuating cognition with pronounced variations in attention and alertness Recurrent visual hallucinations that are typically well formed and detailed Spontaneous features of parkinsonism
3	**Suggestive features** (*if one or more of these is present in the presence of one or more core features, a diagnosis of probable DLB can be made. In the absence of any core features, one or more suggestive features is sufficient for possible DLB. Probable DLB should not be diagnosed on the basis of suggestive features alone*) REM sleep behaviour disorder Severe neuroleptic sensitivity Low dopamine transporter uptake in basal ganglia demonstrated by SPECT or PET imaging
4	**Supportive features** (*commonly present but not proven to have diagnostic specificity*) Repeated falls and syncope Transient, unexplained loss of consciousness Severe autonomic dysfunction e.g. orthostatic hypotension, urinary incontinence Hallucinations in other modalities Systematized delusions Depression Relative preservation of medial temporal lobe structures on CT/MRI scan Generalised low uptake on SPECT/PET perfusion scan with reduced occipital activity Abnormal (low uptake) MIBG myocardial scintigraphy Prominent slow wave activity on EEG with temporal lobe transient sharp waves
5	**A diagnosis of DLB is less likely** In the presence of cerebrovascular disease evident as focal neurological signs or on brain imaging In the presence of any other physical illness or brain disorder sufficient to account in part or in total for the clinical picture If parkinsonism only appears for the first time at a stage of severe dementia
6	**Temporal sequence of symptoms** DLB should be diagnosed when dementia occurs before or concurrently with parkinsonism (if it is present). The term Parkinson's disease dementia (PDD) should be used to describe dementia that occurs in the context of well-established Parkinson's disease. In a practice setting the term that is most appropriate to the clinical situation should be used and generic terms such as LB disease are often helpful. In research studies in which distinction needs to be made between DLB and PDD, the existing one-year rule between the onset of dementia and parkinsonism DLB continues to be recommended. Adoption of other time periods will simply confound data pooling or comparison between studies. In other research settings that may include clinico-pathologic studies and clinical trials, both clinical phenotypes may be considered collectively under categories such as LB disease or alpha-synucleinopathy.

motor features of parkinsonism) are present. Probable DLB can also be diagnosed if one core feature is accompanied by one or more suggestive features (REM sleep behaviour disorder, severe neuroleptic sensitivity, low dopamine transporter uptake in basal ganglia demonstrated by SPECT or PET imaging). Possible DLB can be diagnosed if there is one core feature alone or one or more suggestive features in the absence of any core features. Suggestive features are not in the light of current knowledge considered sufficient, even in combination, to warrant a diagnosis of probable DLB in the absence of any core feature.

Differential diagnosis

There are four main categories of disorder that should be considered in the differential diagnosis of DLB (Table 4.1.5.3).

(a) Other causes of dementia

Of autopsy-confirmed DLB cases, 65 per cent meet the NINCDS-ADRDA clinical criteria for probable or possible AD,[20] and this is the most frequent clinical misdiagnosis of DLB patients presenting with a primary dementia syndrome. This suggests DLB should routinely be excluded when making the diagnosis of AD. Up to one-third of DLB cases are additionally misclassified as vascular dementia by virtue of items such as the fluctuating nature and course of illness. Pyramidal and focal neurological signs are, however, usually absent. The development of myoclonus in patients with a rapidly progressive form of DLB may lead the clinician to suspect Creutzfeldt–Jakob disease.

(b) Other causes of delirium

In patients with intermittent delirium, appropriate examination and laboratory tests should be performed during the acute phase to maximize the chances of detecting infective, metabolic, inflammatory, or other aetiological factors. Pharmacological causes are particularly common in elderly patients. Although the presence of any of these features makes a diagnosis of DLB less likely, comorbidity is not unusual in elderly patients and the diagnosis should not be excluded simply on this basis.

Table 4.1.5.3 Conditions to be considered in the differential diagnosis of dementia with Lewy bodies

Other causes of dementia
Alzheimer's disease
Vascular dementia
Creutzfeldt–Jakob disease
Other causes of delirium
Infective/pharmacological/metabolic/inflammatory
Other neurological syndromes
Parkinson's disease
Progressive supranuclear palsy (Steele–Richardson–Olszewski syndrome)
Multisystem atrophy
Corticobasal degeneration
Rapid eye movement sleep behaviour disorder (RBD)
Recurrent syncope/unexplained falls
Transient disturbances of consciousness
Comlex partial seizures
Late-onset psychiatric disorders
Delusional disorder (late paraphrenia/late-onset schizophrenia)
Depressive psychosis

(c) Other neurological syndromes

In patients with a prior diagnosis of Parkinson's disease, the onset of visual hallucinations and fluctuating cognitive impairment may be attributed to side-effects of antiparkinsonian medications, and this must be tested by dose reduction or withdrawal. Other atypical parkinsonian syndromes associated with poor levodopa response, cognitive impairment, and postural instability include progressive supranuclear palsy and multi-system atrophy. Syncopal episodes in DLB are often incorrectly attributed to transient ischaemic attacks, despite an absence of focal neurological signs. Recurrent disturbances in consciousness accompanied by complex visual hallucinations may suggest complex partial seizures (temporal lobe epilepsy), and vivid dreaming with violent movements during sleep may meet criteria for REM sleep behaviour disorder. Both these conditions have been reported as uncommon presenting symptoms of autopsy-confirmed DLB.[21,22]

(d) Late-onset functional psychiatric disorder

DLB should be considered if a patient spontaneously develops parkinsonian features or cognitive decline (or shows excessive sensitivity to neuroleptic medication) in the course of late-onset delusional disorder, depressive psychosis, or mania.[21]

Laboratory investigations including neuroimaging

Systemic and pharmacological causes of delirium need to be excluded. The standard EEG may show early slowing, epoch by epoch fluctuation, and transient temporal slow wave activity.[23] There are as yet no clinically applicable genotypic or CSF markers to support a DLB diagnosis.[24] There are, however, sufficient studies to conclude that neuroimaging investigations may be helpful in supporting the clinical diagnosis. Changes associated with DLB include preservation of hippocampal and medial temporal lobe volume on MRI[25,26] and occipital hypo-perfusion on SPECT.[27] Other features such as generalized atrophy, white matter changes,[28] and rates of progression of whole brain atrophy[29] appear to be unhelpful in differential diagnosis. Dopamine transporter loss in the caudate and putamen, a marker of nigro-striatal degeneration can be detected by pre-synaptic dopaminergic SPECT. Preliminary studies suggesting high specificity and sensitivity for predicting clinical[30] and pathological diagnoses of DLB have been confirmed in a large multi-centre trial which found 78 per cent sensitivity and 90 per cent specificity for identifying probable DLB versus non-DLB dementia.[31] Diagnostic sensitivity based upon the presence of the three core clinical features alone has been estimated at below 50 per cent and specificity at >90 per cent which suggests that dopaminergic imaging is most useful when significant clinical diagnostic uncertainty exists.

Epidemiology

In population-based clinical studies, prevalences of around 0.7 per cent for DLB in the 65+ age group have been reported suggesting that it could account for up to 10 per cent of all dementia cases, a figure consistent with DLB rates of 10–15 per cent from hospital-based autopsy series. A recent community study of 85+ year olds found 5.0 per cent to meet consensus criteria for DLB (3.3 per cent probable, 1.7 per cent possible) representing 22 per cent of all demented cases,[32] similar to other clinical estimates and consistent with estimates of Lewy body prevalence in a dementia case

register followed to autopsy.[33] One population-based, autopsy study found Lewy bodies to be evenly distributed between the demented and the non-demented, and this may be interpreted as evidence of a substantial pool of pre-clinical cases.[34] Classical epidemiological studies to determine age and sex variation and potential risk factors for DLB have not yet been reported.

Genetics

It is clear from several case studies that familial cases of DLB occur[35,36] and that Lewy bodies are commonly seen in familial cases of Alzheimer's disease.[37] There are recent reports that triplication of the alpha-synuclein gene (SNCA) can cause DLB, Parkinson's disease, and Parkinson's disease dementia whereas gene duplication is associated only with motor Parkinson's disease suggesting a gene dose effect.[38] However, SCNA multiplication is not found in most Lewy body disease patients.

Course and prognosis

Rate of cognitive decline in DLB is generally reported as similar to Alzheimer's disease[39] and survival from onset to death is reduced with self-reports of depression and the presence of extrapyramidal signs as important adverse predictors.[40] The end stage is typically one of profound dementia and parkinsonism. Even in the early stages, personal and social function and performance in daily living skills may be markedly impaired by a combination of cognitive, psychiatric, and neurological disability to a degree significantly greater than in patients with Alzheimer's disease and comparable mental test scores.[41] Psychotic symptoms, particularly visual hallucinations, tend to be very persistent throughout the whole course of illness. There have been three overlapping stages of the illness described.[21]

The first stage is often recognized only in retrospect, and may extend back 1 to 3 years' prepresentation with occasional minor episodes of forgetfulness, sometimes described as lapses of concentration or 'switching off'. A brief period of delirium is sometimes noted for the first time, often associated with genuine physical illness and/or surgical procedures. Disturbed sleep, nightmares, and daytime drowsiness often persist after recovery.

Progression to the second stage frequently prompts psychiatric or medical referral. A more sustained cognitive impairment is established, albeit with marked fluctuations in severity. Recurrent confusional episodes are accompanied by vivid hallucinatory experiences, visual misidentification syndromes, and topographical disorientation. Extensive medical screening is usually negative. Attentional deficits are apparent as apathy, and daytime somnolence and sleep behaviour disorder[17] may be severe. Gait disorder and bradykinesia are often overlooked, particularly in elderly subjects. Frequent falls occur due to either postural instability or syncope.

The third and final stage often begins with a sudden increase in behavioural disturbance, leading to requests for sedation or hospital admission by perplexed and exhausted carers. The natural course from this point is variable and obscured by the high incidence of adverse reactions to neuroleptic medication. For patients not receiving, or not tolerating, neuroleptics a progressive decline into severe dementia with dysphasia and dyspraxia occurs over months or years, with death usually due to cardiac or pulmonary disease. During this terminal phase patients show continuing behavioural disturbance including vocal and motor responses to hallucinatory phenomena. Lucid intervals with some retention of recent memory function and insight may still be apparent. Neurological disability is often profound, with fixed flexion deformities of the neck and trunk and severe gait impairment. Parkinsonian signs and paraplegia in flexion may also occur in advanced AD and other dementias. Parkinsonism occurring for the first time late in the course of a dementia is therefore consistent with a diagnosis of DLB, but not specific for it.

Advice about management

Patient management in DLB is complex and includes: early detection, investigation, diagnosis, and treatment of cognitive impairment; assessment and management of neuropsychiatric and behavioural symptoms; treatment of the movement disorder and monitoring and management of autonomic dysfunction, and sleep disorders. The evidence base for making recommendations about the management of DLB is limited and what follows is based upon consensus opinion of clinicians experienced in treating DLB.[9] The most important practice point in the management of a patient with DLB is caution in (or preferably avoidance of) the use of neuroleptic medications, which are the mainstay of antipsychotic treatment in other patient groups. Severe neuroleptic sensitivity reactions[5,6] can precipitate irreversible parkinsonism, further impair consciousness level, and induce autonomic disturbances reminiscent of neuroleptic malignant syndrome. They occur in 40 to 50 per cent of neuroleptic-treated DLB cases and are associated with a two- to threefold increased mortality. Acute D_2 receptor blockade is thought to mediate these effects; and despite initial reports, atypical antipsychotics seem to be as likely to cause neuroleptic sensitivity reactions as older drugs. A scheme for the management of the neuropsychiatric symptoms of DLB is suggested in Fig. 4.1.5.1.

Until safe and effective medications become available, there is no doubt that the mainstay of clinical management is to educate patients and carers about the nature of their symptoms and to suggest coping strategies. The clinician must ascertain which symptoms are most troublesome for the sufferer and explain the risks and benefits associated with changes in medication. In these circumstances where the clinician is walking a therapeutic tightrope between parkinsonism and psychosis, the best outcome is invariably a compromise between a relatively mobile but psychotic patient and a non-psychotic but immobile individual. The patient and his carers may only be able to decide which is the lesser of these evils after experiencing both states.

Non-pharmacological interventions

Non-pharmacological interventions have the potential to ameliorate many of the symptoms and functional impairments associated with DLB, but none have yet been systematically evaluated. Cognitive dysfunction and associated symptoms such as VH can for example, be exacerbated by low levels of arousal and attention and strategies to increase these by social interaction and environmental novelty may reduce their presence and impact.

Pharmacological treatments

Pharmacological treatment strategies are based upon our knowledge of the neurochemical deficits underlying specific symptoms in DLB. The most clearly established is a correlation between

Explain hallucinations, delusions, and other neuropsychiatric symptoms of DLB to patient and carer as an intrinsic part of the disorder. **EDUCATION ↓**

Establish the nature and extent of cognitive impairment, neuropsychiatric features, sleep disorder, autonomic dysfunction and motor parkinsonism by interview with patient and carer.
Determine the extent to which of these impairs quality of life and requires active treatment.
Record pretreatment scores for each using appropriate rating scales.
BASELINE ASSESSMENT ↓

Gradually reduce, and if possible stop, antiparkinsonian medications in the following order:
- anticholinergics
- L-deprenyl
- amantadine
- direct dopamine agonists
- COMT inhibitors
- levodopa

Gradually reduce, and if possible stop other anticholinergics, sedatives and drugs which may exacerbate confusional symptoms. **REDUCE ANTI-PARKINSONIAN MEDICATIONS ↓**

After each drug change, repeat measures in all relevant symptom domains to monitor for beneficial or adverse responses. **MONITOR RESPONSE ↓**

If psychotic symptoms persist despite the reduction or withdrawal of unwanted medications a cholinesterase inhibitor should be gradually introduced in standard dose. Improvements are generally seen within the first few weeks and rapid relapse may occur if the drug is stopped abruptly. **CHOLINESTERASE INHIBITOR TRIAL ↓**

If psychotic symptoms still persist a cautious trial of an antipsychotic may be justified as long as the patient and carer understand the potential risks of severe adverse side-effects. Since most neuroleptic sensitivity reactions occur during the first 2 weeks of treatment, it may be wise to admit patients into hospital during initiation of neuroleptic therapy. Since side-effects are dose related, treatment should start with the lowest possible dose and slow titration. Approximately 50% of patients are expected to tolerate medication.
NEUROLEPTIC TRIAL—VERY LOW DOSE AND SLOW TITRATION ↓

Neuroleptics should be discontinued if parkinsonism appears for the first time in a DLB patient, and the dose substantially reduced or stopped in patients whose pre-existing parkinsonism worsens. Severe neuroleptic sensitivity reactions should be treated as a medical emergency similar to neuroleptic malignant syndrome.
STOP IF NEUROLEPTIC SENSITIVITY IS SUSPECTED ↓

Other psychotropic medications may offer short-term benefits. Clonazepam can help nocturnal hallucinations and behavioural disturbance. SSRIs and SRNIs may improve mood disorders.
CONSIDER ALTERNATIVE MEDICATIONS

Fig. 4.1.5.1 Management of the neuropsychiatric symptoms of DLB.

substantia nigra neurone loss and severity of parkinsonism. Levodopa responsiveness is less predictable in DLB than in Parkinson's disease. Activity of the cholinergic enzyme choline acetyltransferase is lower in DLB than AD, particularly in temporal and parietal cortex.[42] Clouding of consciousness, confusion, and visual hallucinations are recognized effects of anticholinergic drug toxicity, and the summative effects of subcortical and cortical cholinergic dysfunction probably play a major role in the spontaneous generation of similar fluctuating symptoms in DLB. Reductions in choline acetyltransferase activity are correlated with the severity of cognitive impairment, and hallucinations may be related to hypocholinergic and (relatively) hypermonoaminergic neocortical neurotransmitter function.

Levodopa can be used for the motor disorder of both DLB and PDD.[43,44] Medication should generally be introduced at low doses and increased slowly to the minimum required to minimize disability without exacerbating psychiatric symptoms. Anticholinergics should be avoided. Visual hallucinations are the most commonly experienced psychiatric symptom and are often accompanied by delusions, anxiety and behavioural disturbance. When pharmacological intervention is required the options include cholinesterase inhibitors or atypical antipsychotic medications. Open label studies have demonstrated the effectiveness of all three generally available cholinesterase inhibitors in DLB but placebo controlled trial data is only available to date for rivastigmine.[45] The reported reduction in symptom frequency and intensity of VH appears to be mediated at least in part by improved attentional function and the presence of VH is associated with greater cognitive improvement. Cholinesterase inhibitors also improve cognitive impairment with an effect size that is generally larger than seen with the same drugs when used in AD.[46] There is a risk of symptom of rebound on sudden withdrawal,[47] limited data on long term effects,[48] and none about possible disease modifying effects.

Side effects of cholinesterase inhibitors in DLB include hypersalivation, lacrimation, and urinary frequency, in addition to the usual gastro-intestinal symptoms and a dose dependent exacerbation of extrapyramidal motor features may occur in a minority.[49] There is no evidence that any one cholinesterase inhibitor is better than others.[50] If they are ineffective or if more acute symptom

control of behaviour is required, it may be difficult to avoid a cautious trial of an atypical antipsychotic. The clinician should warn both the carer and patient of the possibility of a severe sensitivity reaction.[5] Second generation atypicals with potentially more favourable pharmacological properties, such as quetiapine, clozapine, and aripiprazole may have theoretical advantages over traditional agents in LB disease but controlled clinical trial data is lacking and clinicians should remain vigilant to the possibility of adverse side effects.

Depression is common in DLB and there have been no systematic studies of its management. At the present time SSRI and SNRIs are probably preferred pharmacological treatment. Tricylic antidepressants and those with anticholinergic properties should generally be avoided. Apathy is also common and may improve with cholinesterase inhibition. Sleep disorders are frequently seen in LB disease and may be an early feature. Rapid eye movement sleep behaviour disorder can be treated with clonazepam 0.25 mg at bedtime, melatonin 3 mg at bedtime, or quetiapine 12.5 mg at bedtime and titrated slowly monitoring for both efficacy and side effects.[7]

4.1.6 Dementia in Parkinson's disease

R. H. S. Mindham and T. A. Hughes

Introduction

Parkinson's disease has been regarded as a neurological condition mainly affecting motor function and arising from specific lesions in the brain stem. The recognition of dementia in Parkinson's disease is of importance in management but the possibility that motor and cognitive functions may be located in the same region of the brain is of theoretical importance.

The nature of dementia in Parkinson's disease

There have been numerous reports of the impairment of specific cognitive functions in patients with Parkinson's disease. Mortimer and colleagues reported cognitive impairment in 93 per cent of a substantial group of patients with Parkinson's disease.(1) Their data showed neither a clear distinction between impaired groups nor the presence of subtypes of Parkinson's disease in which cognitive impairment is a more frequent occurrence. They proposed that cognitive impairment in Parkinson's disease lay on a continuum of severity, rather than as a feature of particular subgroups. The impairments identified included deficits in memory, language, visuospatial functioning, abstract reasoning, slowness in intellectual tasks, and difficulty in shifting from task to task. These deficits are widespread among patients with Parkinson's disease and can occur at an early stage of the disorder.

A proportion of patients with Parkinson's disease show impairment of a range of cognitive functions akin to the global impairment seen in Alzheimer's disease.(2) However, the pattern of impairment is frequently less severe than in Alzheimer's disease where the pathological changes in the brain are known to be widespread. Cognitive impairment in a range of disorders of movement where the main neuropathological changes reside in the subcortical region of the brain led to the concept of 'subcortical dementia', a form of intellectual impairment of lesser degree than in Alzheimer's disease, but affecting several cognitive functions. Albert described a syndrome of which the main features were: emotional or personality changes, impaired memory, defective ability to manipulate acquired knowledge, and a striking slowness in the rate of information processing.(3)

Many issues arose as to the nature of 'subcortical dementia'. Was it a clinical or a pathological concept? Was the difference between this and other forms of dementia simply one of degree? Did the pathological changes occur in the subcortical region of the brain alone? Was the syndrome of cognitive impairment distinctly different from other dementias or did the presence of motor features of the disorder simply give the intellectual impairment a distinct character? Was subcortical dementia a stable condition or a transitional state leading eventually to global dementia? Opinion has ranged from full acceptance of the concept to scepticism.(4,5)

McHugh[6] suggested that the subcortical region subserves functions not only in motor control and cognitive function but also in the control and display of mood. He suggested that these form a 'subcortical triad' of symptoms most convincingly seen in Huntington's disease. A notable difference between this concept and that of subcortical dementia was that the pathological disturbance of mood is only intermittently present, whereas the motor and cognitive changes are persistent.

Cummings[7] suggested that cognitive impairment in Parkinson's disease takes three forms: one which is relatively mild and meets the criteria for subcortical dementia, a more severe form showing wider impairment of cognitive function but neuropathologically distinct from Alzheimer disease and a severe form which shows neuropathological changes in both the subcortical region of the brain, and in the cortex, the latter of Alzheimer type. This proposal provides a basis for viewing cognitive changes in Parkinson's disease, albeit provisional.

Many reports have suggested that global dementia occurs in Parkinson's disease. Whether such a severe change in cognitive function can be regarded as an intrinsic feature of this disease, whether it implies an extension of a neuropathological process more widely in the brain, or whether it suggests a different neuropathology from the outset is, as yet, uncertain. More recently the debate has shifted to whether dementia in Parkinson's disease, dementia with Lewy bodies and Alzheimer's disease should be viewed as a spectrum, or as separate conditions with varying degrees of clinical and pathological overlap.

The methodology of studies of dementia in Parkinson's disease

Research to establish the status of dementia in Parkinson's disease has confronted a range of methodological issues.[8] A major problem is in the diagnosis of Parkinson's disease itself. The original description of paralysis agitans by Parkinson was the identification of a syndrome rather than of a disease. The part played by such agents as heavy metals, infections, and vascular disease was subsequently recognized. In spite of the use of standardized methods, a substantial proportion of patients diagnosed as suffering from Parkinson's disease in life do not show the expected findings in the brain postmortem. In a follow-up study, 80 per cent of cases were shown to have neuropathological changes of Parkinson's disease after death but over 20 per cent were diagnosed as having suffered from progressive supranuclear palsy, multiple system atrophy, or Alzheimer's disease.[9] Furthermore, some dementing illnesses may show disorder of movement as a clinical feature.

Studies of dementia in Parkinson's disease

Cases of dementia in Parkinson's disease have been reported for over a hundred years. The frequency of dementia reported in cross-sectional or prevalence studies ranges from 0 to over 80 per cent. A recent review found a prevalence of between 28 and 44 per cent in community studies but in older samples of subjects the prevalence was much higher.[10]

Follow-up studies have great advantages in studying the frequency of dementia in Parkinson's disease as they allow the diagnosis of Parkinson's disease to be checked, repeated assessment reduces errors in the recognition of dementia, the pattern of evolution of dementia may be followed, the underestimation of dementia by selective loss through death is avoided, and they reveal the incidence rather than the prevalence of the condition. The choice of methods of diagnosis and assessment that will remain appropriate throughout the period of the follow-up remains a problem.

A prospective, controlled study in the United Kingdom reported an incidence of dementia of 19 per cent after 4.5 years observation. A later report on the same cohort of subjects showed an incidence of dementia of 38 per cent after 10 years of observation. The control group showed cases of cognitive impairment but none amounting to dementia.[11,12] A community based, prospective, controlled study, in Norway, showed the risk of dementia was 5.9 times greater than in the control group.[13] A prospective, controlled study in the United States showed that dementia was 3.7 times greater in the Parkinson's disease group with severely affected, elderly patients especially at risk (Table 4.1.6.1).[14,15]

Prediction of dementia in Parkinson's disease

Those most likely to develop dementia are: older people, patients with Parkinson's disease of longer duration, subjects who have a greater severity of motor symptoms and signs of Parkinson's disease, and those who show greater physical disability.[11–15] Some studies have shown that male sex or late onset are associated with dementia. The apparent association between Parkinson's disease treated with levodopa and dementia is probably due to improved survival.

Neuropathology

The basic lesions are the degeneration of the pigmented neurones in the pars compacta of the substantia nigra in the brain stem; the presence of **Lewy bodies** which are intracytoplasmic neuronal inclusions composed of abnormally phosphorylated neural filament proteins aggregated with ubiquitin and alpha-synuclein; gliosis; and the formation of **Lewy neurites** which are degenerating neurites containing ubiquitin and alpha-synuclein. Alpha-synuclein may play an important role in the pathological process leading to the formation of Lewy bodies, but conclusive proof is lacking. Clinical Parkinson's disease is not apparent until about 80 per cent of the nigro-striatal dopaminergic neurones have died. Lewy bodies had come to be regarded as pathognomonic of Parkinson's disease, but are now known to be present in other diseases. An agreed though arbitrary difference between dementia in Parkinson's disease and dementia with Lewy bodies is that in the latter, parkinsonian symptoms must not precede the occurrence of dementia by more than 12 months.

The degenerative changes in the substantia nigra are known to be closely linked with decreased dopaminergic neurotransmission in the brain, and this deficiency leads to the main motor features of the disease, although other neurotransmitters are also deficient. Some of these deficiencies, which have been associated with cognitive impairment in other disorders, include a deficiency in acetylcholinesterase in the cortex, a deficiency of noradrenaline in the cortex, and a deficiency of serotonin in both striatum and cortex. The concentrations of a range of neuropeptides may also be altered.

The neuropathology of cases of Parkinson's disease showing dementia is inconsistent; some show neuropathological changes

Table 4.1.6.1 Some prospective studies of dementia in Parkinson's disease, using control subjects and employing standardized methods of diagnosis and assessment

Study	PD subjects (N)	Control subjects (N)	Length of follow-up (years)	Diagnostic criteria for dementia	% of PD demented	Number demented per 1000 person years	Dementia in PD v controls: relative risk (95% CI), †odds ratio, ‡hazard ratio
1. Biggins *et al.* 1992 (UK)	87	50	4.5	DSM-III-R	19	47.6	–

Notes on studies:

1. Prevalent cases of dementia at entry to study excluded from analysis; PD & controls assessed concurrently; DSM-III-R criteria assessed blind; PD sample drawn from neurological clinics.
2. Same PD cohort and controls, same method of assessment as study 1.
3. Community sample in Norway; controls from community sample in Demark assessed by different instruments and at different intervals. Prevalent cases of dementia excluded from entry to study. DSM-III-R criteria (dementia diagnosis) not assessed blind.
4. Community sample. Prevalent cases of dementia at entry to study excluded from analysis. Concurrent examination of PD and control groups using same instruments; DSM-III-R criteria not assessed blind.
5. Same PD cohort and controls, similar method of assessment, same method of diagnosis of dementia as study3. % PD demented includes 26% cases prevalent at entry to study. Relative risk is for dementia in PD subjects at 4 years versus control subjects at 5 years.
6. Prevalent cases of dementia excluded from entry to study. Elderly sample. DSM-IV criteria not assessed blind.
7. Community sample. Prevalent cases of dementia at entry to study excluded from analysis. DSM-III-R criteria not assessed blind.

extending beyond the subcortical region, whereas in others neuropathological changes are restricted to the subcortical region. Some studies have shown a correlation between the extent of Lewy body pathology and the severity of dementia, but others have not. Lewy bodies may be found in individuals without cognitive impairment and dementia may develop with only minimal cortical Lewy bodies.[16] In some patients with dementia the neuropathological diagnosis is of Alzheimer's disease or of other recognized degenerative conditions of the brain.

Just as there are difficulties in isolating Parkinson's disease from other conditions, there are problems in understanding the interrelationships of dementing disorders. Several distinct neurodegenerative diseases share some aetiological factors, which may represent an interaction between environmental factors and the ageing process but with differing end results arising from factors specific to the process.[17–19] Problems in the diagnosis of Parkinson's disease, the shrinking category of idiopathic Parkinson's disease, and the difficulties occasionally encountered in explaining the development of dementia in the disease, suggests that the interrelationship between causative agents, the clinical features of disorders of movement, the occurrence of cognitive impairment, and the neuropathology of this group of disorders requires substantial further work before it is understood.

The influence of dementia on mortality

Dementia is associated with increased mortality. In Parkinson's disease increased mortality is associated with age, late age of onset of the disease, cognitive impairment, dementia, and, in some studies, male sex. Many of the studies that have been carried out have been methodologically faulty, making comparisons between studies and the identification of the effect of particular factors, including dementia, problematic. One study showed a hazard ratio for Parkinson's disease compared with controls of 1.64, in general, and of 1.94 for to Parkinson's disease with dementia.[20] In another study of mortality almost 50 per cent of those who died were demented compared with a quarter of those who survived.[21]

Clinical aspects of Parkinson's disease with dementia

The most important step in the recognition of dementia in Parkinson's disease is to suspect its presence. The typical blank facial expression seen in Parkinson's disease may obscure a decline in intellectual activity, slowness in movement may conceal intellectual slowness, and sadness may suggest that morbid depression of mood is the reason for a reduction in liveliness. The clinical picture can usually be clarified by careful examination of the mental state. Standardized psychological tests may be useful in some cases.

The clinical importance of dementia in Parkinson's disease is that there is a marked increase in disability, with problems arising in areas of functioning not previously affected by motor impairment alone. Dementia may be accompanied by an increased liability to confusional episodes from the toxic effects of drugs and other causes.[22]

Management of dementia is similar to that for patients suffering from other dementing disorders (Chapter 4.1.3). Controlled trials suggest rivastigmine and donepezil have a moderate effect on cognitive function, but tolerability can be a problem, with worsening

of parkinsonism and gastrointestinal upsets.[23] Rivastigmine is started at 1.5 mg twice daily, and increased by 3 mg per day at intervals of 4 weeks upto a maximum of 12 mg daily. Donepezil should be started at 5 mg in the evenings, increasing to 10 mg after 6 weeks, if tolerated.

4.1.7 Dementia due to Huntington's disease

Susan Folstein and Russell L. Margolis

Introduction

Huntington's disease (HD) was first described in 1872 by an American physician living on Long Island, New York. His father and grandfather practised medicine in the same community, so he had access to case notes from several generations of families who lived there. This long period of record keeping allowed him to document a hereditary form of chorea, similar to 'common (Sydenham's) chorea', but progressing over many years to death. Its sufferers had a tendency to insanity and suicide. Huntington's brief essay, which also included a clear description of autosomal dominant inheritance, remains one of the classical descriptions of a medical disorder.[1]

Clinical features and course of illness

Huntington's disease is an inherited neuropsychiatric disorder mainly affecting the striatum and its direct connections. It is characterized by a triad of clinical features that are common to diseases of this region: a non-aphasic *dementia*, *depression* and other disorders of mood, and a variety of *dyskinesias*, most typically chorea.[2,3] Chorea, from the Greek word for 'dance', describes involuntary non-stereotyped jerky movements. The illness, insidious in onset, may begin with all or any one of these three features. Patients who present initially to psychiatrists usually have dementia, loss of temper, or depression, often with suicidal thoughts or attempts. Symptoms may appear at any time from early childhood to old age, most frequently between 35 and 45 years of age. Once the illness begins, sufferers gradually deteriorate over many years in their cognitive and motor functioning and end in a persistent vegetative state with almost complete loss of voluntary motor

function. Death occurs after about 16 years and is usually caused by inanition or aspiration pneumonia. Some patients die earlier from suicide or subdural haematoma caused by a fall. Patients with early onset progress more rapidly than those whose symptoms begin later in life.

Pathology and genetics

The earliest visible neuropathology is in the striosomes of the caudate/putamen,[4] followed by a dorsal-to-ventral progressive loss of almost all striatal output neurones. The deep layers of multiple cortical regions are also prominently affected, and there can also be milder neuronal loss in some brainstem nuclei. Protein aggregates, most easily detectable in neuronal nuclei, are prominent. Neuroimaging studies have shown that neuropathological changes typically begin before the onset of clinically detectable disease. In particular, the extent of striatal loss in presymptomatic individuals, as measured by MRI, correlates with the predicted time until disease onset.[5] Cortical thinning[6] and white matter loss and disorganization[7,8] have also been detected in presymptomatic gene carriers. Subtle changes that may be related to abnormal brain development have also been reported.

The disorder, with a point prevalence of about 6/100 000,[9] is caused by the expansion of an unstable triplet repeat sequence (CAG) in the first exon of a gene near the telomere of chromosome 4p.[10] It is transmitted as an autosomal dominant trait; if one parent is affected, each offspring (regardless of sex) has an independent 50 per cent chance of inheriting the abnormal gene. Normal repeat lengths range from about 7 to 28 triplets. Individuals with 29–35 triplets will not develop HD but may pass an expanded allele to an offspring, while individuals with 40 or more triplets will develop HD. Repeat lengths of 36–39 triplets may or may not cause disease. The rate of mutation from a normal-length allele to an expanded one is low, so that most patients have an affected parent. Family history, however, can be obscured by multiple factors, including misdiagnosis of the parent, death of the parent before disease onset, adoption, and incorrect paternity. The repeat length does not remain stable at meiosis. In HD, the number of CAG triplets is more likely to increase when the gene is transmitted by fathers. As the number of repeats increases, the age at onset is earlier. Thus, paternal transmission is often associated with 'anticipation', earlier onset in the subsequent generation; most individuals with childhood onset have affected fathers.[11]

The pathogenesis of HD is not well understood but appears to be multifaceted. The gene, *huntingtin*, with the expanded repeat is expressed as a protein, huntingtin. The CAG repeat expansion is translated as an expanded polyglutamine tract, which appears to have neurotoxic properties. The region of the huntingtin protein with the polyglutamine tract may be cleaved from the rest of the protein and adopt an abnormal configuration. This in turn is thought to lead to disruption of cellular functions, including transcriptional machinery, protein degradation processes, and cellular transport. It is also possible that the expansion mutation results in a partial loss of the normal functions of huntingtin, one of which is the stimulation of the neurotrophic factor BDNF; decreased BDNF may contribute to neurotoxicity.[12]

Diagnosis

The most difficult aspect of diagnosis is to think of HD in the differential. Diagnosis remains dependent on a thorough psychiatric history, including a detailed family history and history of changes in social adjustment, mental state examination, including a cognitive examination, and neurological examination. The features vary, depending on how long the patient has been ill.[13] Once the disease is suspected, genetic testing, available through many commercial laboratories, provides the definitive diagnosis.

Diagnosis of patients with early symptoms

Patients with HD who initially consult psychiatrists present with a variety of psychiatric syndromes, including depression, bipolar disorder, obsessive–compulsive disorder, schizophrenia, or excessive anxiety. Irritability is common with any of these or may appear outside the context of another syndrome. These psychiatric syndromes are clinically indistinguishable from idiopathic disorders and may be the only manifestation of HD for several years. It is during this prodromal phase that patients often commit suicide; this may occur even if the patient is unaware of his risk for HD.[14] Presenting symptoms and problems with functioning at work or at home must often be elicited from an informant; the patient may minimize them, be embarrassed, or even unaware of them. These include declines in work speed or accuracy, which may have resulted in demotion or warnings from superiors; a tendency to become irritated or physically aggressive in response to annoying stimuli that would not have elicited such a response in the past; and a decreased interest in activities. Most of these symptoms and behaviours are common in psychiatric disorders, but the cognitive inefficiency and irritability may seem to be out of proportion, relative to the patient's other symptoms. On cognitive examination, the patient may have difficulty recalling dates of important life events and more difficulty than expected with 'serial sevens'. Usually, the cognitive changes are easier to notice after the psychiatric disorder is treated, which can usually be accomplished using standard medications. However, unlike idiopathic disorders, cognitive inefficiency and difficulties at work, apathy (if present), and sometimes irritability remain even after the patient's mood, energy, and sleep patterns have improved. When this happens in the course of treatment of depression, a dementia work-up should be considered and the family history further scrutinized through hospital records and other family informants.

On neurological examination, motor restlessness is usually present but is easily misinterpreted as a manifestation of anxiety. Motor signs may be subtle: slightly slow saccadic eye movements,[15] writhing movements of the protruded tongue or of the fingertips when the arms are held at 90°, or mild disdiadochokinesis.

Diagnosis can be further complicated by the apparent lack of a family history of HD. The family may not have been informed about the affected parent's diagnosis, or may know only that a parent died in a psychiatric institution or committed suicide. In other cases the paternity is uncertain. If the family history is actually negative (this is quite uncommon) or unobtainable (often the case for adopted individuals who frequently present in childhood), the diagnosis may be confirmed by testing for the HD gene expansion.

(a) Diagnosis in childhood and adolescence

When HD starts in childhood or early adolescence,[16] motor signs include parkinsonian-like motor slowness of voluntary movement, with lead pipe or cogwheel rigidity and very slow saccades. Occasional children have a coarse tremor; later myoclonus is seen. Cognitively, the rate of learning in school slows, handwriting

deteriorates, and interest in school and social activities declines.[17] Of the patients who present with a schizophrenic syndrome, most are adolescents. Psychosis and loss of cognitive capacity may be the only clinical features for several years before motor impairment begins. Children with HD often have seizures, which are usually grand mal. Sometimes myoclonus is mistaken for seizures.

(b) The importance of early diagnosis

Even though it can be difficult, it is important to make the diagnosis of HD as early as possible, particularly in employed persons. Poor function at work (or in schoolwork or household duties) occurs early, and patients can lose their jobs, often on suspicion of drug or alcohol abuse. This is usually avoided if the diagnosis is made known to the family and employer, allowing modification of the work environment or retirement on the basis of disability. Prompt diagnosis does not mean that the patient needs to be informed of the diagnosis at that same time. Some patients are too depressed to do this safely; others indicate that they do not wish to be told. Treatment can usually proceed despite the patient's reluctance to label the disorder.

Diagnosis of patients with well-established signs and symptoms

After a few years of illness, diagnosis is easier. The signs and symptoms will have worsened, and usually the motor disorder is obvious. A typical patient who has been ill for about 5 to 7 years is unable to work or manage finances, but lives at home and is able to manage personal needs. Some patients remain active and energetic, continuing to participate as fully in life as their cognitive and motor disabilities allow; others are apathetic most of the time, but irritable when disturbed; still others have severe depression with delusions, obsessions, or compulsions, and most are anxious and easily upset by changes of routine. An uncommon, but very troublesome, feature of HD is sexual abnormality. While most patients become impotent or uninterested in sex, a few are hypersexual and may develop paraphilias.[18] It is important to inquire about these specifically because neither the patient nor spouse will likely mention it.

Cognitively, patients complain of forgetfulness and becoming easily distracted. Thinking is slow; patients have difficulty following a conversation and cannot complete a multistaged task. On cognitive examination, Mini Mental State Examination scores[19] may still be above the 23 cut-off score, but serial sevens will be very poor, and one or two items will be missed on recalling words after a distraction. On neuropsychological testing, IQ will be lower than expected for education, and there will be difficulty learning word lists and performing tests that require changing sets.

Most patients will have obvious involuntary choreic movements, as well as difficulty with control of voluntary motor movements, as seen by clumsiness, slowness, dysarthria, and an unsteady gait. The involuntary movements will wax and wane with the level of arousal; it can be worsened by performing serial 7 s or by fine motor tasks. Speech will have an irregular staccato, often laboured, quality. Saccadic eye movements will be slow or irregular, and the patient will be obviously clumsy on diadochokinesis and finger-thumb tapping, although finger-to-nose testing is normal. Gait will be wide based and irregular, with difficulty with tandem walking. Reflexes are usually brisk, and a history of falls can be elicited.

Diagnosis of patients with advanced disease

After 10 years of illness, dementia is more severe, with poor performance on all aspects of the cognitive examination except naming. Speech is dysfluent with long lapses between the examiner's question and the patient's reply, rather like Brocca's aphasia. Some patients will be almost unable to speak, although language comprehension is relatively preserved. Patients (if they are cooperative) can carry out simple commands and will recognize relatives and nursing staff. Patients may be irritable, particularly when their verbal requests cannot be understood or when routines are altered. Psychiatric syndromes are more difficult to discern, but most can be diagnosed by observing behaviour such as hoarding, sleeplessness, or diurnal variation in mood. Physical disabilities are much worse. Patients often need to be fed, toileted, and helped with most daily needs. They have difficulty walking and may fall, causing further disability through broken limbs or subdural haematomas. Chorea often stabilizes or subsides,[13] but the ability to carry out voluntary movements becomes seriously handicapping. If they survive long enough, patients become unable to initiate speech, swallow with great difficulty, are unable to walk, and have such severely rigid muscle tone that they may be nearly unable to move their bodies. Clonus and positive Babinski signs are present. Patients in this sort of 'persistent vegetative state'[20] are difficult to distinguish from individuals with other advanced movement disorders or dementias; as in early disease, diagnosis will depend on eliciting a family history or genetic testing.

Differential diagnosis

The differential diagnosis of HD is extensive,[3] but only a few of the disorders for which it can be mistaken are common.[2] These include other dementias, other movement disorders, and other psychiatric disorders. The most frequent subcortical dementia is **Parkinson's disease**, which has a similar motor slowness, but a pill-rolling tremor and festinating gait are rare in HD. The dementia associated with **late-life depression** can look very similar to HD, including motor slowness. **Alzheimer's disease** is easily distinguished by the lack of motor signs during the first several years of illness and more prominent difficulty with memory and language, as opposed to attention and calculation. Perhaps most difficult to distinguish clinically are the **frontotemporal dementias**, which present with prominent behavioural disturbances and a positive family history. The clinical presentation may be insufficient to distinguish these various dementias in patients with advanced disease, since they all progress to a persistent vegetative state. The family history and the duration of illness (which is longer for HD than for Alzheimer's disease or frontotemporal dementia) can be helpful.

Several other diseases classified as **movement disorders** include all the features of the subcortical triad. They often have an autosomal dominant inheritance pattern and expansion of unstable trimeric repeat sequences. These include Fahr's syndrome (calcification of the striatum), some forms of spinocerebellar degeneration, chorea acanthocytosis, Huntington's disease-like 2 (HDL2), and dentatorubropallidolusian atrophy (DRPLA). The latter three disorders, while much rarer than HD, can look so similar that they can only be distinguished by genetic testing and by a blood smear for acanthocytes. The most common movement disorder that resembles HD is **tardive dyskinesia**. Patients with HD occasionally have several years of hallucinations and delusions before the

movement disorder begins. If they have been treated with neuroleptics, the subsequent onset of involuntary movements can be mistaken for tardive dyskinesia. On the other hand, the choreoathetotic involuntary movements of severe tardive dyskinesia may involve the trunk and extremities as well as the face and can be mistaken for HD. Usually, it is possible to distinguish the patients with tardive dyskinesia by their normal saccadic eye movements, normal tandem gait, and fluid and fluent speech.[21] However, genetic testing may be necessary in some cases. Wilson's disease also presents with the subcortical triad and should be considered when neither of the parent is affected. It is recessively inherited, so that the only affected relatives are siblings. Very late-onset HD may be diagnosed as 'senile chorea' because the family history appears to be negative. Family members will also present symptoms only late in life and may have died before their manifestation.

The differential diagnosis of nearly all **psychiatric disorders** includes HD, as described above.

Treatment and management

Currently, no treatment influences the course of illness of HD, but based on research on likely genetic mechanisms, clinical trials of agents protective against oxidants, excitotoxicity, and metabolic stress are underway. No agent yet tested has had a dramatic benefit. The development of biochemical assays and cell and animal models that mimic various aspects of HD can be used to screen for effective therapies.

It is possible to alleviate some of the symptoms of HD. Small doses of neuroleptics can be helpful in decreasing involuntary movements in the first stages of the illness, as can tetrabenazine and occasionally benzodiazepines. Doses of more than 5 mg. of haloperidol do not further decrease chorea and may worsen cognition and cause motor stiffness and slowing.[22] Persons with the advanced form of the disease are often unresponsive to neuroleptics. Treatment of psychiatric manifestations significantly improves quality of life for the patients and their families. Clinical experience suggests that depression, anxiety, and obsessive–compulsive disorder associated with HD usually respond to the pharmacological treatments used for the similar idiopathic disorders. SSRIs can be particularly helpful. Because some patients seem unaware of their depressed mood (just as they can be unaware of their involuntary movements) an informant is often needed to elicit the symptoms. It is also important to distinguish depression (from which the patient is miserable and sleepless) and apathy, which does not cause distress. Occasionally, mood and anxiety disorders are chronic and unresponsive to treatment. Severe, unresponsive depression can be treated successfully with electroconvulsive therapy.[23] Bipolar disorder in patients with HD does not usually respond to lithium, but may improve with carbamazepine or valproic acid. Valproic acid, serotonin specific reuptake inhibitors, and low dose antipsychotic agents may also be helpful in the treatment of irritability. Lithium is difficult to administer because patients require high fluid intake and easily become lithium toxic if fluid intake is insufficient. In one case report, high doses of sertraline were effective for intractable aggression.[24] Schizophrenic symptoms can be difficult to treat. Sometimes a combination of an antipsychotic, including clozaril, with an antidepressant will prove helpful. Muscle rigidity and consequent contractions occur in late HD, causing pain and difficulty in positioning the patient to avoid pressure sores. Amantadine (which also has a positive effect on mood) can somewhat decrease the rigidity; chairs and beds must be padded and tailored to each patient's specific needs.

Family and environment

As with most dementias, psychopathology influences, and is influenced by, the patient's environment. Patients do best in a calm, highly predictable environment where cognitive expectations are not too complicated. When the environment is too taxing, patients become irritable, especially towards their family. HD seriously damages family relationships, which in turn affects the patient. The well spouse becomes responsible for supporting the family, caring for children and the patient, and making family and financial decisions. Spouses' lives are further complicated by patients' unwillingness to relinquish financial and family decision-making; patients usually make poor decisions that damage family relationships and finances. Some patients neglect their children or treat them badly. If the other parent cannot prevent this, it is wisest to remove the patient from the home. There is no research on the treatment of sexual aggression, which occasionally occurs in males, but the author has successfully treated a few males with depot progesterone. Supportive psychotherapy for the patient should focus on minimizing demoralization at lost abilities. Spouses can be helped to reorganize family life in ways that maximize the predictability of the patient's environment, diplomatically decrease patients' domestic responsibilities. It is crucial that the spouse has time away from the patient.

Helping persons at risk for HD

People at risk for HD vary in their abilities to deal with the burden of uncertainty, depending on their personal attributes and their experience with the illness in a relative. A few consult physicians for reassurance, but most avoid doctors unless they become ill, and even then many resist medical attention, claiming against all evidence that they are perfectly well. Currently, a minority of asymptomatic persons at risk for HD decide to have genetic testing, but these individuals, skewed towards those whose anxiety is lessened by planning for the future, have usually handled the test results well, regardless of its outcome.[25] When clinical trials are launched for individuals with the HD mutation who are without detectable symptoms, the incentive for presymptomatic testing will likely increase, with a concomitant change in the nature of individuals seeking testing. Foetal and pre-implantation genetic testing are now available in some centers, each with its own set of potentially complicated ethical and practical issues to be sorted out prior to testing.

Presymptomatic genetic testing of any sort should always be preceded by genetic counselling, provided either by a genetic counselor or by a clinician familiar with HD genetics and the potential practical and psychological consequences of both positive and negative test results. Counselling should include a discussion of the motivations for seeking testing, which may include decisions about childbearing, education, employment, finances, participation in clinical trials, or the potential at-risk status of offspring. Many individuals who come for testing have not seriously considered the possibility that they will test positive for the mutation, so that role playing about various outcome scenarios is important. Occasionally, persons request testing who have learned only recently that they are

at risk for HD. Others apply who are depressed or under unusual stress for other reasons. Such persons should be encouraged to delay testing until their situation becomes more settled. Finally, some people who request testing already have symptoms of HD, yet do not wish to have a diagnosis. Considerable care is required to decide how best to support such individuals, and family members or close friends of the person should be consulted.[26]

4.1.8 Vascular dementia

Timo Erkinjuntti

Introduction

Vascular dementia is the second most frequent cause of dementia.[1,2] Because vascular causes of cognitive impairment are common, may be preventable, and the patients could benefit from therapy, early detection, and accurate diagnosis of vascular dementia is desirable.[3]

Vascular dementia is not only multi-infarct dementia, but is related to other vascular mechanisms and pathological changes in the brain, and has other causes and clinical manifestations. Vascular dementia is not a disease, but a syndrome. The origin of this syndrome reflects complex interactions between vascular aetiologies (cerebrovascular disorders and vascular risk factors), changes in the brain (infarcts, white-matter lesions, atrophy), host factors (age, education), and cognition.[4–8]

Conceptual issues related to of vascular dementia include the definition of the cognitive syndrome (type, extent, and combination of impairments in different cognitive domains), and the vascular causes (vascular aetiologies and changes in the brain). Variations in these definitions has led to different estimates of point prevalence, to different groups of patients, and to reports of different types and distribution of brain lesions.[9–11] The cognitive syndrome of vascular dementia is characterized by predominate executive dysfunction rather than deficits in memory and language function.[12] Although the course of cognitive decline may be

stepwise, it is often slowly progressive, and may include periods of stability or even some improvement.

The relationship between vascular lesions in the brain and cognitive impairment is important, but which type, extent, side, site, and tempo of vascular lesions in the brain relates to different types of vascular dementia is not established in detail.[4–6,13]

Current criteria for vascular dementia are based on the concept of cerebral infarcts. For example the widely used NINDS-AIREN criteria include dementia, cerebrovascular disease, and a relationship between these two disorders. The main tools for the diagnosis include detailed history, neurological examination, mental state examination, relevant laboratory examinations, and preferably magnetic resonance imaging of the brain.

Vascular dementia research, until recently overshadowed by that into Alzheimer's disease, is now developing rapidly. There is great promise for intervention. Developments in classification, diagnosis, and treatment are likely.

Aetiology and pathophysiology

Aetiology

The main causes of vascular dementia are cerebrovascular disorders and their risk factors. The prevalent cerebrovascular disorders include large artery disease (artery-to-artery embolism, occlusion of an extra- or intracranial artery), cardiac embolic events, small-vessel disease (lacunar infarcts, ischaemic white-matter lesions) and haemodynamic mechanisms.[13–15] Less frequent causes include specific arteriopathies including cerebral autosomal dominant arteriopathy with subcortical infarcts and leucoencephalopathy (CADACIL) and cerebral amyloid angiopathy (CAA), haemorrhage (intracranial haemorrhage, subarachnoidal haemorrhage), haematological factors, venous disease, and hereditary disorders. There may be as yet undiscovered causes.

In most patients diagnosed with vascular dementia, several aetiological factors are involved. However, the roles these factors play have not been identified in detail, and it is not certain which of these mechanisms distinguish vascular dementia from cerebrovascular disease without dementia.[4,5,7,16,17]

Risk factors for vascular dementia can be divided into vascular factors (e.g. arterial hypertension, atrial fibrillation, myocardial infarction, coronary heart disease, diabetes, generalized atherosclerosis, lipid abnormalities, smoking), demographic factors (e.g. age, education), genetic factors (e.g. family history, individual genetic features), and stroke-related factors (e.g. type of cerebrovascular disease, site and size of stroke).[18,19] Hypoxic ischaemic events (cardiac arrhythmias, congestive heart failure, myocardial infarction, seizures, pneumonia) may be an important risk factor for incident dementia in patients with stroke.[20]

Changes in the brain

Vascular dementia is related to both ischaemic and non-ischaemic changes in the brain.[4,5,13,14] The ischaemic lesions include arterial territorial infarct, distal field (watershed) infarct, lacunar infarct, ischaemic white-matter lesions, and incomplete ischaemic injury. Incomplete ischaemic injury incorporates laminar necrosis, focal gliosis, granular atrophy, and incomplete white-matter infarction.[21,22] In addition, both focal (around the ischaemic lesion) and remote (disconnection, diaschisis) functional ischaemic changes relate to vascular dementia, and the volume of functionally inactive tissue exceeds that of focal ischaemic lesions in vascular dementia.[23] Limitation in current clinical methods have hampered the detection of both incomplete ischaemic injury and functional ischaemic changes related to vascular dementia. Atrophy is the non-ischaemic factor related to vascular dementia. However, there are no methods to distinguish between ischaemic and degenerative causes of atrophy clinically.

Brain imaging findings

Work on the relationship between brain lesions and cognition in vascular dementia has used varying definitions and measures of cognitive impairment, varying techniques to reveal brain changes, and varying criteria for the selection of patients.[17]

CT and magnetic resonance imaging (**MRI**) studies on vascular dementia have shown that bilateral ischaemic lesions are important.[4,5,7,17] Some studies emphasize deep infarcts in the frontal and limbic areas, while others report cortical lesions especially in the temporal and parietal areas. There is disagreement about the number and volume of the infarcts, as well as the extent and location of atrophy. Diffuse and extensive white-matter lesions have been suggested as an important factor leading to functional disconnection of cortical brain areas. Some general conclusions on brain lesions in vascular dementia may be drawn.

1 There is no single pathological feature, but a combination of infarcts, ischaemic white-matter lesions of varying size and type, and atrophy of varying degree and site.

2 Infarcts associated with vascular dementia tend to be bilateral, multiple (more than two), and located in the dominant hemisphere and in the limbic structures (frontolimbic or prefrontal–subcortical and medial–limbic or medial–hippocampal circuits).

3 White-matter lesions on CT or magnetic resonance imaging (MRI) associated with vascular dementia are extensive, extending in periventricular white matter, and confluent to extending in the deep white matter.

4 It is doubtful whether a single small lesion on imaging can be accepted as evidence for vascular dementia.

5 Absence of cerebrovascular lesions on CT or MRI is contrary to a diagnosis of vascular dementia.

Pathophysiology

The extent to which pathological changes in the brain cause, compound, or only coexist with the vascular dementia syndrome is still uncertain. The vascular changes in the brain can be the main cause of cognitive impairment (as assumed in vascular dementia[24,25]), they can contribute to the clinical picture of other dementia syndromes including Alzheimer's disease (AD),[7,26] or they may be coincidental. The occurrence of infarcts may cause an earlier presentation of clinical symptoms in a brain in which there is existing and progressive Alzheimer's disease pathology.[26]

It is not certain which are the critical changes in the brain leading to the clinical picture of vascular dementia. The syndrome has been related to the volume of brain infarcts (with a critical threshold), the number of infarcts, the site of infarcts (bilateral, in strategic cortical or subcortical, or affecting white matter), to other ischaemic factors (incomplete ischaemic injury, delayed neuronal death, functional changes), to the atrophic changes (origin, location, extent), and finally to the additive effects of other pathologies

(Alzheimer's disease, Lewy body dementia, frontal lobe dementias). But it is uncertain which type, extent, side, site, and tempo of vascular lesions in the brain, and which combination with other pathologies, relate to vascular dementia.[4–6,13]

Classification and clinical criteria

Classification

Vascular dementia has been divided into subtypes on the basis of clinical, radiological, and neuropathological features. It is uncertain whether these subtypes are distinct disorders, with separate pathological and clinical features, and responses to therapy.[27] If homogenous subtypes could be identified the comparability of research studies would be greater and multicentre studies easier.[28]

The subtypes of vascular dementia included in most classifications include multi-infarct dementia (cortical lesions), small-vessel dementia or subcortical ischaemic vascular disease and dementia (SIVD) (subcortical deep lesions), and strategic infarct dementia.[12,14,27,29–33] Many include also hypoperfusion dementia.[12,14,30,34] Further suggested subtypes include haemorrhagic dementia, hereditary vascular dementia, and combined or mixed dementia (Alzheimer's disease with cerebrovascular disease).

DSM-IV[35] does not specify subtypes. ICD-10[36] includes six subtypes (acute onset, multi-infarct, subcortical, mixed cortical and subcortical, other, and unspecified). The NINDS-AIREN criteria[30] include, without detailed description, cortical vascular dementia, subcortical vascular dementia, Binswanger's disease, and thalamic dementia. In addition separate research criteria for subcortical vascular dementia, the SIVD, have been proposed.[37]

Main subtypes

Multi-infarct dementia or cortical vascular dementia, and small-vessel dementia or subcortical vascular dementia are the two common subtypes, although their frequencies vary in different series.[12,14,31]

Cortical vascular dementia relates to large-vessel disease, cardiac embolic events, and hypoperfusion. Infarcts are predominantly in the cortical and corticosubcortical arterial territories, and their distal fields (watershed). Typical clinical features are lateralized sensorimotor changes and the abrupt onset of cognitive impairment and aphasia.[31] A combination of different cortical neuropsychological syndromes has been suggested to occur in cortical vascular dementia.[38]

Subcortical vascular dementia, small-vessel dementia, the SIVD[33,37] incorporates the entities 'lacunar state' and 'Binswanger's disease'. It relates to small-vessel disease and hypoperfusion, with predominately lacunar infarcts, focal and diffuse ischaemic white-matter lesions, and incomplete ischaemic injury.[31,33,37–39] Clinically, small-vessel dementia is characterized by pure motor hemiparesis, bulbar signs, dysarthria, depression, and emotional lability, and especially deficits in executive functioning.[38–41]

Clinical criteria

Since the 1970s several clinical criteria for vascular dementia have been published.[11,42,43] The most widely used include those in DSM-IV,[35] ICD-10,[36] and NINDS-AIREN.[30]

The two cardinal elements of any clinical criteria for vascular dementia are the definition of the cognitive syndrome[44] and the definition of the cause.[11,43,45] All clinical criteria are consensus criteria, derived neither from prospective community-based studies on vascular factors affecting the cognition, nor on detailed natural histories.[28,30,42,43,46] All these criteria are based on the concept of ischaemic infarcts. They are designed to have high specificity, but have been poorly validated.[42,46] An important consequence of the different definitions of the dementia syndrome,[9,44] and the vascular cause,[10,11] is that the different diagnostic criteria identify different populations.

Table 4.1.8.1 The DSM-IV definition of vascular dementia

Focal neurological signs and symptoms (e.g. exaggeration of deep tendon reflexes, extensor plantar response, pseudobulbar palsy, gait abnormalities, weakness of an extremity, etc.)
or
Laboratory evidence of focal neurological damage (e.g. multiple infarctions involving cortex and underlying white matter)
The cognitive deficits cause significant impairment in social or occupational functioning and represent a significant decline from a previously higher level of functioning
The focal neurological signs, symptoms, and laboratory evidence are judged to be aetiologically related to the disturbance
The deficits do not occur exclusively during the course of delirium
Course characterized by sustained periods of clinical stability punctuated by sudden significant cognitive and functional losses

The DSM-IV definition of vascular dementia (Table 4.1.8.1) requires focal neurological signs and symptoms or laboratory evidence of focal neurological damage clinically judged to be related to the disturbance.[35] The course is specified by sudden cognitive and functional losses. The DSM-IV criteria do not detail brain imaging requirements. The DSM-IV definition of vascular dementia is reasonably broad and lacks detailed clinical and radiological guidelines.

The ICD-10 criteria[36] (Table 4.1.8.2) require unequal distribution of cognitive deficits, focal signs as evidence of focal brain damage, and significant cerebrovascular disease judged to be aetiologically related to the dementia. The criteria do not detail brain imaging requirements. The ICD-10 criteria specify six subtypes of vascular dementia (Table 4.1.8.3). The ICD-10 criteria for vascular dementia have been shown to be highly selective and only some of those fulfilling the general criteria for ICD-10 vascular dementia

Table 4.1.8.2 The ICD-10 criteria for vascular dementia

Unequal distribution of deficits in higher cognitive functions with some affected and others relatively spared. Thus, memory may be quite markedly affected while thinking, reasoning, and information processing may show only mild decline
There is evidence for focal brain damage, manifest as at least one of the following: unilateral spastic weakness of the limbs, unilaterally increased tendon reflexes, an extensor plantar response, pseudobulbar palsy
There is evidence from the history, examination, or test of significant cerebrovascular disease, which may reasonably be judged to be aetiologically related to the dementia (history of stroke, evidence of cerebral infarction)

Table 4.1.8.3 Characteristics of the vascular dementia subtypes in ICD-10

Acute onset (F01.0)
The dementia develops rapidly (i.e. usually within 1 month but within no longer than 3 months) after a succession of strokes, or (rarely) after a single large infarction
Multi-infarct (F01.1)
The onset of the dementia is more gradual (i.e. within 3-6 months) following a number of minor ischaemic episodes. Comments: it is presumed that there is an accumulation of infarcts in the cerebral parenchyma. Between the ischaemic episodes there may be periods of actual clinical improvement
Subcortical (F01.2)
A history of hypertension, and evidence from clinical examination and special investigations of vascular disease located in the deep white matter of the cerebral hemispheres, with preservation of the cerebral cortex.
Mixed cortical and subcortical (F01.3)
Mixed cortical and subcortical components of vascular dementia may be suspected from the clinical features, the results of investigation, or both
Other (F01.8)
Unspecified (F01.9)
In the ICD-10 criteria no specific diagnostic guidelines are given for these two vascular dementia sybtypes

can be classified into one of the subtypes.[11,45] The shortcoming of these criteria include lack of detailed guidelines (e.g. of unequal cognitive deficits and changes on neuroimaging), lack of aetiological criteria, and heterogeneity.[11,45]

The NINDS-AIREN research criteria for vascular dementia[30] include a dementia syndrome, cerebrovascular disease, and a relationship between these (Table 4.1.8.4). Cerebrovascular disease is defined by the presence of focal neurological lesions and brain imaging evidence of ischaemic changes in the brain. A relationship between dementia and cerebrovascular disorder is inferred from the onset of dementia within 3 months following a recognized stroke, or on abrupt deterioration in cognitive functions, or fluctuating stepwise progression of cognitive deficits. The criteria include a list of features consistent with the diagnosis, as well as a list of features that make the diagnosis uncertain or unlikely. Also, different levels of certainty of the clinical diagnosis (probable, possible, definite) are included. The NINDS-AIREN criteria recognize heterogeneity[47] of the syndrome and variability of the clinical course in vascular dementia, and highlight detection of ischaemic lesions and a relationship between lesion and cognition, as well as stroke and dementia onset.

The NINDS-AIREN criteria are currently most widely used in clinical drug trials on vascular dementia. In a neuropathological series, sensitivity of the NINDS-AIREN criteria was 58 per cent and specificity 80 per cent.[48] The criteria successfully excluded Alzheimer's disease in 91 per cent of cases, and the proportion of combined cases misclassified as probable vascular dementia was 29 per cent.[48] The inter-rater reliability of the NINDS-AIREN criteria is moderate to substantial ($\kappa = 0.46–0.72$).[49]

These three sets of criteria for vascular dementia are not interchangeable; they identify different numbers and clusters of patients. The DSM-IV criteria are less restrictive than the ICD-10 and NINDS-AIREN criteria.[11,50]

Table 4.1.8.4 The NINDS-AIREN criteria for probable vascular dementia

(I) The criteria for the clinical diagnosis of PROBABLE vascular dementia include *all* of the following
1 *Dementia*
2 *Cerebrovascular disease*, defined by the presence of focal signs on neurological examination, such as hemiparesis, lower facial weakness, Babinski sign, sensory deficit, hemianopia, dysarthria, etc. consistent with stroke (with or without history of stroke), and evidence of relevant CVD by brain imaging (CT or MRI) including multiple large-vessel strokes or a single strategically placed infarct (angular gyrus, thalamus, basal forebrain, PCA or ACA territories), as well as multiple basal ganglia and white-matter lacunes or extensive periventricular white-matter lesions, or combinations thereof
3 *A relationship between the above two disorders*, manifested or inferred *by* the presence of one or more of the following
(a) Onset of dementia within 3 months following a recognized stroke
(b) Abrupt deterioration in cognitive functions, or fluctuating stepwise progression of cognitive deficits
(II) Clinical features consistent with the diagnosis of PROBABLE vascular dementia include the following
(a) Early presence of a gait disturbance (small-step gait or *marche a petits-pas*, apraxic–ataxic or parkinsonian gait)
(b) History of unsteadiness and frequent unprovoked falls
(c) Early urinary frequency, urgency, and other urinary symptoms not explained by urological disease
(d) Personality and mood changes, abulia, depression, emotional incontinence, other subcortical deficits including psychomotor retardation and abnormal executive function
(III) Features that make the diagnosis of vascular dementia uncertain or unlikely include the following
(a) Early onset of memory deficit and progressive worsening of memory and other cognitive functions such as language (transcortical sensory aphasia), motor skills (apraxia), and perception (agnosia), in the absence of corresponding focal lesions on brain imaging
(b) Absence of focal neurological signs, other than cognitive disturbance
(c) Absence of cerebrovascular lesions on brain CT or MRI

CVD, cerebrovascular disease; PCA, posterior cerebral artery; ACA, anterior cerebral artery.

Vascular cognitive impairment

Vascular cognitive impairment (VCI) is currently considered the most recent modification of the terminology to reflect the all-encompassing effects of vascular disease or lesions on cognition and incorporates the complex interactions between vascular aetiologies, risk factors, and cellular changes within the brain and cognition.[51,52]

VCI refers to all aetiologies of CVD including vascular risks which can result in brain damage leading to cognitive impairment. The impairment encompasses all levels of cognitive decline, from the earliest deficits to a severe and broad dementia-like cognitive syndrome.[51,53] VCI cases that do not meet the criteria for dementia can also be labelled as VCI with no dementia, vascular CIND.[54]

VCI may include cases with cognitive impairment related to hypertension, diabetes, or atherosclerosis, transient ischaemic attacks, multiple corticosubcortical infarcts, silent infarct, strategic

infarcts, small-vessel disease with white-matter lesions an lacunae, as well as AS pathology with coexisting CVD.[55] The concept and definitions of VCI and vascular CIND are still evolving, but it seems clear that the diagnosis should not be confined to a single aetiology comparable to the traditional 'pure AD' concept.[51,52]

Clinical features

Cognitive syndrome

The cognitive syndrome of vascular dementia is characterized by memory deficit, dysexecutive syndrome, slowed information processing, and mood and personality changes. These features are found especially among patients with subcortical lesions. Patients with cortical lesions often have additional cortical neuropsychological syndromes.[38]

The memory deficit in vascular dementia is often less severe than in Alzheimer's disease. It is characterized by impaired recall, relatively intact recognition, and more benefit from cues.[56] The dysexecutive syndrome in vascular dementia includes impairment in goal formulation, initiation, planning, organizing, sequencing, executing, set-sifting and set-maintenance, as well as in abstracting.[12,38,56] The dysexecutive syndrome in vascular dementia relates to lesions affecting the prefrontal subcortical circuit including prefrontal cortex, caudate, pallidum, thalamus, and the thalamocortical circuit (capsular genu, anterior capsule, anterior centrum semiovale, and anterior corona radiata).[57] Typically, personality and insight are relatively preserved in mild and moderate cases of vascular dementia.

Features that make the diagnosis of vascular dementia disease uncertain or unlikely include early and progressive worsening of episodic memory, and other cognitive cortical deficits in the absence of corresponding focal lesions on brain imaging.[30]

Neurological findings

Frequent neurological findings indicating focal brain lesion early in the course of vascular dementia include mild motor or sensory deficits, decreased co-ordination, brisk tendon reflexes, Babinski's sign, visual field loss, bulbar signs including dysarthria and dysphagia, extrapyramidal signs (mainly rigidity and akinesia), disordered gait (hemiplegic, apraxic–ataxic, or small-stepped), unsteadiness, unprovoked falls, and urinary frequency and urgency.[30,31,39–41] Features that make the diagnosis of vascular dementia uncertain or unlikely include absence of focal neurological signs, other than cognitive disturbance.[30]

In cortical vascular dementia, typical clinical features are lateralized sensorimotor changes and abrupt onset of cognitive impairment and aphasia, and in subcortical vascular dementia disease pure motor hemiparesis, bulbar signs, dysarthria, disordered gait and unsteadiness.[31]

Behavioural and psychological symptoms of dementia

Depression, anxiety, emotional lability and incontinence, and other psychiatric symptoms are frequent in vascular dementia. Depression, abulia, emotional incontinence, and psychomotor retardation are especially frequent in subcortical vascular dementia disease.[12,38]

(a) Ischaemic scores

Cardinal features of vascular dementia disease are incorporated in the Hachinski Ischaemia Score[58] (Table 4.1.8.5). In a neuropathological series, stepwise deterioration (odds ratio, 6.0), fluctuating course (odds ratio, 7.6), history of hypertension (odds ratio, 4.3), history of stroke (odds ratio, 4.3), and focal neurological symptoms (odds ratio, 4.4) differentiated patients with definite vascular dementia from those with definite Alzheimer's disease.[59] Nocturnal confusion and depression did not discriminate. However, the ischaemia score was unable to differentiate the Alzheimer's disease patients with cerebrovascular disease from those with vascular dementia.

Table 4.1.8.5 Hachinski ischaemia score

Item	Score value
Abrupt onset	2
Stepwise deterioration	1
Fluctuating course	2
Nocturnal confusion	1
Relative preservation of personality	1
Depression	1
Somatic complaints	1
Emotional incontinence	1
History of hypertension	1
History of strokes	2
Evidence of associated atherosclerosis	1
Focal neurological symptoms	2
Focal neurological signs	2

Course and prognosis

Traditionally, vascular dementia has been characterized by a relative abrupt onset (days to weeks), a stepwise deterioration (some recovery after worsening), and fluctuating course (e.g. differences between days) of cognitive functions. These features are seen in patients with repeated lesions affecting cortical and corticosubcortical brain structures, i.e. large-vessel multi-infarct vascular dementia, and with watershed infarcts related to haemodynamic problems. However, in patients with small-vessel dementia, i.e. subcortical vascular dementia, the onset is more insidious and course more slowly progressive.[28,30,39,60]

The mean duration of vascular dementia is around 5 years.[2] In most studies survival is less than for the general population or those with Alzheimer's disease.[61,62] Surprisingly little is known about the rate and pattern of cognitive decline, either overall or among different subgroups of vascular dementia.[63] This underlines the lack of studies detailing the natural history of vascular dementia.

Diagnosis and differential diagnosis

The clinical evaluation of patients with memory impairment has two stages, the symptomatic diagnosis, i.e. evaluation of the type and extent of cognitive impairment, and the aetiological diagnosis, i.e. evaluation of vascular cause(s) and related factors. The symptomatic categories other than dementia include the more mild cognitive stages, i.e. VCI or vascular CIND, delirium, circumscribed

neuropsychological syndromes (e.g. aphasia) and functional psychiatric disorders (e.g. depression).[46] Stages of aetiological diagnosis include diagnosis of the specific causes, especially the potentially treatable conditions, evaluation of secondary factors able to affect the cognitive functioning, and more detailed differentiation between specific causes, especially that between vascular dementia disease and Alzheimer's disease.

Clinical evaluation

The cornerstone in the evaluation of a patient with suspected vascular dementia is detailed clinical and neurological history and examination, including interview of a close informant. Assessment of social functions, activities of daily living, as well as psychiatric and behavioural symptoms, is part of the basic evaluation. These patients are challenging and enough time should be allocated time for the consultation, often 40 to 60 min.

Mental status examination

Bedside mental status examination includes the Mini-Mental State Examination.[64] However, this has limitations as it emphasizes language, does not include timed elements and the recognition portion of the memory tests, is insensitive to mild deficits, and is influenced by education and age. Other proposed screening instruments for vascular dementia include a 10-word memory test with delayed recall, cube drawing test for copy, verbal fluency test (number of animals named in 1 min), Luria's alternating hand sequence, or finger rings and letter cancellation test (neglect).[30] Other test include the Clox and Exit designed to screen the dysexecutive features.[65]

Frequently a more detailed neuropsychological test is needed. It should cover the main cognitive domains including memory functions (working memory, episodic memory, semantic memory), abstract thinking, judgement, aphasia, apraxia, agnosia, orientation, attention, executive functions, and speed of information processing.[44,66]

Brain imaging

Brain imaging should be performed at least once during the initial diagnostic workout. MRI is preferred because it has high sensitivity and the ability to demonstrate medial temporal lobe and basal forebrain areas. Depending on the criteria of vascular dementia used, focal brain infarcts have been revealed in 70 to 100 per cent, and more extensive white-matter lesions in 70 to 100 per cent of cases.[13,25,30,67,68]

Single-photon emission CT and positron-emission tomography may reveal patchy reduction of regional blood flow and metabolism, as well as decreased white-matter flow and metabolism.[69]

Other investigations

Chest X-ray, electrocardiography, and screening laboratory tests are part of the basic evaluation.[15,70,71] In selected cases extended laboratory investigations, analysis of the cerebrospinal fluid, and EEG are performed, as well as examinations of the extra- and intracranial arteries and detailed cardiological investigations.[15,70,71]

In vascular dementia EEG is more often normal than in Alzheimer's disease, and if abnormal more frequently suggests a focal abnormality. Abnormalities increase with more severe intellectual decline both in vascular dementia disease and Alzheimer's disease.[60]

At present there is no specific laboratory test for vascular dementia. Tests may reveal risk factors and concomitant disorders such as hyperlipidaemia, diabetes, and cardiac abnormality.[60] Apolipoprotein E_4 is a established risk factor for Alzheimer's disease, but its relationship to vascular dementia has not been consistent.[72] Determination of apolipoprotein E status is currently not part of clinical evaluation in vascular dementia.

Differential diagnosis of vascular dementia disease

(a) Alzheimer's disease

Typical Alzheimer's disease is characterized by insidious onset and slowly progressive intellectual deterioration, absence of symptoms and signs indicating focal brain damage, and absence of any other specific disease affecting the brain.[73] Alzheimer's disease has typical clinical stages ranging from early changes to profound dementia.[74,75]

When patients with vascular dementia have a clinical history, neurological examination, and brain imaging findings compatible with ischaemic changes of the brain, the differentiation from Alzheimer's disease can be made clinically.[25]

Diagnostic problems arise when Alzheimer's disease is combined with cerebrovascular disease. Difficult clinical problems include stroke unmasking Alzheimer's disease in patients with post-stroke dementia, insidious onset, and/or slow progressive course in vascular dementia patients, and cases where it is difficult to assess the role of white-matter lesions or of infarcts found on neuroimaging. A solution to recognize patients with Alzheimer's disease and cerebrovascular disease would be to discover reliable biological markers for clinical AD. Other potential markers include early prominent episodic memory impairment, early and significant medial temporal lobe atrophy on magnetic resonance imaging, bilateral parietal hypoperfusion on single-photon emission computed tomography and low concentrations of cerebrospinal fluid amyloid peptides with high tau protein concentrations. The distinction would be also less difficult if there were more detailed knowledge of the sites, type, and extent of ischaemic brain changes critical for vascular dementia, and the extent and type of medial temporal lobe atrophy critical for Alzheimer's disease.

Other important conditions to be differentiated from vascular dementia include normal pressure hydrocephalus,[76] frontal lobe tumours and other intracranial masses,[15] Lewy body disease,[77] frontotemporal degenerations,[78] Parkinson's disease and dementia,[79] progressive supranuclear palsy,[80] and multisystem atrophy.[81]

Epidemiology

Vascular dementia is the second most common cause of dementia accounting for 10 to 50 per cent of cases, depending on the geographic location, patient population, and clinical methods used.[1,2] The prevalence of vascular dementia is from 1.2 to 4.2 per cent of persons aged 65 years and older, and the incidence is 6 to 12 cases per 1000 persons aged over 70 years per year.[2] The prevalence and the incidence of vascular dementia disease increases with increasing age, and men seem to have a higher prevalence of vascular dementia than women. Epidemiology of vascular dementia has been affected by variations in the definition of the disorder, the clinical criteria used, and the clinical methods applied.[18,82,83]

The frequency of vascular dementia disease has been higher than previously reported in recent series comprising older subjects.[10] Stroke and cerebrovascular disorders relate also to a high risk of cognitive impairment and dementia.[24,84] Finally, vascular factors such as stroke and white-matter lesions have a clinical effect on Alzheimer's disease.[26] Thus, vascular factors may even be the leading cause of cognitive impairment worldwide especially when cognitive impairment as opposed to dementia is considered.[51,85]

Treatment

The objectives of targeted treatment of vascular dementia include symptomatic improvement of core symptoms (e.g. cognitive, behavioural), slowing progression of the disorder, and treatment of secondary factors affecting cognition (e.g. depression, anxiety, agitation).

A number of drugs have been studied in the symptomatic treatment of vascular dementia including cerebro- and vasoactive drugs, nootropics, and some calcium antagonists, but largely these studies have shown negative results.[86] Studies on symptomatic improvement in vascular dementia have mostly had small numbers, short treatment periods, variations in diagnostic criteria and tools, mixed populations, and have had variation in clinical endpoints applied.

First nimodipine,[87] memantine,[88] and propentofylline[89] raised expectations for a symptomatic treatment of vascular dementia. However, all the studies failed to fulfil the current requirement by the regulators for and treatment indication in vascular dementia.[90,91]

More recently cholinesterase inhibitors (donepezil, galantamine, rivastigmine) have been tested in large randomized controlled trials in patients with probable vascular dementia. All showed significant cognitive improvement compared to placebo, but failed to show significantly better global outcome with the Alzheimer-type measures. Accordingly, none of the acetylcholinesterase inhibitors have received marketing authorization for the treatment of vascular dementia.[91] Patients with Alzheimer's disease with coexisting cerebrovascular disease show good benefit from galantamine.[92]

Possibilities for prevention

For primary prevention the target is the brain at risk of cerebrovascular disease and cognitive impairment. The methods relate to the treatment of putative risk factors of vascular dementia, and the promotion of potential protective factors. Risk factors include those related to cerebrovascular disorders and stroke, to vascular dementia, to post-stroke dementia, to white-matter lesions, and to cognitive impairment or dementia, and also those related to Alzheimer's disease.[8] The vascular risk factors include arterial hypertension, atrial fibrillation, myocardial infarction, coronary heart disease, diabetes, generalized atherosclerosis, lipid abnormalities, and smoking. The demographic factors include age and education. One putative protective factor is oestrogen.[93]

Knowledge of effects of primary prevention on these risk factors in populations free of cognitive impairment is still scant.[8,94] In a European study, treatment of mild systolic hypertension decreased the incidence of dementia.[95] Positive effects in primary prevention of stroke support the idea that action on vascular risk factors could reduce the numbers of patients with vascular dementia.

For secondary prevention the target is the brain already affected by cerebrovascular disease and at risk of vascular dementia. Actions include diagnosis and treatment of acute stroke in order to limit the extent of ischaemic brain changes, prevention of recurrence of stroke, and treatment of risk factors. Treatment is guided by the aetiology of cerebrovascular disorder such as large artery disease (e.g. aspirin, dipyridamole, carotid endarterectomy), cardiac embolic events (e.g. anticoagulation, aspirin), small-vessel disease (e.g. antiplatelet therapy), and haemodynamic mechanisms (e.g. control of hypotension and cardiac arrhythmias).[15,29,46] A recent large study showed some benefit from perindopril and indapamide in the prevention of post-stroke dementia.[96] Hypoxic ischaemic events (cardiac arrhythmias, congestive heart failure, myocardial infarction, seizures, pneumonia) are an important risk factor for incident dementia in patients with stroke and should be taken into account in the secondary prevention of vascular dementia.[20]

Detailed knowledge of the effects of secondary prevention of vascular dementia is lacking. In a small series of patients with established vascular dementia, control of high arterial blood pressure,[97] cessation of smoking,[97] and use of aspirin[98] improved or stabilized cognition. It has been suggested that lowering of plasma viscosity could also have an effect in vascular dementia.[99] The absence of progressive cognitive decline in patients receiving placebo in treatment trials of vascular dementia may also reflect an effect of intensified risk factor control.[89]

4.1.9 Dementia due to HIV disease

Mario Maj

Introduction

The first description of a syndrome consisting of cognitive, motor, and behavioural disturbances in patients with AIDS was published in 1986.[1] The syndrome was named 'AIDS dementia complex'. In 1990, the World Health Organization (WHO) introduced the term 'HIV-associated dementia',[2] pointing out that subclinical or mild cognitive and/or motor dysfunctions without impairment of performance in daily living activities cannot be subsumed under the term 'dementia'. The expression 'mild cognitive/motor disorder' was proposed for those conditions. The same distinction was made in 1991 by the American Academy of Neurology,[3] which identified an 'HIV-associated dementia complex' and an 'HIV-associated minor cognitive/motor disorder'. The present chapter focuses on the dementia syndrome associated with HIV infection.

Clinical features

The onset of HIV-associated dementia is usually insidious. Early cognitive symptoms include forgetfulness, loss of concentration, mental slowing, and reduced performance on sequential mental activities of some complexity (the subject misses appointments, or needs lists to recall ordinary duties; loses track of conversations or his or her own train of thought; needs additional time and effort to organize thoughts and to complete daily tasks). Early behavioural symptoms include apathy, reduced spontaneity and emotional responsivity, and social withdrawal (the subject becomes indifferent to his or her personal and professional responsibilities; his or her work production decreases, as well as the frequency of social interactions; the subject complains of early fatiguability, malaise, and loss of sexual drive). Depression, irritability or emotional lability, agitation, and psychotic symptoms may also occur. Early motor symptoms include loss of balance and coordination, clumsiness, and leg weakness; the subject is less precise in normal hand activities, such as writing and eating, drops things more often than usual, trips and falls more frequently, and perceives the need to exercise more care in walking.[1,4]

Routine mental status tests, in this early stage, may be normal or show only slowing in verbal or motor responses and/or difficulty in recalling a series of objects after 5 min or more. Neurological examination may show tremor (best seen when the patient sustains a posture, such as holding the arms and fingers outstretched), hyperreflexia (particularly of the lower extremities), ataxia (usually seen only on rapid turns or tandem gait), slowing of rapid alternating movements (of the fingers, wrists, or feet), frontal release signs (snout reflex, palmar grasp), dysarthria. Tests of ocular motility may show interruption of smooth pursuits, and slowing or inaccuracy of saccades.

In the late stages of the disease, there is usually a global deterioration of cognitive functions and a severe psychomotor retardation. Speech is slow and monotonous, with word-finding difficulties and possible progression to mutism. Patients become unable to walk, due to paraparesis, and usually lie in bed indifferent to their illness and their surroundings. Bladder and bowel incontinence are common. Myoclonus and seizures may occur. Pedal paraesthesias and hypersensitivity may appear, due to concurrent sensory neuropathy. The level of consciousness is usually preserved, except for occasional hypersomnolence.

Classification

The WHO criteria for HIV-associated dementia[2] are as follows:

1 The research criteria for dementia of the ICD-10 are met, with some modifications:
   (a) decline in memory may not be severe enough to impair activities of daily living;
   (b) decline in motor function may be present, and is verified by clinical examination and, when possible, formal neuropsychological testing;
   (c) the minimum requested duration of symptoms is 1 month;
   (d) aphasia, agnosia, and apraxia are unusual.
2 Laboratory evidence for systemic HIV infection is present.
3 No evidence of another aetiology from history, physical examination, or laboratory tests should be present (specifically, cerebrospinal fluid analysis and either computed tomography (CT) or magnetic resonance imaging (MRI) should be done to exclude active central nervous system opportunistic processes).

The American Academy of Neurology criteria[3] require the following:

1 Laboratory evidence for systemic HIV infection.
2 Acquired abnormality in at least two of the following cognitive abilities (present for at least 1 month): attention/concentration, speed of processing of information, abstraction/reasoning, visuospatial skills, memory/learning, and speech/language.
3 At least one of the following:
   (a) acquired abnormality in motor function or performance;
   (b) decline in motivation or emotional control or change in social behaviour.
4 Absence of clouding of consciousness during a period long enough to establish the presence of 2.
5 Absence of evidence of another aetiology.

Both the WHO and the American Academy of Neurology criteria distinguish three levels of severity of the dementia syndrome (mild, moderate, and severe), on the basis of the degree of the impairment in activities of daily living.

Diagnosis and differential diagnosis

Neuropsychological tests

Neuropsychological examination supports the clinical diagnosis of HIV-associated dementia, by providing evidence of cognitive and

motor dysfunction. Moreover, it may be useful in the differential diagnosis with a depressive syndrome.

The most prominent impairment is observed on tests of fine motor control (finger tapping, grooved pegboard), rapid sequential problem solving (trail-making A and B, digit symbol), visuospatial problem solving (block design), spontaneity (verbal fluency), and visual memory (visual reproduction). In contrast, naming and vocabulary skills are largely preserved even in the most advanced cases.

The signs that should alert to the possible presence of a depressive 'pseudodementia' are as follows:[5]

1 the intratest variability of performance (i.e. missing easy items and then correctly answering more difficult questions);
2 mood-congruent complaints, which are at odds with objective performance (i.e. the subject complains of having difficulties with a test, whereas his or her performance is near perfect);
3 responses of 'I don't know' or giving up, which are followed by the correct answer, when the subject is further urged to respond.

It should be considered, however, that dementia and depression may coexist in HIV-seropositive subjects.

Brain imaging

Brain imaging provides additional support to the diagnosis of HIV-associated dementia, especially by excluding central nervous system opportunistic processes, in particular cerebral toxoplasmosis and primary central nervous system lymphoma.

The predominant finding in HIV-associated dementia is cerebral atrophy: both CT and MRI demonstrate widened cortical sulci and, less commonly, enlarged ventricles. Furthermore, MRI frequently shows high-intensity signal abnormalities on the T_2-weighted image (diffuse widespread involvement, patchy localized involvement, focal distinct areas of involvement, or punctuate white-matter hyperdensities). These lesions are without mass effect and are most commonly located in the periventricular white matter and the centrum semiovale (less frequently, in the basal ganglia or in the thalamus).

As to differential diagnosis, both CT and MRI are able to demonstrate the multiple bilateral ring-enhancing lesions that are characteristic of cerebral toxoplasmosis, and the contrast-enhancing mass lesions of primary central nervous system lymphoma.

Cerebrospinal fluid analysis

Cerebrospinal fluid analysis can support the clinical diagnosis of HIV-associated dementia, especially by excluding several central nervous system opportunistic infections, in particular cryptococcal meningitis.

The most frequent cerebrospinal fluid findings in HIV-associated dementia are the increase of total proteins and of the IgG fraction and index. A mononuclear pleocytosis may occur. The presence of the HIV core antigen p24 can be detected, although this finding is possible also in neurologically normal subjects. HIV RNA can be demonstrated in the cerebrospinal fluid by using the polymerase chain reaction. Increased cerebrospinal fluid levels of neopterin, β_2-microglobulin, and quinolinic acid (non-specific markers of immune activation), soluble Fas and Fas ligand (associated with apoptosis), as well as several cytokines (interleukin 1β, interleukin 6, tumour necrosis factor-α), have been reported, but may be detected also during central nervous system opportunistic infections.

As to differential diagnosis, Indian ink staining, cryptococcal antigen titres, and fungal culture can be decisive for the identification of cryptococcal meningitis. Other central nervous system opportunistic infections that can be identified by cerebrospinal fluid analysis include central nervous system tuberculosis, cytomegalovirus encephalitis, and neurosyphilis.

Epidemiology

There has been a decrease in the incidence of HIV-associated dementia after the introduction of highly active antiretroviral therapy (HAART): while between 1990 and 1992 the mean incidence was 21.1 cases per 1000 person-years, between 1996 and 1998 it decreased to 10.5 cases per 1000 person-years.[6] However, the incidence seems to have increased again in 2003.[7] A post-mortem neuropathologic study reported that, while severe HIV encephalopathy was not detected anymore in the HAART era, the prevalence of mild and moderate encephalopathy increased, probably reflecting the longer survival time after initial HIV infection.[8]

Pathogenesis

HIV crosses the blood-brain barrier by a Trojan-horse-type mechanism, using the macrophages it infects.[9] Once in the brain, it infects glial cells. Infected and activated macrophages and microglia release neurotoxins which lead to neuronal damage and apoptosis.[10] It is possible that direct effects of viral proteins on neurones also contribute to neurodegeneration. Post-mortem studies have revealed the presence of HIV in frontal lobes, subcortical white matter and the basal ganglia.[11]

Course and prognosis

In the pre-HAART era, HIV-associated dementia often progressed rapidly to severe deterioration and death, especially in patients with advanced systemic disease. Today, many patients present an attenuated form which is slowly progressive or static. The mean survival, which was 5 months in 1993–1995, increased to 38.5 months in 1996–2000.[12] Prominent psychomotor slowing, a history of intravenous drug use and low CD4 T-lymphocyte count seem to predict a more rapid progression.[13]

Available treatments

Antiretrovirals are not always successful in crossing the blood-brain barrier, but, as mentioned above, have been able to reduce the incidence and modify the course of HIV-associated dementia. There is evidence that they can improve specific aspects of cognitive functioning, such as psychomotor speed performance, in people with HIV-associated dementia.[14] The optimal HAART regimen for the treatment of HIV-associated dementia has not been established.

Neuroprotective drugs whose beneficial effect on cognitive performance in patients with HIV infection has been preliminarily documented include the monoamine oxidase inhibitor deprenyl (a putative antioxidant and antiapoptotic agent) and peptide T (which blocks the HIV gp120 envelope protein). Other investigational drugs include memantine and nitroglycerin (which are *N*-methyl-D-aspartate receptor antagonists), nimodipine (a calcium-channel blocker), pentoxifylline (an inhibitor of the production

and activity of tumour necrosis factor-α), and lexipafant (an antagonist of platelet-activating factor).

The psychostimulant methylphenidate has been found to be useful in treating apathy and cognitive slowing in patients with HIV-associated dementia, with relatively mild side effects. Only anecdotal evidence is available concerning the usefulness of cholinesterase inhibitors such as donepezil.

Patients with AIDS, when treated with typical antipsychotic drugs for the presence of psychotic symptoms or behavioural dyscontrol, are particularly prone to develop extrapyramidal side effects and neuroleptic malignant syndrome. According to preliminary research evidence, some atypical antipsychotics are well tolerated even by patients who had to stop standard neuroleptics due to extrapyramidal side effects.

AIDS patients with depressed mood have been found to respond to tricyclic antidepressants and selective serotonin reuptake inhibitors (SSRIs) as well as HIV-seronegative subjects. There is a preliminary evidence that SSRIs (or at least some of them) are better tolerated than tricyclic antidepressants, except in patients with diarrhoea.

Management

Patients with HIV-associated dementia often have additional disease processes which may aggravate the cognitive impairment, including secondary infections and metabolic disturbances. These conditions should be adequately diagnosed and managed.

An appropriate HAART regimen should be implemented and constantly monitored (taking into account that cognitive dysfunction may have a negative impact on adherence to treatment). If psychotic symptoms, behavioural dyscontrol, or mood disturbances are present, the same strategies which are used for other people with these problems should be implemented, taking into account that HIV-infected patients have an increased sensitivity to the side effects of antipsychotics and antidepressants, and that adverse interactions may occur between psychotropic drugs and antiretrovirals (for instance, the administration of St. John's Wort induces the metabolism of the protease inhibitor indinavir, thus decreasing its serum concentration to levels which may cause treatment failure).[15] Methylphenidate (5–20 mg/day) may be used to reduce apathy and psychomotor slowing.

Psychosocial interventions in HIV-associated dementia should include maintenance of a structured daily schedule, titration of external stimuli, restriction to familiar environments, frequent orienting interactions with significant others, and monitoring of personal and financial affairs. Psychoeducational intervention with families and significant others is also essential.

The care of patients with HIV-associated dementia will make increasing demands on health services, as well as on volunteer and community support systems. It is uncertain, at present, whether such care is best provided in specialized units (e.g. inpatient AIDS units), or within general psychiatric or medical services. Special management problems may arise when the behavioural disturbance (e.g. poor impulse control, sexual acting-out behaviour) is such as to constitute a risk for other patients or staff members. Placement of patients in the terminal stage of the disease may also represent a problem: the lack of appropriate options in the community may obstruct their timely and humane discharge from the hospital.

4.1.10 The neuropsychiatry of head injury

Simon Fleminger

Head injury 'imparts at a blow both physical and psychological trauma',[1] and the consequences are often devastating and enduring.[2] Not infrequently head injury leads to a psychiatric consultation, which will need to take into account the interplay between the brain and its injuries as well as the psychodynamic processes that follow from the injury.

In the immediate aftermath of the head injury, the management rests with the acute surgical and medical team.[3] The psychiatrist is usually not involved at this stage. Nevertheless, to understand the later neuropsychiatric effects of head injury it is first necessary to know what happens to the brain when it is injured.

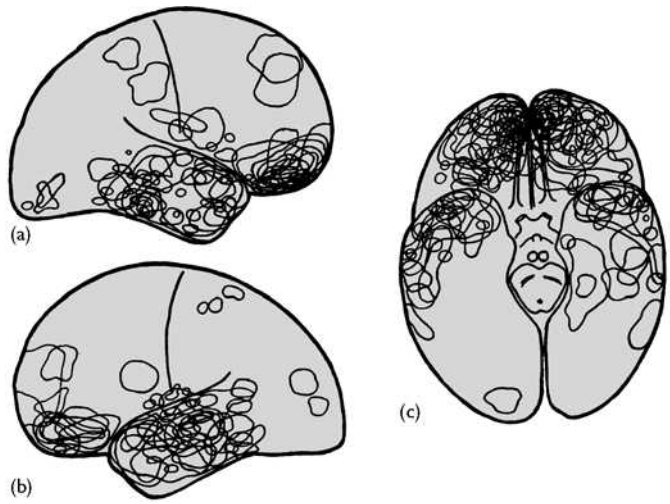

Fig. 4.1.10.1 A composite of the contusions found in 50 cases of people dying from head injury. (Reproduced with permission from Courville, C.B. (1937). *Pathology of the central nervous system*, Part IV. Pacific Press, Mountain View, CA)

Neuropathology

Open head injuries

In open head injuries there is penetration of the skull often with considerable destruction of brain tissue local to the trauma, but relatively less at a distance—particularly for lower velocity injuries such as stabbing. Open head injuries may therefore be associated with little, if any, loss of consciousness, which is generally a marker of diffuse brain injury.

Closed head injuries

(a) Contusions

In closed head injuries acceleration/deceleration forces and shearing forces damage the brain. The soft brain moves within its hard bony box and is damaged. Contusion of the brain occurs, ranging from slight localized small vessel bleeding into surrounding tissue to almost complete local destruction of the brain.

The medial orbital frontal cortex and the tips and undersurface of the temporal lobes are particularly vulnerable to contusions (Fig. 4.1.10.1). The brain becomes traumatized on adjacent bone of the floor of the skull. Contrecoup localization of contusions is sometimes evident.

(b) Intracerebral haemorrhage

Localized haemorrhage into the brain occurs at the site of a contusion. Scattered intracerebral haemorrhages found at the interface between grey and white matter are thought to be associated with diffuse axonal injury (see below). A large isolated haematoma suggests that a blood vessel has ruptured.

In very severe injury haemorrhages are also found round the aqueduct in the brainstem, perhaps caused by distortion of the brainstem as a result of cerebral herniation into the posterior fossa due to raised intracranial pressure. They are associated with prolonged coma or death.

(c) Extradural and subdural haemorrhage

Haemorrhage into the extradural or subdural space will act as a space-occupying lesion and contribute to raised intracranial pressure. The extradural haemorrhage, being under high pressure, can rapidly cause coma and death. The patient may 'talk and die', regaining consciousness after the head injury, only to lapse a few hours later into severe coma. Without acute neurosurgical intervention to drain the blood these patients will die.

Subdural haematomas tend to run a subacute course and as such are of more interest to the psychiatrist. They may present with a failure to improve, or fluctuating drowsiness, weeks or months after the head injury. They may regress spontaneously or may require surgical drainage, but they do have a propensity to recur.

(d) Diffuse axonal injury

Diffuse axonal injury occurs in the white matter tracts of the cerebral hemispheres, including the corpus callosum, and the brainstem, particularly the cerebellar peduncles. Axons break up over the course of the first 24 to 48 h following brain trauma with the formation of 'retraction balls'-globular structures at the end of transected axons.[4]

(e) Oedema and ischaemia

Oedema of damaged brain occurs over the first few hours following brain injury. The resulting raised intracranial pressure compromises the cerebral circulation and results in ischaemia, which may further contribute to brain injury. Cerebral oedema tends to resolve over the course of a few days or weeks.

(f) Neuronal death

Two fairly distinct processes result in neuronal death from traumatic brain injury.[4] Necrotic cell death occurs when there is massive cell disruption either from the direct effects of the trauma on the cell membrane or from anoxia. It is a relatively passive process though may involve toxic effects of high levels of intracellular calcium, excitatory transmitters, and free radicals. On the other hand apoptotic cell death, 'cell suicide', is a more active process triggered by various routes including ligand binding to cell death receptors. These activate, for example, endonucleases which attack cellular DNA. Markers of apoptotic cell death are elevated in the days and weeks after injury.

(g) Late effects

Ventriculomegaly may develop over the weeks and months following injury. Often it is the result of atrophy of the white matter of the cerebral hemispheres, usually attributed to diffuse axonal injury, and is associated with atrophy of the corpus callosum. More localized atrophy is observed when contusions resolve to leave a loss of brain tissue.

Of greater importance is hydrocephalus resulting from the residual effects of subarachnoid blood interfering with the normal cerebrospinal fluid flow and preventing it from escaping into the venous system. This may require insertion of a ventriculo-peritoneal shunt to prevent deterioration in cognitive function.

Fractures to the floor of the skull, particularly if they are associated with cerebrospinal fluid leaks, may allow infection into the subarachnoid space, causing meningitis sometimes years after injury. Cerebral abscesses may take months before they become clinically evident.

Loss of consciousness following head injury

The mechanism of loss of consciousness after mild blows to the head is poorly understood. Based on animal work some researchers suggest it is produced by activation of cholinergic nuclei in the pons.[5]

Loss of consciousness lasting for more than a few minutes is likely to damage either cortical areas necessary for consciousness or the subcortical arousal systems. Raised intracranial pressure, partly as a result of compromising cerebral circulation, causes coma. Large or multiple haematomas are likely to be associated with a period of coma, particularly if they are associated with cerebral oedema.

Some patients, however, show prolonged coma with little to be found on brain scan apart from some evidence of generalized cerebral oedema. In these patients, diffuse axonal injury may be the cause of their coma, possibly by damaging the white matter tracts that carry arousal signals from the brainstem to the cortex.

Remember that the head injury may have been caused by an accident triggered by a loss of consciousness, for example, due to hypoglycaemia, alcohol intoxication, or an epileptic fit. Systemic effects (e.g. hypoxaemia or fat emboli) may exacerbate unconsciousness due to head trauma, as may drug intoxication.

Head injury severity

It is surprisingly difficult to predict the degree of brain injury from the size of the blow to the head. Some patients after a severe blow to the head sustain little injury to the brain. Others will suffer severe brain injury associated with prolonged unconsciousness, merely as a result of hitting their head on the ground by falling over from the standing position. Perhaps in the very occasional case significant brain injury occurs when there is no, or only momentary, loss of consciousness (see post-concussion syndrome below). The presence of a skull fracture says little about the severity of the brain injury incurred.

There are several clinical indicators of head injury severity (Box 4.1.10.1). Of these the duration of retrograde amnesia is probably the least valuable: it correlates very poorly with head injury severity.

Box 4.1.10.1 Clinical indicators of head injury severity

- The duration of retrograde amnesia—the period leading up to the injury for which memories have been lost. Tends to shrink as the patient recovers.
- The depth of unconsciousness as assessed by the worst score on the Glasgow Coma Scale—a score of 3 indicates absent responses with severe coma, 15 is normal consciousness.
- The duration of coma—this may be difficult to ascertain because of routine sedation and ventilation following severe head injuries.
- Neurological evidence of cerebral injury—abnormality on neuroimaging or EEG.
- The duration of post-traumatic amnesia—interval between injury and the return of normal day-to-day memories.

The duration of post-traumatic amnesia is probably the best marker of outcome,[6] and is particularly useful because it can be assessed retrospectively. Most patients with a post-traumatic amnesia of less than 1 week will be left with little if any disability, while a duration of more than 1 month indicates that there is likely to be enduring and significant disability.

Predictors of a worse outcome after head injury are a previous head injury, older age, *APOE e4* positive status, and alcohol dependence.

There is no universally accepted classification of head injury severity. However, the most widely used grading system is based on the lowest rating of the Glasgow Coma Scale (**GCS**)[7] following injury.

- Mild: GCS score 13 to 15. Likely to be associated with a loss of consciousness of less than 30 min and a post-traumatic amnesia of less than 24 h. There must be clinical evidence of concussion.
- Moderate: GCS score 9 to 12. Likely to be associated with a loss of consciousness of more than a few minutes but less than 6 h and a post-traumatic amnesia of more than 1 day but less than 2 weeks.
- Severe: GCS score 3 to 8. Likely to be associated with a loss of consciousness of more than 6 h or a post-traumatic amnesia of more than 2 weeks.

Epidemiology

On average 200–300/100 000 population attend hospital with a head injury every year.[8] About one-sixth of those attending hospital will be admitted. This reflects the fact that about 80 per cent of head injuries are mild, 10 per cent moderate, and 10 per cent severe.

At greatest risk are 15- to 25-year-olds. The sex ratio is about two to three males to one female. Risk factors include alcohol misuse as well as lower socio-economic class. Road traffic accidents are the largest single cause of head injury in most civilian cohorts, followed by assaults and falls. A significant proportion will sustain their head injury as a result of deliberate self-harm.

The prevalence rate for those experiencing considerable disability as a result of head injury is in the order of 100 per 100 000.

Investigations

Neuroimaging

In the emergency room or on the trauma unit CT brain scanning is generally the preferred investigation, with its faster acquisition time and good visualization of subdural and extradural haematomas.

For later neuropsychiatric assessment magnetic resonance imaging (MRI) is preferred.[9] Cerebral contusions are often found near the bone–brain interface (see above) where the image quality of CT is reduced because of imaging artefacts from the adjacent bone. MRI has no such limitation and generally has better sensitivity and anatomical definition. MRI is able to detect, on T_2-weighted images, changes in signal associated with a diffuse axonal injury when the white matter would have appeared normal on CT brain imaging. Gradient echo MRI sequences should be performed to detect haemosiderin deposits from old small traumatic haemorrhages.

Despite its greater sensitivity a normal MRI does not rule out significant brain injury. On the other hand, particularly in the elderly, MRI may detect abnormalities unrelated to the head injury. It may not be possible to perform an MRI scan if there is magnetic material present in the body (e.g. a pacemaker).

The MRI scan can be normal and yet functional imaging of cerebral metabolism using single-photon emission computed tomography or positron-emission tomography will detect abnormalities. In general, changes on functional imaging correlate better with neuropsychological test performance than do lesions found on structural imaging.[10] However, abnormalities on functional imaging are not necessarily due to brain injury. Hypometabolism may be seen in mental illness without brain injury, for example in depression. Marked hypometabolism on positron-emission tomography imaging has been observed in a man with cognitive impairment occurring immediately after a psychological trauma.[11] He had sustained no head injury.

Electroencephalography

Electroencephalography (EEG) may be useful in the investigation of a deteriorating conscious level or unexpectedly prolonged unconsciousness, and in the investigation of unusual behavioural disturbances that may be attributable to epilepsy. However, EEG is not a good predictor of post-traumatic epilepsy and is generally not useful as a guide to prognosis.

Neuropsychological assessment

A neuropsychological assessment is an invaluable accompaniment to the psychiatric history and examination, and good liaison with the neuropsychologist is essential. Areas of impaired performance can be documented and quantified. This is often useful as a baseline for future assessments and to guide rehabilitation.

The National Adult Reading Test, for people whose first language is English, gives a good estimate of pre-injury IQ.[12] This can then be compared with the present performance on cognitive testing, to estimate the impairment produced by the head injury.

Subtle neuropsychological impairments, which are often not obvious clinically, suggest that the patient may have more problems when they return to work than would otherwise have been expected. On the other hand, if there is clinical evidence of underperformance, and yet standard neuropsychological test results are normal, then it is particularly important that executive function is tested.[13]

Function and health

Psychological symptoms far outstrip neurophysical symptoms (e.g. hemiparesis or dysarthria) as determinants of chronic disability and suffering, both of the patient and their carer, following brain injury.

The ideas encapsulated in the International Classification of Functioning, Disability and Health (ICF) (http://www3.who.int/icf/icftemplate.cfm) are important for understanding recovery from brain injury. ICF is so named because it wishes to emphasize health and functioning by moving away from a dichotomous distinction between those who are healthy and those who are disabled. ICF is a development of the earlier classification ICIDH based on:

- Impairments—abnormalities of structure, or physiological or psychological function.
- Disability—concerned with performance of activities.
- Handicap—reflects limitations fulfilling the person's normal social role and participation in society. It is very responsive to external, e.g. environmental and societal, factors.

In ICF an individual's position on the spectrum between health and disability is considered according to (i) functioning and disability and (ii) contextual factors. ICF details the environmental impacts on functioning, e.g. the consequences of living in an area prone to flooding in somebody who is wheelchair dependent. What a person can do in a standard environment (their capacity) is distinguished from what they actually do in their usual environment (their performance).

Recovery and long-term outcome from head injury

Most recovery takes place in the first year. As a general rule, the milder the head injury the sooner the patient achieves the asymptote of their recovery curve. After a mild head injury most patients will have fully recovered within 6 months. After very severe injury significant further improvements in impairment may be seen after the first year post-injury. Neuropsychological impairments tend to continue improving after neurophysical impairments are static. Nevertheless most of the recovery of cognitive function occurs within the first year.[14] Psychiatric symptoms, with their multifactorial aetiology, generally show no simple pattern of recovery.

Improvement in functioning and participation may continue long after the recovery of the underlying impairment has stopped. These further improvements often reflect improved coping strategies and environmental measures to facilitate independence. This will be the focus of the community rehabilitation team as they attempt to help minimize handicap, for example by improving access to local shops. Memory aids may enable the person to return to work. Continuing improvements in participation in social life and work can take place 5 to 10 years after head injury.[15]

But sometimes early gains are made, for example as a result of being in a return-to-work rehabilitation programme, which are subsequently lost over the longer term. In one study,[16] 25 per cent

had deteriorated at 5 years follow-up, with a similar proportion improving compared with how they were at 6 months. Those who deteriorated were more depressed and anxious, had lower self-esteem and had more problems with alcohol than those who improved.

In the longer term, decades after injury, it has been suggested that the reduced reserve of the injured brain makes it particularly vulnerable to the effects of ageing. Some studies have found an accelerated cognitive decline compared with age matched controls, for example in head-injured soldiers 25 years later.[17] Head injury may be a risk factor for the development of Alzheimer's disease, particularly in men.[18] However the evidence, both for an accelerated cognitive decline and for an increased risk of Alzheimer's disease, is inconsistent.

Aetiology of psychological sequelae

To understand the mental symptoms that follow head injury it is necessary to know about the person who has been injured, what brain injuries they sustained, and the consequences. However, the interaction between these is complex and poorly understood.

Pre-traumatic factors

People who take risks or get into fights are more likely to sustain a head injury; therefore these personality traits, present before injury, are over-represented in head-injury survivors. Young men are at high risk, as are those who have already had a head injury or have cognitive dysfunction.[19]

The poor social adjustment of many patients before the head injury partly explains why so many run into behavioural problems afterwards. But premorbid characteristics do not strongly predict who will develop emotional and behavioural problems. Nevertheless, traumatic brain injury probably has the potential to turn pre-injury personality traits into post-injury personality disorders.

The trauma

The extent of brain injury probably explains less than 10 per cent of the variance in the amount of psychiatric morbidity that follows brain injury.[20] In general, early psychiatric symptoms, within weeks and months of the injury, correlate better with the extent and location of brain injury than do late psychiatric symptoms. Left hemisphere damage seems to be associated with greater psychiatric morbidity. Specific relationships between the location of brain injury and the psychiatric symptoms are discussed below.

But the head injury is also a psychological trauma. Amnesia for the event, as a result of the head injury, protects against post-traumatic stress disorder. However, it is a mistake to believe that amnesia for the event prevents a psychological stress reaction to the event itself.

- The meaning of the event may be distressing to the patient.[21] In the case of assaults, the head injury may signal the potential for further assaults. An accident may have been life-threatening and a shocking reminder to the patient that they are mortal. They may feel aggrieved by an employer's negligent action that caused the accident.
- The patient may be amnesic for the event, lacking explicit memories of what happened, but retain implicit memory of what happened. The consequences of these implicit memories may be akin to that observed in one of Claperède's amnesic patients.[22] The doctor shook the patient's hand, pricking it while doing so with a concealed drawing pin. The next day the patient could not remember having met the doctor, but flinched from shaking his hand when it was offered.
- They may have islets of intact memories that may be extremely frightening.[23]

Post-traumatic factors

Post-traumatic factors deserve special attention because they are most likely to be amenable to intervention. The psychiatrist needs to consider the patient's reaction to any disability, as well as the consequences of the disability on the role of the patient in the family and society. There may be reinforcing cycles of maladaptive behaviour, and compensation claims may complicate the picture.

Cognitive impairment

Cognitive impairment correlates with measures of head injury severity better than any of the other mental sequelae. For example, there is a strong correlation between the duration of post-traumatic amnesia and the severity of cognitive impairment.

Attention and concentration

Non-specific cognitive impairments include slowness and reduced concentration. The severely injured patient is likely to be stimulus bound, i.e. responding to each and every stimulus they are exposed to in a rather concrete way. At the same time they may show perseveration, with previous responses inappropriately interfering with the answers to subsequent questions, or when the topic of a conversation has been changed.

Dysexecutive syndrome

More specific impairments, generally referred to as the dysexecutive syndrome, result from a disturbance of the executive system responsible for organizing, planning, scheduling, prioritizing, and monitoring cognitive activities.[24] In some patients with isolated medial orbito-frontal lesions or dorso-lateral prefrontal lesions, the dysexecutive syndrome may stand alone. Disturbance of the executive system also results in difficulties in attending to two things at once, and distractibility.

Patients with the dysexecutive syndrome may be much more impaired in everyday life than is predicted by their performance on standard neuropsychological tests. They can manage with the clear instructions of the well-structured and constrained test situation. But in the real world these are absent; priorities have to be set, a strategy planned, decisions taken, and the unexpected dealt with, all without guidance. In the real world, impairment of the executive system may be catastrophic. Tests of the dysexecutive syndrome have been developed in order to be better predictors of these real-life problems. [13]

Memory impairment

Memory impairment is perhaps the most common cognitive impairment that follows head injury, and can be very disabling.[25] People will have problems remembering where they put things, what to do next, how to get home from the shops, or what they did

yesterday. Anterograde amnesia refers to these enduring problems laying down new memories, and must be distinguished from retrograde and post-traumatic amnesia (see Box 4.1.10.1).

No consistent pattern of brain injury is associated with anterograde amnesia and it seems likely that it is the combined damage to several areas which causes the amnesia. Frontal injury may be particularly implicated perhaps by interfering with the executive processes required for normal memory, for example in memory retrieval. As with most amnesic states the amnesia following brain injury is for explicit memories, namely those which are consciously remembered. Implicit memory, for example remembering and learning a motor skill, is relatively well preserved.

Anterograde amnesia is often characterized by distortions and inaccurate recall with poor monitoring and insight. Confabulations are often seen.

Communication

Dysphasia is quite common after head injury, and may be rather different from that seen after stroke. The more diffuse and widespread injury of traumatic brain injury results in additional cognitive impairments which colour the picture. Monitoring of language errors is often particularly poor and the patient may demonstrate a jargon aphasia such that they are apparently unaware that their speech is completely incomprehensible. Dysphasia often continues to improve even many years post-injury.[26]

Dysprosody, in which the normal rhythms and intonations of speech are lost, is also seen, more so after right hemisphere damage. This interferes with social communication because the voice sounds flat and fails to convey emotion. Social communication is disrupted for other reasons, for example the patient fails in the turn-taking necessary for normal conversation. Word-finding difficulties are common.

Visuospatial impairments

Visuospatial impairments may contribute to spatial disorientation. Visual agnosia is easy to miss in someone with quite widespread cognitive impairments. Hemi-neglect can be troublesome.

Personality change

Personality change after head injury results in more suffering than any other single sequel.[27,28] In general, personality change goes hand in hand with cognitive impairment. However, a severe personality change is occasionally found in somebody with almost no impairment of cognitive function. Normal test scores for memory and intellect do not rule out brain injury as a cause of personality change after head injury.

Aetiology

It is not easy to predict who will develop a change in personality after head injury. Sometimes a personality trait present before the injury becomes much more troublesome, but often there is no obvious predisposition. The site of the brain injury may play a role.[29] Lesions of the medial and lateral surfaces of the frontal lobe can produce impairments of drive. Whereas orbito-frontal lesions, on the undersurface of the frontal lobe, may cause a more troublesome personality change with impairments in social behaviour.

Post-traumatic factors also need to be considered. Some patients seem to learn maladaptive patterns of behaviour; for example the response of the carers may unwittingly reinforce unwanted behaviours. Chronic mental illness, aggravated by chronic psychosocial stressors, may be manifest as personality change. Dependence on drugs, particularly alcohol, frequently confounds the picture.

Characteristics of the personality change

Changes in personality[27] include apathy and impairment of motivation and ambition. Patients are often described as childish; this covers a range of traits including impulsivity, poor tolerance of frustration, being demanding and self-centred, and generally lacking the ability to take on the adult role in terms of independent decision-making. Patients may be fatuous and facetious. Antisocial behaviours (see below) and disinhibition are severe handicaps that make integration back into the community difficult. Sexual disinhibition of any type is particularly worrisome. A spectrum of severity is seen, ranging from being inappropriately flirtatious through to indiscriminate sexual assaults. Head injury is probably a risk factor for borderline personality disorder.[30]

In acquired antisocial personality disorder the person is often self-centred and relatively oblivious to the needs of others. They are likely to be tactless and, on occasion, offensively rude. Irritability and aggression and impulsive behaviour are seen. They may show a lack of remorse for violent behaviour. These personality traits often are accompanied by the dysexecutive syndrome. Thus not only does the person show disturbed social decision-making, resulting in antisocial behaviours, but also disruption of the planning and organizational skills needed for cognitive tasks. For example, helpful and supportive friends may be alienated in favour of disreputable acquaintances, at the same time as money is impulsively spent and lost, on risky projects without any attempt to weigh up the options.

Effects on family and carers

Families find personality change particularly difficult to cope with.[31] Children may be ignored and the partner's needs, particularly emotional needs, forgotten. The healthy balance of the relationship with the partner may be destroyed, with the head-injured person now unable to take an effective part in the household. The partner becomes a carer and the change in roles may have a serious impact on the sexual relationship. Divorce not infrequently follows. However, parents may find the childish personality of the brain-injured person easier to cope with; they revert to taking on the parental role.

Personality change may deteriorate. Supportive social networks are lost and social isolation and financial problems may contribute to depression or alcohol abuse, which then cause a deterioration in the behavioural problems associated with the personality change. Follow-up studies lend some support to this argument. Some behavioural problems are found to have deteriorated at 5 years after head injury,[32] and family burden increases over this period.

Early mental symptoms following brain injury

On recovery of consciousness many patients after a severe head injury go through a period of delirium with clouding of consciousness. The clouding of consciousness may resolve, leaving a confusional state in clear consciousness with disorientation and thought

disorder consisting of muddled thinking, rambling talk, and perseverations. This state is often dominated by misperceptions and misrecollections as the patient flits from one false observation to another.[33] Fear is common.

Distortions of memory

Confabulations, brief-lived false memories, emerge at about this time. Confabulations occur particularly in association with memory disturbance associated with frontal injury. The patient almost invariably shows poor insight into their memory problems, and is likely to be disorientated.

Occasionally after a severe head injury there are islets of memory in the dense amnesic period immediately around the time of the injury. These may be recollections of something that was consciously experienced at the time. On the other hand, the memories may have been fabricated from information subsequently given to the patient about what happened, or the memories may have no basis in reality and be properly described as a delusional memory.

Alterations of mood and perception

In the early recovery period oneroid states may be seen. The patient may be perplexed. He or she may feel that the trauma never occurred and that the whole event, including being in hospital, is a fabrication. Derealization/depersonalization may be associated with prominent anxiety, with the patient constantly asking for reassurance. Agitation occurs in about 10 per cent of patients with severe brain injury.[34]

Hallucinations, particularly visual, are occasionally observed, whereas illusions of familiarity are quite common after brain injury. The patient may have a sense of *déja vu*, or that he or she has met clinical staff or patients before. Distortions of the sense of familiarity seem to be implicated in many of the delusions observed early after brain injury.

Apathetic states

In many patients the recovery period lacks the positive features described above and is dominated by an apathetic withdrawn state.

Psychosis after brain injury

Early psychotic symptoms

The vast majority of the delusions and hallucinations occurring during the recovery period will themselves remit spontaneously and not relapse. However, it has been shown that, in some patients who have recovered from these early delusions, amylobarbitone can produce a return of symptoms.[35] This suggests that generalized disturbance of brain function plays an important part in the development of early delusions.

(a) Delusional misidentification

Delusional misidentifications of place, persons, objects, and events may be observed early in the course of recovery. Of these the one that is most pathognomonic of brain injury, and which is also associated with other causes of organic mental disorder, is reduplicative paramnesia. The term reduplicative paramnesia covers a range of phenomena which involve duplication of events or places. Pick,[36] who introduced the term, used it to describe a patient who believed she had visited a duplicate hospital.

Delusional disorientation for place may involve the belief that the current location is a duplicate of the true location or in some way displaced, for example that the hospital is in a different country. The patient may have two incompatible attitudes to orientation; this is sometimes referred to as a double orientation. For example, a patient who lives in Edinburgh acknowledges that he is in a hospital in London, but says that his home is just a few yards down the road. A common delusional disorientation is the patient's belief that they are still at work, despite the fact that they remain in hospital recovering from their injuries. Such patients lack insight into their injuries and report, for example, that they have been sent to complete some work assignment and that staff on the ward are colleagues from work.

Whereas isolated delusional misidentifications of place are rare in the absence of manifest organic brain disease, most cases of delusional misidentification of person (e.g. Capgras syndrome) are to be found in schizophrenia. Delusional misidentifications of person may also be observed following brain injury, often alongside a reduplicative paramnesia (see also Chapter 4.4).

Delusional misidentification syndromes can best be understood as the result of an interaction between organic brain disease and psychological disorder.[37] Lesions of the right hemisphere, often in combination with frontal injury or more diffuse evidence of brain disease, are particularly associated with delusional misidentification.

Late psychosis

(a) Schizophrenia-like psychosis

A psychotic illness may develop long after the acute confusional state has resolved. The patient may develop a typical schizophrenia indistinguishable from idiopathic schizophrenia. Would he or she have developed schizophrenia regardless of having had a head injury?

Davison and Bagley, almost 40 years ago,[38] estimated that patients after a head injury had a two- to three-fold increased risk of developing a schizophrenia-like psychosis compared with the general population. But there were large variations in the different studies they examined, and most were cohorts of war veterans who will have suffered open head injuries.

Any apparent association between head injury and schizophrenia might be explained by the fact that the period from late teens to early 20s is both the period of greatest risk of head injuries and the time when schizophrenia tends to start. In addition people at risk of schizophrenia may also be at increased risk of suffering a head injury ('reverse causality'[39]). Two large studies from Denmark[40] and Sweden,[41] based on linkage of nation wide hospital case registers, have shown that there appears to be no elevated risk of being admitted to hospital with a diagnosis of schizophrenia in those who have previously suffered a head injury. However, the second study did suggest that other non-affective psychoses, not diagnosed as schizophrenia, might be more common after a head injury. This fits with clinical experience; the patients whose psychosis seems most convincingly related to their head injury are those with more severe injuries. They would be diagnosed as suffering an organic psychosis, not schizophrenia.

(b) Paranoid psychosis

Paranoid psychoses may emerge after brain injury. Not infrequently this occurs relatively early and in a patient with severe cognitive impairment and personality change. Memory impairment will facilitate the development of persecutory ideas; for example, the

patient believes that belongings have been stolen. Persecutory ideas or delusions of reference are a fairly common cause of aggression and may be hidden by communication difficulties.

Mood disorders, including anxiety disorders

Depression

The study of depression after head injury raises two fundamental questions about the nosological status of depression.[42] First, with a severe disability should the belief that life is not worth living be regarded as a symptom of depression or a 'rational' reaction to an intolerable predicament? Second, what is one to make of symptoms of apathy or anhedonia when the brain pathways involved in generating spontaneous behaviour or the experience of pleasure have been damaged? Most of the biological symptoms of depression can be produced by brain injury.

The diagnosis of depression therefore relies heavily on identifying a depressive mood. Symptoms like self-deprecation or guilt are also particularly helpful in diagnosis. Estimates of the prevalence of depression after head injury vary, partly because of the lack of uniformity in defining depression. Perhaps 25 per cent of patients meet DSM-IIIR criteria for major depression 1 month after injury.[43] A similar rate of depression at 1 year is described in several studies, though perhaps the more conservative figure of 14 per cent[44] is more realistic. Over the first year many who are initially depressed recover, to be replaced by those previously not depressed who become depressed.

Aetiological factors include a personal history of depression, which is twice as common in those who become depressed, and lack of social support. Depression after head injury interferes with rehabilitation, and is associated with aggression. It may exacerbate cognitive impairment and in some cases produce a pseudodementia.

Emotional lability may occur, particularly after severe head injury, and is frequently associated with the presence of depression.

Mania

Manic illness after head injury is much less common than depression. It needs to be distinguished from the neurobehavioural symptoms of, for example, disinhibition and fatuous behaviour that may follow frontal injury. Mania is particularly associated with aggressive and assaultative behaviour following brain injury.

Anxiety disorder

Symptoms of anxiety are common after head injury,[45] particularly in those who have suffered mild injury. Generalized anxiety disorder occurs in perhaps 10–15 per cent of cases.[46]

Early symptoms may be observed in relation to derealization/depersonalization symptoms, or perplexity. Early on, the amnesic period surrounding the injury may cause great distress. In the catastrophic reaction, which is observed in patients with moderate to severe cognitive impairment, sudden distress occurs when they fail to perform a task, or because of their inability to communicate.

Anxiety symptoms, particularly in those with a mild head injury, may develop over the weeks and months following a head injury. It is then more likely to be associated with depression, post-concussion syndrome, and with post-traumatic stress disorder. Phobic avoidance is seen, for example when there is travel anxiety following a road traffic accident. Apprehension is a common complaint, perhaps reflecting problems caused by cognitive impairments, and the person may be indecisive. Therefore anxiety symptoms may emerge on return to work. Anxiety symptoms will be inflated in the presence of financial or family stress.

Obsessive–compulsive disorder is recognized sequelae of head injury. This may partly reflect the inflexibility and rigidity of the brain-injured person, or a response to doubt resulting from memory disorder.

Suicide

The risk of suicide is increased following head injury occurring in about 1 per cent of cases over the first 15 years or so after injury.[47] This represents about a three-fold increase in suicide rate compared with the age matched population rates. There is no evidence of a specific at risk period. At least some of the increased risk is probably because those at increased risk of head injury also have a greater risk of suicide. Rates of attempted suicide are increased after head injury.

Agitation and aggression

The psychiatrist is more likely to be asked to advise about the management of agitation and aggression following head injury than any other mental symptom.

Agitation in the early recovery period after severe brain injury will generally spontaneously improve over the course of days or weeks.[34] Early agitation may be followed by more intractable aggressive behaviour.[48] A major predictor of aggression is antisocial behaviour before the head injury.

If the aggressive behaviour emerges early, namely during the confusional state or shortly after it resolves, then this suggest that the aetiology is largely organic. A pattern of aggression that is highly stereotyped, or erupts over seconds with no or trivial triggers, or is bizarre, and is against a background of calm behaviour, suggests the possibility of epilepsy.

Other causes need to be considered. It is important to rule out any medical or surgical complications of the head injury, for example a subdural haematoma. Likewise pain and sources of infection, for example a UTI. The patient's worries and fears need to be explored, and phobic anxiety disorder considered. Drugs may make agitation worse and paradoxical effects of sedative medication occur if the medication increases confusion or disinhibition, or results in akathisia. The patient may be in a withdrawal state having stopped a drug they were taking regularly before the head injury. Drug and alcohol dependence may be especially problematic. Symptoms of mental illness may not be immediately obvious because of communication difficulties. It is therefore necessary to search for evidence of persecutory delusions, mania, depression, and anxiety. Any mental illness should be treated before considering medication specifically to treat agitation (see below).

Alcohol and head injury

Alcohol dependence complicates the management of the head-injured person several-fold. The person may have suffered several previous head injuries, as well as the effects of alcoholic brain damage before the head injury. A blow to the head may result in much greater brain injury for reasons that are poorly understood.[49] Poor physical health is likely to prejudice immediate management after the head injury. Subdural haematomas may be problematic.

Alcohol craving may interfere with medical care and rehabilitation.[50] Social networks are often poor, thus complicating discharge from hospital.

Very occasionally a head injury seems to cure the alcohol dependence. Unfortunately alcohol dependence often gets worse, perhaps because the head injury has weakened impulse control. Indeed some patients develop alcohol dependence when they find that alcohol relieves their anxiety symptoms.

Post-concussion syndrome

The post-concussion syndrome is poorly defined.[51] The term is perhaps most usefully reserved to describe a constellation of symptoms that may result in surprisingly severe disability after mild head injury. These symptoms may be observed after moderate and severe head injuries, in which case they are likely to be in the company of other symptoms more readily understood as resulting from brain injury. There is no consistent relationship between the prevalence of post-concussion symptoms and injury severity.

Phenomenology

Early symptoms tend to have a more neurological flavour and include headache, dizziness, and for example diplopia. Mild head injury fairly consistently results, in the immediate aftermath, in impairment of speed of information processing and concentration. Fatigue is also evident from early on, along with symptoms of noise sensitivity. Anxiety, depression, and irritability are common and may appear after a latent period. The symptoms of post-concussion syndrome overlap with those of post-traumatic stress disorder, and chronic fatigue. Other symptoms occasionally reported include tinnitus, unsteadiness, and muscle pain.

In general after a mild to moderate injury symptoms will have recovered by 2 to 6 months. But a few patients, sometimes after a latent period, develop persistent symptoms that last for years. Psychological factors are likely to be important in such patients, particularly if their injury is mild.

Aetiology

(a) Brain injury

Several observations support the contribution of brain injury, even in those with mild injury. Microscopic lesions in the brain have been described at post-mortem, following mild head injury.[52] Imaging, particularly functional imaging with single-photon emission CT or positron-emission tomography, may show abnormalities. Early after mild head injury there is evidence of cerebral dysfunction. One month after a mild head injury patients undertaking a working memory task showed more widespread activation of cerebral cortex compared to controls, even though their actual performance on the task was normal.[53]

(b) Psychological factors

Psychosocial factors have also been found to play a part in post-concussion syndrome, more so in those with symptoms lasting longer than 1 year. If the accident occurs at work, particularly if the person blames their employer, symptoms are more likely. A meta-analysis of the effects of compensation on symptoms, any symptom, after head injury concluded that, on average, being involved in compensation claims increases symptoms by about 25 per cent.[54] This effect was larger in those with milder injuries.

(c) Model of interaction

Lishman has proposed a model in which early disturbance of brain function after mild head injury results in the early symptoms of post-concussion syndrome.[1] In most patients these gradually resolve and a good recovery is made. However, the post-concussion syndrome may develop if psychological effects interfere with the normal process of recovery. Anxiety is thought to play a large part in impeding recovery; the patient worries about the symptoms and focuses on them. These may be aggravated if the patient is vulnerable to somatization, or there are compensation issues at stake. The symptoms may cause secondary disability provoking yet more anxiety, which will be made worse if there are additional psychosocial stressors. The role of psychological factors is greatest in those with very mild head injuries and very chronic symptoms.

Post-traumatic epilepsy

Early fits, within the first week, are relatively benign, sensitive to prophylactic anti-convulsants, and are only weak predictors of later epilepsy.

Only about 5 per cent of closed head injuries go on to develop late seizures, compared with 30 per cent after an open head injury. The majority of these late seizures start in the few years following injury. By the time 5 to 10 years have elapsed without seizures any subsequent seizure development may be unrelated to the head injury.[55]

The likelihood of developing seizures in patients with a closed head injury is increased by the presence of a depressed skull fracture, intracranial haematoma, and early seizure, as well as by the severity of the injury. Mild head injuries result in only a small increased risk of epilepsy above population norms. The EEG is generally not a good predictor of post-traumatic epilepsy.

Post-traumatic epilepsy increases psychiatric morbidity, particularly mood disorders, and may increase the risk of late dementia.

Prophylactic anti-convulsants have no effect on reducing the incidence of late post-traumatic epilepsy.[56] Carbamazepine, rather than phenytoin, is the drug of choice if an anti-convulsant is needed because it has less effect on cognition.[57] Half of all patients with post-traumatic epilepsy from open head injuries are found to be in remission by 5 to 10 years.

Head injury in children

Children, compared with adults, are more likely to suffer cerebral oedema and early post-traumatic epilepsy. They tend to develop a relatively stereotyped pattern of changes in personality with emotional lability, overactivity, reduced attention span, and irritability with outbursts of temper and rage. Apart from personality changes the commonest psychiatric disorders that follow childhood head injuries are attention-deficit hyperactivity disorder, and obsessive–compulsive disorder.[58] Children who develop attention-deficit hyperactivity disorder after head injury tend to demonstrate less hyperactivity than is seen in the idiopathic form.

It is sometimes said that the greater potential for plasticity which may be present in the younger person's brain, results in a better outcome compared to adults. There is some evidence for this for mild and moderate head injuries. However, children with severe head injuries are likely to be left with persistent cognitive deficits

and behavioural problems. Very young children with severe head injury suffer a double hazard[59] with both loss of acquired skills and interference with further development. This is often complicated by the fact that many of these children will have demonstrated pre-injury behavioural problems. The quality of parenting has a powerful effect on outcome; those with poor parenting are much more likely to develop behavioural problems.[60]

Boxing

In the past, when the average number of career bouts was about 300, 10 to 20 per cent of professional boxers went on to develop a chronic traumatic encephalopathy,[61] the punch-drunk syndrome. However now, with an average boxing career of 13 bouts, cases are much less frequently seen.[62]

Patients with chronic traumatic encephalopathy suffer damage to the extrapyramidal system as well as cerebellar and pyramidal pathways. They are slow and ataxic. Cognitive impairment, in particular memory impairment, is a frequent accompaniment and about 50 per cent have dementia. Upper brainstem lesions may explain the neurological symptoms, while cerebral atrophy, white matter changes, and damage to diencephalic structures may account for cognitive changes. Perforation of the septum pellucidum, which separates the two lateral ventricles, is a characteristic finding. *APOE e4* status increases vulnerability to the punch-drunk syndrome,[63] and this is consistent with the finding that amyloid is often present.

Professional footballers may show evidence of subtle impairments of thinking. This raises the possibility that repeated blows to the head from heading the ball may be sufficient to cause slight brain injury; but a more likely explanation for any injury is head-to-head contact.[64]

Management of early neurobehavioural problems

Interventions aimed at reducing the risk of enduring post-concussional symptoms after milder injuries, using brief educational, and supportive therapy in the early days post-injury, have been shown to be effective.[65]

But there is little evidence to guide the management of behavioural problems and mental symptoms arising in the days and weeks following a more severe brain injury. Such symptoms should be regarded as a flag to indicate the need to check on the progress of recovery. The history needs to be reviewed, paying attention to the period leading up to injury. The patient will need to be examined physically including a thorough neurological examination and checking for fever. It is essential to document the conscious level and orientation. Routine blood tests should be performed, and blood gases and a chest radiograph considered. Medication needs to be scrutinized. A neurological or neurosurgical opinion may be needed with a view to considering neuroimaging or an EEG. A lumbar puncture, for example looking for meningitis, should probably not be done without specialist advice.

Causes of deterioration after head injury are listed in Box 4.1.10.2. Once these have been excluded then the principle of care should be to allow recovery to take place in a safe environment, paying attention to the general principles of the care of the delirious or demented patient as indicated. Explanation to the patient and his or her family as to what is happening, is required.

Box 4.1.10.2 Causes of late deterioration in cognitive function after brain injury

Specific

- Subdural haematoma
- Hydrocephalus
- Epilepsy, particularly complex partial status
- Late intracranial infection, including cerebral abscess

Non-specific

- Systemic illness, including fat emboli and pain
- Drug intoxication
- Severe mental illness, in particular depression
- The patient 'gives up' as he or she gains insight
- Independent dementing process

Management of late mental sequelae

The reader is referred to Chapter 4.1.14 for many of the management principles relevant to patients with severe cognitive impairment after a head injury.

Psychological interventions

(a) Evidence of effectiveness

A small RCT has shown that cognitive behavioural treatment may be useful in those with persistent post-concussion syndrome.[66] Inpatient cognitive rehabilitation is probably needed only in those with more severe injuries.[46] Community therapy can improve handicap.[67] The evidence that behavioural strategies can improve behavioural problems, particularly aggression, in those with brain injury rests very largely on single case studies[68] or case series showing marked improvement in patients with very long-standing symptoms.[69]

(b) Principles of management

The first step, after medical issues have been excluded (Box 4.1.10.2), is to ensure that the patient has received adequate rehabilitation. In those with severe cognitive impairment once the patient is medically stable appropriate inpatient rehabilitation, perhaps on a locked unit, will probably be required. Problems arise if patients have to be sedated to ensure their safety, and the safety of other patients, while they remain inappropriately in an acute hospital bed. Timely access to rehabilitation is likely to reduce the risk of mental sequelae. Not infrequently psychological problems arise if any part of this process has not gone smoothly, or is perceived to have failed. Education, and access to information, is an important part of the care plan. Good advice on strategies for return to work can be invaluable, and some will require formal vocational rehabilitation. A social worker should be asked to undertake a community care assessment, which may identify the need for respite care or modifications to the home.

The management of any mental sequelae rests on a good understanding of the severity of the brain injury in order to estimate the likely contribution of brain damage to the mental sequelae.

A neuropsychological assessment, to determine injury severity and the pattern of impairments, may be needed. The severity of brain injury will suggest whether a particular symptom is mainly due to brain injury or to psychological processes. The degree of cognitive impairment may indicate whether or not the patient is capable of benefiting from certain psychological therapies. Those with less severe impairments should be offered CBT as appropriate, for example to treat travel anxiety or depression. In addition, the individual and their family should have access to support and guidance as they try to adjust to the changes forced on them by the head injury. Sometimes carers or family will need advice on how to manage challenging behaviours, particularly if their responses seem to be reinforcing the behaviour.

Pharmacological management

By and large patients should be given psychotropics only if absolutely necessary,[70] attending to the principles described in Box 4.1.10.3 and avoiding multiple drugs given concurrently. There is an emerging literature on drugs which may enhance cognition.[71]

(a) Agitation and aggression

Evidence—There are no good trials of medication for agitation and aggression after brain injury.[72] Only β-blockers have been exposed to randomized controlled trials. These studies showed a slight effect in favour of medication. But despite this β-blockers are rarely used in the management of agitation and aggression. In the RCTs very large doses of β-blockers were used that will almost inevitably cause worrying side effects in most patients.

Management—Because of the lack of controlled trials, prescribing for agitation and aggression after brain injury is very much trial and error, requiring good monitoring and documentation of the behaviour. If there is no evidence of benefit then the drug should be withdrawn and another drug tried. Be wary of responding to every episode of aggression by increasing the dose or adding a new drug.

For many psychiatrists, based on little more than anecdotal evidence, valproate, or carbamazepine are the drugs of first choice for aggression after brain injury. They have the advantage of anticonvulsant as well as mood-stabilizing effects. Perhaps a third of patients will respond.

Antipsychotics should be used if delusions or persecutory ideas of reference or fear are also present. But akathisia may perpetuate agitated behaviour which would otherwise have resolved spontaneously. Atypical antipsychotics, having less risk of motor side effects, are to be recommended.

Antidepressants may be helpful particularly if symptoms of anxiety or depression are present. Selective serotonin-reuptake inhibitors should be given in preference to tricyclics. Trazodone given at night may be useful if there is sleep disturbance.

Benzodiazepines should be considered for agitation and aggression during the early recovery from severe head injury. But be wary of increasing the confusion, and paradoxical violence due to disinhibition. Because of the potential for addiction, benzodiazepines should not be given to a patient with a chronic aggressive disorder.

Box 4.1.10.3 Prescribing psychotropics in brain injury

No knee jerk reaction—if possible wait to see if the problem goes away spontaneously
Small doses—start low, go slow
Only continue treatment if good evidence of effect
Drug profile—choose drugs with less potential for:

- Lowering seizure threshold—avoid clozapine
- Anticholinergic activity—to minimize potential for increasing confusion
- Extrapyramidal side-effects—especially akathisia, parkinsonism, and neuroleptic malignant syndrome
- Enzyme induction or other pharmacodynamic interaction with other drugs

Regular medication with long-acting anxiolytics, compared with short-acting drugs as required, is less likely to produce:

- Withdrawal syndrome
- Development of addiction
- Reinforcement of unwanted behaviour but may produce raised blood concentrations

(b) Mood disorders and psychosis

Evidence—Good studies evaluating the efficacy of medication for depression or psychosis after head injury are lacking.[71]

Management—Depression after a head injury is probably more difficult to treat than in those without brain injury.[73] However, some studies in head-injured depressed patients have found good response rates. The selection of an antidepressant is no different from that used to treat depression in the absence of brain injury, provided that the principles given in Box 4.1.10.3 are taken into account.

Confabulations and delusions early after brain injury should be allowed to resolve spontaneously where possible. For established psychotic symptoms atypical antipsychotics are probably to be recommended.

(c) Apathy

Bromocriptine and methylphenidate may be useful for treating apathetic states but controlled trials are lacking. Methylphenidate, with its risk of addiction and troublesome side effects, should only be prescribed if bromocriptine has not been successful, and under consultant supervision.

(d) Drugs which enhance memory and concentration

Evidence—Preliminary evidence supports the use of methylphenidate for deficits in attention and speed of information processing,[74] donepezil for attention and memory problems[75] and bromocriptine for executive problems.[76]

Management—There is now a case for considering medication to enhance cognitive function after brain injury. Drugs are available that may result in small improvements in attention, memory, and executive function. However in almost every case the evidence relies heavily on a single fairly small randomized controlled trial. Longer-term adverse consequences are uncertain. These drugs should only be considered:

- for patients with definite moderate to severe brain injury to account for their cognitive complaints,

- after discussion with the patient and their family about the uncertainties of treatment,
- if there is good reason to believe that a small increase in cognitive function can result in significant improvement in handicap,
- with close monitoring of response and side effects.

Insight, capacity, and detention in hospital

Insight and capacity to consent to treatment should be assessed in all patients. Lack of awareness of deficits is a common problem for the head-injured person[77] and affects compliance with, and capacity to consent to treatment. The Mental Capacity Act, 2005 (http://www.opsi.gov.uk/acts/acts2005/20050009.htm or http://www.dca.gov.uk/menincap/legis.htm) governs decision-making on behalf of adults in England and Wales who lack capacity to consent to treatment and manage their affairs. In these patients if there is no family or friend to act on their behalf, an independent advocate may be needed. The clinical team will need to ensure that all reasonable measures have been taken to enable the patient to take part in any decision-making. Any decision to act in the patient's 'best interests' should take into account what is known about their previous views and opinions. Very occasionally advance decisions may be in place which dictate how the patient wishes to be treated.

The psychiatrist may be called when the patient demands to leave hospital against medical advice. Only the very exceptional patient who is demanding to leave hospital following a head injury, and who as a result would be putting his or her health severely at risk, will be found to be competent. If they are not, it may be necessary to consider detention under the Mental Health Act, 1983 (England and Wales) or equivalent.

Patients will also need to be assessed to see if they are capable of managing their finances and affairs. If they are not, appropriate legal arrangements should be made; in the United Kingdom a receiver may need to be appointed to protect their interests. The prospect of compensation should be considered and, if appropriate, they should be enabled to pursue a personal injury claim.

4.1.11 Alcohol-related dementia (alcohol-induced dementia; alcohol-related brain damage)

Jane Marshall

Introduction

Long-term heavy alcohol consumption causes significant brain abnormalities and impairs cognitive functioning. A number of terms have been used to describe these effects, including: 'alcohol-related dementia', 'alcohol-induced dementia', and 'alcoholic dementia'.[1] The more pragmatic umbrella term 'alcohol-related brain damage' (ARBD) is also used. The literature is beset with limitations, in particular the lack of a diagnostic gold standard, and the difficulty in making a clinical diagnosis. Many individuals labelled as having an alcohol-related dementia are, in fact, suffering from the Wernicke–Korsakoff syndrome (WKS).[2] (This is a specific neuropathological disease caused by thiamine deficiency, which can occur secondary to alcohol misuse. It is considered in Chapter 4.1.12.) When considering the topic of 'alcohol-related dementia' it is probably sensible to take a broad clinically-based diagnostic view that includes both WKS and other cases of 'dementia' that appear to be alcohol-related.[3]

Diagnostic criteria

Diagnostic criteria for 'substance-induced persisting dementia' are included in DSM-IV[4] (Table 4.1.11.1), which also states that there must be evidence from the history, physical examination, or laboratory findings that the deficits are aetiologically related to the persisting effects of substance use (in this case alcohol). No specific inclusion criteria are offered to distinguish alcohol-related dementia from other dementias. In ICD-10,[5] the Korsakoff syndrome is listed separately under the amnesic syndrome heading (F10.6) whereas alcohol-induced 'dementia' and 'other persisting cognitive impairment' are included under the 'residual and late-onset psychotic disorder' category (F10.73 and F10.74 respectively), where diagnostic guidelines can be found.

Diagnostic criteria for establishing a diagnosis of 'alcohol-related dementia' have been proposed, conceiving it as a spectrum of alcohol-related intellectual and neurological syndromes, ranging from moderate deficits to the more severe Wernicke–Korsakoff syndrome.[3] 'Alcohol-related dementia' is thus defined as a syndrome that results from several aetiological mechanisms including the direct neurotoxic effects of alcohol, metabolic dysfunction during intoxication and withdrawal, trauma, vascular injury and thiamine or other nutritional deficiencies.

Table 4.1.11.1 DSM-IV diagnostic criteria for substance-induced persisting dementia

A.	The development of multiple cognitive deficits manifested by both (1) memory impairment (impaired ability to learn new information or to recall previously learned information) (2) one (or more) of the following cognitive disturbances: (a) aphasia (language disturbance) (b) apraxia (impaired ability to carry out motor activities despite intact motor function) (c) agnosia (failure to recognize or identify objects despite intact motor sensory function) (d) disturbance in executive functioning (i.e. planning, organization, sequencing, abstracting)
B.	The cognitive deficits in criteria A1 and A2 each cause significant impairment in social or occupational functioning and represent a significant decline from a previous level of functioning.
C.	The deficits do not occur exclusively during the course of a delirium and persist beyond the usual duration of substance intoxication or withdrawal
D.	There is evidence from the history, physical examination, or laboratory findings that the deficits are aetiologically related to the persisting effects of substance use (e.g. a drug of abuse, a medication)

Prevalence

Adequate epidemiological studies to determine the size of the problem have not been carried out. It has been estimated that 'alcohol-related dementia' accounts for 10 per cent of the dementia population.[1] Indeed alcohol misuse may contribute to as many as 21–24 per cent of all cases of cognitive impairment in mid-adulthood.[6] The prevalence is likely to be higher in areas of socio-economic deprivation, with most cases presenting between the ages of 50 and 60 years.[7] Early onset has been associated with poorer prognosis and potential for recovery. Recent evidence suggests that the prevalence of the Wernicke–Korsakoff syndrome, caused by thiamine deficiency, may be increasing.[8,9] Early identification and intervention can help to maximize optimum recovery.

Causal mechanisms

There is no single cause of 'alcohol-related dementia'. Individual susceptibility may be influenced by age; age of onset of drinking and the drinking history; gender; genetic background; family history of alcohol dependence; nutrition; alcohol exposure before birth; and general health status.[10] Causal mechanisms include: the neurotoxic effect of alcohol and its metabolite acetaldehyde; repeated episodes of intoxication and withdrawal; dietary neglect and vitamin deficiencies; repeated episodes of head trauma; cerebrovascular events; and liver damage. In particular, thiamine depletion, and metabolic factors, such as hypoxia, electrolyte imbalance, and hypoglycaemia, all of which result from acute or chronic intoxication and withdrawal, are important and interrelated. It is difficult to determine the relative contributions of these mechanisms. A number of theories have been advanced by Lishman and others to explain the mechanisms by which chronic alcohol use might lead to dementia.[1,6]

- The brain might be vulnerable to both thiamine depletion and alcohol neurotoxicity, the former affecting the basal brain regions and the latter both the basal brain and the frontal cortex.[1] Individual genetic vulnerability is likely to have a role in influencing these processes.
- Wernicke–Korsakoff pathological processes in the basal brain have the potential to damage nearby cholinergic fibres projecting to the cerebral cortex: the so-called cholinergic hypothesis.[1,6]
- Alcohol-induced brain pathology couples with other processes including 'ageing, trauma, vascular changes, and hepatic dysfunction' leading to cognitive decline: the coupling hypothesis.[1,6]
- Ethanol stimulates pituitary corticotrophin leading to elevated corticosteroid levels and possible injury to the hippocampus.
- Recurrent alcohol withdrawal has been hypothesized to have a kindling effect.[11] During alcohol withdrawal there is increased *N*-methyl-d-aspartate (NMDA) function which is postulated to lead to increased neuronal excitability and to glutamate-induced neurotoxicity.[12] The way in which alcohol interferes with glutamatergic neurotransmission, especially through the NMDA receptor, is probably central to an understanding of its long-term effects on the brain.
- Alcohol might lead to an accelerated ageing process.

Areas of the brain affected

There is evidence that the frontal lobes and sub-cortical areas such as the limbic system, the thalamus and the basal forebrain are particularly vulnerable to alcohol-related damage. The cerebellum is also vulnerable. Alcohol-related brain changes in the frontal lobes become more prominent with age.[13] Emotional processing is affected by long-standing heavy alcohol use and dependence, and probably reflects abnormalities in the limbic system and the frontal lobes.[14] This is manifested as difficulty with interpreting non-verbal emotional cues and recognizing facial expressions of emotion.

Alcohol-related brain damage has been studied using a variety of methods, ranging from the neuropathology of the post-mortem alcoholic brain to neuro-imaging techniques focusing on structural, functional and biochemical changes. There is also a considerable neuropsychological literature.

Neuropathology

Early neuropathological studies of the alcoholic brain described fairly uniform cerebral atrophy, mainly over the dorso-lateral frontal regions, widened sulci, a narrowed cortical ribbon, and enlargement particularly of the anterior horns of the lateral ventricles.[1]

The reduction in cerebral volume seen in the alcoholic brain is due mainly to the loss of white matter in the cerebral hemispheres.[15] The reduced white matter is not related to changes in hydration or changes in the chemical structure of the myelin. Selective neuronal loss in the superior frontal cortex was reported in one study[15] but not confirmed in another.[16] However, there is evidence that individual neurones are shrunken in regions where neuronal numbers are normal, such as the superior frontal, cingulate, and motor cortices.[15,16]

Animal research suggests that alcohol has a direct neurotoxic effect on the brain. Chronic ingestion of ethanol by well-nourished rats has been shown to be toxic to cholinergic projection neurones[17] and to reduce the complexity of dendritic arborization in hippocampal pyramidal neurones.[18] In the former study, transplantation of cholinergic neurones into the hippocampus and neocortex corrected the cholinergic deficits and memory abnormalities. In the latter, abstinence led to an increase in dendritic arborization.

Structural neuroimaging

Neuroimaging studies (CT and magnetic resonance imaging (MRI)) have compared recently detoxified alcoholics without obvious cognitive impairment with age-matched controls. CT studies confirmed diffuse atrophy of brain tissue, with the frontal lobes showing most extensive shrinkage.[19] Follow-up studies showed that abstinence was associated with reversibility of brain shrinkage,[19] particularly in younger individuals and in women.[20]

Structural MRI studies have reported reduced volume of both grey and white matter in the cerebral cortex, especially the frontal lobes, which are used for reasoning, judgement, and problem solving,[13] particularly in older age groups. Changes have also been shown in other structures involved in memory, such as the hippocampus (in adolescents and adults), mammillary bodies, thalamus and cerebellar cortex.[21–24] Other abnormalities include thinning of the corpus callosum and reduced volume in the pons.[25] Reduced white-matter volume is also seen in the temporal lobes (in alcohol dependent subjects with seizures) and in the cerebellar

vermis where the loss is associated with deficits in postural stability.[26] More recent MRI studies have not supported the idea of increased vulnerability among women. [27] Abstinence is associated with recovery of tissue volume.

Functional neuroimaging

Functional neuroimaging studies have reported hypometabolism in the frontal and parietal cortices of chronic alcoholics without major neurological impairment, when compared with normal controls.[28–31] These abnormalities improve following abstinence,[31,32] mainly during the 16 to 30 days after the last use of alcohol. Metabolic recovery is most marked in the frontal area.[31]

Proton magnetic resonance spectroscopy can be combined with MRI, allowing ***in vivo*** insight into brain metabolism.[33–35] The metabolic changes observed in the few magnetic resonance spectroscopy studies that have been carried out suggest neuronal loss and compensatory gliosis.

Neuropsychology

Many individuals with a history of chronic excessive alcohol consumption show evidence of moderate impairment in short- and long-term memory, learning, visuoperceptual abstraction, visuospatial organization, the maintenance of cognitive set, and impulse control.[36] This tendency for alcoholics to show proportionally greater visuospatial than language-related impairments suggests that alcohol might have a selective effect on the right hemisphere: the so-called 'right hemisphere hypothesis'.[37] However, right hemisphere functions also decline with ageing and the current view is that the functional lateralities of 'alcoholics' and ageing individuals are similar to normal controls.[37]

Neuropsychological performance improves with abstinence. However, impairments can be detected in apparently healthy, abstinent alcohol dependent individuals[38] and are still detectable even after 5 years of abstinence.[39] Performance on neuropsychological tests has generally been poorly correlated with structural imaging changes,[19,40] particularly with changes in grey-matter volume. However, one MRI study reported significant correlations between cortical (sulcal) and subcortical (ventricular) fluid volumes and some cognitive measures.[22] Another study, using a combination of structural (CT or MRI) and functional imaging (positron emission tomography) together with neuropsychological tests in older alcohol-dependent patients who were abstinent, found a significant correlation between degree of atrophy/metabolic functioning in the cingulate gyrus, and performance on the Wisconsin Card Sort Test.[41]

Neuropsychological test scores do not predict outcome in alcohol-dependent patients.[42, 43]

Management

Difficulties in establishing a diagnosis of alcohol-related dementia/brain damage mean that it remains an 'invisible disability'[7], usually goes unrecognized, and is often masked by other problems such as continuing alcohol consumption and withdrawal, physical ill-health, depression and associated traumatic brain damage.

All dementia work-ups should include a history of past and present alcohol use, confirmed with a collateral history.[6] Appropriate treatment of alcohol withdrawal syndromes, assessment and re-assessment should be carried out over a two-year period. Ongoing assessment and care planning are important as these patients have the capacity to improve with abstinence. The possibility of Wernicke–Korsakoff pathology in cognitively impaired patients with an alcohol use disorder should prompt swift and appropriate treatment with parenteral thiamine.[44] Oral B vitamins should be continued long-term.

The mainstay of long-term treatment in alcohol-related dementia is abstinence. This can be facilitated by a supportive non-drinking social network, and cognitive behavioural methods to teach recognition of factors that predispose to relapse and alternative coping strategies.[6] Families and care-givers facilitate success and must be actively educated and supported. A rehabilitation approach to activities of daily living and occupation is also a key factor.

Patients with alcohol-related dementia are younger and more physically active than the usual dementia population. They do not fit neatly into any category of care and are at risk of falling 'through the net'. Services lack the capacity to manage this population so they are passed between services and find it difficult to access specialist assessment or care.

Conclusions

Alcohol-related dementia should be recognized as a preventable condition. However, identification is hampered by a lack of clarity in terminology, and a lack of standardized and specialized screening instruments and assessment procedures.[45] These individuals make repeated use of Accident and Emergency Departments, general medical, and long stay wards. Early identification would reduce their need for these services. Abstinence is the key to recovery. Treatment services should be integrated and flexible.

4.1.12 Amnesic syndromes

Michael D. Kopelman

Introduction

Amnesic disorders can be broadly classified across two orthogonal dimensions. Along the first dimension, there can be transient or discrete episodes of amnesia as opposed to persistent memory impairment. On the second dimension, memory loss can result from either neurological damage or psychological causation, although admixtures of these factors are, of course, very common. The notion of confabulation has traditionally been associated with amnesic syndromes, particularly the Korsakoff syndrome, although it may have a separate basis, and false memories are now known to arise in a number of different situations. With the advent of drugs purporting to influence memory, there is increasing interest in the psychopharmacology of memory disorders. This chapter will consider findings from investigations of patients with memory disorders and a few selected psychopharmacological studies of relevance. It will not review the extensive literature on functional imaging in normal subjects.

Transient amnesias

Transient global amnesia

Transient global amnesia (TGA) most commonly occurs in the middle-aged or elderly, more frequently in men, and it results in a period of amnesia lasting several hours. It is characterized by repetitive questioning, and there may be some confusion, but patients do not report any loss of personal identity (they know who they are). It is sometimes preceded by headache or nausea, a stressful life event, a medical procedure, or vigorous exercise. Hodges and Ward[1] found that the mean duration of amnesia was 4 h and the maximum was 12 h. In 25 per cent of their sample, there was a past history of migraine, which was considered to have a possible aetiological role. In a further 7 per cent of the sample, the patients subsequently developed unequivocal features of epilepsy (there had been no focal signs or features of epilepsy during the original attack) and the memory loss was therefore attributed, in retrospect, to previously undiagnosed epilepsy. There was no association with either a past history of vascular disease, clinical signs suggestive of vascular pathology, or known risk factors for vascular disease. In particular, there was no association with transient ischaemic attacks. In 60 to 70 per cent of the sample, the underlying aetiology was unclear.

More recently, Quinette *et al.*[2] reviewed the findings in 1353 patients reported in the clinical literature since 1956 and their own data from 142 patients, seen between 1994 and 2004. In general, the findings were consistent across the two sources. There was no sex bias, and the vast majority of attacks occurred between the ages of 50 and 80 (mean = 60.3 ± 9.6). Most patients had a single attack, but the annual rate of recurrence ranged from 2.9 per cent to 26.3 per cent (6.3 per cent in their own study). In the literature, the duration of attacks ranged from 15 min to 24 h and, in their own investigation, the range was 30 min to 16 h (mean = 5.6 h). These authors investigated putative predisposing and precipitating factors in great detail, concluding that TGA may encompass at least three different groups of patients: (i) younger patients with a history of migraine, in whom spreading neurochemical depression may be implicated, (ii) women who have experienced acute emotional or physical stress, and often have a history of anxiety or depression, and (iii) men who, following physical exertion, develop venous congestion in the context of insufficient jugular vein valves and a precipitating Valsalva manoeuvre.

In instances of TGA where neuropsychological tests have been administered to patients during the acute episode of memory loss,[1,3] the patients show a profound anterograde amnesia, as expected, on tests of both verbal and non-verbal memory. However, performance on tests of retrograde memory is variable. Follow-up studies show either complete or almost complete recovery of memories, several weeks to months after the acute attack. In general, retrograde amnesia recovers before anterograde amnesia; the degree of shrinkage of retrograde amnesia is heterogeneous; and anterograde memory (new learning) recovers gradually.

The general consensus is that the amnesic disorder results from transient dysfunction in limbic-hippocampal circuits, crucial to memory formation. Medial temporal abnormalities have been reported bilaterally in terms of single-photon emission CT (SPECT) measures of perfusion, positron emission tomography (PET) measures of metabolism, diffusion weighted imaging (DWI), and small hippocampal cavities on T2 reversed magnetic resonance imaging (MRI) images.[4,5] In addition, venous duplex sonography has shown jugular vein valve insufficiency in a proportion of cases.[5]

Transient epileptic amnesia

This term was coined by Kapur,[6] and it refers to the minority of patients with transient global amnesia in whom epilepsy appears to be the underlying cause of the syndrome.[1] Where epilepsy has not previously been diagnosed, the main predictive factors for an epileptic aetiology are brief episodes of memory loss (an hour or less) with multiple attacks.[1] It is important to note that standard electroencephalography (EEG) and CT findings are often normal. However, an epileptic basis to the disorder may be revealed on sleep EEG recordings.[1,7]

Patients with transient epileptic amnesia may show residual deficits in between their attacks, associated with their underlying neuropathology. Kopelman *et al.*[7] found a moderate degree of residual anterograde memory impairment in their patient, related to subsequent (unpublished) findings of small foci of MRI signal alteration and PET hypometabolism bilaterally in the medial temporal lobes. Several authors have reported patients who describe 'gaps' in past personal memories, and Manes *et al.*[8] have reported disproportionate inter-ictal retrograde amnesia. The latter group also reported abnormal long-term forgetting of verbal material, but whether these gaps in memory result from faulty encoding (because of subclinical ictal activity), impaired consolidation (giving rise to accelerated forgetting), or deficits in retrieval remains controversial.

Epilepsy may, of course, give rise to automatisms or post-ictal confusional states. Where there is an automatism in such circumstances, there is always bilateral involvement of the limbic structures involved in memory formation, including the hippocampal and parahippocampal structures bilaterally as well as the mesial diencephalon. Consequently, amnesia for the period of automatic behaviour is always present and is usually complete.

Head injury

In head injury, it is important to distinguish between a brief period of retrograde amnesia, which may last only a few seconds or minutes but can be weeks or months, a longer period of post-traumatic amnesia, and islands of preserved memory within the amnesic gap.[9] Occasionally post-traumatic amnesia may exist without any retrograde amnesia, although this is more common in cases of penetrating lesions. Sometimes there is a particularly vivid memory for images or sounds occurring immediately before the injury, on regaining consciousness, or during a lucid interval between the injury and the onset of post-traumatic amnesia. These vivid ºmemories may become the intrusive flashbacks of a post-traumatic stress disorder (PTSD) syndrome.

Post-traumatic amnesia (PTA) is generally assumed to reflect the degree of underlying diffuse brain pathology, in particular rotational forces giving rise to axonal tearing and generalized cognitive impairment. The length of PTA is predictive of eventual cognitive outcome, psychiatric outcome, and social outcome.[10] However, the duration of PTA is often not well documented in medical records, and these relationships are often weaker than is generally assumed. In addition, contusion to the frontal and anterior temporal lobes is a common consequence of head injury. The clinical features and underlying pathophysiology of head injury have recently been well described elsewhere.[11]

Post-traumatic amnesia needs to be distinguished from the persisting anterograde memory impairment, which may be detected on clinical assessment or cognitive testing long after the period of PTA has ended. Moreover, forgetfulness is a common complaint within the context of a post-traumatic syndrome, which may include anxiety, irritability, poor concentration, and various somatic complaints. Commonly, these complaints persist long after the settlement of any compensation issues.[11]

Alcoholic blackouts

Alcoholic blackouts are discrete episodes of memory loss for significant events, which should not be confused with withdrawal seizures or other ictal phenomena. Alcoholic blackouts are associated with severe intoxication, usually in the context of a history of prolonged alcohol abuse. Goodwin *et al.*[12] described two types of blackout—the *fragmentary* and the *en bloc*. However, alcohol-induced state-dependent experiences can be viewed as related phenomena, and it has been suggested that the three represent gradations of alcohol-induced memory impairment. In state-dependent effects, subjects when sober cannot remember events or facts from an episode of intoxication, which they recall easily when they again become intoxicated. In fragmentary blackouts, the subjects are aware of their memory loss on being told later of an event; there are islands of preserved memory; and the amnesia tends to recover partially through time by shrinkage of the amnesic gap. In *en bloc* blackouts there is an abrupt beginning and end to the period of memory loss, and the lost memories are very seldom recovered. Blackouts may be more common in binge drinkers, because they are related to a high blood alcohol level. Hypoglycaemia may also be a contributory factor, and blackouts are more common where there is a history of previous head injuries.

After electroconvulsive therapy

This is an iatrogenic form of transient amnesia. Benzodiazepines and anticholinergic agents can also give rise to transient memory loss in more moderate form.[13]

Subjects tested within a few hours of electroconvulsive therapy (ECT) show a retrograde impairment for information from the preceding 1 to 3 years, a pronounced anterograde memory impairment on both recall and recognition memory tasks, and an accelerated rate of forgetting.[14] When retested approximately 6 to 9 months after completion of a course of ECT, memory generally returns to normal on objective tests. However, complaints of memory impairment can persist, and they may be evident three or more years after a course of ECT has been completed.[15] It seems that patients with persistent complaints of memory loss tend to be those who have recovered least well from their depression,[14,15] although their complaints tend to focus upon the period for which there was an initial retrograde and anterograde amnesia. A recent American study suggested that sine wave stimulation induces cognitive slowing in terms of reaction time, and that multiple bilateral ECT administrations can produce impairments in autobiographical memory retrieval 6 months following treatment.[16]

Verbal memory appears to be particularly sensitive to disruption. Unilateral electroconvulsive therapy to the non-dominant hemisphere produces considerably less memory impairment than bilateral ECT, although it is important to identify the non-dominant hemisphere by a valid procedure. Attempts to minimize memory disruption by either making changes in premedication or the concomitant administration of other substances—such as glycopyrrolate, physostigmine, thyroxine, dexamethasone, or acetylcholine—have produced limited or no benefit.

Post-traumatic stress disorder

This clinically important syndrome is described in Chapter 4.6.2. Post-traumatic stress disorder (PTSD) is characterized by vivid, intrusive thoughts and memories ('flashbacks'), avoidance and anxiety phenomena, and hyper-arousal and hyper-vigilance symptoms. However, there may be instances of brief memory loss, distortions, or even frank confabulations. For example, a victim of the *Herald of Free Enterprise* disaster at Zeebruge described trying to rescue a close friend still on board the ship, when other witnesses reported that the close friend had, in fact, not been seen by the victim from the moment the ship turned over. Cases of PTSD may, of course, be confounded by other factors, such as head injury. Nevertheless, it is of interest that PTSD symptoms can occur even when a subject is completely amnesic for an episode.[17] PTSD victims can show deficits in anterograde memory on formal tasks many years after the original trauma, and there is also evidence that they may show loss of hippocampal volume on magnetic resonance imaging (MRI) brain scan, which has been attributed by some to a surge in glucocorticoid secretion. Brewin[18] has recently reviewed four controversies in autobiographical memory for trauma. He found that qualitative and quantitative differences do exist between trauma and non-trauma memories in PTSD victims, and that memories for trauma can be either better or worse than non-trauma memories. In other words, some incidents may be recalled particularly vividly, and others may be forgotten.

Psychogenic fugue

A fugue state is a syndrome consisting of a sudden loss of all autobiographical memories and knowledge of personal identity, usually associated with a period of wandering, for which there is a subsequent amnesic gap on recovery. Characteristically, fugue states last a few hours or days, up to about 3 weeks. There are also

descriptions in the literature of persisting autobiographical memory loss, in which personal identity has been 're-learned', and these are better known as 'psychogenic focal retrograde amnesia'.[19] However, whenever such complaints persist, the suspicion of simulation must arise. Fugue states differ from transient global amnesia or transient epileptic amnesia in that the subject does not know who he or she is, and repetitive questioning is not a characteristic feature in fugues.

As discussed elsewhere,[20] fugue states are always preceded by a severe precipitating stress. Second, depressed mood is also an extremely common antecedent for a psychogenic fugue state, and may be associated with manifest suicidal ideas just before or following recovery from the fugue. Third, various authors have noted that there is often a past history of a previous transient neurological amnesia, such as epilepsy or head injury. In brief, it appears that patients who have experienced a previous transient organic amnesia, and who become depressed and/or suicidal, are particularly likely to go into a fugue in the face of a severe, precipitating stress. That stress may consist of marital or emotional discord, bereavement, financial problems, a criminal charge, or stress during wartime. Fugues have been described as a 'flight from suicide'. Recent neuro-imaging investigations have examined people purportedly in a fugue state with very inconsistent results, probably because the delay until imaging, the imaging techniques employed, and the clinical situations themselves have varied considerably across studies.

Amnesia for offences

This is a phenomenon commonly brought to the attention of psychiatrists, particularly forensic psychiatrists, although the empirical literature on this disorder is scanty. Amnesia is claimed by 25 to 45 per cent of offenders in cases of homicide, approximately 8 per cent of perpetrators of other violent crimes, and a small percentage of non-violent offenders.[21] It is necessary to exclude underlying neurological or endocrine factors such as an epileptic automatism, post-ictal confusional state, head injury, sleepwalking, or hypoglycaemia. Underlying medical disorder can be grounds for a so-called 'insane' automatism in English law (if the result of an internal brain disease) or a 'sane' automatism (if the consequence of an external agent), but otherwise amnesia per se does not constitute grounds for alleviation of responsibility for an offence.

Amnesia for an offence is most commonly associated with the following:

1 States of either extreme emotional arousal or peri-traumatic dissociation, in which the offence is unpremeditated, and the victim usually a lover, wife, or family member. This is most commonly seen in homicide cases ('crimes of passion').

2 Alcohol intoxication (sometimes in association with other substances), usually involving very high peak levels ('alcoholic blackout'), and often a long history of alcohol abuse. The victim is not necessarily related to the offender, and the offence may vary from criminal damage, through assault, to homicide.

3 Florid psychotic states or depressed mood. Occasionally offenders describe a delusional account of what has happened, quite at odds with what was seen by other observers, and sometimes resulting in confessions to crimes that the person could not actually have committed (a paramnesia or delusional memory). In many other cases, depressed mood is associated with amnesia for an offence, just as it is a common associate of psychogenic fugue.

Pyszora *et al.*[22] examined the psychiatric reports of all offenders given a life sentence in England and Wales in 1994, 29 per cent of whom claimed amnesia. Detailed, follow-up reports at 3 years were also examined, and these suggested that approximately one-third of those who had claimed amnesia at trial reported complete recovery, one-third showed partial recovery, and one-third reported no change in their amnesias. Only about 2 per cent were thought to have been malingering.

Persistent memory disorder

The amnesic syndrome can be defined as follows:

> An abnormal mental state in which memory and learning are affected out of all proportion to other cognitive functions in an otherwise alert and responsive patient.[23]

The Korsakoff syndrome can be defined in the same way but with the addition of the following phrase:

> . . . resulting from nutritional depletion, notably thiamine deficiency.

In fact, Victor *et al.*[23] used the first description as a definition of the Korsakoff syndrome, but it is important to distinguish between amnesic syndromes in general (for which the Victor *et al.* definition suffices) and the particular clinical condition described by Korsakoff,[24] whose cases can all be viewed (with hindsight) as having suffered nutritional depletion, whether of alcoholic or non-alcoholic causation. Various disorders can give rise to an amnesic syndrome.

The Korsakoff syndrome

As mentioned, this is the result of nutritional depletion, namely a thiamine deficiency. Korsakoff[24] described this condition as resulting from alcohol abuse or from a number of other causes, but by far the most common nowadays is alcohol abuse.

(a) Clinical

There are frequent misunderstandings about the nature of this disorder. 'Short-term memory', in the sense that psychologists employ it, is intact but learning over more prolonged periods is severely impaired, and there is usually a retrograde memory loss which characteristically extends back many years or decades.[20] Korsakoff himself noted that his patients 'reason about everything perfectly well, draw correct deductions from given premises, make witty remarks, play chess or a game of cards, in a word comport themselves as mentally sound persons'.[24] However, he also noted repetitive questioning, the extensive nature of the retrograde memory loss, and a particular problem in remembering the temporal sequence of events, associated with severe disorientation in time. As will be discussed below, he gave examples of confabulation reflecting the problem with the temporal sequence memory, such that real memories were jumbled up and retrieved inappropriately, out of temporal context.

Many cases of the Korsakoff syndrome are diagnosed following an acute Wernicke encephalopathy, involving confusion, ataxia, nystagmus, and opthalmoplegia. Usually, not all these features are present, and the opthalmoplegia in particular responds rapidly to treatment with high-dose vitamins. These features are often associated with a peripheral neuropathy. However, the disorder can also

have an insidious onset, and such cases are more likely to come to the attention of psychiatrists; in these cases, there may be either no known history of or only a transient history of Wernicke features. There are also reports that the characteristic Wernicke–Korsakoff neuropathology is found much more commonly at autopsy in alcoholics than the diagnosis is made in life, implying that many cases are being missed.

Victor *et al.*[23] reported that 25 per cent of patients with the Korsakoff syndrome 'recover', 50 per cent show improvement through time, and 25 per cent remain unchanged. Whilst it is unlikely that any established patient shows complete recovery, the present author's experience is that substantial improvement does occur over a matter of years if the patient remains abstinent. It is probably correct to say that 75 per cent of these patients show a variable degree of improvement, whilst 25 per cent show no change.[20]

(b) Pathology

The characteristic neuropathology in what is often known as the Wernicke–Korsakoff syndrome consists of neuronal loss, microhaemorrhages, and gliosis in the paraventricular and periaqueductal grey matter.[23] However, there has been a debate as to which particular lesions are critical for the manifestation of chronic memory disorder. Victor *et al.*[23] pointed out that all 24 of their cases in whom the medial dorsal nucleus of the thalamus was affected had a clinical history of persistent memory impairment (Korsakoff syndrome), whereas five cases in whom this nucleus was unaffected had a history of Wernicke features without any recorded clinical history of subsequent memory disorder. By contrast, the mammillary bodies were implicated in all the Wernicke cases, whether or not there was subsequent memory impairment. However, Mair *et al.*[25] provided a careful pathological and neuropsychological description of two patients with the Korsakoff syndrome, whose autopsies showed lesions in the mammillary bodies, the midline, and anterior portion of the thalamus, but not in the medial dorsal nuclei. Mayes *et al.*[26] obtained very similar findings in two further patients with the Korsakoff syndrome, who had also been very carefully described both neuropsychologically and at autopsy. Harding *et al.*[27] reported that pathology in the anterior principal thalamic nuclei was the critical difference between eight patients who suffered a persistent Korsakoff syndrome, and five others who experienced only a transient Wernicke episode. Taken together, these findings suggest that the mammillary bodies, the mammillothalamic tract, and the anterior thalamus may be more important to memory dysfunction than the medial dorsal nucleus of the thalamus.

There is also evidence of general cortical atrophy particularly involving the frontal lobes in patients with the Korsakoff syndrome, and this is associated with neuropsychological evidence of 'frontal' or 'executive' test dysfunction in these patients.[20]

There have been a number of neuro-imaging studies of the Korsakoff syndrome. CT scan studies indicated a general degree of cortical atrophy, particularly involving the frontal lobes.[28] MRI studies have indicated more specific atrophy in diencephalic structures.[29] PET investigations show variable findings, but hypometabolism has been reported in thalamic, orbito-medial frontal, and retrosplenial regions.[30]

Herpes encephalitis

This can give rise to a particularly severe form of amnesic syndrome.[31] Many cases are said to be primary infections, although others may involve a reactivation of the virus. Characteristically, there is a fairly abrupt onset of acute fever, headache, and nausea. There may be behavioural changes. Seizures can occur. The fully developed clinical picture with neck rigidity, vomiting, and motor and sensory deficits seldom occurs during the first week. Moreover, some cases commence more insidiously with behavioural change or psychiatric phenomena, the confusion and neurological features becoming evident only later. Diagnosis is by the PCR test or a raised titre of antibodies to the virus in the cerebrospinal fluid. A presumptive diagnosis is sometimes made on the basis of the clinical picture as well as severe signal alteration, haemorrhaging, and atrophy in the temporal lobes on MRI brain imaging.

Neuropathological and neuro-imaging studies usually show extensive bilateral temporal lobe damage,[29,32] although occasionally the changes are surprisingly unilateral. There may be frontal changes, often in the orbito-frontal regions, and there may be focal changes elsewhere as well as a variable degree of general cortical atrophy. The medial temporal lobe structures are usually particularly severely affected, including the hippocampi, amygdalae, entorhinal, and perirhinal cortices, and other parahippocampal structures. Encephalitis, like head injury, can also implicate basal forebrain structures which give cholinergic outputs to the hippocampi; this may further exacerbate the damage.

The chronic memory disorder in herpes encephalitis is often very severe,[31] but it shows many resemblances to that seen in the Korsakoff syndrome, consistent with the fact that there are many neural connections between the thalami, mammillary bodies, and the hippocampi. Patients with herpes appear to have better 'insight' into the nature of their disorder, and a 'flatter' temporal gradient to their retrograde memory loss (i.e. less sparing of early memories), and they may have a particularly severe deficit in spatial memory when the right hippocampus is involved.[20] However, the similarities in the episodic memory disorder tend to outweigh the differences.

On the other hand, a more extensive involvement of semantic memory is characteristic in herpes encephalitis, and this results from the widespread involvement of the lateral, inferior, and posterior regions of the temporal lobes. Semantic memory refers to a knowledge of facts, concepts, and language (see Chapter 2.5.3). Left temporal lobe pathology in herpes encephalitis commonly gives rise to an impairment in naming, reading (a so-called 'surface dyslexia'), and other aspects of lexico-semantic memory. Right temporal lobe damage may lead to a particularly severe impairment in face recognition memory or knowledge of people.

Severe hypoxia

Severe hypoxia can give rise to an amnesic syndrome following carbon monoxide poisoning, cardiac and respiratory arrests, or suicide attempts by hanging or poisoning with the exhaust gases from a car. Drug overdoses may precipitate prolonged unconsciousness and cerebral hypoxia, and this quite commonly occurs in heroin abusers. Zola–Morgan *et al.*[33] described a patient with repeated episodes of hypoxia and/or cardiovascular problems who developed a moderately severe anterograde amnesia. At autopsy 6 years later, this patient was shown to have a severe loss of pyramidal cells in the CA1 region of the hippocampi bilaterally, with the rest of the brain appearing relatively normal. Hippocampal atrophy on MRI has found in hypoxic, amnesic patients,[29]

and also thalamic hypometabolism on FDG–PET scanning.[34] In brief, the memory disorder is likely to result from a combination of hippocampal and thalamic changes, related to the many common neural pathways between these two structures. However, Caine and Watson[35] in an important review reported that less than 20 per cent of hypoxic patients described in the literature show either a specific amnesic syndrome (in the absence of other cognitive deficits) or damage solely confined to the hippocampi.

Vascular disorders

Two types of specific vascular lesions can particularly affect memory, as opposed to general cognitive functioning, namely thalamic infarction and subarachnoid haemorrhage. However, memory disorder may be the first manifestation of the vascular form of 'mild cognitive impairment'.

In an elegant CT scan study, von Cramon *et al.*[36] showed that damage to the anterior thalamus was critical in producing an amnesic syndrome. When the pathology was confined to the more posterior regions of the thalamus, memory function was relatively unaffected. The anterior region of the thalamus is variably supplied by the polar or paramedian arteries in different individuals, both of which are, ultimately, branches of the posterior cerebral artery that also supplies the posterior region of the hippocampi. When there is a relatively pure lesion of the anterior thalamus, anterograde amnesia without an extensive retrograde memory loss commonly results. However, cases in whom there is also retrograde memory loss, or even a generalized dementia, have been described following thalamic infarction, and this presumably relates to the extent to which thalamic projections are also implicated in the infarction.

Subarachnoid haemorrhage following rupture of a berry aneurysm can result in memory impairment, whether the anterior cerebral or posterior cerebral circulation from the Circle of Willis is involved. Most commonly described in the neuropsychological literature have been ruptured aneurysms from the anterior communicating arteries, because these affect ventro-medial frontal structures and the basal forebrain. Gade[37] has argued that it is whether or not the septal nuclei of the basal forebrain are implicated in the ischaemia which determines whether a persistent amnesic syndrome occurs in such patients. Others have attributed the florid confabulation, which these patients often exhibit, to concomitant orbito-frontal damage.[38]

Head injury

As discussed above, severe head injury can produce a persistent amnesia which may or may not be associated with generalized cognitive impairment. There may be direct trauma to the frontal and anterior temporal lobes, resulting in contusion and haemorrhaging, contrecoup damage, intracranial haemorrhage, and axonal tearing and gliosis following acceleration-deceleration or rotational forces. Memory function is commonly the last cognitive function to improve following an acute trauma, and patients can show the characteristic features of an amnesic syndrome. The phenomenon of 'isolated retrograde amnesia' has been described: in such cases, it seems likely that a mild head injury has precipitated a more purely psychiatric phenomenon. Traumatic head injury is considered in more detail in Chapter 4.1.10 and by Fleminger.[11]

Other causes of an amnesic syndrome

Deep midline cerebral tumours can give rise to an amnesic syndrome, and this may be exacerbated by surgical or irradiation treatment for pituitary tumours. Other infections, such as tuberculous meningitis or HIV, may, on occasion, give rise to an amnesic syndrome. Mild cognitive impairment and the very early stages of Alzheimer dementia may manifest themselves as a focal amnesic syndrome. Surgical treatment to the temporal lobes for epilepsy can result in profound amnesia, if there is bilateral involvement. There is increasing evidence that focal lesions in the frontal lobes can also produce severe memory impairment on aspects of anterograde and retrograde memory.[20] This can occur even in the absence of basal forebrain involvement, but it probably results from particular aspects of memory being implicated, including planning and organization, source and context monitoring, and particular aspects of retrieval processes.[39]

Neuropsychological aspects

The terms 'short-term' and 'long-term' memory should be abolished from psychiatric discourse, as they cause confusion across disciplines. It is more useful to consider current or recent memory versus remote (or autobiographical) memory. In addition, 'prospective memory' refers to remembering to do something.

Concepts of memory are considered in Chapter 2.5.3. As described in that chapter, a distinction is generally drawn between so-called 'working memory', which holds information for brief periods (a matter of several seconds) and allocates resources, and secondary memory, which holds different types of information on a permanent or semi-permanent basis. Secondary memory, in turn, can be subdivided into an episodic (or 'explicit') component, semantic memory, and implicit memory. Episodic memory refers to incidents or events from a person's past, such that he/she can 'travel back mentally in time'; this is characteristically severely affected in the amnesic syndrome. As mentioned previously, semantic memory refers to knowledge of facts, concepts, and language. The learning of new semantic memories is variably affected in the amnesic syndrome, although there is now some evidence that new facts can be learned even in the presence of severe, bilateral medial temporal lobe damage. Other aspects of semantic memory, including naming, reading, and comprehension, are affected in disorders where there is concomitant widespread temporal lobe pathology, such as herpes encephalitis, Alzheimer dementia, or semantic dementia (a form of frontotemporal dementia). Implicit memory refers to procedural or perceptuomotor skills, and to the facilitation of responses in the absence of explicit memory, known as 'priming'. Both these aspects are characteristically spared in the amnesic syndrome,[40] although the precise extent of sparing does depend on particular features in the experimental design.[41]

Over the years, there has been extensive debate concerning whether the primary deficit in the amnesic syndrome lies in the initial encoding of information, or some kind of physiological 'consolidation' into secondary memory, or accelerated forgetting of that information, or in retrieval processes.[20] There is still very little agreement about this debate, but, if anything, the consensus is that retrieval problems are secondary to initial acquisition and consolidation impairments, at least in anterograde amnesia. Retrieval deficits may be more important where there is an

extensive retrograde memory loss,[20] which might account for why there is generally a poor correlation between scores on anterograde memory measures and retrograde memory measures.

Much recent research has focused on the specific function of the hippocampi, and how there their role is distinct from other structures within the medial temporal lobes, more lateral temporal lobe regions, and the frontal lobes. Suggestions include a particular contribution to the binding of complex associations, relational memory, the binding of the distributed features of an episode into a coherent trace, novel or incremental learning, and a contribution to retrieval processes.[20,42] Aggleton and Brown[43] have suggested that the hippocampi are critical to the recall of contextual richness and detail, involved in 'remembering' or 'recollection', whereas the perirhinal cortex is particularly implicated in the familiarity judgements essential in recognition memory. The frontal lobes are generally thought to contribute to planning and organization in memory, aspects of context and source memory, awareness of memory performance (metamemory), prospective memory, and to particular aspects of retrieval processes.[20,39]

There are also many controversies concerning the nature of the extensive retrograde memory loss found in many of the above disorders. Modern neuropsychological studies have confirmed that this retrograde memory loss can extend back many years or decades, but that it often shows a 'temporal gradient' with relative sparing of early memories. The gradient is characteristically steeper in the amnesic syndrome than in dementing disorders such as Alzheimer dementia or Huntington's disease. Differing patterns of retrograde memory loss can occur; left temporal lobe damage seems to affect memory for facts and for the more linguistic components of remote memory, whereas right temporal lobe damage may affect memory for the incidents in a person's life.[20] One theory of retrograde amnesia and of the temporal gradient is that, as memories become 'consolidated' through time, they become independent of the medial temporal lobes and are relatively protected against brain injury to these structures. A second theory is that, through time, episodic memories adopt a less vivid, more 'semantic' form, and this protects earlier memories from the effects of brain injury. A third theory suggests that the hippocampi are always involved in the retrieval and reactivation of memories, and that every time a memory is retrieved, a new trace is laid down, resulting in 'multiple traces' protecting against the effects of brain injury.[44] These three theories make differing predictions and, at present, the underlying basis of retrograde amnesia remains hugely controversial.

Confabulation disorders

Confabulation can be subdivided into 'spontaneous' confabulation, in which there is a persistent, unprovoked outpouring of erroneous memories, and 'momentary' or 'provoked' confabulation, in which fleeting intrusion errors or distortions are seen in response to a challenge to memory, such as a memory test.[20,45]

Confabulation is widely believed to be particularly associated with the Korsakoff syndrome, but this is incorrect. Spontaneous confabulation arises in confusional states and in frontal lobe disease.[45] The link with frontal lobe pathology, particularly in the ventro-medial region, has been established in many investigations.[20,38] Spontaneous confabulation is often seen in the confusional state of a Wernicke encephalopathy, but it is rare in the more chronic phases of the Korsakoff syndrome. On the other hand, fleeting intrusion errors or distortions ('momentary confabulation') do occur in the chronic phase of a Korsakoff syndrome, when memory is challenged. However, such intrusion errors are also seen in healthy subjects when memory is 'weak' for any reason, such as a prolonged delay until recall.[45] They are also seen in Alzheimer dementia and other clinical amnesic syndromes, and they are certainly not specific to the Korsakoff syndrome.

There has been considerable interest of late in the nature of spontaneous confabulations. Confabulation can extend across episodic, personal semantic, and more general semantic memories.[46] A theory put forward by Korsakoff himself, as well as other authorities,[24] emphasizes problems in the temporal ordering of memories. In a particularly elegant study, Schnider *et al.*[47] found that a group of 'spontaneous confabulators' could be differentiated from other amnesic patients and controls on the basis of their errors on a temporal context memory task, but not on other memory or executive tests. More recently Schnider[48] has interpreted these findings in terms of a failure in 'reality monitoring'. Somewhat similarly, Johnson *et al.*[49] has argued that confabulation may reflect an interaction between a vivid imagination, an inability to retrieve autobiographical memories systematically, and source or context monitoring deficits. By contrast, Gilboa *et al.*[38] found that a failure to make fine-grained distinctions within memory could account for Schnider's observations. They argued that a failure in strategic retrieval and post-retrieval monitoring, related to ventromedial and orbito-frontal pathology, is critical for spontaneous confabulation to arise. Somewhat similar hypotheses have been put forward by Burgess and Shallice[50] It has also been argued that the content of confabulations may be heavily influenced by motivational factors.[51]

The notion of 'confabulation' or 'false memory' has now been extended to a variety of other disorders, including delusional memory, confabulation in schizophrenia, false confessions, apparently false memories for child sexual abuse, pseudologia fantastica, and dissociative identity disorder. Whilst each of these can potentially be accounted for in terms of a general model of memory and executive function, provided that the social context and some notion of 'self' is incorporated, there are likely to be differing mechanisms which give rise to these different types of false memory.[20]

Neurochemistry and neuropharmacology of memory disorders

The Korsakoff syndrome is relatively unusual among memory disorders in that there is a distinct neurochemical pathology with important implications for treatment. Since animal studies in the 1930s and 1940s, and the important observations of De Wardener and Lennox[52] and others in malnourished prisoners of war, it has been known that **thiamine depletion** is the mechanism which gives rise to the acute Wernicke episode, followed by a Korsakoff memory impairment. However, the genetic factor that predisposes a minority of heavy drinkers to develop this syndrome before they develop hepatic or gastrointestinal complications of alcohol abuse remains unclear. Transketolase is the enzyme which requires thiamine pyrophosphate (TPP) as a cofactor. Thiamine depletion affects six neurotransmitter systems (including acetylcholine, glutamate, aspartate, and GABA), either by reduction of TPP-dependant enzyme activity or by direct structural damage. Direct genomic PCR sequences of a high-affinity thiamine transporter gene

(SLC19A2) have identified three genetic variants in the Wernicke–Korsakoff syndrome.[53] Whatever the underlying genetic mechanism, treatment as soon as possible with high doses of parenterally administered multivitamins is essential in patients with the Wernicke–Korsakoff syndrome. The Wernicke features respond well to high-doses of vitamins, and such treatment can prevent the occurrence of a severe, chronic Korsakoff state.[20,23] The small risk of anaphylaxis is completely outweighed by the high risk of severe brain damage and the appreciable risk of litigation if such treatment is not administered.

There has been an extensive literature on the effects of **cholinergic antagonists** (such as scopolamine) upon memory. Kopelman and Corn[54] found a pattern of impairment in anterograde memory that closely resembled that seen in the amnesic syndrome. It has been argued that cholinergic blockade produces an effect upon the 'central executive' component of working memory, but Rusted[55] has concluded that this is not sufficient to account for the drug effect upon memory processes. Although some have argued that the predominant effect of scopolamine is on attention, it has been found that covarying for the sedation or psychomotor effects of the drug did not eliminate the strong drug effects on episodic memory tests.[13,54] The anticholinesterases, donepezil, rivastigmine, and galantamine are now widely used in the management of Alzheimer dementia.

Despite their very different pharmacological actions, the effects of the **benzodiazepines** upon memory and attention are remarkably similar to those of scopolamine. When recall or recognition is tested after a delay, benzodiazepines produce a marked anterograde impairment in explicit or episodic memory, similar to scopolamine.[13] As with scopolamine, however, once learning has been accomplished, the rate of forgetting is normal, and benzodiazepines do not produce any retrograde deficits.[13] Procedural learning tasks after both benzodiazepine and scopolamine administration show similar effects, with learning curves on the active drug generally paralleling those for placebo.[13,54] Benzodiazepine effects can be attenuated by coadministration of the benzodiazepine antagonist, flumazenil.

The effects of **catecholamines** upon memory have been studied for many years, but the general consensus is that they act upon 'tonic attentional processes' rather than directly upon the storage or retrieval of memories. In an elegant study, Cahill *et al.*[56] examined the effects of the β-adrenergic receptor antagonist propranolol on memory for an emotionally arousing story, compared with a carefully matched neutral story. As expected, subjects given a placebo recalled more of the emotional than the neutral story, when tested 1 week later. Subjects given propranolol recalled the neutral story as well as the placebo subjects, but were impaired on the emotional story, whereas stimulation of noradrenaline (with yohimbine) produced some enhancement of the emotional elements, and benzodiazepines impaired memory equally for both the neutral and emotional elements of the story.[13]

Some years ago, there was interest in the **serotonergic system** and alcohol-induced memory impairment. Early reports suggested that zimelidine, a serotonin reuptake inhibitor, reversed the memory impairment in healthy volunteers after the administration of ethanol. Later, it was claimed that fluvoxamine improved memory performance in five patients with the Korsakoff syndrome, and that the improvements correlated significantly with reductions in a cerebrospinal fluid breakdown product. The samples were small, and the benefits were minor. Nevertheless, 3,4-methylenedioxymethamphetamine (ecstasy) has been reported to produce memory impairments either by direct or indirect effects.[57] Some of the apparent cognitive effects of serotonergic agents may be the by-product of their effects on mood.[13]

Of forensic psychiatric importance are agents which produce transient but profound amnesia, and may be implicated in offences such as 'date rape'. These include flunitrazepam (Rohypnol) and gammahydroxybutyrate (GHB), and this topic has recently been reviewed by Curran.[58]

Conclusions

Systematic clinical descriptions of amnesic disorders and their underlying pathology have become more detailed and rigorous over the years. In particular, recent advances in neuro-imaging (structural, metabolic, and activation) have provided the opportunity to relate particular cognitive abnormalities to specific changes in brain function. The use of pharmacological agents, in parallel with such imaging techniques, may promote the development of pharmacological agents more potent than the meagre array that we have at present for the treatment of severe memory disorder.

4.1.13 The management of dementia

John-Paul Taylor and Simon Fleminger

Introduction

The term dementia is used in two different ways. First there are the **dementias**. These are **diseases** that cause progressive and diffuse cerebral damage, of which Alzheimer's disease is the most common. Second, dementia can be used to refer to a **clinical syndrome**. Thus dementia is 'an acquired global impairment of intellect, memory, and personality, but without impairment of consciousness'.[1] For clinicians this is the preferred usage, and the one adopted in this chapter. It demands that the cause of the dementia is explored, and makes no comment on the likely prognosis.

This chapter will focus on the management of dementia regardless of the cause; however given the burden of dementia in older age, the discussion will be invariably, but not exclusively, slanted towards the management of dementia in this age group. Aspects of management specific to individual diseases which produce dementia will be avoided. In addition, a discourse on the management of cognitive and memory problems is excluded as these are described elsewhere (see Chapters 2.5.4 and 6.2.7). Patients who suffer the dementia before 18 years of age will, by and large, not be included; their needs are often best met by services provided for people with intellectual disability.

The newly diagnosed patient with dementia

Given that it is now possible to diagnose dementia early in the course of the disease it is important to consider when and how to disclose the diagnosis. This is often seen by clinicians as a difficult task and one to be avoided until the diagnosis is absolutely certain. Stigma is associated with the diagnosis of dementia; it is perceived as a chronic debilitating illness, with a progressive deterioration in mental faculties that ultimately leads to a loss of self-identity and an unpleasant death. The clinician may believe there is not much to offer until later in disease, and so there is not much point in disclosing the diagnosis at an early stage. Furthermore, they may find it difficult to break 'bad news', particularly when an individual with dementia may not understand or retain information.

Nevertheless, leaving these discussions until the diagnosis is certain may be too late; the patient's ability to take part in decisions about their future treatment, and their family's future, may by then be jeopardized by cognitive decline. Only early in the course of the illness will they be able to make a power of attorney, settle their will, and discuss with their doctors how they wish to be treated once the disease is well advanced.

The way in which the diagnosis is given will affect how patients and their families cope and deal with the diagnosis in long-term. Although there are no specific strategies for disclosure of a dementia diagnosis, techniques developed for breaking bad news in disclosure of cancer diagnosis are probably applicable; for example, the excellent protocol devised by Baile *et al.*[2]

Formal psychotherapy and counselling may help patients and their families come to terms with the diagnosis.[3] Clear simple pamphlets or information sheets should be available so that patients and their families can assimilate the diagnosis and its consequences outside of the interview. Referrals can also be made to dementia support groups and local dementia societies; these can provide psychoeducation, befriending services, and networking groups for patients and their families.

After initial meeting and disclosure, it is important that a follow-up meeting is arranged; this will allow patients and families to take on board the diagnosis and formulate any questions they might have. Detailed management strategies are probably best discussed during follow-up appointments, as patients and their families might be overwhelmed at the initial appointment.

Genetic counselling and testing for dementia

Many patients and their families are concerned about the heritability of the condition and will ask if any genetic tests can be performed. But such a request needs to be considered carefully.

In only about 5–10 per cent of cases is the dementia directly due to a high penetrance genetic mutation (for example, early-onset Alzheimer's, frontotemporal dementia, and dementia associated with Huntington's disease). Low penetrance gene variants, such as the apolipoprotein E (APOE) genotype, while modulating, for example, the risk of development of Alzheimer's dementia, do not adequately predict disease development. Consensus groups have therefore advised against using APOE predictive testing.[4–6]

There are also significant social ramifications of genetic testing for the relatives of patients with dementia; positive tests could have serious implications for employment, family planning, and insurance. Therefore access to appropriate pre-test counselling is important.

Box 4.1.13.1 shows a current modus operandi, based on United Kingdom guidelines produced by the National Institute of Clinical Excellence in dealing with this difficult subject.[4] However, the clinician is advised to keep abreast of current best practice given the likely rapid advances in this area.

The younger patient with dementia

The incidence of dementia under the age of 65 is rare. However dementia in younger people has significant additional consequences. Often the younger person with dementia has dependents and considerable financial commitments. Spouses may have to give up

Box 4.1.13.1 Guidelines for genetic testing for dementia

- People likely to have a genetic cause for their dementia (for example, familial autosomal dominant Alzheimer's disease or frontotemporal dementia, cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy [CADASIL], or Huntington's disease) and their unaffected relatives should be offered referral for genetic counselling and testing.
- All patients referred for testing should have appropriate counselling in helping deal with psychological and social consequences.
- If a specific genetic cause for dementia is not suspected, as is the case in late-onset dementia, genotyping should not be undertaken for clinical purposes.

work to care for their partners and there are very high rates of caregiver burn-out.

Specialist service provision for the younger patient with dementia is often lacking. These patients have different life expectations than their elderly counterparts. Many will be physically fit and often do not fit easily into the service models provided for their elderly counterparts. Specialist multidisciplinary teams allied to traditional dementia services have been advocated[4] although actual implementation is still required.

Driving

Decisions about whether or not a person with dementia should be allowed to drive are often difficult. The patient's right to autonomy needs to be balanced against their social and legal responsibilities. The clinician has a duty to consider the safety of other people on the road, as well as the patient themselves. But there is no clear consensus on the best way of making the decision, although a number of regulatory authorities have issued guidance. As a rule of thumb, patients with moderate or severe dementia should not be driving; patients with mild dementia need a careful assessment.

Advice: Begin with a history from family and relatives; this may need to be done while the patient is not present. Have there been any accidents or near accidents? Do they feel the patient is unsafe and shouldn't be driving? A cognitive assessment (especially of executive and visuospatial function, and psychomotor speed) and physical examination of the patient is of some value although not definitive. The gold standard is a driving assessment on the road; a driving simulator test is an alternative.

Often, as in the United Kingdom, patients are legally obliged to inform their driving licensing authority about their diagnosis. The clinician should advise the patient and their relative of this, and document the discussion. Difficulties arise when a patient who is not fit to drive fails to inform the authority and continues to drive. A written warning to stop driving is often sufficient, particularly if the patient and their relatives are reminded that their car insurance policy is no longer valid. In some cases where the patient presents a real risk the clinician may need to break confidentiality and inform the authorities.

If the patient is deemed fit to continue driving, then they should be advised about risk reduction, for example keep to well-known routes and avoid busy roads, driving in bad weather conditions, or at night. They should be regularly reassessed with regard to their fitness to drive. Often this has to happen in any case because they will only be issued a short-term license (e.g. 1 year).

Behavioural and neuropsychiatric symptoms in dementia

Background

Behavioural and Psychological Symptoms in Dementia (BPSDs) have been defined by the International Psychogeriatric Association (1996) as 'signs and symptoms of disturbed perception, thought content, mood, or behaviour that frequently occur in patients with dementia'.[7]

Identification, assessment, and management of BPSDs are central to good dementia care. These heterogeneous symptoms are highly prevalent in dementia; one study[8] found that 61 per cent of 329 patients with dementia exhibited BPSDs, with the most common symptoms being apathy (27 per cent), depression (24 per cent), and agitation/aggression (24 per cent). The presence of BPSDs is cited by carers and relatives as being the most significant determinant in generating carer stress,[9] carer burden,[10] and increasing the likelihood of subsequent institutionalization.[11]

There appears to be only a weak correlation between the level of cognitive impairment and the occurrence and severity of BPSDs. Stronger associations have been noted between the presence of BPSDs and the degree of impairment in activities of daily living.[12]

A complex interplay of factors can give rise to these symptoms and include intrinsic host attributes and extrinsic environmental influences (Fig. 4.1.13.1). Therefore the same symptom in different individuals may be due to different causes. For example, aggression may be the response to a delusion in one individual, and the reaction to a change in caregiver in another. Often several different problem behaviours are seen in the same patient, such as wandering and sleep disturbance. There may be causal links between different BPSDs, for example the presence of distressing auditory hallucinations and persecutory delusions is strongly associated with consequent aggression.[13] Particular constellations of BPSDs are often associated with specific dementia syndromes (Table 4.1.13.1). BPSDs will change over time; for example aggression and psychosis tend to occur in the early to middle stages of Alzheimer's dementia whereas incontinence is invariably a feature of late disease.

Of all the symptoms that patients with dementia suffer, it is the problems caused by BPSDs that are most likely to trigger a pharmacological intervention or institutionalization. But whether or not a BPSD is reported as being a problem depends heavily on the informant and the situation. For example, night-time wandering may be tolerated by the spouse with the patient in their own home, but not by nursing staff in an acute medical ward.

Assessment

Assessment of a BPSD begins with a carefully taken informant history to assess the nature, history, and severity of the BPSD, and to garner the background medical, psychiatric, and social history. For example, there may be a history of phobic disorder, which is now manifest as agitation, or a lifelong tendency to aggression. Alcohol or other drug abuse must be addressed. The effect of recently prescribed, and recently stopped, medications needs to be

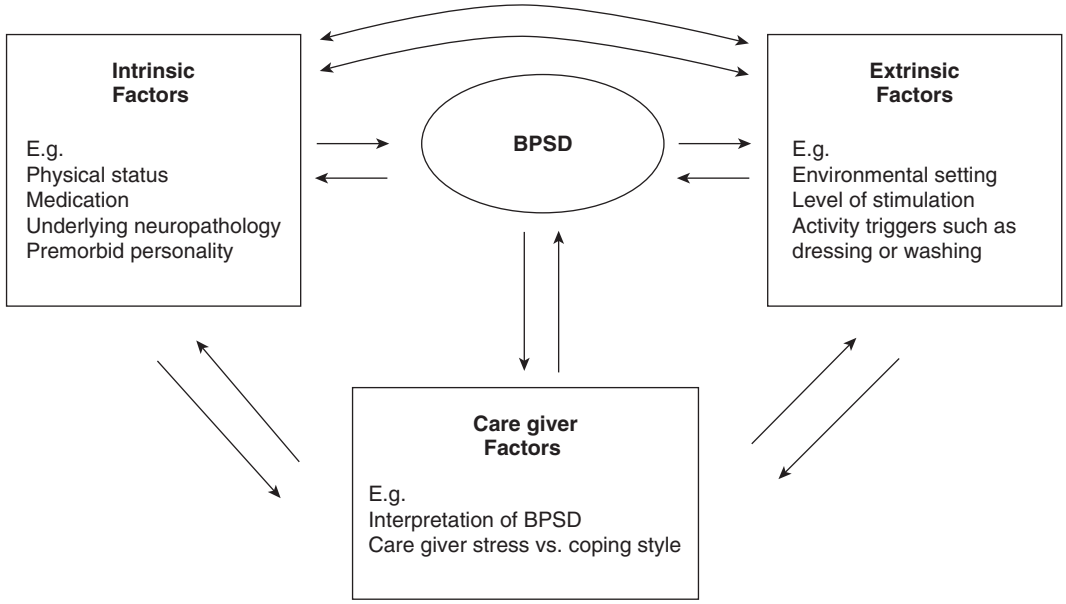

Fig. 4.1.13.1 Interaction between intrinsic host factors, extrinsic factors, and caregiver factors in the aetiology of BPSDs.

considered. The impact of the BPSD on the patient and the carer should be determined. Consider environmental influences; ask when the BPSD first occurred and whether it now occurs at any specific time, and whether it is related to any prior activity or antecedents. This will aid in formulation of specific behavioural management strategies (see below).

The mental state examination will look for evidence of anxiety, depression, or psychosis and persecutory delusions, and ascertain the patient's insight and understanding of their behavioural/neuropsychiatric symptoms. With specific problem behaviours direct observation of the behaviour can be very useful. A thorough physical examination will be needed to exclude physical illnesses; if suspected then appropriate medical investigations should be considered such as a midstream urine sample or chest X-ray. In agitated behaviours, sources of pain and fear should be considered, as well as the possibility of sleep loss or constipation, cold, or hunger. The presence of any sensory deprivation (e.g. hearing loss) should be looked for. Conversely the patient may be over-stimulated, as commonly occurs on general medical or surgical wards because of the noise and hustle and bustle.

Table 4.1.13.1 Common BPSDs in major dementia syndromes

Dementia	Common BPSDs
Alzheimer's dementia	Agitation, apathy, depression, anxiety, delusions
Vascular dementia	Depression, apathy
Dementia with Lewy bodies	Visual hallucinations, delusions, depression
Frontotemporal dementia	Disinhibition, repetitive behaviours, altered eating patterns, apathy

Assessment scales

A range of objective instruments for the measurement of BPSDs now exist.[14] Some measure multiple domains, for example the Behavioural Pathology in Alzheimer's Disease rating scale.[15] Other instruments are specific for one symptom, such as the Cohen–Mansfield Agitation Inventory[16] or Cornell scale for depression in dementia.[17] There are several caveats to the use of such scales, including the large intra-individual variations in scale scores which reflects the dynamic nature of BPSDs and variable reporting patterns of different observers. Some scales take a long time to complete or require training to administer. Nevertheless in clinical practice, the judicious use of such scales can allow for more reliable assessment of the response to a specific behavioural or pharmacological intervention.

Management of agitation and challenging behaviour

Agitation includes behaviour that is aggressive or abusive and occurs at an inappropriate frequency or is socially inappropriate.[18] Challenging behaviour has been used as a 'catch all' for a number of different behaviours including aggression, combativeness and disruptive vocalizations and may or may not be associated with agitation.

(a) Behavioural interventions

Evidence: Research into the effectiveness of behavioural techniques for agitation and challenging behaviour is based largely on studies using A–B–A–B or single-case design, and case series. Recent systematic reviews suggest that individually tailored behavioural interventions are effective.[19–22]

Advice: An intervention programme would start with a situational, or ABC, analysis:

- Antecedents—what was happening before the behaviour started?
- Behaviour—a clear description of the behaviour.

- Consequences—what happened as a result of the behaviour, particularly looking for possible reinforcers of the behaviour?

The frequency and severity of the behaviour then need to be charted as a baseline before introducing the specific intervention. Many programmes rely on the differential reinforcement of other behaviour (**DRO**); this involves positive reinforcement of other, appropriate behaviours, with the hope that these will then replace the challenging behaviour. A useful technique to be used alongside DRO is 'time out on the spot' (**TOOTS**), in which the unwanted behaviour is met with immediate withdrawal of social contact; appropriate behaviours receive warm social contact.

Unfortunately the limiting factor in use of behavioural interventions in dementia is the lack of trained individuals; often behavioural programmes can only be implemented in specialist units. In addition, the whole nursing/multidisciplinary team must be aware of the principles of reinforcement and extinction of behaviour, because behavioural programmes are unlikely to be effective unless consistently applied across the team. Evidence for the effectiveness of educating carers/family members in behaviour management techniques is currently inconclusive.[22] An alternative view which is gaining prominence is that while some challenging behaviours may not be amenable to interventions, it is possible to change the caregiver perception of the problem; this can lead to a reduction in caregiver distress and often by improving an aberrant interaction between caregiver and patient, there is a reduction in the challenging behaviour itself.

(b) Psychosocial and environmental interventions

Evidence: Despite numerous studies there is still a paucity of high quality evidence for the effectiveness of psychosocial and environmental interventions.[19,20,22] Some interventions have shown some promise helping ameliorate aggressive or disruptive behaviours in dementia. A non-exhaustive selection of the major psychosocial interventions that have been used is shown in Table 4.1.13.2.

Advice: The interventions should be tailored to the individual person taking account of their level of function and response to the approach. Psychosocial interventions are best applied when there is no clear cause for the disruptive behaviour; they should be only considered when a thorough assessment of the behaviour has be carried out to exclude treatable causes, for example, pain or psychosis. Even though certain psychosocial approaches may only have modest efficacy in decreasing disruptive behaviour, they may still be useful care adjuncts in improving general patient well-being.

(c) Antipsychotics

Evidence: Short-term treatment with atypical antipsychotics is of benefit in treating aggression, agitation, and psychosis, although the effect size is modest.[4,23,24] With regard to typical antipsychotics, meta-analyses have suggested that haloperidol might improve symptoms of aggression.[25,26] There is no evidence for benefit of longer term treatment (i.e. greater than 3 months).

Adverse effects of antipsychotics may be troublesome, particularly in the elderly; indeed outcomes from the Clinical Antipsychotic Trials of Intervention Effectiveness for Alzheimer's disease suggested that the adverse effects of atypical antipsychotics offset treatment

Table 4.1.13.2 Psychosocial interventions in dementia

Intervention	Description	Evidence for effectiveness
Psychoeducation to staff	Educating staff about dementia, neuropsychiatric symptoms, and reduced use of restraint	Possibly effective—might have sustained benefits
Reminiscence therapy	Uses materials related to patient and their era for example, old photographs and news articles, to stimulate memories and allow sharing of experiences	Possibly effective
Cognitive stimulation	Similar to reality orientation therapy, based on information processing rather than orientation knowledge	Possibly effective—might have sustained benefits
Music therapy	Can consistent of playing music as part of activity sessions or at specific times of the day. Music often of patient's era	Possibly effective—but no evidence of prolonged benefit
Snoezelen/multi-sensory therapy	Combined relaxation and use of sensory stimuli e.g. sounds, lights, touch	Possibly effective—but benefit wears off quickly. Also time/staff intensive
Aromatherapy	Mostly using lemon balm oil and lavender oil either inhaled or applied by massage	Possibly effective for agitation and restlessness
Bright light therapy	Sustained exposure to high levels of light (up to 10 000 lux)	Possibly effective (may be more benefit in sleep disturbance than behavioral disturbance). Time/staff intensive
Pet therapy	Contact with animals	Inconclusive
Exercise	Walking or light exercise sessions	Inconclusive
Simulated presence	Audiotape recorded by caregiver/family member played to patient where positive autobiographical memories are reiterated	Not effective
Reality orientation	Regular provision of orientating information e.g. time, date, etc.	Not effective
Validation therapy	Rogerian-based therapy; allowing resolution of unfinished conflicts, the acceptance of the reality and the expression of feelings	Not effective

advantages in patients with Alzheimer's disease.[24] Antipsychotic use is also an independent risk factor for falls in people with dementia.[27] Confusion may deteriorate, particularly with drugs with anticholinergic effects, and sedation may be problematic. In addition, the risk of emergent extra-pyramidal symptoms appears to be significantly increased with the use of haloperidol and risperidone;[28] these side-effects manifest even at low doses (for example, 1–2 mg of risperidone). Neuroleptic sensitivity is particularly evident in dementia with Lewy bodies; severe neuroleptic reactions can occur in up to 50 per cent of these patients.[29]

There is some evidence for an increased mortality risk for olanzapine and risperidone. There may be an increased risk of cerebrovascular adverse events in people with dementia taking these medications.[30] It is unclear whether this is drug specific or a class effect. Meta-analyses have indicated that there is a 1.5- to 1.7-fold increase in mortality risk for people with Alzheimer's disease treated with atypical neuroleptics. In 2005, the FDA asked the manufacturers of olanzapine, risperidone, aripiprazole, quetiapine, clozapine, and ziprasidone to include warning labels indicating increased risk of death on their products.[31] In the United Kingdom, the Committee for the Safety of Medicines (2004) advised that risperidone and olanzapine should not be used for the treatment of behavioural symptoms of dementia.[30] More recently, Wang *et al.* (2005), reported increased mortality rates in patients over the age of 65 treated with typical neuroleptics compared with atypicals; the risk was greatest shortly after initiation of the treatment and when higher doses were used.[32] Neuroleptic use has also been suggested to hasten cognitive decline although a more recent study refutes this.[33]

Advice: A high level of caution needs to applied to the use of antipsychotics in dementia. A careful weighing of benefits versus the risks is required. General principles for the use of antipsychotics (and other psychotropics) in dementia are similar to psychotropic prescribing for people with head injury (Box 4.1.10.3 in Chapter 4.1.10). Additionally, in dementia:

- Use drugs only if psychosocial or behavioural strategies have failed, and only if absolutely necessary.
- Review prescriptions regularly looking for side-effects. Patients with dementia often have physical co-morbidities and as a consequence take multiple medications; do not allow cocktails to build up.
- Do not prescribe for prolonged periods. Regularly reassess the need for the drug; can alternative interventions be applied now the situation is containable?
- For mild to moderate behavioural disturbances, consider the use of cholinesterase inhibitors or memantine (see below).

(d) Benzodiazepines

Benzodiazepines can be effective in agitation, particularly if it is associated with anxiety, sleep disturbance, or restlessness. However side effects are frequently associated with benzodiazepine use in people with dementia including sedation, worsening of cognitive function, paradoxical increased agitation, and increased risk of falls. The use of benzodiazepines should therefore be judicious and on a needs only basis. Short-acting benzodiazepines, for example oxazepam or lorazepam, are recommended by some, particularly in the elderly, because they are less likely to result in steadily accumulating blood levels.

(e) Mood stabilizers

There is limited evidence that carbamazepine may be beneficial in the treatment of agitation, although there are concerns about its safety in elderly patients given its propensity to induce haematological abnormalities.[23] High dose valproate does appear to reduce agitation, but, again, there is a significant risk of serious side effects.[34]

(f) Cholinesterase inhibitors and memantine

Evidence: In addition to providing benefits for cognition in dementia (see Chapter 6.2.7), cholinesterase inhibitors may help reduce BPSDs in people with dementia (see Ballard and Howard, 2006, for discussion).[28] However in most studies behaviour improvements have been secondary outcomes and a recent multi-centre 12-week trial of donepezil in patients with Alzheimer's disease found that donepezil was no more effective than placebo in treating agitation.[35] One group who do appear to gain clear benefit from cholinesterase inhibitor use is people with Lewy body dementia. Rivastigmine at a dose of up to 12 mg/day for 20 weeks appeared to significantly reduce psychotic symptoms in this group.[36] There is conflicting evidence for the use of memantine for the treatment of behavioural symptoms.

Advice: In terms of prescribing, it is probably worth considering the use of cholinesterase inhibitors and memantine in BPSDs, given their low propensity for serious adverse side effects.

(g) Other agents

Trazodone, a sedative medication, in preliminary findings appeared to be helpful in the treatment of behavioural disturbances. However more recent randomized control trials (RCTs) have refuted the benefits of this medication in dementia.[28]

Citalopram, aside from its antidepressant properties may have some beneficial effects on irritability and restlessness.[37] Propranolol has been considered; however, most trials for its effectiveness are from old, open label trials. If used, blood pressure and the ECG need to be closely monitored.

(h) Wandering

Many people with dementia will wander, and others will abscond or demand to leave. A risk assessment may be needed to determine their safety outside, for example assessing road safety and their ability to find their way back home.

Evidence: The use of two-dimensional grid patterns by the door of the ward, environmental sign-posting, or concealing the exit by use of a mirror may possibly reduce inappropriate exiting behaviour; however the evidence for these strategies is relatively weak.[22] There is probably better evidence for behavioural interventions (see above).[21]

Advice: Number entry locks which the patient with dementia cannot use can be helpful although it may frustrate the patient. The use of identification bracelets or tagging systems which sound an alarm if the patient leaves the unit is controversial and the subject of ethical debate. An inpatient or residential unit will need both an 'absent without leave' policy, which will include the protocol for informing family and police, and a locked door policy which must take into account what happens if there is a fire. Detention under a mental health or mental capacity act may need to be considered.

Mood disturbance

(a) Depression and apathy

Depression in people with dementia is quite common. Therefore it is important to consider depression as a cause for almost any change in function or behaviour, and to look for risk factors for depression, for example a recent bereavement, in the history. A screening test to detect depression may be appropriate (see above). Apathy, another common symptom in dementia, may be both a symptom of depression and a consequence of organic brain disease affecting those brain systems involved in motivation.

If the patient is depressed then review the general medical state, including any drugs that may produce depression. Make sure that all general psychosocial issues have been addressed, for example appropriate support services, leisure activities, and housing. Specific psychological therapy, for instance cognitive therapy, for depression in people with dementia is generally unavailable. However there is some limited evidence that a cognitive behavioural approach may help in treating depressive symptoms in people with dementia and be of benefit to carers.[38]

(i) Evidence for pharmacological treatment

There is some suggestion that antidepressant treatment of depression in patients with dementia is effective, although the evidence is limited.[39] The treatment of apathy in the absence of depression is less clear. The is some evidence that cholinesterase inhibitors improve apathy[40] and case series suggest that bromocriptine and methylphenidate are effective, though clinical experience indicates that the effects may be short-lived.

(ii) Advice on pharmacological treatment

The choice of which antidepressant drug to use will depend heavily on their side-effect profile. Newer antidepressants such as the serotonin reuptake inhibitors, having less anticholinergic activity and less cardiotoxicity, are generally preferred. Some method to evaluate the effectiveness of the treatment needs to be in place, preferably before treatment is started to get a baseline measure. For example, a measure of activities of daily living may be the target outcome to see whether it improves with antidepressant treatment.

Mania

Mania is rare in dementia, though there is possibly a specific association with Huntington's chorea. There is no evidence to suggest that mania treatment in a person with dementia be any different from normal protocols.

Psychotic symptoms

The phenomenology of psychotic symptoms influences treatment choice. For example, the occurrence of auditory hallucinations with secondary persecutory delusions may be more responsive to antipsychotic therapy whereas delusions of theft, founded on memory impairment, may respond better to psychosocial interventions such as strategies to help the person keep tags on where they put things.

Evidence: There are few hard data on which to base decisions about pharmacological treatment for relieving psychotic symptoms in dementia although there is reasonable evidence that cholinesterase inhibitors are successful in treating visual hallucinations in dementia with Lewy bodies.[36]

Advice: The choice of which antipsychotic to use is likely to be determined by its profile of side-effects. The same cautions and advice given for antipsychotic use in agitation in dementia (above) need to be applied for their use in treating psychotic symptoms.

Disorders of sexual behaviour

(a) Impotence or reduced libido

Reduced sexual activity and interest is the most common disorder of sexual behaviour associated with dementia, though it is the least likely to come to the attention of the clinician. It probably plays a part in the high rates of divorce seen, for example, in young couples after one partner has sustained a brain injury. Psychological effects, in particular the change in the patient's role in the partnership as a result of dementia, as well as the physiological effects of brain dysfunction on erectile function, contribute to impotence and reduced libido.

The first and most important step is to recognize the problem and talk about it. The couple may wish to be referred to a sexual disorders clinic. If reduced libido is part of a more generalized apathy or depression then it may respond when these features are appropriately treated (see above). Erectile dysfunction may respond to oral phosphodiesterase inhibitors such sildenafil.

(b) Sexual disinhibition and overactivity

Any display of sexual disinhibition, although uncommon in dementia, is likely to become a major management issue and needs a thorough behaviour assessment. Occasionally it may be part of a Klüver–Bucy-like syndrome with hyperorality and excessive eating.

Sexual disinhibition may respond to behavioural/psychosocial strategies. It may, for example, be necessary to ensure that only men nurse the patient if all the sexual disinhibition is directed towards female staff. A full behavioural programme to try to extinguish the behaviour may be effective, but if the behaviour involves touching and groping then it is essential to discuss and monitor the programme with those involved in the hands-on care of the patient. Staff often find such behaviour particularly upsetting.

Antipsychotics may reduce sexually disinhibited behaviour. The antiandrogens, cyproterone acetate, and medroxyprogesterone (Depo-Provera), may need to be tried if all else fails.

Sleep disturbance

Patients with dementia often have a disturbed sleep pattern and this is most troublesome when the sleep–wake cycle is inverted, with the patient asleep during the day but awake at night.

(a) Assessment

It is worth considering restless legs or rapid eye movement (REM-sleep) behaviour disorder as a cause of sleep disturbance. REM-sleep behaviour disorder, often a feature of dementia with Lewy bodies can be successfully treated with low dose clonazepam. Does the patient have to get up at night to empty his or her bladder because of prostatism or bladder dysfunction? Are there other medical reasons why the patient may be waking at night, for example because of pain from a duodenal ulcer? Sleep apnoea, more common in the elderly, produces sleep disturbance and is a contraindication for benzodiazepines and other drugs that may suppress respiration. Is the sleep disturbance due to depression? Has there

been any recent change to the sleeping arrangements? If so any sleep disturbance may be self-limiting.

(b) Management

Hypnotics are likely to have deleterious effects on cognition and functional abilities, and increase the risk of falls; these drugs should only be considered after techniques to improve sleep hygiene have been tried.

If sleep hygiene techniques fail, there is little definitive evidence to guide the clinician as to which hypnotic to select in patients with dementia. Benzodiazepines should, if possible, not be given indefinitely; particular caution is needed if the patient already shows disinhibition. Trazodone has been tried, particularly if there is co-morbid depression, although the evidence for its efficacy is questionable (see above). It has been suggested that bright light therapy (Table 4.1.13.2) can resynchronize aberrant circadian rhythms, but there is no definite evidence that it is effective.

Incontinence

Dementia in the elderly roughly doubles the risk of urinary incontinence. To minimize incontinence, toilets should be easily identifiable and readily accessible. Clothing may need attention to ensure that it is easy to remove. For urinary incontinence reversible causes, such as urinary tract infection, constipation, and medication (such as diuretics or drugs with anticholinergic side-effects causing urinary retention and overflow) should be excluded.

A diary recording frequency of voiding on the toilet and frequency of incontinence should be kept to see if toileting times can be adjusted to minimize incontinence. Prompted voiding (asking the person hourly if they want to go to the toilet and giving praise for successful toileting) is effective for some individuals. A behavioural programme may be needed for the patient who urinates or defecates in inappropriate places.

If incontinence persists get the advice of a continence advisor before considering drug treatment.

Risk management in dementia

Risk assessment is an important part of the management of patients with dementia and Table 4.1.13.3 suggests various areas of risk that need to be considered. A good history from carers and others involved in the patient's care is essential for a full risk assessment, which is rarely complete without an assessment by an occupational therapist.

It is important to use the outcome of risk assessment to facilitate independence. This is done by introducing appropriate strategies to minimize risk. In addition, a risk–benefit analysis may demonstrate that it is appropriate to run a risk of some adverse event happening if there are clear benefits of doing so. For example, a patient may be at risk of wandering and getting lost from his or her home; however, if the strategy to prevent this involves moving the patient to new accommodation away from family and familiar surroundings, then this may itself be regarded as a sufficiently adverse event to make transfer inappropriate. But before implementing such a strategy discuss it with other clinicians involved in the case, and with the carers, family and, if possible, the patient. Document the outcome of these discussions as well as the rationale for the management plan.

Table 4.1.13.3 Risk assessment in dementia

Consider the following areas:	
Anti-social and other behaviour	
◆ *Violence/aggression*	—towards others —towards self
◆ *Sexual disinhibition/assault*	
◆ *Other antisocial behaviours*	—which may provoke assaults e.g. argumentative, spitting, etc.
◆ *Wandering/agitation*	
Safety associated with impaired memory and cognition and poor judgement	
◆ *Home safety*	—leaving kettles, fires, etc., on. —leaving doors/windows, etc. open —cigarettes
◆ *Out and about*	—getting lost —road safety —pedestrian —driving
◆ *Financial*	—not able to handle money, loses money —inapproriately spends money, poor judgement
◆ *Work*	—fails to monitor and check for errors —unsafe with dangerous machinery
◆ *Supervising others*	—especially children (and consider aggression/sexual behaviour)
Vulnerability to	
◆ *Abuse by others*	—physical, sexual, emotional, and financial
◆ *Self neglect*	—including not eating, squalor
Physical health	
◆ *Falls*	
◆ *Managing their illness*	—e.g. diabetes, diet —taking their medication—note risk of abruptly stopping anticonvulsants, or steroids —drug dependence
◆ *Epilepsy*	

Caregivers

The impact and burden of dementia on family and caregivers is profound. In addition to the burden of caring, caregivers may experience adverse financial consequences, loss of independence, and social isolation. As a result, caregivers often exhibit high levels of psychological and physical morbidity.

The role of caregivers needs be acknowledged in maintaining individuals with dementia in the community. Significant caregiver burden and stress drastically increases the likelihood of care home admission. Therefore support of the caregiver is intrinsic to good dementia care.

Evidence: There have been a large number of studies examining the effectiveness of interventions to support the caregiver. Even though these various studies rarely used the same outcome measures a recent meta-analysis was able to show that caregiver interventions can be beneficial in reducing caregiver psychological morbidity and,

importantly, might also delay nursing home admission.[41] Intensive interventions that focus on psychoeducation, stress management, and include the person with dementia, seem particularly effective.

Advice: Support for the family and carers should consist of several components.[4] Start with education about the cause of the dementia, the possible prognosis, and the symptoms—both current and those that may develop. Family and friends need to understand that cognitive and behavioural symptoms arise from damage to the brain and are part of the illness. Caregivers need advice on the principles of care and skills training, for example ensuring that communication is simple and direct, avoiding changes to routine, not arguing with the patient, but on the other hand not endorsing false beliefs. They will need guidance on when and how to call on professional advice. Caregivers may also need help in obtaining social services input, additional care at home (including cleaning, nursing, and meals-on-wheels), as well as legal and financial advice. Voluntary organizations such as Alzheimer's Society UK (http://www.alzheimers.org.uk) and local self-help groups are often excellent sources of information and support for caregivers.

The burden of caring for someone with a dementia may result in depression and other signs of stress. The carer should have the opportunity of talking about any problems they have, if necessary getting their own psychiatric care.

Caregivers who are under stress are probably more likely to abuse, either physically or emotionally, the person with dementia. Try to ensure that any physical and emotional abuse of the demented person is picked up early. It helps if everybody involved in the person's care knows how to report any concerns they may have about what is happening.

Management of end-stage dementia

Previously, little attention was given to the end stages of the neurodegenerative dementias; most patients would die in hospital or long-term care facilities. However palliative care strategies are increasingly being used in dementia care. These emphasize physical, psychological, social, and spiritual aspects of care, with non-curative interventions aimed at maximizing quality of life. An important principle of treatment in palliative care is proportionality; any treatment should only be implemented if the balance of clinical benefit outweighs the burden such a treatment imposes.

For patients with dementia good palliative care includes management of BPSDs. In addition there are a number of end of life issues relevant to dementia:

Swallowing difficulties and aspiration pneumonia: These are common in end-stage dementia. Ethical consensus has indicated that the use of nasogastric and percutaneous endoscopic gastrostomy (PEG) tubes is seldom warranted in end-stage dementia although there may be individual cases in which the use of feeding tubes is not futile.[42] The use of antibiotics is more controversial. Certainly in other branches of palliative care there is evidence that even in the terminal stages of illness, antibiotics can relieve the distress caused by infected bronchial secretions.

Pain: Patients with dementia are often unable to communicate their distress. Be alert to the possibilities of pain; indeed always consider if a behavioural symptom is manifestation of pain. The management of pain in dementia is similar to pain management in other conditions. The aetiology of the pain should direct the choice of treatment. Adequate doses of analgesics to achieve good pain relief should be prescribed.

4.1.14 Remediation of memory disorders

Jonathan J. Evans

Introduction

Memory problems are a feature of the majority of psychiatric and neurological conditions. Any condition that affects the physical or functional integrity of the brain is likely to have an impact on some aspect of a person's ability to remember, as successful remembering involves many different interacting cognitive systems (see Chapter 2.5.3 on the neuropsychology of memory and Chapter 4.1.12 on the amnesic syndromes). Furthermore, mood disorders such as anxiety or depression, which impair concentration, also reduce the efficiency of memory.

Remembering difficulties disrupt the ability to participate effectively in activities of daily living, as well as social, leisure, and vocational activities. For some, memory problems will be mild and cause only minor inconvenience in everyday life. Others, such as those with the amnesic syndrome that accompanies dysfunction in limbic system structures, may be severely disabled by their memory impairment. People forget to do things (e.g. take medication, turn-off the cooker, pay bills, attend appointments, pass on messages), forget what they have been told, forget people's names, forget where they left things (e.g. keys, the car in the car park), find it difficult to remember routes or learn new procedures, have difficulty recollecting personal experiences, and so on. Such problems lead to frustration, lowered self-confidence, and dependence on others. As such they represent an important therapeutic target.

Assessment of the nature of the memory disorder and the functional consequences for the individual should precede remediation intervention planning. As far as remediation of memory is concerned, although the future in terms of biological treatments is promising,[1] for the present time pharmacological options remain limited (see Chapter 6.2.7). The most effective treatments are cognitive rehabilitation techniques. These include use of memory aids, which function as cognitive prostheses, and methods of learning that promote more effective acquisition of knowledge or skills.

Planning memory remediation—assessment

The World Health Organization International Classification of Functioning, Disability and Health[2] provides a helpful framework for the assessment and remediation of cognitive deficits including memory impairment.[3] ICF, which complements the diagnostic approach of ICD, emphasizes that health (or illness) and functioning can be considered at the level of body structure (pathology), body function (impairment), activities, and participation. Application of this framework in relation to assessment of memory is illustrated in Box 4.1.14.1.

An assessment of memory should therefore address both the impairment *and* the functional consequences for the individual patient. This is important because treatment interventions will differ depending on the form and severity of the memory impairment and the nature of the everyday problems. Such an assessment will of course typically be just one part of a broader assessment of cognition—memory impairment is the focus here, but the same principles apply to all other cognitive impairments.

Box 4.1.14.1 The WHO ICF model and its relationship to assessment of memory

ICF classification	Example in relation to assessment of memory	Approaches to assessment/ investigation
Body structure (*Pathology*)	Loss of cholinergic neurones in basal forebrain region affecting functioning of medial temporal lobe limbic system (Alzheimer's disease)	Physical investigations (e.g. routine medical and brain imaging investigations)
Body function (*Impairment*)	Episodic memory deficit	Standardized neuropsychological assessment tools (e.g. Wechsler Memory Scales III; Rivermead Behavioural Memory Test)
Activities (*Disability*)	Failure to remember to do important tasks, failure to remember events that have happened, or things previously told	Clinical interview with patient and significant other, questionnaires, and observation
Participation (*Handicap*)	Inability to work; increased dependence on others; inability to participate in leisure activities	Clinical interview; quality of life measures

Assessment of memory impairment

Memory impairment is assessed through the use of standardized neuropsychological assessment tools (see Chapter 1.8.3).

Assessment of functional consequences of memory impairment

Activity limitations arising from memory disorders can be assessed through clinical interview with the patient and proxy, but it can also be helpful to use a standardized questionnaire to aid information gathering. Several questionnaires exist for this purpose. The Prospective and Retrospective Memory Questionnaire[4] is one example of a useful, brief questionnaire with self-rating and proxy-rating forms that address both prospective remembering (e.g. Do you fail to do something you were supposed to do a few minutes later even though it's there in front of you, like take a pill or turn off the kettle?) and retrospective remembering (e.g. Do you fail to recall things that have happened to you in the last few days?). This questionnaire also has normative data for self-rating and proxy-ratings.[5,6]

Awareness of the functional consequences of memory impairment may be limited on the part of the patient and the carer (see section on assessment of awareness below). It is possible that functional consequences will also be minimized (again by patient and under some circumstances the carer). In some cases there may be significant impairment of memory and associated limitations of activity, but a spouse/family may take on most or all of the remembering responsibility and hence the significant disability on the part of the patient may not represent a problem for patient or spouse/family. In this circumstance it is important to investigate whether there is adequate awareness of rehabilitation options.

Assessment of use of memory aids and strategies

Pre-morbid and current use of memory aids and strategies should also be discussed as part of the clinical interview. Given that the most effective approaches to memory rehabilitation are those that enable people with memory dysfunction to compensate for their impairment, it is important to understand what past experience of use of memory aids the patient has, and which aids/strategies are used currently. Some people will have made extensive use of memory aids and strategies throughout their life, and continue to do so in response to onset of memory problems. Others may have used aids and strategies in the past, but then do not use them despite the onset of memory problems. Others have little previous experience. Some examples of aids and strategies to investigate, drawn from a survey of use of memory aids by people with memory impairment,[7] are shown in Box 4.1.14.2.

Assessment of awareness of memory deficits

Awareness of impairment should also be examined as this will impact on the approach to remediation that will follow. To what extent is the patient aware of his or her memory (and any other cognitive) problems? Insight and awareness is a complex issue. Clare[8] presents a biopsychosocial model of the construction of awareness in Alzheimer's disease, though the principles of the

Box 4.1.14.2 Assessment of pre-morbid and current use of memory aids and strategies

Use of memory aids and strategies is a central component of memory rehabilitation. Investigation of prior experience, and current use, of aids and strategies is an important part of the assessment process. Below are examples of aids and strategies that are most commonly used by people with memory impairment.[3] This list is not exhaustive and it is important to ask whether any other aids/strategies are used.

- Wall calendar/chart/memo board
- Notebook
- Lists (e.g. things to do/shopping)
- Checklists (e.g. instructions for how to operate washing machine)
- Appointment diary/personal organizer (e.g. Filofax)
- Asking others to remind you to do something or of things that have happened
- Mental retracing (e.g. of steps when lost an object)
- Placing objects in unusual places (e.g. by door if need to take it when leaving or as reminder to do something)
- Leaving notes in special places
- Dosett box or other pill reminder
- Repetitive practice (learning something new by frequent repetition)
- Making associations
- Watch with date/alarm
- Having a daily routine
- Journal (a daily diary record of personal experiences)
- Daily timetable
- Alarm clock/timer
- Mobile phone (e.g. with alarm reminder/GPS navigation function)
- Electronic organizer (Personal Digital Assistant—PDA)
- NeuroPage (paging-based reminding system)

model apply to most neurological and indeed many psychiatric conditions. Another simple model, but one that is useful in clinical practice, is the hierarchical model of Crosson and colleagues[9] which suggests that awareness may be *intellectual*, *emergent*, or *anticipatory*. Intellectual awareness refers to knowing that you have an impairment, but not necessarily recognizing the occurrence of problems as they occur. Emergent awareness refers to 'online' awareness of problems as they occur, whilst anticipatory awareness refers to using knowledge of deficits to anticipate problems and taking steps to prevent problems occurring. This tripartite model of awareness can be helpful in formulating a patient's level of awareness of memory problems. The extent to which the patient's reporting of problems is discrepant from their relative's account (in interview or on questionnaires), or from what might be expected on the basis of standardized test results will give some indication of level of awareness. In addition it is useful to establish the extent to which the patient is aware of the type of memory problems that arise and the extent to which s/he makes attempt to compensate for the problems. Bear in mind that severe memory impairment may itself impact on awareness—patients may have difficulty remembering that, or what, they forget.

Planning memory remediation—treatment approaches

Memory remediation interventions must take account of several factors, including the form and severity of memory impairment, the presence/absence of additional cognitive impairment, and awareness of the deficit. With regard to form of impairment, the major distinction that is drawn is between primary/working memory and secondary/-term memory.

Remediation of primary/working memory

Primary/working memory refers to the process of briefly holding verbal or visuospatial information in mind, and in the case of working memory, manipulating information in the mental workspace. Primary/working memory processes are reflected in tasks such as digit span, with backward digit span seen as taxing working memory. Working memory is considered to be crucial for effective mental control and executive functions such as problem solving. There is some evidence, primarily from studies of patients with a diagnosis of schizophrenia that cognitive training (involving extensive practice on tasks, sometimes computerized, which make demands on working memory) improves working memory performance over and above control conditions.[10,11] Intervention for working memory problems as part of a more comprehensive cognitive remediation programme should therefore be given serious consideration, at least for patients with schizophrenia.[12] Perhaps ironically, given the acknowledgement that cognitive rehabilitation for schizophrenia has its roots in neurorehabilitation for traumatic brain injury,[10] there is a much more limited evidence base relating to the effectiveness of this type of intervention with other neurological conditions.[13]

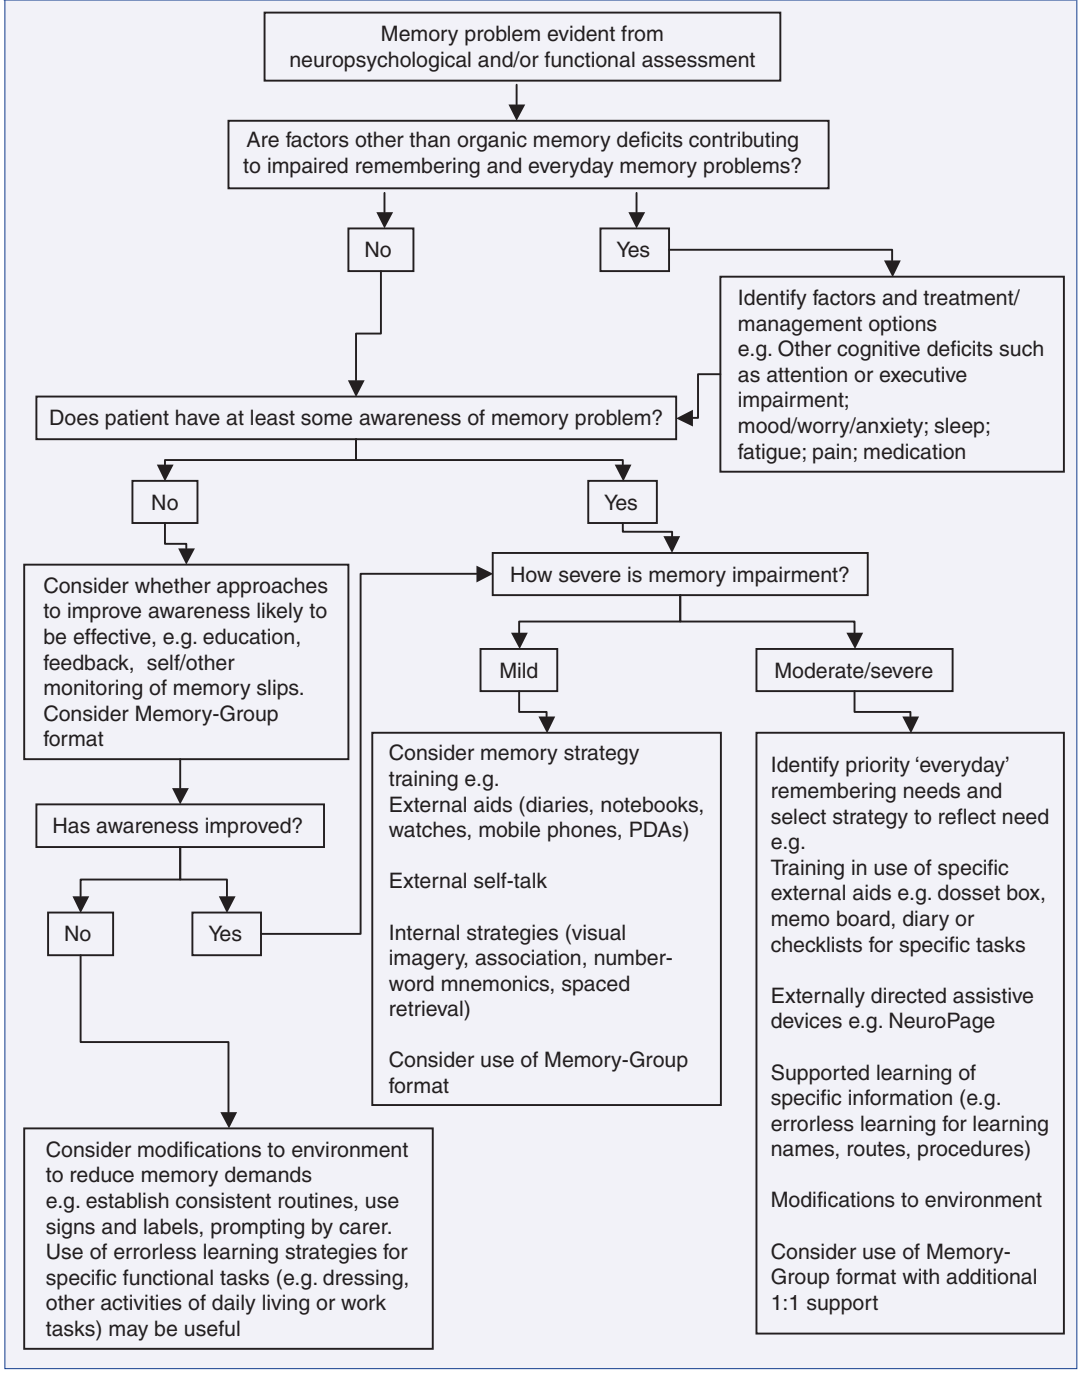
Remediation of secondary/long-term memory problems

Secondary or long-term memory refers to the process of encoding, storage, and retrieval of memories after a delay, where 'delay' means anything from a few minutes to a lifetime. Secondary memory is what is used to recall episodes, to acquire knowledge and to remember to do things. It is secondary memory that is impaired in amnesia. Box 4.1.14.3 provides a decision tree that reflects some of the processes involved in identifying memory remediation interventions.

(a) Are there contributory factors?

As part of the assessment and formulation of memory disorders and their functional consequences, one must consider whether a range of other factors are contributing to the functional disability. If so, then one should include intervention for these factors in the treatment plan. This includes treatment of mood disorders, sleep disorders, management of fatigue and pain, or adjustment of medication where possible. In some patients, memory problems will be secondary to

Box 4.1.14.3 Guidelines for genetic testing for dementia



impaired attention and concentration and if this is the case, then interventions to address these problems should be considered.

(b) Is the person aware of the problem?

The question of the patient's awareness of memory problems should be addressed. If there is no awareness then it is important to consider means of improving awareness before pressing on with specific remediation strategies. Improving awareness is sometimes straightforward and a question of providing basic information and feedback, but often it is more complex. Use of education and self/other monitoring of memory slips in conjunction with feedback can help. This must be done sensitively as minimizing of problems may be a psychological

coping mechanism and insensitive confrontation may be threatening. Working with patients in a group format can contribute to improving awareness—patients can be supported to provide feedback to each other. Patients may feel more able to acknowledge problems if others are also doing this in the group context.[14] *If awareness cannot be improved* (which may be the case if memory problems are occurring in the context of more global and severe cognitive impairment) then the strategy of modifying the environment to reduce memory demands on the patient must be considered. Environmental modifications include the use of prominent signs/labelling (e.g. of toilets, cupboards, draws, rooms) to support orientation in the physical environment. Establishing very fixed daily routines can also help develop behavioural habits. It may be the case that the patient requires prompting from carers. If this is the case then the minimal level of prompting required should be established and regularly monitored, and if possible prompting can be gradually reduced as behavioural sequences are learned.

(c) Strategies for mild problems

If the patient demonstrates at least some awareness of memory problems then the severity of the memory problem should be considered. Systematic reviews of cognitive rehabilitation[15,16] have recommended that different approaches are required for different levels of severity of memory disorder. There is no evidence that 'drill and repetitive practice' without additional strategy training is effective in improving memory.[17,18] However, in the context of mild memory impairment then memory strategy training is recommended.[15] Memory strategy training can be carried out on a 1:1 basis or in a group. The aim is to provide information and training in the use of a range of memory strategies which the patient learns to apply independently in specific situations in their own life, via homework tasks, over the course of the training programme. The patient is provided with a range of strategy options that s/he can select according to personal needs. This includes training in the use of external memory aids, such as many of those listed in Box 4.1.14.2. Internal memory strategies are also trained. These include strategies to aid deeper encoding of information. It is a well-established principle that deeper (more meaningful, personally relevant, emotionally salient), multi-modal (i.e. visual and verbal) processing of information results in more effective learning and recollection of that information.[19] For those with severe amnesia whether or not the information is processed deeply will make little difference, but for those with more mild impairment, strategies to enhance processing are more relevant. Strategies include visual imagery, categorization, association with established knowledge, motor movement (e.g. rehearsing in mind an action that has to be carried out at some later time) and spaced retrieval/expanding rehearsal (gradually increasing the time between successive trials of testing recollection of material to be learned). Craik and colleagues[20] and Evans[1] discuss internal strategies further.

(d) Strategies for more severe problems

For those with more severe memory impairment general strategy training is unlikely to be effective as the demands of learning a range of strategies and applying them when required are too great.[18] The approach recommended in this context is to try to map specific everyday remembering priorities to specific strategies. In other words, rather than providing a tool box of strategies and relying on the patient independently selecting the right tools for the right task when needed, the clinician establishes with the patient and carer what is essential to be learned/remembered and then considers how can this be achieved. For some this will be just one task for which one remembering strategy will be established. For others a more complex 'memory system' can be constructed to allow several remembering tasks to be achieved. Some of the commonly used external aids (memory notebooks, diaries, memo boards) will be used. For people with more severe impairment, formal training in learning how to use these aids consistently is required. A number of studies have shown that comprehensive training approaches can lead to effective use of memory journals, even in people with severe amnesia.[21–23] Kime[24] provides instruction on devising needs-led practical approaches to compensating for memory deficits.

(e) Electronic memory aids

These aids offer the major advantage of having the facility to prompt an action using alarms and so are particularly valuable in relation to prospective memory (remembering to do things). They also provide a means of combining a number of different memory aid functions (e.g. alarmed reminders, schedule, contact information, to-do list) into one portable tool. The most extensively evaluated electronic reminding system is NeuroPage.[25] Reminder messages are sent to standard alpha-numeric pagers worn by people with memory and/or planning problems, according to a pre-arranged schedule. This system has now been evaluated in randomized clinical trials and single case studies and shown to be very effective.[25,26] In recent years there has been a massive worldwide increase in use of mobile phones such that the vast majority of people acquiring cognitive impairment now will have had exposure to this technology before the onset of their memory deficit. This opens up the possibility of much greater use of portable reminding technology delivered via mobile phones, including the use of SMS text messaging.[27,28]

(f) Errorless learning

Another approach to remediation can be applied when there is a need to learn specific information or a procedure. Errorless learning is based on the principle that for those with severe memory impairment, learning will be most effective if errors can be avoided during the learning process. This is because memory-impaired patients may be more likely to repeat errors (as a result of intact *implicit* memory processes), but are unable to recollect that a response was an error. Thus errors become reinforced. Errorless learning techniques have been used for many years to teach new skills to people with learning disabilities and more recently this technique has been used with people with acquired neurological impairment and with schizophrenia. Baddeley and Wilson[29] published the first study demonstrating that people with amnesia learn better when prevented from making mistakes during the learning process. This finding has been replicated with people with a diagnosis of schizophrenia.[30] These were theoretical studies of word list learning. However, several single case and group studies have shown the benefit of errorless learning methods in teaching more practical, everyday information including learning names of people important in a person's life,[31] work tasks.[32] Kessels and de Haan's[33] meta-analysis concluded that errorless learning was more effective than standard, 'trial and error' conditions.

Many of the treatment interventions described here are relatively labour-intensive requiring a significant amount of clinician/therapist time for them to be successfully implemented. Occupational Therapists and Clinical Psychologists specializing in neuropsychology have relevant training in the assessment and treatment of memory disorders and hence memory remediation should be considered within the interdisciplinary context.

Summary and conclusions

Memory disorders are frequently encountered in clinical practice and cause significant disability. Memory should therefore be carefully assessed as part of routine clinical assessment. Restoration of normal functioning is not typically possible and remediation is therefore usually concerned with compensating for impaired memory. A range of treatment approaches is available, and the treatment of choice will depend on the form and severity of memory disorder and the functional problems faced by the patient.

4.2.1 Pharmacological and psychological aspects of drugs abuse

David J. Nutt and Fergus D. Law

Drug abuse, misuse, and addiction are major issues in society because of their enormous personal, social, and economic costs and their important psychiatric components.[1] Many drug treatment programmes are run by psychiatrists, and the evidence strongly supports the notion that a significant proportion of severe drug abusers are psychiatrically ill. Moreover, drug misuse appears to be becoming more frequent in patients with other psychiatric disorders, where it can lead to problems in treatment and poorer outcomes. It is therefore essential for all psychiatrists and related health professionals to have a good understanding of the basis of drug misuse.

Why do people take drugs?

A very common misconception is that drug misuse is simply a **search for fun**. In fact, people take drugs for many reasons other than to get the buzz or high. Indeed, studies have shown that straightforward pleasure seeking is the primary reason for initiation of drug use in fewer than 20 per cent of individuals. Whilst the high or buzz is the most obvious pleasurable effect, many people also describe using drugs to feel comfortably numb, pleasantly drowsy, or full of energy and confidence. Many others will be chasing the high or buzz that they first experienced, always seeking the intensity of their first experience. Still others will be self-medicating for anxiety, anger, pain, boredom, lack of motivation,

lack of self-confidence, and many other aversive states including drug withdrawal.

The main reason to try to ascertain the reasons for drug use is that in many cases identification of the cause can lead to effective interventions. For example, many **alcoholics** will point to **anxiety** as their reason for drinking;[2] indeed, social anxiety is one of the most common causes of alcoholism in young men.[3] If this can be treated (e.g. by selective serotonin reuptake inhibitors) then they are frequently able to become abstinent or even drink normally. **Social anxiety** and **attention-deficit disorder** are common reasons for the use of stimulants. **Depression**, is particularly likely to lead to excess alcohol intake, and a vicious cycle can develop because both alcohol and its withdrawal are depressogenic. Alcohol is also one of the most serious risk factors for suicide. There is increasing use of **stimulants** and **cannabis** by **schizophrenic** patients. In part this reflects the behaviour of their peer group but in part is because they can offset some of the more negative aspects of the illness and medication side effects. As both these types of drugs can worsen psychotic illness, dealing with drug misuse in this group is a priority.

Other factors affecting drug use may be less amenable to psychiatric intervention, such as **pressure from peers** or others. For instance, female opiate addicts often have a male partner who also uses drugs or even deals drugs. Should she stop use, relapse is almost certain to occur if she continues to live with this partner. Another reason for drug use is to reduce **pain** or **boredom**, the latter being a common reason given by disadvantaged youth in areas of high unemployment and poor environmental quality such as inner cities or out-of-town housing estates. Other reasons for drug use, especially with the psychedelics, include the **search for meaning** or for **mystical experiences**. Whilst not directly relevant to psychiatry, this use can precipitate psychotic episodes in susceptible individuals and may trigger schizophrenia.

Finally, it is important to remember that the reasons for use of a specific drug are not static. An opiate addict may use the same dose of **heroin** to get going in the morning, to 'top off' a pleasant experience later in the day, to deal with angry feelings when they occur, and to promote sleep at night. Similarly during a **drug-using career** different motivations may become dominant. This has been well characterized in opiate users where for many the initial use was for pleasure or escape. Over months, as physical dependence becomes increasingly apparent, use becomes driven by the need to avoid withdrawal and to feel normal at almost any cost.

Drug use and misuse

It is possible to view the issue of drug abuse from different perspectives, which range from the molecular and genetic through the pharmacological to the psychological and social. Each view has its merits and is important, but there is little doubt that an integrated view is necessary, because for most drugs and for most societies no one perspective can explain all the known features of drug abuse. However, for the purpose of this chapter we have concentrated on the psychological and pharmacological.[1,4–6]

Problem use, addiction, dependence, and craving

These are some of the most commonly used terms regarding drug misuse but at the same time they are also the most problematic. The use of drugs in any circumstance, therapeutic, or otherwise, can be associated with problems, although the nature and scale of this varies (see Table 4.2.1.1). The terms problem use and misuse usually refer to use of drugs (prescription or otherwise) for pleasure but with disregard for the personal or social dangers. For example, alcohol misuse can lead to irresponsible behaviour whilst intoxicated and, if prolonged, to liver, gastric, and nervous system damage without the individual necessarily being addicted or dependent.

Table 4.2.1.1 Potential problems with drug use

Type of drug use and associated issues	Examples/effects
Therapeutic use	
Adverse effects	Sedation, poor driving
Drug interactions	Increased drug levels
Withdrawal	Convulsions, delirium tremens
Drug use with pain	Difficulty reducing opiate dose
Misuse/problem use	
Illegality	Criminal records; social stigmatization
Intoxication	Physical/social damage
Excessive regular use	Physical/social damage
Injecting drug use	Infections, thromboses, Hepatitis C
Dependence	
Tolerance	Dose escalation
Withdrawal	Physical dependence
Urge to use/cannot abstain	Psychological dependence
Craving/drug seeking	Drug dominates life
Drug becomes dominant life goal	Personal/social decline
Reinstatement on relapse	Cycles of dependency

Addiction is a term that had become so misused in general parlance and had acquired such a pejorative edge, that in the past two decades attempts have been made to remove it from the psychiatric lexicon. Unfortunately, the replacement terminology of **dependence**, or the dependence syndrome, has been similarly devalued by popular usage. In fact there exists a spectrum of dependence ranging from physiological supplementation (as with insulin in diabetes mellitus) through to life-altering dependence on illicit drugs such as heroin (see Table 4.2.1.1). Addiction is still a useful construct if it is reserved for the collection of phenomena that occur at the extreme end of the dependence spectrum, and includes the concept of social and personal decline associated with drug use, as well as **craving, tolerance**, and **withdrawal** symptoms (cf. DSM-IV and ICD-10).

Another area of some confusion is the distinction between **physical and psychological dependence**. When originally conceived, this distinction was helpful in that it emphasized that drug dependence was more than just physical adaptation to drugs as manifest by withdrawal symptoms, and that psychological processes, especially drug liking, were also important. However, drugs without obvious physical withdrawal syndromes (e.g. stimulants) also result in measurable physiological withdrawal changes in sleep and activity as well as measurable psychological changes such as those in mood. In addition, new neuroimaging techniques such as **PET, SPECT,** and **functional MRI** are beginning to reveal the brain circuits underlying the pleasurable effects of drugs, and this has

resulted in a blurring of the distinction between physical and psychological processes. For example, the plate shows a PET scan of heroin addicts in which the brain regions showing increased blood flow activated by craving for heroin are illuminated using the radiotracer oxygen-15 (Plate 4.2.1.1). Similar studies have revealed the brain regions involved in the pleasurable effects of opiates and stimulants.[7] Thus there is a clear convergence in terms of mechanisms, but in terms of treatment regimens the distinction between physical and psychological remains.

Craving is also a term that is widely used yet ill-defined. Craving is a desire, which most commonly is taken to mean a strong and sometimes irresistible desire to use a drug. The emotional valence of craving is not necessarily pleasurable. Craving can reliably be elicited in situations of negative valence. It is commonly found in withdrawal, when it can lead to relapse. Craving can also be present as an urge or desire to use a drug although the sufferer may be actively denying or resisting its presence. The complex interplay of physical and psychological processes is well exemplified by the physical responses that craving can produce. For example when opiate-dependent subjects are shown drug-related paraphernalia they may experience emotions that range from pleasurable anticipation to early withdrawal (shaking, tearing of the eyes, pupil dilatation, etc.). Each one of these experiences can lead to a desire to use the drug, that is craving.

Studies in both animals and humans have demonstrated that **conditioning** occurs to both the positive and negative aspects of craving.[8] **Tolerance** is to a large extent a conditioned response, particularly related to the environmental context in which a drug has been taken.[9] Thus an environmental context which is drug familiar results in physiological changes in the brain in preparation for the drug effect, and thus less actual drug effect occurs (i.e. tolerance). However, in a novel context, such preparatory changes do not occur so that a standard drug dose will result in a larger drug effect and a potentially fatal outcome. Thus the lethality of a drug is largely dependent on the environment in which it is taken.

Attempts have been made to dissect out the subcomponents of craving using questionnaires. The best known of these are the set designed by Tiffany *et al.*[10] who independently rate the five main subcomponents of craving—urges and desires to use, intention and planning to use, anticipation of positive outcome, anticipation of relief from withdrawal or negative outcome, and loss of control over use. Ongoing neuroimaging studies are beginning to support this multiprocess view of craving by revealing activation or inhibition of different brain regions to be correlated with individual symptom clusters.

There is also increasing evidence that the particular **cognitions** of patients may be important for treatment, especially during withdrawal. Just as panic disorder patients have catastrophic cognitions, addicted patients may have a high fear of craving and other withdrawal symptoms in association with related catastrophic cognitions. This detoxification fear has been measured in opiate addicts, and shown to predict outcome.[11] Withdrawal expectations also play a significant role,[12] and a 15 to 30 min explanation of what the opiate detoxification involves may reduce the measured withdrawal distress by over one-third. Indeed, such is the strength of psychological factors in addiction treatment, there is little doubt that drug treatments should always be combined with the appropriate psychological interventions.

Psychological processes and treatment implications

One of the most influential models in addiction treatment is known as the **stages of change model**.[13] The stage of change that a person can be identified as being at determines the therapeutic approach and type of treatment offered. Thus at the precontemplation stage where there is no recognition of a need for treatment, there is no point in offering intensive treatment interventions. Similarly, at the contemplation stage when treatment is being considered, the appropriate intervention is to help the person clarify their views and build their motivation to change rather than offering active treatment. Indeed, it is only in the decision and action stages that treatment should be actively offered and facilitated.

The brief counselling technique of **motivational interviewing**[14–16] has been proved to improve outcome effectively, and ties in well with the stages of change model. In the early stages the therapy is focused on encouraging the patient to reduce or resolve their ambivalence, which acts as their psychological barrier to treatment. The patient in this client-centred but focused therapy is facilitated to discover the solutions to their own problems themselves. This approach of accepting the client's current level of thinking (rather than offering ready-made solutions, or confronting them, or trying to argue them into the solution) has been shown to be surprisingly effective in the clinical trials.[16] The effectiveness of this technique has resulted in a new understanding of motivation, which is seen as a dynamic state rather than as a fixed state, and one which can be influenced by the therapeutic stance.

Other cognitive therapies also make significant contributions to treatment. **Relapse prevention** involves the teaching of cognitive and behavioural strategies for dealing with high-risk situations and mental states.[17,18] **Other cognitive behavioural therapies**, including extinction of conditioning, contingency management, community reinforcement techniques,[19] and indeed Beck's cognitive therapy,[20] have been effectively applied to substance misuse. The very large Project MATCH (matching alcoholism treatments to client heterogeneity) study of alcohol treatments compared three types of treatment and found that motivational enhancement, 12-step facilitation, and cognitive behavioural therapy were equally effective overall, although each therapy excelled in certain subgroups.[21,22] Based on these results it seems likely that specific therapies targeted at specific issues of importance in patients with addiction are roughly equally effective overall, but that we do not yet know enough to confidently match specific patient subtypes to specific therapies.

A number of **other therapies** have also been shown to be effective, particularly in the alcohol field, including self-control training, self-help groups, marital and family therapy, coping and social skills training, anxiety and stress management, aversion therapies, and brief intervention strategies.[23,24] The Cochrane reviews found that there was insufficient evidence to prove the effectiveness of psychosocial interventions used alone, but that there was added benefit from combining such interventions with pharmacological treatments in both maintenance and detoxification.[4–6]

Personality variables and the genetics of addiction

The role of personality in addiction is a major issue, with some believing in an 'addictive personality' and others suggesting

different personality types might predispose to different aspects or forms of drug misuse.[1] In this highly controversial field a few facts are generally agreed. Predisposition to experiment with both licit and illicit drugs is more likely in those with sensation-seeking or impulsive behaviour traits, and in extroverts rather than introverts. However, once drug dependence is established, those with obsessional, dependent, or anxious characteristics find it hardest to stop.[1]

The genetics of drug abuse are beginning to be unravelled and already these studies have thrown up some important insights in relation to personality. The best studied dependence is that on alcohol, where the Scandinavian adoption studies have found the risk of alcoholism in male children of male alcoholics is the same regardless of whether the child is reared with the alcoholic father or by a non-drinking adoptive family. Building on these data, Cloninger[25] has identified two main forms of alcoholism. Type I is the late-onset form that has low inheritance and is associated with anxiety and stress which drinking is used to relieve, often in binges. In contrast, Type II alcoholism starts at a younger age with a heavy regular intake and is associated with antisocial personality traits and criminality. This form is male limited, is associated with impulsivity, and may be related to underfunctioning of brain 5-hydroxytryptamine systems, as genetic polymorphisms of 5-hydroxytryptamine receptors and enzymes have been found in these subjects.[26]

How abused substances affect the brain

The brain works by transmitting information between neurones using the primary neurotransmitters. The **primary neurotransmitters** are glutamate, which is stimulatory (i.e. it turns neurones on), and the closely related amino acid γ-aminobutyric acid (GABA), which is inhibitory (i.e. it turns neurones off). The appropriate balance between these neurotransmitters leads to the brain processes underlying action, sensation, learning, and memory. **Secondary transmitters** are the monoamines and peptides such as dopamine, 5-hydroxytryptamine, noradrenaline (norepinephrine), acetylcholine, and endogenous opiates. These add the tone, valence, and emotion to the primary processes, and some such as noradrenaline are important in memory formation. All 'drugs' (probably even solvents through indirect effects) act by interfering with these neurotransmitters in ways summarized in Table 4.2.1.2. However, it is important to realize that the brain has its own **endogenous 'addictive' neurotransmitters**. The best known are the endogenous opioid peptides such as the endorphins and enkephalins, but there are also endogenous cannabinoids (anandamide) and probably others. It is not yet known whether these endogenous substances are mediators of addiction to cannabis or other drugs, although this would certainly seem possible.[27–29]

What is certain is that some of the most addictive agents (especially the full agonist opiates such as heroin/morphine) act on the endogenous **opioid neurotransmitter pathway**, but with a much greater effect than the natural transmitter. The profound ability of opiates such as heroin to produce addiction is because these drugs highjack the natural transmitter system leaving normal levels of stimulation seeming tame by comparison. Treatment with partial agonist opiates such as **buprenorphine** offer a compromise in that they are less addicting than heroin yet restore some of the

Table 4.2.1.2 Drugs and transmitters

Drug class	Endogenous transmitter	Treatment implications
Mimic natural transmitters		
Opiates (alcohol)	Endorphins/enkephalins	Antagonists (naltrexone) Partial agonists (buprenorphine)
Cannabis	Anandamide/others	Antagonists
Alcohol	GABA	GABA modulator (? acamprosate)
Benzodiazepines/barbiturates	GABA	Partial benzodiazepine agonists Antagonists (flumazenil)
Nicotine	Acetylcholine	Antagonists (mecamylamine) Partial agonist (varenicline)
Release transmitters		
Cocaine (buproprion)	DA	Other uptake site blockers
Amphetamines	DA	D2-receptor antagonists/partial agonists As cocaine
Nicotine	DA	As cocaine
Ecstasy	5-HT/DA	5-HT uptake blockers/antagonists
Alcohol, solvents?	NA/DA	NA/DA uptake blockers
Block transmitters		
Alcohol	Glutamate	Glutamate modulators (acamprosate)
Barbiturates	Glutamate	Glutamate modulators
LSD/other psychedelics	5-HT	Antagonists

DA, dopamine; GABA, γ-aminobutyric acid; 5-HT, 5-hydroxytryptamine; NA, noradrenaline.

brain's deficiency of opiate tone. They also have the advantage of being much safer than full agonists in overdose and rarely cause death from respiratory depression.[30] Other drugs, in particular alcohol, seem to act in part by indirectly stimulating the endogenous opioid system, which is why opioid antagonists such as naltrexone can be useful treatments.[31]

Other drugs act on the natural stimulant transmitter **dopamine**. Dopamine deficiency (for instance in Parkinson's disease) has long been known to limit motor behaviour. Stimulant drugs increase energy and stamina by increasing the synaptic levels of dopamine, either by increasing the release or by blocking its reuptake in the basal ganglia. Many drugs of addiction can also increase dopamine availability in other brain regions, the two most important being the nucleus accumbens and the prefrontal cortex.[32] A huge body of evidence points to the nucleus accumbens as being a critical gateway in drug misuse. Most abused substances (with possible exceptions of opiates and benzodiazepines) act to increase dopamine release in this region. How they do this varies—cocaine and nicotine act at the level of the dopamine terminals, whilst cannabis and alcohol activates the cell bodies in the brain stem. The net effect is to increase dopamine transmission out of the nucleus accumbens into the basal ganglia and thalamus, frontal cortex, amygdala, and hypothalamus.[1]

This circuit is the one that was shown by Olds in the 1950s to sustain electrical self-stimulation in rats and is the brain's own **reward circuit**. It is normally activated by positive reinforcers, such as food, water, and sex that are critical to survival. Because drugs of abuse produce greater effects than the natural reinforcers, the resultant effect is that the brain directs its normal drives away from the natural reinforcers and towards the more pleasurable drugs. In severe addiction, which frequently occurs with the most powerful reinforcers (such as heroin and cocaine), all natural drives may be subsumed to an overwhelming search for and use of the drug. Thus addicts may give up sex, grooming, hygiene, relationships, work, hardly eat or drink, and ignore health problems.

The routes and risks of addiction

In addition to its impact on the social aspects of life, drug misuse can lead to significant medical problems. The dangers of drug abuse relate to two main factors; the route of use of the drug and the effects the drug has outside of the reinforcement circuit of the brain.

For most drugs of abuse the faster the drugs reach their target site in the brain the better they are liked and the more psychologically reinforcing they are. Indeed, the 'pharmaceutical' history of most abused drugs illustrates the progressive refinement of their preparation, in order to accelerate their rate of entry into the brain. A good example is **cocaine**. The Andean Indians originally experienced its effects from chewing coca leaves, which released low levels of cocaine slowly. An increase in vigour and a resistance to fatigue is produced, but little pleasure. Over the centuries cocaine has become more refined, first to paste and then to cocaine hydrochloride powder (snow) which when taken nasally produces high levels in the brain within 5 to 10 min and a clear 'high'. Further refinement to the free base produces a more lipophilic form (crack) that can be smoked, resulting in entry into the brain in seconds. Intravenous drug use also serves the same purpose of getting the drug to the active site very fast.

A similar process of pharmaceutical refinement to accelerate brain entry has taken place with the **opiates**. Smoking opium is a method of delivering morphine and related substances reasonably quickly but in low amounts. Refining opium into its active constituents (e.g. morphine) means that higher doses are more easily ingested. However, morphine crosses the blood–brain barrier relatively slowly and has therefore been largely supplanted by opiates such as heroin that cross more rapidly. Heroin is a diacetylated synthetic derivative of morphine that is more lipophilic, meaning that it is able to enter the brain more rapidly and give a better rush. Interestingly, the active form of heroin is morphine; heroin has to be deacetylated before it can act, which proves that pharmacokinetic differences are the critical variable with opiate preference. Similarly, codeine is also inactive until metabolized to morphine, but because this happens very slowly codeine has less abuse potential than morphine.

The **benzodiazepines** were abused relatively rarely until the advent of gel-filled capsules of temazepam. These provided experienced intravenous opiate users with a convenient source of a concentrated drug, which they began to experiment with in the late 1980s. In an attempt to stop this, the drug was reformulated in wax, which led to users heating up the caplets until they melted and then injecting the hot solution into their veins (hot lining). Unfortunately at body temperature the wax solidified, blocking the veins and arteries into which it was administered, leading to severe ischaemia that often lead to gangrene and the loss of the limb. Since there are no therapeutic advantages of temazepam over other benzodiazepines that are much less abusable, this drug has recently been put under a higher degree of regulatory control in the United Kingdom in order to deter its prescription and misuse.

As well as affecting the relative reinforcing actions of abused drugs, **the rate of brain entry** also contributes to risk. A very rapid drug entry makes dose adjustments difficult or impossible and so predisposes to overdose. This is most obvious for intravenous use of opiates where respiratory depression is the main cause of death, but is less common with smoked opiates as intake can more easily be titrated to the desired effect.

The **route of use** also affects risk, most notably with the risk of infection from intravenous use, especially when needles are not cleaned or are shared. The majority of current intravenous users are Hepatitis C positive and we can therefore expect cirrhosis to become a major cause of their death in the next decade or so. This also raises ethical and economic issues; interferon treatment significantly reduces the progression of the disease but is costly and its routine use in addicts would be massively expensive and likely to cause public disquiet. The other main infections are hepatitis B and AIDS. The frightening rise of AIDS in drug abusers, where it occurred faster than in any other group, was the main impetus to the harm-reduction approach becoming the treatment style of the 1990s. Needle-exchange programmes and increased methadone availability were both proven to reduce the spread of AIDS and have become the cornerstone of treatment in many countries.

Relative risks of abused drugs

This is a critical issue in relation to directing legal as well as medical inputs into drug abuse. There are four main factors, which have to be taken into account in determining relative risk:[33]

- risk due to the route of use
- risk of the drug itself

- extent to which the drug controls behaviour (addictiveness)
- ease of stopping

The risks due to the route have been covered above. The risks of the drugs themselves are determined by standard tests and clinical experience and can be encapsulated in concepts such as the **therapeutic index**. This is the ratio of toxic dose to therapeutic (or usual) dose. The ratio is very low for heroin and similar opiates, for cocaine especially crack, and for intravenous temazepam and oral ecstasy. It is quite high for psychedelics, cannabis, benzodiazepines, and orally used stimulants such as amphetamines. Another important consideration is the **health complications** of long-term use, which by and large reflects the therapeutic index. An exception to this is the opiates, which, provided sterile administration is used, are thought to have little detrimental effect, even when used chronically and intravenously. Chronic cocaine can lead to cardiac damage, and heavy cannabis smoking causes precancerous change in the same way as tobacco smoking, as well as causing greater levels of chronic bronchitis.

The degree of **control over behaviour** that the drug elicits is a major factor in drug dependence, and is the closest concept to addictiveness. Although the route of administration is another critical variable, we can make some reasonable generalizations. Strong opiates and cocaine are the most addictive, being overall as addictive as nicotine. The benzodiazepines, ecstasy, and psychedelics are the least addictive, and are significantly less addictive than alcohol.

There are three main factors contributing to drugs gaining control over behaviour, all of which affect the ease with which a drug may be stopped. The first is the pleasure a drug produces—the positive drive for use (pleasure giving and seeking). The others both involve the pain of abstinence—withdrawal in both physical and psychological terms—which leads to drug use to relieve it (discomfort escape). The pattern of drug use during an addiction career generally begins with the quest for pleasure and progressively evolves into the escape from withdrawal pain as neuroadaptive processes develop. In this context it may be thought that withdrawal discomfort is best limited to symptoms with a clear physical symptomatology, that is the autonomic symptoms indicative of physical dependence. But in terms of addictiveness, psychological withdrawal may in fact be more important than physical withdrawal. This is illustrated by the finding that those dependent on opiates for medical reasons, although physically dependent, experience little craving and risk of relapse once detoxified, provided the reason for being on the opiate resolves. The ease of stopping the drug thus depends on both the physical and psychological withdrawal symptoms, as well as the ability of the drug to provide positive reinforcement.

It is possible to provide rough guides for these three processes for each drug, so that the overall addictiveness potential can be gauged (Table 4.2.1.3). For completeness, the main licit drugs are also shown as well as another highly motivated behaviour which can produce a state of addiction/dependence, that is gambling.

Table 4.2.1.3 Addictiveness of various agents and activities

	Pleasure giving	Physical withdrawal problems	Psychological withdrawal problems
Opiates	+++	+++	+++
Amphetamines	++	+	+
Crack/cocaine	+++	++	+++
Cannabinoids	+	+	+
Barbiturates	++	+++	++
Benzodiazepines	+	++	++
Ecstasy	++	+	0
Psychedelics	++	+	0
Cigarettes	+++	+	+++
Alcohol	++	+++	++
Caffeine	+	+	+
Gambling	++	0	++

0 none; + slight; ++ moderate; +++ strong.

4.2.2 Alcohol use disorders

Contents

4.2.2.1 Aetiology of alcohol problems

Juan C. Negrete and Kathryn J. Gill

Introduction

Approximately 8 out of every 10 persons living in Europe and the Americas would report consuming alcoholic beverages in their lifetime,[1] and the norm is for drinking to start in adolescence: in 2003 the average age of first drink in the United States was 14 years old.[2] Also in the year 2003, 79.3 per cent of persons aged 15 years or more in Canada reported to be current users of alcohol, and 22.6 per cent admitted to having exceeded the country's safe drinking guidelines (i.e. no more than 14 units/week for males and 12 units/week for females). The same survey elicited a rate of 'hazardous drinkers' of 13.6 per cent, defined as all respondents who scored 8+ on the AUDIT screening questionnaire.[3]

Epidemiological data in the United States indicates that roughly one in seven persons who start drinking will develop an alcohol dependence disorder in the course of their lives.[4] The figure is higher among men when compared to women. Of course it is also higher if other clinical forms of alcohol misuse (i.e. alcohol abuse/harmful drinking) are included in the rates in addition to dependence.

A moderate level of alcohol use appears to be relatively harmless; and there exist public health guidelines on 'safe' drinking practices. The recommendations vary considerably from country to country, but they all assume a greater vulnerability to alcohol effects in the female gender. In the United Kingdom, for instance, hazardous drinking is thought to start at 21 units/week for men and 16 units/week for women;[5] and in the United States the equivalent guidelines are 14 and 7 drinks per week.[6] It is among alcohol users who exceed such guidelines that the prevalence of dependence is the highest; up to 40 per cent of the more frequent violators.[7]

The expression 'alcohol problems' encompasses a wide range of untoward occurrences, from maladaptive, impaired, or harmful behaviour, to health complications and the condition of alcohol dependence. Alcohol problems are not incurred just by chronic excessive drinkers, but also by persons who drink heavily on isolated occasions (e.g. accidents, violence, poisoning, etc.). Given their

high frequency and social costs, these consequences of acute inebriation represent the most significant public health burden of drinking.[8] This section focuses rather on the causes of problems of a clinical nature, the ones presented by individuals who engage in patterns of repeated excessive drinking, i.e. 'alcohol dependence' and 'alcohol abuse' (DSM-IV nomenclature) or 'harmful drinking' (ICD-10 nomenclature).

The causality of alcohol misuse

Alcoholism is a bio-psychosocial phenomenon par excellence; it results from the contribution of multiple individual and environmental risk factors. The complex dynamics influencing its development have been well acknowledged in the literature. Theories have taken many disparate facts into consideration, from the effects of alcohol policy to the influence of familial and sociocultural environments across cultures and over time. Some ethnic groups, for instance, have traditionally had low rates of alcoholism (Asians, Jews, and some North American Aboriginals) and the prevalence is generally higher in males across both age cohorts and ethnicities. Another layer of complexity lies in the fact that alcoholism is a clinically heterogeneous disorder with variable age of onset, drinking patterns, severity, and comorbidity with other mental disorders. In general, alcoholics have one or more clinical diagnoses in addition to alcohol dependence, including drug abuse, antisocial personality disorder, anxiety, and depression. The course of the disorder is variable with high rates of remission and relapse; its manifestation changing in pattern and severity in response to life events (stressors) and other aspects of the environment. A summary of the etiological factors that have been shown to influence the development of alcoholism is shown in Box 4.2.2.1.1.

Box 4.2.2.1.1 A bio-psychosocial model of the aetiology of alcoholism

The comunity/sociocultural environment

- policies affecting availability and price (temperance, prohibition, taxation)
- cultural patterns of consumption, social acceptability of drinking/drunkenness
- availability of other reinforcers (sources of pleasure/recreation)
- employment and/or educational opportunities (anomie/marginalization)
- peer influences/role models (affiliation with deviant subculture)

The family environment

- marital breakdown (lower socio-economic status, poor parental monitoring)
- family attitudes (availability of drugs/alcohol, modelling of siblings/parents)
- intrauterine exposure to alcohol/drugs (potential effects of alcohol, nicotine and other drugs on behaviour and cognition)
- familial substance abuse (poverty, violence, and increased rates of early life trauma including neglect and physical/sexual abuse)

Individual/host factors

- heritable genetic factors (genetic loading for alcohol/drug dependence, depression, anxiety disorders in first-degree relatives)
- differences in response to alcohol (low sensitivity in terms of physiological responses and subjective effects)
- metabolic differences (thiamine deficiency, alcohol metabolizing enzymes)
- high risk taking behaviours (male sex)
- childhood psychopathology (conduct disorder, untreated ADHD)
- psychiatric disorders (bipolar, depression, anxiety, schizophrenia)

Sociocultural factors

Macrocultural influences such as values, beliefs, and mores; social role functions; local economy; customs and dietary habits; rapid social change; and cultural stress do shape and dictate the way alcohol is used in human societies. But even within a single society, there is variance in the alcohol problems profile of different subgroups. For instance, drinking, heavy drinking, alcohol use disorders, and treatment for alcoholism are more frequently recorded in men than women,[1] the risk of hospital admission for alcoholic psychosis, acute intoxication, and liver cirrhosis is elevated in unskilled and blue-collar workers when compared with higher occupational categories; alcoholics are over-represented in occupations with flexible work schedules, in those less supervised, and in the ones which facilitate access to alcohol,[9,10] and although there are a larger proportion of regular alcohol users among the older, the wealthier, and the better educated, frequency of heavy drinking (i.e. episodes of intoxication, 5+ drinks at a time) is inversely correlated with age, income, and level of education.[3]

Cultural beliefs about drinking and related social norms largely determine the manner in which alcohol is used. Disorderly conduct and drunken violence are more likely to occur in societies which, while allowing drinking, do view alcohol as an evil substance. Similar consequences can be expected if drunkenness is culturally considered as a 'time out', when socially unacceptable behaviours are tolerated or excused.[11] In fact, the social condoning of drunkenness is considered as an epidemiological risk factor. The availability of alcohol and the social promotion of frequent or heavy drinking are examples of social risk. But environmental facilitation *per se* does not explain the genesis of an alcohol dependence disorder in specific individuals. This disorder is best understood as the result of social prompting and individual vulnerabilities.

Psychological factors

Alcoholics do not present a homogeneous premorbid personality profile. However, some distinctive trait clusters have been identified which seem to characterize different types of alcoholics.[12] One such group (type 1) tend to score low in novelty seeking and high in harm avoidance and reward dependence. Another group (type 2) is formed by the natural thrill seekers, who appear to ignore harmful consequences and punitive responses. This latter cluster, which prevails mostly in males with early-onset alcoholism,

is also typical of antisocial personalities. Of all personality features, conduct disorder and antisocial behaviour are the strongest predictors of alcohol misuse.[13]

(a) Psychodynamic processes

Early psychodynamic writings portrayed alcoholism and other addictions as regressive behaviours caused by unconscious conflicts over libidinal pleasures, homosexuality, and aggression. More recent formulations emphasize ego and self-developmental problems, and consider psychoactive substance abuse as a response to psychological suffering; an attempt at re-establishing homeostasis. This is known as the *self-medication hypothesis* of addictions,[14] according to which, persons with self-regulatory deficiencies in the areas of self-care, self-esteem, self-object relations, and affect tolerance, would drink to palliate their distress.

(b) Learning

Alcohol abuse as seen by some as a behavioural pattern which has been learned through mechanisms of classical (i.e. Pavlovian) and operant conditioning. According to this interpretation, the perpetuation of heavy drinking results from its association with conditioned stimuli (cues), and from the action of positive (pleasant effects) or negative (stress reduction) behavioural reinforcement. Additional components of this equation are the so-called alcohol 'expectancies'. Alcohol abusers tend to overemphasize the pleasant aspects of drinking and to ignore the negative ones; the learning theory of alcoholism assumes that such a cognitive set is also acquired through social exposure. The Social Learning Theory posits that the positive expectancy of relaxation following a drink can facilitate more frequent alcohol use and thus contribute to the development of dependence.[15]

(c) Psychiatric comorbidity

Community and clinical epidemiology findings point to the presence of other psychiatric disorders as one of the most significant psychological risk factors in alcoholism.[16] The co-occurrence is sometimes sequential, with the psychiatric disorder preceding alcoholism; in which case a causal role in the development of heavy/frequent drinking is attributed to the former. While this is often observed in cases of conduct disorder, social phobia, attention deficit-hyperactivity (untreated) and depression, there are other psychiatric disturbances such as panic disorder, generalized anxiety and dysthymia that often become clinically significant only after the person has been abusing alcohol for sometime. These *alcohol-induced* mood and anxiety disorders represent a sizeable proportion of the comorbidity rates.[17] Whether or not it is 'primary', psychological stress is a widely recognized factor in alcoholism treatment failure and relapse.

Yet the comorbidity of some psychiatric disorders (e.g. bipolar disorder, schizophrenia) and alcoholism appears to develop in no predictable sequence, so that if not random, their co-occurrence could be assumed to result from common genetic influences (see below) and pathophysiological mechanisms. One such interpretation is the 'reward deficiency syndrome' hypothesis; it purports that both psychiatric disturbances (e.g. negative symptoms of schizophrenia) and the tendency to abuse addictive substances arise from a basic dysfunction of the dopamine mesocorticolimbic reward system.[18] The 'primary addiction' theory is another such explanation for comorbidity; it contends that a single neurobiological deficiency—primary abnormalities in the hippocampus and the frontal cortex—facilitate the development of schizophrenic symptoms and the person's toxicophilia in a parallel manner.[19]

Genetic factors in the development of alcoholism

In recent decades the biological perspective on the aetiology of alcoholism has gained considerable ground. Findings from family, twin and adoption studies demonstrate that there is significantly higher risk for alcoholism among individuals with an alcoholic biological parent or first-degree relative.[20–23] Meta-analysis has been used to jointly analyze data from twin and adoption studies grouped by country of origin (Scandinavian versus United States of America). Based on all available data, genetic factors accounted for between 40 and 60 per cent of the variance in alcoholism risk, with the effects of environment (shared and non-shared) estimated between 15 and 33 per cent. In a methodologically rigorous study, Prescott and Kendler[24] examined the concordance for alcoholism among a population-based sample from the Virginia Twin Registry. Monozygotic (MZ, $n = 861$) and dizygotic (DZ, $n = 653$) male twins were diagnosed using structured interviews and DSM criteria. Concordance rates for alcohol dependence were significantly higher for MZ (48 per cent) compared to DZ (32 per cent) twins, and analyses indicated that 48–58 per cent of the variation in alcoholism liability could be attributed to additive genetic factors.

Alcoholic males with family history of alcoholism (FHP) have been reported to have greater severity of alcoholic symptoms and poorer outcomes than alcoholics that are family history negative (FHN). Box 4.2.2.1.2 describes some characteristics of familial alcoholism. Onset of drinking prior to age 15 is associated higher rates of alcoholism,[25] ADHD, conduct and anxiety disorders, as well as a host of other negative events including unintentional injuries, physical fights, nicotine/drug dependence, and poor school performance. Children of alcoholics are significantly more likely to be exposed to high-risk environments that include poor prenatal care (alcohol/nicotine exposure, nutritional deficiencies), as well as homes in which there is more poverty and violence. Overall, it

Box 4.2.2.1.2 Characteristics of familial alcoholism

Family history positive (FHP) alcoholism is associated with:

- Earlier onset (<15 at age first drink is associated with increased rates of alcoholism, nicotine dependence, drug use, and conduct disorder. Early age of alcohol use is familial, heritable and may be related to transmission of disinhibitory psychopathology in males)
- Behavioural disturbances during childhood (conduct disorder, emotional lability, aggressivity, low attention span, low soothability)
- More severe alcohol dependence (higher levels of physical dependence, negative consequences)
- Lower educational and occupational achievement
- Deficits in executive cognitive functioning (poor problem solving, abstraction, and perceptual-motor skills)

appears likely that there are common genetic and environmental influences on a host of externalizing disorders—as well as gene–environment interactions.

Linkage studies to identify the genes underlying the heritability of alcoholism

A number of large-scale international linkage studies are currently underway that are aimed at mapping genes for alcoholism including the Irish Affected Sib Pair Study,[26] and the Collaborative Study on the Genetics of Alcoholism (COGA).[27] COGA is a multi-center program designed to detect and map susceptibility genes for alcoholism that is currently underway in the United States. Using a family-based linkage strategy, the study is examining a number of quantitative intermediary phenotypes (endophenotypes) including P300 evoked potentials, alcohol sensitivity, and personality traits (harm avoidance, novelty seeking, and reward dependence) in relation to both alcohol consumption, and alcohol dependence. In addition, the study is examining the association between polymorphisms in specific candidate genes such as alcohol dehydrogenase (ADH), monoamine oxidase (MAO_B), and the serotonin transporter and alcohol-related phenotypes. In early work, COGA-reported associations between alcoholism and regions on chromosomes 4 and 15 that encode genes for the inhibitory neurotransmitter, gamma-aminobutyric acid ($GABA_A$). Most recently, linkage and association genome scans for a broader 'addiction' vulnerability phenotype provided strong evidence for linkage to chromosome 4. Further assessment of single nucleotide polymorphism (SNP) genotypes within the chromosome 4 region provided strongest support for the involvement of the $GABA_A$ receptor $\alpha 2$ subunit (GABRA2 gene).[28] $GABA_A$ has been implicated in mediating some of the psychopharmacological effects of alcohol,[29] and the genetic studies provide convergent evidence suggesting that the predisposition to alcoholism may be inherited as a general state of CNS disinhibition/hyperexcitability that results from an altered responsiveness to GABA. However, this remains to be confirmed by additional genetic and experimental studies.

Other candidate genes and processes

It has been shown that genetic factors may influence a number of important processes such as initial sensitivity to the effects of alcohol, as well as the development of tolerance, sensitization, and physical dependence (including withdrawal complications such as seizures and delirium tremens). Several lines of research have suggested that sensitivity to alcohol may influence the propensity to abuse. Sensitivity refers to drug effects such as intoxication, physiological reactivity, and activation (tendency towards stimulation versus depression following ingestion). For example, Schuckit[30,31] found that individuals with low sensitivity to alcohol as measured by lower psychomotor responses and less subjective intoxication following alcohol dosing were *more* likely to be alcohol dependent at follow-up 10 years later.

Peripheral and central levels of alcohol metabolizing enzymes may be important modulators of the psychopharmacological response to alcohol. Ethyl alcohol (ethanol) is converted to acetaldehyde via the actions of alcohol dehydrogenase (ADH). There is evidence for linkage of gene(s) located on chromosome 4 (as discussed above) and two ADH genes closely linked on chromosome 4 (ADH1B and ADH1C) that encode for isozymes that differ in their kinetic properties. The allele ADH1B*2 (found largely in individuals of East Asian and Jewish descent) encodes a more active isozyme that has been associated with protection from alcohol dependence. Most recently Edenberg *et al.*[32] genotyped 110 SNPs across seven ADH genes in a COGA sample. There was strong evidence that variations in ADH4 were associated with alcoholism, and among African-Americans there was evidence that the ADH1B*3 allele was protective. Acetaldehyde produced by ethanol oxidation is rapidly metabolized by the enzyme aldehyde dehydrogenase (ALDH). A single base pair substitution in mitochondrial ALDH, termed the 'oriental' mutation (ALDH2*2 allele), is present in a large percentage of the Asian population. This mutation renders the enzyme inactive and produces a flushing response (warm-flushed face, tachycardia, nausea) following ingestion of small quantities of alcohol due to the buildup of acetaldehyde, particularly among ALDH2*2 homozygotes. Due to the aversive nature of the flushing response, the ALDH2*2 mutation is a significant protective factor against alcoholism.

In addition to the examination of metabolic factors that may account for some of the genetic variance in the development of alcohol dependence, there is an intense search for other neurogenetic factors related to the effects of alcohol in the brain. As shown in Box 4.2.2.1.3, a large number of candidate markers and putative genetic loci that have been investigated to date. For example, abstinent alcoholics and approximately 35 per cent of sons of alcoholics have been shown to have lower amplitude of a P300 event-related brain potential. Analyses of COGA data indicate that P300 amplitude reduction (P3-AR) is heritable, but more recent analyses have demonstrated that the P3-AR is associated with risk for substance dependence generally (e.g. frequent use of cannabis).[33]

The analysis of various neurotransmitters (including synthesis, release, receptor density, second messengers, polymorphisms) in relation to alcoholism and other alcohol-related endophenotypes is a well-developed area of research. The high degree of comorbidity between alcoholism and other mental disorders suggests that there may be common neurobiological pathways, including those that

Box 4.2.2.1.3 Potential candidate genes and markers for alcoholism

- Brain waves (P300 event-related brain potential)
- Brain enzymes (e.g. monoamine oxidase, adenylate cyclase)
- Alcohol and aldehyde metabolizing enzymes (ADH, catalase, ALDH, cytochrome P450IIE1)
- Opioids (e.g. kappa OPRK1receptor and prodynorphin ligand)
- Serotonin (e.g. polymorphisms of the 5-HT transporter and receptors (e.g. 5-HT1B, 5-HT2A, 5-HT2C), tryptophan hydroxylase TPH (218AC))
- Dopamine (polymorphisms of D_2, D_3, D_4 receptors and the dopamine transporter (DAT))
- GABA (polymorphisms in receptor subunits, variants in glutamate decarboxylase-2 (*GAD2*))

Note that this list is not exhaustive. For a more complete review consult references 32–5.

modulate reward, compulsive behaviour, anxiety, depression, and stress responses.[34] In this context, dysregulation of the serotonin (5HT) system has been implicated in the aetiology of a number of psychiatric disorders (depression, OCD, eating disorders) and alcoholism. In particular, polymorphisms in the promoter region of the 5HT transporter (5HTTLPR) producing the short ('S' allele) or long ('L' allele) variants differentially modulate transcriptional activity of the promoter, yielding differences in 5HT uptake activity in human platelets and brain. Most recently analyses conducted in the COGA sample have failed to find an association between the 5HTTLPR polymorphism and alcohol dependence. In a family-based association analyses (n = 1913 Caucasians) there was evidence for association of the S allele with depression, but not with alcohol dependence.[27]

Numerous studies have examined the association between alcohol dependence and the A1 allele of the dopamine D2 receptor (DRD2), however results have been debated for more than a decade. In general, the A1 allele is not consistently associated with alcoholism, and it does not consistently co-segregate in families with alcoholism. The effect size of this allele is likely to be very small. The human genes for the dopamine D3 and D4 receptors are polymorphic and studies are currently underway examining the potential relationship between various alleles of these receptors and substance dependence.

As noted above, synaptic actions of GABA have been implicated in the psychopharmacological effects of alcohol. Associations between variants in glutamate decarboxylase-2 (*GAD2*), a gene encoding for a major enzyme in the synthesis of GABA have been reported. In particular a functional promoter *GAD2* -243 A > G variant may influence risk for alcohol dependence in populations exhibiting severe alcoholism.[35]

In summary, plausible candidate genes for alcoholism include loci associated with alcohol and aldehyde metabolism, as well as variants within the GABA, opiate, and serotonin systems. The strongest candidate to date is for the involvement of the $GABA_A$ receptor $\alpha 2$ subunit (GABRA2 gene) on chromosome 4. Notably, associations between various loci and alcoholism reported in the literature have not been consistently replicated. Discrepancies in the literature have beesn attributed to variations in sampling (ethnicity, diagnostic criteria, severity of alcoholism, sample sizes), as well as to the clinical and genetic heterogeneity of alcoholism. Thus in this context, it is important to note that possible mechanisms for indirect transmission of an alcoholism phenotype include personality traits, and comorbid psychopathology including anxiety, depression, and conduct disorder.

4.2.2.2 Alcohol dependence and alcohol problems

Jane Marshall

Introduction

The problem of excessive alcohol consumption is a major cause of public health concern in most countries of the world today. Heavy consumption, which involves far more than 'dependence', can cause untold misery to the individual, who is usually affected by other physical, psychological, and social disabilities as well.

As early as 1950, the World Health Organization (WHO) viewed the lack of a commonly accepted terminology as a serious obstacle to international action in the alcohol field.[1]

Definitions of 'alcoholism' have been proposed by a range of professional and other bodies, from biomedical scientists, medical doctors and psychiatrists, psychologists, sociologists, patients in treatment, to the general public.[2] Terms such as 'alcoholism', 'addiction', and 'chemical dependence', have passed into everyday speech, becoming 'popularly enriched' and 'technically impoverished'.[2] These terms mean different things to different people and often have pejorative connotations. The lack of a precise definition of 'drinking problems' has hampered interdisciplinary communication.

In this section, the evolution of the term 'alcohol dependence' will be traced and put into context as but one aspect of a wider spectrum of alcohol-related problems. The concept of the alcohol dependence syndrome (ADS)[3] will be introduced and its influence on the 10th revision of the *International Classification of Diseases* (ICD-10)[4] and the fourth edition of the *Diagnostic and Statistical Manual of Diseases* (DSM-IV) will be reviewed.[5] The terms 'harmful use' (ICD-10) and 'alcohol abuse' (DSM-IV) will also be discussed. Finally 'alcohol-related problems' will be considered.

The development of classification systems for alcohol use disorders

From the time of its inception in 1948, WHO played a major role in formulating public health definitions of 'alcoholism', 'addiction', and 'dependence' through a series of expert committees. Early definitions stressed the sociological rather than the physical aspects of dependence, and thus had limited utility for biological research and psychiatric classification.

'Alcoholism' was classified under 'Other non-psychotic mental disorders' in ICD-8.[6] This definition of 'alcoholism' was generic, and included the subcategories of episodic excessive drinking, habitual excessive drinking, and alcohol addiction. Alcohol addiction was defined as:[6]

> a state of physical and emotional dependence on regular or periodic, heavy, and uncontrolled alcohol consumption, during which the person experiences a compulsion to drink. On cessation of alcohol intake there are withdrawal symptoms, which may be severe.

In ICD-9 the term 'alcoholism' was dropped in favour of the 'alcohol dependence syndrome'.[7] It was, however, still classified under the category 'Other non-psychotic mental disorders'.

At the same time as WHO was formulating public health definitions of 'alcoholism', 'addiction', and 'dependence', a trend towards formal diagnostic criteria was emerging in the United States. This was driven by practical considerations such as the need for better communication between clinicians, researchers, and the general public. Other influential factors included the growing need to categorize persons in an objective fashion for legal, medical, or psychiatric reasons, to collect and communicate accurate public health information, and to standardize practice nationally and internationally. The first two editions of the *Diagnostic and Statistical Manual (DSM-I and DSM-II)*, published in 1952 and 1968 respectively, classified 'alcoholism' as a category of personality disorder. In DSM-III,[8] it was included under a new and separate category of 'Substance use disorders'. The terms 'alcoholism' and 'addiction' were dropped and the terms 'dependence' and 'alcohol abuse' were used instead. Dependence was distinguished from abuse by the presence of tolerance or withdrawal symptoms.

By the mid-1980s, DSM-III and ICD-9 were undergoing reviews for the purposes of revision. The diagnostic criteria for dependence were broadened in DSM-IIIR[9] to incorporate the elements of the alcohol dependence syndrome as hypothesized by Edwards and Gross.[3] The essential feature of the DSM-IIIR dependence category was defined in the text as a 'cluster of cognitive, behavioural, and physiological symptoms, indicating that the person has impaired control over drinking and continues to drink despite adverse consequences'.

The alcohol dependence syndrome

Clinical description

In 1976, Edwards and Gross proposed the existence of alcohol dependence within a syndrome model.[3] Their description was based on the clinical observation that certain heavy drinkers manifested an interrelated clustering of signs and symptoms. They hypothesized that dependence was not an all-or-nothing phenomenon but existed in degrees of severity. The elements of the syndrome, as originally formulated, are summarized in Table 4.2.2.2.1. Not all the elements need always be present, nor always present with the same intensity. Edwards and Gross[3] also acknowledged the fact that not everyone who drinks too much is necessarily dependent on alcohol. They hypothesized that alcohol dependence should be conceptually distinguished from alcohol-related problems.

By drawing a clear distinction between the alcohol dependence syndrome and alcohol-related problems, Edwards and Gross introduced the concept of a bi-axial model. This was described further in the report of a WHO scientific group published in 1977.[10] Alcohol-related problems are defined as comprising those physical, psychological, and social problems that are a consequence of excessive drinking and dependence. Consumption may be viewed on a third axis.

The alcohol dependence syndrome was proposed in the first instance as an empirical formulation that would require research to confirm its assumptions. Unlike previous models of 'alcoholism' that had observational elements but no theoretical input, the alcohol dependence syndrome was influenced by psychological theory and proposed as a synthesis of both general learning theory and specific conditioning models of dependence.[11,12]

Establishment of the validity of the alcohol dependence syndrome

A considerable amount of scientific research evaluating the ADS has been carried out over the past 30 years, much of it supporting its validity.[13] Studies have focused on the degree to which the elements of the syndrome co-occur.[14,15] Other areas of research have included construct validity,[16] concurrent validity,[15,17,18] and predictive validity.[19,20] Field trials conducted as background to the preparation of ICD-10, DSM-IIIR, and DSM-IV, have all contributed to the body of research evidence.[5, 21–25] Difficulties have been encountered in operationalizing elements such as narrowing of repertoire, subjective change, and reinstatement.[25]

These studies have shown a remarkable similarity in terms of the coherence and dimensionality of the syndrome, and are particularly impressive because of the diversity of methods and populations used.[11]

Table 4.2.2.2.1 Key elements of the alcohol dependence syndrome

Narrowing of repertoire
Salience of drinking
Increased tolerance to alcohol
Withdrawal symptoms
Relief or avoidance of withdrawal symptoms by further drinking
Subjective awareness of compulsion to drink
Reinstatement after abstinence

Individual elements of the alcohol dependence syndrome

(a) Narrowing of the drinking repertoire

Most drinkers vary their alcohol consumption from day to day and week to week. The pattern of their drinking is influenced by a range of internal cues and external circumstances. Heavy drinkers may initially widen their drinking repertoire. As dependence advances, so a diminished variability in drinking behaviour emerges. The dependent person begins to drink in the same manner every day. The daily pattern established ensures that a relatively high blood-alcohol level is maintained and that symptoms of alcohol withdrawal are avoided. As drinking becomes stereotyped with advanced dependence, dependent drinkers are able to describe their drinking day in minute detail.

(b) Salience of drinking-seeking behaviour

With advancing dependence, individuals give priority to maintaining their alcohol intake. Alcohol consumption is maintained despite painful direct consequences such as physical illness, rejection by family, and lack of money. They will 'beg, borrow, or steal' to obtain money for alcohol.[3]

(c) Increased tolerance to alcohol

Regular drinkers become tolerant to the central nervous system effects of alcohol and can sustain blood alcohol levels that would incapacitate the non-tolerant drinker. In short, they can 'drink others under the table'. Tolerance may decrease in the later stages of dependence, with individuals becoming intoxicated on much less alcohol than would previously have affected them. Cross-tolerance extends to other drugs, notably barbiturates and benzodiazepines.

(d) Withdrawal symptoms

The term 'alcohol withdrawal' describes a broad range of symptoms and signs, from the relatively trivial to the life-threatening. At first the symptoms are intermittent and mild, but as the degree of dependence increases, so do the frequency and intensity of withdrawal symptoms. Symptoms vary from person to person and do not require abstinence to appear; they can occur when blood-alcohol concentrations are falling. When the picture is fully developed, the dependent drinker typically has severe multiple symptoms every morning on waking; these symptoms may wake him in the middle of the night. Those who are severely dependent usually experience mild withdrawal symptoms during the day whenever their alcohol levels fall.

Withdrawal symptoms cannot occur without a high degree of central nervous system tolerance, but tolerance can occur without clinically manifest withdrawal symptoms.[3]

The spectrum of symptoms is wide, but the four key symptoms are tremor, nausea, sweating, and mood disturbance. A range of other symptoms can also occur, including sensitivity to sound (hyperacusis), ringing in the ears (tinnitus), itching, muscle cramps, sleep disturbance, perceptual distortion, hallucinations, generalized (grand mal) seizures, and delirium tremens.

The four key symptoms will be described in further detail.

(i) Tremor

The first experience of alcohol withdrawal tremor may be recalled vividly: 'One afternoon I went to cut the grass at a friend's house. She gave me a cup of tea and my hands kept shaking. I kept rattling

the cup on the saucer and couldn't put the cup to my mouth. I had to put them down and pretend that I had finished.' Men often find it difficult to shave first thing in the morning and merely getting the first drink of the day to the mouth may be an ordeal in itself.

(ii) Nausea

Dependent drinkers commonly say that their bodies want to vomit first thing in the morning, but that they have nothing to bring up. This may be described as 'dry retching' or 'the dry heaves'. Typically they find it difficult to eat breakfast and to brush their teeth. The first drink of the day is often vomited back.

(iii) Sweating

Dependent drinkers commonly describe waking up in the early morning (3 a.m. or 4 a.m.) to find the bed sheets 'drenched'. In the earlier stages of dependence they may report feeling clammy.

(iv) Mood disturbance

This is an important feature of the withdrawal syndrome. Mildly dependent individuals may feel 'a bit edgy'. Severely dependent individuals may present with clinically significant symptoms of anxiety and depression.

(e) Relief or avoidance of withdrawal symptoms by further drinking

In the early stages of dependence, individuals may find that they need a lunchtime drink to alleviate discomfort. As dependence progresses there emerges the need for an early morning drink to relieve the symptoms of alcohol withdrawal coming on after a night's abstinence. Later, individuals may wake in the middle of the night for a drink, and alcohol is often kept by the bed. If they have to go for 3 or 4 hr without a drink during the day, they value the next drink for its relief effect.

Clues to the degree of dependence can be obtained by taking a detailed history of the first drink of the day. The person drinking from a bottle kept by the side of the bed before they get up is more dependent than the person who has breakfast and reads the paper first. The woman who pours whisky into her first cup of tea is more dependent than the librarian who slips out to the lavatory at midday to drink from a quarter bottle of vodka hidden in her handbag.

(f) Subjective awareness of compulsion to drink

This describes an altered subjective experience of an inability to limit drinking to an acceptable level. Although the familiar term 'loss of control' has been used to denote this element, it is more likely that control has been 'impaired' rather than lost.

Another complex experience is that of 'craving', the subjective experience of which is greatly influenced by environment. Individuals can experience craving of very different intensities on different occasions. Cues for craving include the experience of intoxication, the withdrawal syndrome, mood (anger, depression, elation), or situational cues (being in a pub or (bar), passing an off-licence (liquor store).

Here the key experience may best be described as a compulsion to drink. The desire for a further drink is seen as irrational, and is resisted, but despite this a further drink is taken.

(g) Reinstatement after abstinence

Alcohol dependent individuals who begin to drink again after a period of abstinence invariably relapse back into the previous stage of the dependence syndrome. This process occurs over a variable time course, with moderately dependent individuals perhaps taking weeks or months and severely dependent individuals taking a couple of days.

Influence of the alcohol dependence syndrome on ICD-10 and DSM-IV

Both DSM-IV and ICD-10 diagnostic approaches have drawn on the original concept of the alcohol dependence syndrome.[26,27] Although they have undoubtedly contributed to the standardization of psychiatric practice nationally and internationally, they picture dependence as an all-or-nothing phenomenon rather than as a dimensional state.[28]

ICD-10[4]

ICD-10 includes six items under dependence, most of which are similar to DSM-IV. For a diagnosis of dependence, three or more items should have occurred in the past year. The 'strong desire or sense of compulsion to take the substance' is viewed as a central descriptive characteristic of dependence in ICD-10. This compulsive-use indicator is not included in the DSM-IV concept of dependence (Table 4.2.2.2.2).

DSM-IV[5]

In view of the major changes in criteria that had occurred between 1980 and 1987, the DSM-IV Substance Use Disorders Work Group was reluctant to make any additional major changes to DSM-IIIR. The repetitive nature of the problem was highlighted in that three or more of the items should have occurred during the same 12-month period and the associated difficulties must have led to clinically significant impairment or distress. DSM-IV also uniquely allows for the subtyping of dependence with and without physiological dependence (Table 4.2.2.2.2).

Alcohol abuse and harmful use

Alcohol abuse

DSM-III; DSM-IIIR; DSM-IV

The term 'alcohol abuse' appeared infrequently in the American literature before 1970, when the United States National Institute on Alcohol Abuse and Alcoholism was formed. It was adopted as a formal diagnostic category by DSM-III,[8] which defined abuse as a behavioural concept: 'A pattern of pathological use for at least a month that causes impairment in social or occupational functioning'. Although enshrined in DSM-IIIR and DSM-IV, the term 'abuse' has been variously regarded as 'unscientific and pejorative'[29] and 'oppobrious' and 'vindictive'.[30]

The DSM-IV Substance Use Disorders Workgroup carried out extensive analysis in an effort to define abuse more precisely. Accordingly, in DSM-IV, four separate items, not included in dependence, are listed for the diagnosis of abuse, focusing on social, physical, legal, and interpersonal problems associated with alcohol use. These problems must have occurred repeatedly over a 12-month period, and caused 'clinically significant impairment or distress' (Table 4.2.2.2.3). In practice, the DSM-IV alcohol abuse definition includes a mixture of dependence and harm criteria which could be scaled along a single continuum of severity of alcohol dependence.

Table 4.2.2.2.2 Comparison of ICD-10 and DSM-IV criteria for substance dependence

ICD-10	DSM-IV
A diagnosis of dependence should usually be made only if three or more of the following have been experienced or exhibited at some time during the previous year:	A maladaptive pattern of substance use, leading to clinically significant impairment or distress, as manifested by three (or more) of the following at any time in the same 12-month period
Evidence of tolerance such that increased doses of the psychoactive substance are required in order to achieve effects originally produced by lower doses	Tolerance as defined by either of the following: ◆ need for markedly increased amounts of the substance to achieve intoxication or desired effect ◆ markedly diminished effect with continued use of the same amount of substance
A physiological withdrawal state when substance use has ceased or been reduced, as evidenced by: ◆ the characteristic withdrawal syndrome for the substance or ◆ use of the same (or a closely related) substance with the intention of relieving or avoiding withdrawal symptoms	Withdrawal as manifested by either of the following: ◆ the characteristic withdrawal syndrome for the substance ◆ the same (or closely related) substance is taken to relieve or avoid withdrawal symptoms
A strong desire or sense of compulsion to take the substance	No equivalent criterion
No equivalent criterion	There is a persistent desire or unsuccessful efforts to cut down or control substance use
Difficulties in controlling substance-taking behaviour in terms of its onset, termination, or levels of use	The substance is often taken in larger amounts or over a longer period than was intended
Progressive neglect of alternative pleasures or interests because of psychoactive substance use	Important social, occupation or recreational activities are given up or reduced because of substance use
Increased amount of time necessary to obtain or take the substance or recover from its effects	A great deal of time is spent in activities necessary to obtain the substance, use the substance, or recover from its effects
Persisting with substance use despite clear evidence of overtly harmful consequences. Efforts should be made to determine that the user was actually, or could be expected to be, aware of the nature and extent of the harm	The substance use is continued despite knowledge of having a persistent or recurrent physical and psychological problem likely to have been caused or exacerbated by the substance. *Specify if:* *With Physiological Dependence:* evidence of tolerance or withdrawal (either item is present) *Without Physiological Dependence:* no evidence of tolerance or withdrawal

Reproduced from ICD-10 and DSM-IV:[4, 5]

Table 4.2.2.2.3 Comparison of criteria for abuse or harmful use of substances

ICD-10 criteria for harmful use

A pattern of psychoactive substance use that is causing damage to health, either physical or mental. The diagnosis requires that actual damage should have been caused to the mental or physical health of the user. Socially negative consequences, or the disapproval of others are not in themselves evidence of harmful use.
Harmful use should not be diagnosed if dependence syndrome, a psychotic disorder or another specific form of alcohol-related disorder is present.

DSM-IV criteria for substance abuse

A.
A maladaptive pattern of substance use leading to clinically significant impairment or distress by one (or more) of the following occurring within a 12-month period:
- Recurrent substance use resulting in a failure to fulfill major role obligations at work, school or home
- Recurrent substance use in situations in which it is physically hazardous
- Recurrent substance-related legal problems
- Continued substance use despite having persistent or recurrent social or interpersonal problems caused or exacerbated by the effects of the substance

B.
The symptoms have never met criteria for substance dependence

Reproduced from ICD-10 and DSM-IV:[4, 5]

Harmful use

(a) ICD-10

The ICD-10 criteria for harmful use of alcohol differ significantly from the DSM-IV abuse classification. An ICD-10 diagnosis of harmful drinking requires a pattern of drinking that has caused actual physical or psychological harm to the user. This definition excludes social harms such as marital problems and does not overlap with the DSM-IV definition of alcohol abuse.

The future

Revision of the DSM and ICD classification systems must address the fact that the current systems do not address the continuum of severity of alcohol use disorders (AUDs). Research is needed to explore the relationship between AUDs and the quantity, frequency, and pattern of drinking.[31] Further refinements of the alcohol dependence diagnosis should focus on the essential or core features of the disorder.

Alcohol-related problems

Not everyone experiencing an alcohol problem or alcohol-related disability will be suffering from alcohol dependence. Both dependent and non-dependent drinkers, particularly binge drinkers, are at risk of problems related to heavy alcohol consumption. Indeed, epidemiological evidence supports the view that most alcohol-related

harm in the general population occurs in heavy non-dependent drinkers.

Alcohol-related problems are extremely diverse. They have been defined as 'those problems that may arise in individuals around their use of beverage alcohol, and that may require an appropriate treatment response for their optimum management'.[32] The phrases 'alcohol problems' or 'alcohol-related problem' contain an assumption of causality.[33] This issue is a complex one, involving individual differences and the social context of drinking as well as the pattern, duration, and intensity of alcohol use.

Alcohol-related problems can be related to the acute or chronic consumption of alcohol. A fractured ankle sustained by falling over while acutely intoxicated is an example of the former category. Cirrhosis of the liver is an example of a chronic problem. An individual who drinks in binges will experience different problems compared with someone who drinks the same amount of alcohol spread out over a week or a month or a year. The way in which a person behaves while intoxicated is another important factor determining the nature of alcohol-related problems. The social consequences of drinking such as job loss, imprisonment, marital and family break-up, and drunk-driving have profound effects on the well being of the drinker, their family, and society.[33]

Types of alcohol-related problems

Although somewhat artificial, it is helpful to classify alcohol-related problems in individuals into physical, psychological, and social categories. There is often considerable overlap between these three areas. The more severe the dependence, the greater the likelihood of problems of all three kinds.[18]

Alcohol-related physical and psychological problems are discussed in the next section. Some of the social problems can be included here, for example the acute adverse consequences of drinking such as trauma resulting from road traffic accidents, injuries from fights, and death from overdose.[33]

The social problems that can result from drinking are legion. Alcohol is involved in all types of accidents and contributes to traffic deaths, home, and leisure injuries.[33] It is associated with domestic violence, child abuse, crime, homicide, and suicide and is also related to poor work performance, dismissal, unemployment, debt and housing problems, and crimes of violence.

There is a continuity between moderate and excessive drinking and between harmless drinking and drinking that results in harm or in problems. Such problem-clustering may reflect alcohol dependence, certainly amongst a proportion of these drinkers. Given this heterogeneity, no one form of treatment is likely to be effective for all individuals with alcohol problems.[32] A range of treatments is required and it should be possible for non-specialists to offer brief interventions (see Chapter 4.2.2.4).

The study of alcohol-related problems remains underdeveloped, compared with the study of alcohol dependence.[34] There may be several reasons for this, not least the difficulties inherent in measuring alcohol-related problems. Another important issue, central to these difficulties, is the extent to which alcohol is causally related to the problem.

Several questionnaires, measuring a variety of alcohol-related problems, have been developed. The Alcohol Problems Questionnaire (APQ)[34] is a standardized inventory, which includes 46 items covering eight problem domains: physical, psychological, friends, finances, police, marital, children, and work. All questions apply to the 6-month period prior to the completion of the questionnaire. The shorter or core version includes the first five domains (23 items). This questionnaire can make a useful contribution to the overall assessment, and is of potential value in outcome research.

Conclusions

An understanding of the concepts of alcohol dependence and alcohol-related problems is central to the therapeutic process with individual patients.

The development of diagnostic criteria has helped to standardize practice nationally and internationally, and aided interdisciplinary communication. The diagnostic criteria for dependence are imperfect because they view the syndrome as an all-or-nothing phenomenon rather than as a dimensional state. The concepts of abuse and harmful use need further refinement. The totality of alcohol problems is a vast area with major implications for the general population, not just dependent drinkers.

4.2.2.3 Alcohol and psychiatric and physical disorders

Karl F. Mann and Falk Kiefer

Intoxication

Clinical symptoms of alcohol intoxication are associated with both, blood alcohol concentration (**BAC**), and the individual's level of tolerance. Whereas in healthy persons without alcohol tolerance mild intoxication (BAC ≤ 100 mg per cent), medium intoxication (BAC 100–200 mg per cent), and severe intoxication (BAC >200 mg per cent) differ clinically, this schema does not work in patients suffering from alcoholism. In these people, different levels of tolerance can lead to completely different clinical pictures despite their having similar blood alcohol concentrations. Thus, psychopathology is more important than blood alcohol concentrations for estimating the severity of an acute intoxication state. With increasing BAC we observe elated mood, disinhibition, impaired judgement, belligerence, impaired social and occupational functioning, mood lability, cognitive impairment, reduced attention span, slurred speech, incoordination, unsteady gait, nystagmus, and stupor or coma.

The term 'pathological intoxication' can still be found in the older literature (reviewed by Lishman[1]). It was described as an outburst of aggression and uncontrollable rage, which might have led to serious destructions. As a rule, this behaviour, which was not typical for the individual, ended in terminal sleep and subsequent amnesia. However, since there is not enough empirical evidence for the existence of this syndrome, it was no longer considered in DSM-IV.[2]

Alcohol-induced amnesias ('blackouts')

This term refers to a transient state of amnesia after drinking excess. Usually patients' behaviour is no different from their behaviour during other periods of intoxication without blackouts. Nevertheless, the memory gap usually lasts for hours, but may be as long as a day or more. In extreme cases, patients find themselves in strange places with no recollection of how they got there.

Withdrawal

Withdrawal without complications

When alcohol is used regularly and withdrawn rapidly, a characteristic withdrawal syndrome can develop. It includes autonomic hyperactivity like hand tremor, insomnia, sweating, tachycardia, hypertension, and anxiety. The symptoms generally occur between 6 and 12 h after the last alcohol consumption. Depending on their severity they may last for up to 4 or 5 days. The neurobiological basis for withdrawal is a gradual upregulation of *N*-methyl-D-aspartate receptors under the influence of chronic alcohol use. As soon as the alcohol, which acts as a central nervous system depressant, is withdrawn, an overwhelming excitatory action in the brain mediated by the glutamatergic system is observed.

Withdrawal with perceptual disturbances

The individual usually experiences more discomfort and anxiety if transient visual, tactile, or auditory hallucinations or illusions are present. In this state, reality testing is still intact: the person still knows that the hallucinations are induced by the substance. If this is no longer true, a substance-induced psychotic disorder or a delirium tremens is likely.

Withdrawal with grand mal seizures (alcoholic convulsions, 'rum fits')

In about 30 per cent of the cases the typical grand mal seizures are followed by a delirium tremens. The electroencephalograph picture is only abnormal at the time of the fits, hence, alcohol convulsions differ pathophysiologically from latent epilepsy.

Alcohol-induced psychosis (delirium tremens)

In delirium tremens the symptoms of alcohol withdrawal described earlier are accompanied by a reduced level of consciousness, disorientation in time and place, impairment of recent memory, insomnia, and perceptual disturbances. The latter include misinterpretation of sensory stimuli and hallucinations; most are visual, but auditory and haptic hallucinations also occur. The hallucinations may be Lilliputian or of normal size, and may be of complex, frightening, and extremely realistic scenes. The patient is restless and fearful, and may become severely agitated. There is marked tremor, and ataxia when standing. Some patients experience vestibular disturbance. Autonomic disturbance includes sweating, tachycardia, raised blood pressure, and dilated pupils. There may be a mild pyrexia. Patients are usually dehydrated, often with abnormal electrolytes, leucocytosis, and impaired liver function. As in other forms of delirium, symptoms are worse at night.

Delirium tremens is the most severe of the states following withdrawal of alcohol, with a reported mortality of up to 5 per cent. In its fully developed form it is uncommon; the more frequent states are acute tremulousness, transient hallucinations with tremor, and uncomplicated fits. Delirium tremens usually begins after 3 to 4 days of abstinence from alcohol, although occasionally it starts while drinking continues. In the latter cases it is assumed that alcohol levels have fallen below a critical level. It is not known by what mechanism alcohol withdrawal leads to the clinical syndrome. Delirium tremens often appears to start suddenly, although close enquiry may reveal a prodromal stage of restlessness, anxiety, and insomnia. It usually lasts for 2 to 3 days, often ending with deep and prolonged sleep from which thepatient wakes symptom free and with little memory of the period of delirium. Rarely, the patient is left with an amnesic syndrome, perhaps the consequence of previous undetected Wernicke's encephalopathy.

Treatment is by sedation, usually with a benzodiazepine, together with fluid replacement under close observation. The possibility of accompanying head injury or infection should be investigated. Sedation should be adequate to prevent withdrawal seizures, with frequent monitoring of the response. High-potency vitamins are usually given to prevent Wernicke's encephalopathy. An anticonvulsant is given when there have been withdrawal seizures in the past. Cardiovascular collapse and hyperthermia occur occasionally and require urgent medical treatment.

Hallucinosis

Alcoholic hallucinosis is a rare condition in which auditory hallucinations are present in clear consciousness and without autonomic overactivity, usually in a person who has been drinking excessively for many years. The hallucinations often begin as simple noises, but are gradually replaced by voices, which may threaten, abuse, or reproach the person. Usually the voices speak to the person, but sometimes they discuss him or her in the third person. The voices may be occasional or relentlessly persistent. They may command the patient, who may respond with unrestrained or suicidal behaviour. Delusions are secondary interpretations of the hallucinations. Autochthonous hallucinations suggest schizophrenia, as do thought disorder or incongruity of affect. The patient is usually distressed, anxious, and restless.

In both ICD-10 and DSM-IV, the disorder is classified as a substance-induced psychotic disorder and not, as has been suggested in the past, a form of schizophrenia (released by heavy drinking). The differential diagnosis includes transient auditory hallucinations occurring during withdrawal from a period of heavy drinking, and delirium tremens in which auditory hallucinations may accompany the more prominent visual ones. In both conditions the auditory hallucinations are transient and disorganized, and in the latter consciousness is impaired. In contrast, the auditory hallucinations of an alcoholic hallucinosis are persistent and organized, and occur in clear consciousness. Other differential diagnoses are depressive disorder with psychotic symptoms and schizophrenia, both of which can be accompanied by heavy drinking.

The hallucinations usually respond rapidly to antipsychotic medication. The prognosis is good; usually the condition improves within days or a couple of weeks provided that the person remains abstinent. Symptoms that last for 6 months generally continue for years.[3]

Psychiatric disorders

Alcohol-dependent patients often present with symptoms of anxiety or depression. These states are generally referred to as

comorbid disorders or dual diagnosis. Alcoholism can be a consequence of anxiety and mood disorders ('secondary alcoholism'). It can develop independently after anxiety and depression, or it can precede anxiety and depressive symptoms ('primary'). As the former are discussed elsewhere in this textbook, here we concentrate on the latter.

Alcohol-induced mood disorders

Alcohol is a central nervous system depressant. Taken regularly in high doses it may provoke feelings of sadness. Episodes of withdrawal or relative withdrawal can lead to excitability and nervousness, including anxiety. The more a person drinks, the more likely it is that these symptoms will occur. Finally in the stage of alcohol dependence, up to 80 per cent of people report depressive symptoms at some time in their life. About one-third of male patients and up to 50 per cent of female patients have experienced longer periods of severe depression.[4] These high prevalence rates are noteworthy, since more than 20 per cent of alcoholics have attempted suicide once or more and about 15 per cent die in their attempt. Besides depressive features, alcohol-induced mood disorders may also comprise manic symptoms or mixed features. However, the diagnosis should only be used when the symptoms cause clinically significant impairment or distress in social, occupational, or other areas of functioning.

Concerning treatment, it is interesting to note that despite the vast majority of patients who present with depressive symptoms at the beginning of treatment for alcoholism, only very few need specific antidepressant medication or specific psychotherapy. In most other cases depressive symptoms disappear within weeks of controlled abstinence.[5]

Alcohol-induced anxiety disorders

This diagnosis should only be used when anxiety symptoms are thought to be related to the direct physiological effects of alcohol. The symptomatology may involve anxiety, panic attacks, and phobias. Both alcohol-induced anxiety disorders and mood disorders can develop during intoxication, withdrawal, or up to 4 weeks after cessation of alcohol consumption. During intoxication or withdrawal, the diagnosis should only be given when the symptomatology clearly exceeds what would be expected from anxiety or depressive symptoms during a regular intoxication or withdrawal episode.

Anxiety disorders are among the most common groups of psychiatric disorders in the general population, with prevalence rates of up to 25 per cent.[6] In clinical studies between 20 and 70 per cent of patients with alcoholism also suffer from anxiety disorders.[7] On the other hand, between 20 and 45 per cent of patients with anxiety disorders also have histories of alcoholism.[8] However, it has been argued that the comorbidity figures are overestimated, because in some of the studies the focus was on drinking patterns rather than on alcohol dependence or they describe anxiety symptoms rather than disorders according to diagnostic criteria.[9] Family studies analysing the comorbidity of alcoholism and anxiety disorders might be a means of clarifying this controversy. For instance, in the Yale study the presence of anxiety disorders in the probands slightly increased the risk for alcohol dependence in their relatives, whereas alcohol dependence in the proband did not increase their relative's risk for anxiety disorders.[10] Similarly, Maier *et al.*[11] demonstrated an increased risk of alcoholism in probands with panic disorders, but not the reverse. Kendler *et al.*[12] in a study of female twins, found evidence that common genetic factors may underlie both alcoholism and panic disorder.

Effects on the brain

Cerebral cortex

Chronic alcohol consumption leads to structural and functional changes in the brain. Alcoholic dementia is dealt with in Chapter 4.1.11. Most of the tissue loss from the cerebral hemispheres in alcoholics is accounted for by a reduction in the volume of the cerebral white matter, additionally there is a slight reduction in the volume of the cerebral cortex. This has been demonstrated both pathologically[13] and using magnetic resonance imaging with quantitative morphometry.[14]

Harper *et al.*[15] documented neuronal loss in alcoholics. There was a 22 per cent reduction in the number of neurones in the superior frontal cortex (Brodmann's area 8), while surviving neurones showed shrinkage in the superior frontal, motor, and frontal cingulate cortices.[16] This finding of cortical damage in alcoholics is consistent with neuroradiological studies.[14]

Ferrer *et al.*[17] examined the dendritic tree of cortical neurones in alcoholic subjects using Golgi-apparatus impregnation techniques. They described a significant reduction in the basal dendritic tree of layer III pyramidal neurones in both the superior frontal and motor cortices. These studies suggest that, even though there is no significant reduction in the numbers of cortical neurones in the motor cortex, there are cellular structural abnormalities that could have important functional implications.

Wernicke's encephalopathy

The best-known features of heavy alcohol consumption in adults are Wernicke's encephalopathy and Korsakoff's syndrome. Wernicke's encephalopathy is directly caused by thiamine deficiency, which results from a combination of inadequate dietary intake, reduced gastrointestinal absorption, decreased hepatic storage, and impaired utilization. Only a subset of thiamine-deficient alcoholics develop Wernicke's encephalopathy, perhaps because they have inherited or acquired abnormalities of the thiamine-dependent enzyme transketolase, which reduces its affinity for thiamine. Wernicke's encephalopathy is characterized by degenerative changes, including gliosis and small haemorrhages in structures surrounding the third ventricle and aqueduct: namely, the mammillary bodies, hypothalamus, mediodorsal thalamic nucleus, colliculi, and midbrain tegmentum. Clinical features associated with the Wernicke–Korsakoff syndrome include memory deficits, ocular signs, ataxia, and global confusional states. Most can be related to damaged functional systems in the hypothalamus, midbrain, and cerebellum. In a large Scandinavian neuropathological study, 12.5 per cent of all alcoholics exhibited signs of Wernicke's encephalopathy.[18]

Korsakoff's syndrome

About 80 per cent of alcoholic patients recovering from Wernicke's encephalopathy develop Korsakoff's amnesic syndrome. It is characterized by marked deficits in anterograde and retrograde memory, apathy, an intact sensorium, and relative preservation of other intellectual abilities. Korsakoff's amnesic syndrome may also appear without an antecedent episode of Wernicke's

encephalopathy. Acute lesions may be superimposed on chronic lesions, suggesting that subclinical episodes of Wernicke's encephalopathy may culminate in Korsakoff's amnesic syndrome. The memory disorder correlates best with the presence of histopathological lesions in the dorsomedial thalamus. (Amnesic syndrome is considered further in Chapter 4.1.12.)

Cerebellar degeneration

Many alcoholic patients develop a chronic cerebellar syndrome related to the degeneration of Purkinje cells in the cerebellar cortex. Quantitative studies revealed a significant loss of cerebellar Purkinje cells (by 10–35 per cent) and shrinkage of the cerebellar vermal, molecular, and granular cell layers.[19] Evidence for a direct toxic effect caused by ethanol is provided by animal models.[20] In neuroimaging studies, however, cerebellar ataxia in alcoholics does not correlate with the daily, annual, or lifetime consumption of ethanol. As in Wernicke's encephalopathy, thiamine deficiency due to poor nutrition has also been implicated. Cerebellar atrophy has been reported to occur in about 40 per cent of chronic alcoholics.[19] In a clinical study of alcoholic inpatients, 49 per cent had at least discrete clinical signs of cerebellar atrophy.[21]

The diagnosis of alcoholic cerebellar ataxia is based on the clinical history and neurological examination. The ataxia affects the gait most severely. Limb ataxia and dysarthria occur more often than in Wernicke's encephalopathy, whereas nystagmus is rare. Computed tomography or magnetic resonance imaging scans may show cerebellar cortical atrophy, but a considerable number of alcoholic patients with this finding are not ataxic on examination. Whether these represent subclinical cases in which symptoms will develop subsequently is unclear. It is interesting to note that impaired cerebellar function improves significantly when abstinence is maintained.[22]

Hepatocerebral degeneration

Hepatic encephalopathy develops in many alcoholics with liver disease, and is characterized by altered sensorium, frontal release signs, 'metabolic' flapping tremor, hyperreflexia, extensor plantar responses, and occasional seizures. Whereas some patients progress from stupor to coma and then death, others recover and suffer recurrent episodes. The brains of patients with hepatic encephalopathy show enlargement and proliferation of protoplasmic astrocytes in the basal ganglia, thalamus, red nucleus, pons, and cerebellum, in the absence of neuronal loss or other glial changes.[23]

Patients who do not recover fully after an episode of hepatic encephalopathy go on to develop a progressive syndrome of tremor, choreoathetosis, dysarthria, gait ataxia, and dementia. Hepatocerebral degeneration may progress in a stepwise fashion, with incomplete recovery after each episode of hepatic encephalopathy, or slowly and inexorably, without a discrete episode of encephalopathy.

Rare disorders

The **Marchiafava–Bignami syndrome** is a disorder of demyelination or necrosis of the corpus callosum and adjacent subcortical white matter. The course may be acute, subacute, or chronic, and is marked by dementia, spasticity, dysarthria, and an inability to walk. Patients may lapse into coma and die, survive for many years in a demential condition, or occasionally recover.

Central pontine myelinolysis is a disorder of the cerebral white matter that usually affects alcoholics, but it also occurs in non-alcoholics with liver disease including Wilson's disease, malnutrition, anorexia, burns, cancer, Addison's disease, and severe electrolyte disorders such as thiazide-induced hyponatraemia; however, the majority of cases occur in alcoholics, suggesting that alcoholism may contribute to the genesis of central pontine myelinolysis in, as yet, undefined ways.[23] Myelinolytic lesions can be reduced experimentally by rapid correction of chronic hyponatraemia. Symptoms include loss of pain sensation in the limbs, bulbar palsy, quadriplegia, disordered eye movements, vomiting, confusion, and coma.

Reversibility of brain damage

Alcohol-related neuroanatomical brain changes have been shown to be partially reversible. These findings created an ongoing debate on possible mechanisms and clinical correlates.[22]

Foetal alcohol syndrome

The first description of the foetal alcohol syndrome was given by French scientists in 1968.[24] As a research paradigm, it has a major impact on our understanding of alcohol's effects on the brain. Clinically the syndrome is characterized by: growth retardation involving height, weight, and head circumference; deficient intellectual and social performance and muscular coordination; minor structural anomalies of the face, together with more variable involvement of the limbs and the heart.

The basis of this pathology is a cascade of effects exerted by alcohol on the developing cell. Under normal conditions growth factors enhance the growth of cells and their differentiation, but alcohol can diminish these effects.[25] A second way of damaging the developing nerve cell is through the production of free radicals that allow calcium to accumulate in the cells.[26] The induction of a free-radical formation is induced by alcohol. The result of both pathogenic processes is a decrease in the overall size of the brain and a diminution in the thickness of the outer layers of the cortex, due to decreases in the total numbers of cells. Impaired nerve cell migration might also play a role in the development of the foetal alcohol syndrome.[27]

The effects of alcohol on the developing brain are clinically measured by assessing the head circumference, with a clear dose-dependent effect.

The foetal alcohol syndrome is considered further in Chapter 9.2.7.

Effects on the body

Malnutrition and vitamin deficiency

Malnutrition can be a consequence of deficient food intake. More important in alcoholics seem to be maldigestion and malabsorbtion ('secondary malnutrition'). Apart from the direct toxic effect of alcohol on most body tissues, malnutrition is an important contributor to organ damage in alcoholics.[28] Vitamin metabolism may be profoundly affected by chronic alcohol consumption. As a consequence, many alcoholics have deficiencies in vitamins B1 (thiamine), A, D, B6, and E, and folate. This can lead to a variety of physical consequences, including damage to different organs.

Peripheral neuropathy

Besides its effect on the central nervous system, alcohol also damages motor, sensory, and autonomic nerves that control muscles and internal organs. Symptoms are weakness, numbness, pain, and a prickly feeling or burning of the skin, especially the feet. Usually on neurological examination, the tendon reflexes are diminished or have completely disappeared and skin sensibility is reduced, especially in the feet and in the lower limbs. When patients abstain from alcohol, the progression of the symptoms can be stopped and even partial recovery is possible.

Muscle

Alcohol is toxic to skeletal muscles in a dose-dependent way. Alcoholics often suffer from malnutrition, which adds to the chronic changes in muscles. Chronic myopathy can be found in 40 to 60 per cent of alcohol-dependent patients.[29] Pathophysiological mechanisms of muscle damage include alterations in membrane fluidity, ion channels, and pumps, as well as protein synthesis and hormonal dysfunction. Patients complain of pain and weakness. Swelling of the muscle can be easily detected. In chronic states, muscle atrophy is evident. There is no acute treatment for alcoholic myopathy other than abstinence, when acute myopathy can rapidly disappear; chronic myopathy usually only improves, leaving persistent weaknesses.

Liver

The effects of ethanol on the liver are among the first and best-known symptoms of alcoholism. The first manifestation of alcoholic liver diseases is the fatty liver. It is followed by early fibrosis, which can be associated with alcoholic hepatitis. If the process continues, irreversible damage leading to severe fibrosis and to cirrhosis is observed.[30] These effects occur through heavy alcohol consumption even in the absence of dietary deficiencies.

Mortality from liver cirrhosis has long been an important correlate of the per capita consumption in a given population. Liver damage is also important because it produces an increase in liver enzymes such as aspartate transaminase, alanine transaminase, and γ-glutamyl transferase, which again are of great practical value as diagnostic markers of severe alcohol consumption. Alcohol accounts for more than 80 per cent of all cirrhosis deaths, a consequence that seems to be even more pronounced in women.[31]

Pancreas

About 5 per cent of alcoholics develop chronic pancreatitis. Ethanol seems to damage the pancreas slowly. In general, it takes between 10 and 15 years of heavy drinking before pancreatitis becomes clinically apparent. In the presomatic phase certain changes such as fibrosis, calcium deposits, and especially loss of functioning in enzyme- and hormone-producing cells can be demonstrated. The acute symptoms are abdominal pain and vomiting. Chronic complications include weight loss, steatorrhoea, and diabetes mellitus.[32]

Skin

Originally it was believed that skin alterations in alcoholics are due to alcoholic liver disease. However, more recent research has revealed that the skin may be affected much earlier by alcohol misuse.[33] Whereas the palmar erythema and spider naevi are well-known consequences of alcoholic liver disease, which also serve as diagnostic markers for alcoholism, psoriasis and facial erythema have less often been linked with high alcohol consumption. Alcohol clearly has to be on the list of agents known to exacerbate psoriasis. One possible mechanism of the action of alcohol on the skin could be a defect in the immune system.

Heart

Cardiac myopathy is one of the oldest known physical consequences of high alcohol consumption. Similar to ethanol's effects on skeletal muscles, the cells of the heart muscle are damaged by ethanol's influence on ion channels and pumps etc. Atrophy leads to a dilatation of the heart as a whole.

Recently, the effect of alcohol on coronary heart disease has been widely discussed. Indeed, it seems that there is a beneficial effect of moderate alcohol consumption. Although the reasons are currently under discussion, recent data suggest, that the combination of several actions including changes in lipid metabolism, antioxidant effects, changes in haemostasis and platelet aggregation, arterial vasodilatation mediated by NO release and the expression of cardioprotective proteins contribute to these 'French Paradox'.[34] It seems that an alcohol-induced increase in high-density lipoproteins and a decrease in low density lipoproteins may play a role in this process—an alteration in platelet aggregation could be one possible mechanism of action. Besides cardiomyopathy, cardiac arrhythmias are prominent consequences of alcohol consumption. Close to one-third of all cardiomyopathies can be attributed to alcohol consumption.

Hypertension

A dose-response relationship between drinking and diastolic and systolic blood pressure has been shown consistently.[31] In alcohol consuming population, the amount of alcohol consumption is significantly associated with hypertension and cardiovascular as well as all cause mortality. It is not clear, however, whether this relationship can only be seen above a threshold level of consumption.

Cancer

There is very clear evidence that alcohol increases the risk of cancer at the upper bronchodigestive tract. This includes cancer of the mouth, pharynx, larynx, and oesophagus. Additionally, alcohol consumption correlates with primary liver cancer. A possible link between alcohol and breast cancer is still a matter of debate: the association is not strong and not necessarily causative, at least for moderate consumption.[35] The same seems to be true for the correlation between beer drinking and cancer of the rectum.

4.2.2.4 Treatment of alcohol dependence

Jonathan Chick

A chronic relapsing disorder

Some people repeatedly put themselves or others at risk by drinking. One view is that such people could drink sensibly if they were more considerate and used more will power. Another increasingly accepted view is that many such individuals are in a state, existing in degrees of severity, in which the freedom to decide whether to change their drinking, and to adhere to that decision, is reduced compared with other drinkers. This state partly depends on perceived pay-offs for changing, and on acquired dispositions, which are less accessible to conscious control. Such persons become aware of a wish, or urge, to drink, which overcomes rational thought. They may then make up an explanation, for example, 'No wonder I feel like a drink, I've had a hard day'.

Such individuals benefit from help to unlearn those patterns, and to learn different approaches to problems. Discussion, care, and encouragement from others can bolster their will to do so. Assistance to set-up controls within or from outside themselves may help. Some people can do this without external help, and others with the help of Alcoholics Anonymous (**AA**) alone.[1]

This approach argues that dependence on alcohol should be managed like other relapsing disorders, such as diabetes and asthma,[2] by using long-term monitoring coupled with intermittent or continuous treatment.

Starting treatment

The initial interview

Assessment is the first step of intervention; clumsy interviewing alienates an ambivalent patient. The key to success is accepting that the patient is probably in two minds about the interview and about changing his or her drinking habits. Avoid confrontation. The drinking has probably already shown its resistance to deterrence by fear or pain. Gently nudge the matrix of conflicting motivations in the direction of action.

Patients may or may not have been referred for help with alcohol problems. Even if they have, the interview should begin with enquiry into the patient's current concerns. Reflective listening[3] helps the patient to clarify these concerns, conveys empathy, and avoids premature closure. A spirit of collaborative enquiry helps patients to reach their own conclusions about the role of alcohol in their troubles. This will be more convincing than a recitation of medical advice. People are more likely to believe what they hear themselves say than what others tell them. The interview is less likely to slip into confrontation if the doctor conveys recognition that, for the patient, drinking alcohol has been pleasurable. Therefore the assessment should not proceed in a series of closed questions, such as: 'Do you drink more than you intend to?' 'Does alcohol make you depressed?' Instead, ask open-ended questions: 'Tell me about your pattern of drinking. What are the good aspects . . . and what are the disadvantages?' 'How does alcohol fit in with these periods of hopelessness you describe?' The patient may want it understood that at times alcohol has dulled pain. Only then will there be a concession that the cumulative effect has been to worsen mood.

A comment such as 'I'm just a heavy social drinker, not an alcoholic' is not a gauntlet to be seized—an argument about definitions will distract from the work of clarifying and planning how to deal with the current problems. Instead, a response such as 'I gather you don't like labels' may reveal pertinent fears and prejudices (e.g. that alcoholics are failures, who get locked up in hospital).

Denial permits dismissal of unpleasant or unwanted facts and feelings. It hurts to admit that you have lost your family's respect, or that you will have to give up alcohol, which you enjoy. Alcohol problems still carry disgrace. In Islamic cultures, where alcohol is forbidden, denial from shame may be deepened by fear of punishment from the authorities.

Explain symptoms

Help the patient to understand withdrawal symptoms and how they can abort attempts to reduce consumption. Patients frequently attribute withdrawal symptoms to other causes; for example, waking at 4 a.m. with sweats and anxiety may be attributed to worry, and trembling hands in the morning to stress.

Informant

If the partner, a close friend, or a relative is present from the start, the salient points usually emerge more rapidly. However, the patient should also be seen alone because matters to do with the police, an employer, the bank, or a lover may still be unknown to the partner. Relatives should hear the exchange between doctor and patient, otherwise the version they hear later from the patient may be diluted: 'The doctor says I'm not an alcoholic'. This can leave relatives even angrier than before, convinced that no one understands their distress and that the drinker has once again deceived the doctor.

Assessments

The use of a breathalyser or saliva test to measure blood alcohol concentration puts alcohol consumption firmly into the objective arena. Use the test before the individual starts to detail recent drinking, there is nothing to be gained from showing that the patient sometimes minimizes the drinking.

Physical signs may be helpful. Heavy drinking may cause excessive capillarization in the conjunctivae or in the skin of the nose and cheeks. The liver may be enlarged. Look for tremor in the outstretched tongue, which is less commonly concealed (or exaggerated) than tremor in the fingers. Tachycardia is another useful sign of withdrawal. In a hyperaroused fearful patient, who has already been without a drink for 24 h, a pulse of over 110 beats/min may presage delirium tremens.

Clinicians vary in how structured an assessment they prefer, but at some point in the first one or two interviews the following should be noted: drinking patterns, history of withdrawal symptoms, previous attempts to stop drinking, use of drugs (prescribed and not prescribed), physical complications including head injuries, police, or Court involvement (past and current), dwelling arrangements, problems at home, trouble at work (specifying whether the employer has commented on drinking alcohol and/or started disciplinary action), psychiatric illness, family history, previous treatments, and experience of AA.

Medical assistance for withdrawal

Medical assistance to reduce the short-term discomfort of withdrawal can be the beginning of restructuring of thoughts and lifestyle towards long-term abstinence.

If dependence is severe, especially in an unplanned situation where a very heavy drinker is suddenly deprived of alcohol because of an accident, illness, or police arrest, care must be taken to prevent the life-threatening complications of convulsions or delirium. Anticipation is the key.

When dependence is less marked, withdrawal symptoms are mild and the person can stop drinking by gradual reduction, encouraged by the physician or a friend.

When the patient's aim is 'controlled drinking'(see below), this may also entail an initial stage of withdrawal, as the final goal is more likely to be achieved after abstinence for 2 or 3 months.

The setting

Controlled studies have shown that outpatient withdrawal is safe and effective for mild and moderately dependent alcoholics.[4,5] Advice for patients withdrawing at home is given in Box 4.2.2.4.1. Hayashida *et al.*[4] randomly allocated 164 mild to moderately affected patients to either inpatient or outpatient detoxification. Completion was successful in 95 per cent of the former and 72 per cent of the latter; inpatient care cost eight times more than outpatient care.

Box 4.2.2.4.1 Advice to patient on withdrawing from alcohol at home

If you have been chemically dependent on alcohol, stopping drinking causes you to become tense, edgy, perhaps shaky or sweaty, and unable to sleep. There can be vomiting or diarrhoea. This 'rebound' of the nervous system can be severe. Medication controls the symptoms while the body adjusts to being without alcohol. This usually takes 3 to 7 days from the time of your last alcoholic drink. If you did not take medication, the symptoms would be worst in the first 48 h, and then gradually disappear. This is why the dose starts high and then reduces.

You have agreed not to drink alcohol. You may become thirsty. Drink fruit juices and water but do not overdo it. You do not have to 'flush' alcohol out of the body. More than 3 l of fluid could be too much. Do not drink more than three cups of coffee or five cups of tea. These contain caffeine, which disturbs sleep and causes nervousness.

Aim to avoid stress. The important task is not to give in to the urge to take alcohol. Help yourself relax by going for a walk, listening to music, or taking a bath.

Sleep. You may find that even people with capsules, or as they are reduced, your sleep is disturbed. You need not worry about this lack of sleep as it does not seriously harm you, but starting to drink again does. Your sleep pattern will return to normal in a month or so. It is better not to take sleeping pills so that your natural sleep rhythm returns. Try going to bed later. Take a bedtime snack or milky drink. The capsules may make you drowsy so you must not drive or operate machinery. If you become drowsy, miss out a dose.

Meals. Even when you are not hungry, try to eat something. Your appetite will return.

Admission to a hospital is indicated when the home social milieu is inimical to abstinence, or when there is a history of withdrawal convulsions or delirium; it is urgent when there are any signs of Wernicke's encephalopathy.

Medication

A benzodiazepine[6] is prescribed for two reasons: first, to reduce the risk of severe withdrawal symptoms with delirium or convulsions (indicated if recent consumption has been more than 15 units/day for more than 10 days); second, to assist the individual whose wish to abstain or reduce drinking is overcome by longing for alcohol (craving), shaking, anxiety, insomnia, or nausea and vomiting.

A typical outpatient regimen would be chlordiazepoxide 20 to 30 mg four times daily, reducing to zero over 5 days, with the larger doses given at night (Table 4.2.2.4.1). Medication is issued on the understanding that the patient does not also take alcohol. If there is any doubt that this instruction will be followed, medication is issued daily and a check made (ideally by breath or saliva tests) that drinking has not been resumed. Chlordiazepoxide is preferred to diazepam for outpatient use because it has a lower street value and is therefore less likely to be sold on. When managing severe withdrawal symptoms with marked agitation and tremor, or incipient delirium, diazepam (starting at 10 mg four times daily) is preferred because it has a more rapid action and can be given parenterally. A benzodiazepine with one metabolite only and a shorter half-life (e.g. oxazepam, lorazepam) is preferred if liver function is significantly impaired (i.e. there is jaundice, ascites, oedema, low serum albumin, or raised serum bilirubin).

Table 4.2.2.4.1 Example of a fixed-dose regime for outpatient alcohol withdrawal using capsules of chlordiazepoxide 10 mg

	First thing	12 noon	6 p.m.	Bedtime
Day 1		3	3	3
Day 2	2	2	2	3
Day 3	2	1	1	2
Day 4	1	1		2
Day 5		1		1

For inpatients, a benzodiazepine such as diazepam 10 mg may be given every hour until symptoms are controlled (symptom-triggered dosing). This procedure leads to lower total prescription of benzodiazepine, less oversedation, and quicker discharge from hospital.[7]

If the patient is vomiting, give metoclopropamide 10 mg intramuscularly 30 min before the first benzodiazepine tablet and/or perhaps choose a benzodiazepine that can be administered parenterally; lorazepam 1 mg is absorbed adequately from the intramuscular site, or diazepam 10 mg can be given intravenously (or rectally).

Treating convulsions

With the aim of preventing further convulsions, the patient who has just had a fit or is in a fit is given 10 mg diazepam. Consider giving 15 to 20 mg in a patient who has been taking benzodiazepines regularly prior to this event, or is much above average weight. It is illogical to commence an anticonvulsant, which may take 2 to 3 days to reach a therapeutic serum level. Rather, increase the dose of the benzodiazepines. A convulsion may presage delirium.

Preventing convulsions

Deaths have occurred in hospital, prison, and police cells from repeated alcohol withdrawal fits. When withdrawal is planned in patients with a history of fits of any cause the risk can be reduced by commencing phenytoin (300 mg daily) 4 days before the cessation of drinking. In an acute situation, larger than normal doses of long-acting benzodiazepines are given in the first 36 h without waiting until the blood alcohol level has fallen to zero. The benzodiazepine should be started as soon as the blood alcohol level can be presumed to be falling, even though the patient still smells of alcohol or has a positive breath test, provided that he or she is sober enough to understand and cooperate with the procedure.

Treating delirium tremens

Increasing the dose of the benzodiazepine may be sufficient to control the agitation. If not, the slight epileptogenic effect of antipsychotic drugs should not deter their use, especially if delusions and hallucinations have developed, provided that anticonvulsant protection by a benzodiazepine is in place. Parenteral haloperidol plus parenteral lorazepam is usually effective. When a patient's

behaviour is uncontrolled or dangerous, transfer to a secure unit may be needed. Authoritative calm nursing reduces the risk of aggression. Hospitals should have an emergency team of sufficient personnel to manage disturbed patients.

Preventing delirium tremens

If confusion and hallucinations develop, this usually occurs 48 to 72 h after the last drink. Sufficient benzodiazepine, given early in the withdrawal, reduces the risk, as does sensitive nursing in a quiet evenly-lit environment. Explaining symptoms and orientating the patient reduces anxiety, paranoia, and confusion.

Vitamin therapy

It is reasonable to prescribe thiamine 50 mg orally three times a day for 2 to 3 weeks, as thiamine stores may be depleted because of poor diet and alcohol-impaired gut absorption. Wernicke–Korsakoff syndrome is life-threatening and steps must be taken to avoid it developing.[8] The malnourished patient, or the patient who shows any sign of Wernicke's encephalopathy (confusion, ataxia, ophthalmoplegia, nystagmus—do not wait for the 'triad' of symptoms), must be given immediate parenteral B vitamins. Anaphylactic shock was a very rare complication of some older preparations. It is less likely with intramuscular than intravenous injection; infusion saline drip, when practicable, is probably preferable to slow bolus injection.

Interventions to reduce relapse

The evidence

With appropriate help, withdrawing from alcohol is not the dependent drinker's main difficulty. The main difficulty is avoiding relapse into further problematic drinking or dependence.

Before the era of randomized controlled trials, psychiatrists typically would explore with patients possible personality or psychological causes of their excessive drinking—trying to find out 'why?'. However, evidence that this reduced relapse was lacking. Indeed, it may have sometimes had an adverse effect by reinforcing the drinkers' perception of having a need to drink and by creating transference problems which might later trigger drinking.[9] Non-directive counselling may also sometimes have had negative effects, acting as a confessional, with a sense of absolution allowing further drinking.

In recent years, several systematic reviews and meta-analyses have been conducted of treatments to prevent relapse in alcohol dependence. Drawing on data from high quality trials a consensus has emerged.[10–12] Effective treatment are social skills training based on behavioural cognitive therapy principles,[13] motivational enhancement[14] albeit tested sometimes in less severe groups of patients, the community reinforcement approach,[15] behaviour contracting, and behavioural marital therapy[16] and the pharmacotherapies described below.

Abstinence or 'controlled drinking'?

Harmful or hazardous use of alcohol without severe dependence can sometimes revert to risk-free drinking. Patients with social supports (family and job) and without impulsive personalities and many social problems are most likely to succeed. For others, including most of those dependent on alcohol, the goal of abstinence is better.[29] Among patients attending specialized clinics, the proportion who can sustain problem-free drinking for at least 1 year is small—5 per cent is a typical finding.[17–19] A randomized trial comparing the goals of controlled drinking and abstinence did not favour controlled drinking.[20] However, for patients without established dependence, reduction programmes (whether or not towards abstinence) using FRAMES (Table 4.2.2.4.2) proved to be more effective than no intervention.[21–23] Interventions in primary care are discussed in Chapter 4.2.2.5.

Table 4.2.2.4.2 FRAMES: ingredients of a brief intervention

Feedback about personal risk or impairment
Responsibility: emphasis on personal responsibility for change
Advice to cut down or, if indicated because of severe dependence or harm, to abstain
Menu of alternative options for changing drinking pattern
Empathic interviewing
Self-efficacy: an interviewing style which enhances this

Reproduced with permission from T.H. Bein, *et al.* (1993), Motivational interviewing with alcoholic outpatients, *Behavioural and Cognitive Psychotherapy*, **21**, 347–56, copyright 1993, with permission from Cambridge University Press.

If controlled drinking is the agreed goal, the patient and physician collaborate to monitor the amount and pattern of the drinking as follows:

1 Limit number of days of drinking and number of drinks on any occasion.
2 Slow the rate of drinking, and/or reduce alcoholic strength of drinks.
3 Develop assertiveness skills for refusing drinks.
4 Design reward system when goals are achieved.
5 Develop awareness of triggers to overdrinking.
6 Practise other ways of coping with triggers.
7 Record pattern and amount of drinking, for example in a diary.
8 Physician and patient monitor γ-glutamyl transferase blood test results.

Maintaining motivation and compliance

Enhancing motivation has a place not only at onset, but throughout the clinical contact. Treatment aimed only at enhancing motivation was for most outcome measures equal to cognitive behavioural therapy, and intensive intervention aimed at linking patients with AA.[24] Randomized controlled studies have shown the advantage of motivational interviewing over traditional supportive therapy.[10–12,25] The style of the opening interview using motivational interviewing techniques has already been discussed. The patient is encouraged not to forget the harm that drinking caused and the benefits of abstinence, but the losses and problems of being sober are not denied. Strategies for maintaining abstinence emerge from collaborative dialogue, and are owned by patients rather than offered as advice from the clinician. If medication is part of the treatment plan, unwanted effects are actively enquired into, and are recognized and not dismissed, and remedies are sought. Any discrepancies that patients reveal between their present view of themselves and how they would like to be, or between what patients say they believe and how they actually behave, are

used as a fulcrum for shifting attitudes and testing alternative strategies. These techniques were elaborated by Miller and Rollnick[3] and enshrined as motivational enhancement therapy[26] by Project MATCH (see below).

Helping motivation: the social matrix

It is said that the only successful way to change your drinking is 'to do it for yourself'. Nevertheless, many of those dependent on alcohol start on the road to recovery because of pressure from outside. For example, if the person finds himself in Court, or has lost his driving licence, authorities may seek evidence that the offender has taken steps to alter harmful drinking patterns. Perhaps the partner is now being firmer, even demand a separation or divorce; or the employer has given a warning.

Friends, partners, colleagues at work, and even employers sometimes adopt an approach that they believe to be motivating but which has the opposite effect and enables the drinker to continue drinking. For example, they may cover-up, gloss over, make excuses, or even blame themselves for what is going wrong. This cushions drinkers from experiencing the harmful consequences of their drinking or allows them to believe that alcohol is not the chief problem, despite evidence that alcohol is in fact the critical common factor in their downward spiral.

A physician can help the parties improve communication so that important messages are not lost. If the message from the employer or partner, or even the children, is clear and positive, it can have a powerful motivating effect: 'We value our relationship with you. But the way you are drinking is harming that relationship and we will not tolerate it'.

Some physicians are overcautious about confidentiality in this situation. If a doctor is asked by a partner or an employer to comment on the patient's condition, he or she may or may not have permission, or feel it appropriate, to do so. But doctors can usefully help partners or employers clarify for themselves what they want, and then encourage a clear and firm, but positive message.

Sometimes doctors unwittingly collude in a cover-up. The smokescreen that can be set-up by a drinker who is severely dependent and ambivalent about change can be hard to penetrate: 'It's depression, doctor'; 'It's stress at work'; 'If only my wife was more understanding/my sleep was not so disturbed/I didn't get these memory blanks which I think are some kind of stroke'. The doctor may need to wait for that medical moment, perhaps a crisis, to help such an individual. Or, if the doctor has patience, the drip, drip of non-judgemental evidence, and perhaps some social pressure, may bring about the necessary change in the patient's understanding and thus the perceived motivational pay-offs. Understanding may lead to action. However, as Fig. 4.2.2.4.1 shows, that action may not be sustained and the process of helping understanding may need to be repeated many times.[27]

There are few randomized controlled studies allocating patients to different intensities of external motivation. However, alcoholics coerced into treatment have medium-term outcomes similar to those who attend voluntarily.[28]

Coping skills therapies

When incentives are powerful, many newly abstinent patients are able to abstain for short periods. Others lack the skills to cope with the triggers to drinking even when their motivation to abstain has been strong. Cognitive behavioural therapies seem to improve the coping skills of these patients. If the triggers are in social situations, assertiveness, or conversation skills training can help. If the trigger is related to relationship of work problems, checking beliefs and attitudes, and reframing stressors may reduce the urge to use alcohol as a sedative.[13] Some patients are helped by learning to handle frustration and criticism without harbouring anger and resentments. Treatment can be in groups, where the opportunity to discuss these topics with others who have similar problems is appreciated. Groups also enable learning through role playing and by modelling on others. 'Relapse prevention therapy' as originally formulated has not stood up to meta-analytic critique.[11]

Cue exposure

The smell or sight of alcoholic drinks can be a powerful stimulus to drinking. Initial studies[30] found that 'deconditioning' by exposing inpatients to the sight and smell of their preferred drinks in a laboratory setting, without drinking, was associated in the coming 6 months with a longer period without a relapse. However, this is not a stand-alone treatment. Patients should not court danger by going into pubs and bars—these are places where people go to drink alcohol.

Couples should decide together whether or not to have alcohol in the house, but patients should not be encouraged to 'test themselves'.

Alcoholics Anonymous

There are many ingredients in the healing process of AA. Newcomers are helped to identify with others as members tell their stories. They see that it is possible to be frank about past errors and the hurt caused to others through the drinking. Telling their own story helps the members not to forget the harm that accrued from drinking. This reduces complacency, which is one of the most common precursors of relapse.

Alcoholism is viewed by AA as a physical, psychological, and spiritual illness, which can be arrested (by avoiding another drink) but cannot be cured. The meetings offer a new social network. Emotional openness is encouraged. Members learn to express warmth, and to accept that they and others have failings. The AA advice on coping with emotions and relationship difficulties has much in common with cognitive behavioural therapy and relapse prevention therapy. The method has some attractively simple concepts ('Just don't pick up that first drink'; 'HALT'—being alert to four of the most common triggers to relapse, i.e. hunger, anger,

Box 4.2.2.4.2 The 12 steps of Alcoholics Anonymous

Step 1 We admitted we were powerless over alcohol-that our lives had become unmanageable.
Step 2 Came to believe that a power greater than ourselves could restore us to sanity.
Step 3 Made a decision to turn our will and our lives over to the care of God *as we understood him*.
Step 4 Made a searching and fearless moral inventory of ourselves.
Step 5 Admitted to God, to ourselves, and to another human being the exact nature of our wrongs.
Step 6 Were entirely ready to have God remove all these defects of character.
Step 7 Humbly asked him to remove our shortcomings.
Step 8 Made a list of all persons we had harmed, and became willing to make amends to them all.
Step 9 Made direct amends to such people wherever possible, except when to do so would injure them or others.
Step 10 Continued to take personal inventory and when we were wrong promptly to admit it.
Step 11 Sought through prayer and meditation to improve our conscious contact with God *as we understood him*, praying only for knowledge of his will for us and the power to carry that out.
Step 12 Having had a spiritual awakening as a result of these steps, we tried to carry this message to practice these principles in our affairs.

loneliness, tiredness). There is a deeper aspect, which is to replace preoccupation with self by handing over to the group process, or to a 'Higher Power'.

Accepting that you are 'powerless' to control your drinking is the 'first step' in AA. This entails ceasing the struggle and letting the 'Higher Power' take over. Members vary in their interpretation of the 'Higher Power', and avowed atheists should not be deterred from sampling AA. Residential, outpatient, and day programmes, which teach the AA approach are sometimes called 12-step programmes (Box 4.2.2.4.2). One of their strengths is linking patients to the AA network. In Project MATCH,[24]

A psychiatrist can introduce patients to AA through a contact member who will tell the patient how AA works, will not ask personal details, and will extend an invitation to a meeting. Doctors are welcome to attend 'open' AA meetings to see how it works. A contact number is given in local telephone directories. AA does not work for everyone, but since it is difficult to predict who will be helped, it is good practice to offer contact to all patients with impaired control of their drinking.

A warning, often based on personal experience, may be given at AA meetings about transferring dependence from alcohol to other drugs. This usually refers to use of barbiturates or benzodiazepines, or to the danger of relying on a medication instead of adjusting one's way of living. The use of prescribed medication is not formally disapproved of by AA.

Evidence of efficacy

Naturalistic non-randomized studies have shown that treatment programmes using the AA approach are associated with outcomes in drinking and overall functioning similar to those of programmes using the cognitive behavioural approach. Patients in 12-step programmes improve on self-efficacy and coping skills scores much as patients treated by cognitive behavioural therapy.[31] Following the steps of AA is associated with improving drinking and psychosocial outcomes.[32]

Only two randomized controlled studies of 12-step programmes have been conducted. One compared inpatient treatment (with fewer hours of psychotherapy than many such programmes) with a 12-step inpatient programme (with slightly more hours of therapy). There was a non-significant trend towards a greater total abstinence programme and less relapse in the 12-step programme.[33] In Project MATCH, patients were randomly allocated to cognitive behavioural therapy, motivational enhancement therapy, or '12-step facilitation', which instructed patients in the tenets of AA, and assisted and encouraged them to attend AA meetings. The three treatments resulted in similar outcomes after 1 and 3 years. However, for those who had been relatively free of psychiatric problems at entry to the study, 12-step facilitation was associated with slightly better outcomes after 1 year. After 3 years the 12-step facilitation led to better outcome for patients who, at entry to the study, had family, social, or work environments bringing them into frequent contact with drinking.[34]

Help for the family

The family of someone with a drinking problem may suffer for years without recognition and can benefit from advice and understanding. They are a vital monitor of the patient's progress. Good family cohesion and low expressed emotion predict better outcome, even after controlling for the predictors of demographic variables and severity of alcohol dependence.

Life in the family becomes increasingly restricted. Finances dwindle. The children fear that the parent may be drunk, and so stop inviting friends to visit. They dread that arguments between mother and father will become violent. The drinker's behaviour becomes slovenly. He or she may wet the bed. Despite these hurts, the drinker may still make the family believe that they are the reason he or she drinks.

The invitation to a family member or partner to attend with the patient may be rejected if the drinker is the messenger, and the message is distorted to: 'The doctor says you're part of the problem'. A direct letter or telephone call from the clinician requesting 'your views on how I can assist' reduces the partner's fear of being burdened with extra guilt or responsibility.

The clinician can help reduce family behaviours, such as hostility or cover-up, that are damaging to the family and counterproductive for the drinker's recovery. Communication between the drinker and the spouse or children has often broken down. In many countries family groups, such as Al-Anon, provide help to families.

Behavioural marital therapy

When the patient is in a relationship, its quality can be motivating or demotivating. Reciprocal contracts are aimed at making the relationship more rewarding for each partner. Although abstinence is a prerequisite, specific agreements should not be contingent on the drinking[35]; otherwise, a relapse means that the partner ceases to work on the relationship. Another prerequisite might be that physical violence is excluded. Contracting could start thus: 'Although you

are responsible for not drinking, is there anything that your partner could do more of, or less of, that would help you stick to the plan?' Check that the requests are reasonable and available before the partner is asked to agree. The partner makes reciprocal requests and negotiation follows. Even requests for small changes can start the process.

The partners should give clear messages, owning their statements: 'This is what I would like', 'It makes me feel good if you . . . '. They will need to be reminded to state the positives and to practise being good listeners, giving non-verbal signals that they are listening, and not butting in with unsolicited good advice.

Violence in the partnership may require specific attention. If the drinker is intoxicated, the partner is advised to back off and avoid argument. Sometimes each partner is asked to sign an agreement that neither will threaten nor hit the other. If they do, time-out in another room is agreed in advance to permit slow-breathing to aid calming down, or one of them will leave the house and go to a designated place for 36 to 72 h.

When the partner 'brings up the past', this can be a major irritant to the drinker. But this can be reframed as the partner 'helping the couple not repeat their past': the partner who feels heard and understood is more ready to look at changes that he or she might also make.

Efficacy

Behavioural marital therapy produces better outcomes of drinking and marital relations than individual counselling or similar control conditions. The superior effects last for 24 months after treatment. Outcome at 1 year is better if sessions of behavioural marital therapy continue after the end of treatment to reinforce what has been learnt and rehearse relapse prevention plans.[36]

Deterrent medication

Disulfiram

If taken in a sufficient dose for at least the preceding 3 to 4 days, disulfiram causes an unpleasant reaction to develop 15 to 20 min after alcohol enters the body. The reaction is due to accumulation of acetaldehyde, an intermediate metabolite of ethanol. The reaction includes flushing, headache, pounding in the chest or head, tightness in breathing, nausea, and sometimes vomiting. Hypotension can occur and is potentially dangerous. (In some countries, calcium carbimide, which has the same action is also available.) The disulfiram–ethanol reaction varies in intensity. It is recognized practice to increase the dose of disulfiram up to 400 mg daily if the patient has tested the alcohol reaction and it has not been severe enough to act as a deterrent.

Disulfiram is an aid, not a cure. The individual can become used to life without alcohol. This allows time for confidence to recover—in the family, at work, or in the social services if there have been concerns about the safety of children. Patients may object that it is weakness to take a deterrent, and they prefer to show that they can use will power. Explain to the patient that will power is not always there when most needed. With disulfiram a decision to drink or not still has to be made, but only once a day.

Unwanted effects which occur even when no alcohol is taken include drowsiness, bad breath, and headache. These make the drug unacceptable to some patients. Concerns that disulfiram can harm the liver are based on a few case reports (the risk is about 1 in 25 000 patient-years). It appears to be a hypersensitivity reaction, and if it is to occur it is likely to be in the first month. Overall, disulfiram is associated with improved liver function tests compared with control groups, presumably owing to reduction of drinking.[37] Peripheral neuropathy (almost always reversible) has been reported following several months at doses of over 250 mg: the risk maybe greater when the patient takes other drugs such as antidepressants which are metabolized in the liver. There are a few reports of psychosis induced by disulfiram, and psychotic illness has been a formal contraindication in the licensing in some countries. The risk is so low and the need to help schizophrenic patients with alcohol problems is sometimes so great that in other countries this contraindication has been changed to a 'caution'. There are many documented cases where improvement has occurred in psychotic patients while taking disulfiram, and in a dose of up to 250 mg daily there are no problems from unwanted actions or interactions with medication for the psychiatric illness.[38]

(a) Efficacy

Disulfiram will only aid recovery if it is taken regularly in a sufficient dose to deter. Earlier studies without attempts to increase adherence to the medication did not show efficacy unlike studies in which enhanced compliance was enhanced by arranging supervision. In some of these studies there was a degree of coercion; for example, if the patient ceased taking the disulfiram the partner might withdraw from some agreed item, or disciplinary action at work might be reinstated.

The disulfiram effect depends on the patient knowing that they have ingested the disulfiram, and so only single blind studies are appropriate to test its efficacy. Single blind studies over 1 year have shown, in patients with a family member to supervise the medication, that disulfiram is associated with less relapse than acamprosate[39] and naltrexone.[40]

(b) Suggested mode of use

Before prescribing, a physical examination and baseline liver function tests are performed. The patient is encouraged to ask the partner, a nurse, or welfare officer at work or at the health centre, or a pharmacist to see that the disulfiram is taken. This can be daily, or three times a week, provided that the total weekly dose is sufficient, i.e. at least 7 × 200 mg. Some specialist clinics have follow-up clinics thrice weekly to supervise disulfiram. A programme commencing for the first months with frequent clinic attendance, and thereafter encouragement to continue using disulfiram, reported abstinence rates of over 50 per cent in patients followed for up to 7 years.[41] The product is available in a dispersible form to be taken in water so that it can be seen to be swallowed.

There should be medical follow-up, but there is no consensus as to whether monitoring of liver function tests should be carried out beyond the first month. However, monthly follow-up is appropriate to check for signs of drinking and of any unwanted effects.

It is common to prescribe disulfiram for 6 months, but many patients ask to continue for longer and there may be slips when disulfiram is withdrawn, even after long periods of abstinence. Some patients keep a supply to use when they feel an increased risk of drinking, for example on a business trip or at a social event.

Specific neurotransmitter antagonists

(a) Acamprosate (calcium acetyl homotaurinate)

Acamprosate enhances γ-aminobutyric acid (**GABA**) transmission and antagonizes glutamate transmission, probably by antagonizing *N*-methyl-D-aspartate receptors (see Chapter 6.2.8). It reduces drinking in alcohol-dependent animals, and reduces the reinstatement of drinking behaviour in animals re-exposed to alcohol after a period of abstinence. Animals do not seek out acamprosate as they do addictive substances, and it does not have mood-altering or drug-abuse potential in humans.[42] It has no deterrent or disulfiram-like effect.

Acamprosate is excreted unchanged in the kidney. It has few unwanted effects; diarrhoea, and abdominal discomfort are the only ones reported in more than 10 per cent of patients (up to 20 per cent) and these are mild and transient. It does not exacerbate psychomotor impairment caused by alcohol. There are no known drug interactions. Systematic follow-up after the end of acamprosate treatment shows no sudden relapse and no discontinuation symptoms in patients who have received the medication for up to 1 year.

(i) Efficacy

Acamprosate has a dose-related effect of improving abstinence rates in recently detoxified patients. There are no studies comparing the advantages of differing lengths of treatment. Meta-analysis of published studies finds that acamprosate is associated with improvement in abstinence rate compared to placebo with an odds ratio of 1:88 and greater cumulative days of abstinence.[43]

Acamprosate has only been tested in patients who intend to abstain from alcohol. It has not been tested formally in patients aiming for controlled drinking. However, in literature, patients who resume drinking, consume less alcohol in subsequent days[44] if they had been allocated to acamprosate than to placebo.

(ii) Suggested mode of use

Acamprosate is indicated for patients who have withdrawal symptoms and relief drinking typical of severe alcohol dependence and requiring medical assistance to withdraw. It is started 2 to 7 days after the last drink (steady state pharmacokinetics are reached after 5 days). Patients who relapse while on acamprosate are advised to continue taking the medication and exert effort to limit the lapse. However, acamprosate is not normally continued in patients who relapse more than once despite regularly taking the drug. Those who appear to be benefiting from it should continue the drug for at least 6 months, and up to 1 year if there has been a history of repeated relapsing while in treatment.

Several studies have shown that acamprosate reduces self-reported craving for alcohol. Some newly abstinent patients experience strong craving, but others experience very little and there is no evidence that this should be a criteria for deciding to whom this medication should be offered.

Acamprosate may sometimes help prolong abstinence among patients who choose to take disulfiram.[45]

(b) Opiate antagonists

Endorphins are released in one of ethanol's many acute actions on the limbic system. It has been suggested that this effect contributes to loss of control.[46] Naltrexone (and nalmefene) antagonize the neurotransmitter action of endogenous endorphins. Naltrexone has been shown to reduce ethanol-seeking in alcohol-dependent animals. It does not exacerbate the psychomotor impairment caused by alcohol.

Some patients who drink alcohol while taking naltrexone report that they feel less of the ethanol 'high'. This could lead to less impulse to carry on drinking.[47,48] However, some studies have reported an increase in total abstinence as well as a reduction of drinking overall.[48,49] It is possible that the reduced craving for alcohol and the reduced likelihood of picking up the first drink occur because the strength of the previous triggers—emotional, cognitive, or environmental—is attenuated.

Nausea following the first few doses is the commonest unwanted effect, occurring in about 10 per cent of patients. Concerns in the 1970s that naltrexone might cause dysphoria seemed to be supported by statements from heroin addicts given naltrexone to help them abstain from opiates. However, laboratory studies and randomized controlled trials in subjects who have not been opiate dependent have not found evidence of dysphoria or loss of feelings of pleasure.[50]

(i) Efficacy

Short-term administration of naltrexone reduced the rate of relapse to heavy drinking (odds ratio 0:62 in the meta-analysis of Bouza *et al.*[43] but although individual studies have reported an advantage in rates of total abstinence, this is not upheld in meta-analysis.[43]

Even though the dose is once daily, adherence has been low in some studies, and a beneficial effect only demonstrable in compliant patients.[51] Developed partly to improve compliance, a long-acting injection given monthly has become available and found to be acceptable to patients. It was more effective in reducing relapse to heavy drinking than a monthly injection of the vehicle without active naltrexone.[49]

When supervised oral naltrexone was compared to supervised disulfiram it was found to be less effective in preventing relapse to heavy drinking.[40] However, when oral naltrexone has been compared to acamprosate it was more effective.[52–54]

(ii) Suggested mode of use

Opiate antagonists have a particular role in reducing relapse to heavy drinking in patients who will not or cannot attain abstinence. As well as prescribed as a daily dose, their targeted used has also been supported in patients trying to limit the amount consumed per session, when the patient takes a dose only on days when at risk of drinking or planning to drink.[55,56] Several studies have found that patient with a positive family history of alcohol dependence are more likely to benefit from an opiate antagonist than those without.

Interactions. Opiate antagonists such as naltrexone will precipitate an immediate opiate withdrawal syndrome if given to patients who are actively dependent on opiates, and will prevent pain relief of opiate analgesics.

Helping women with alcohol problems

It has been said that when a woman has an alcohol problem, there is a man in her life with a similar problem—usually her partner or her father. When the partner also drinks heavily, he should be invited to some joint therapy meetings. Some partners have adopted a controlling role, especially if the spouse has been unreliable in

managing the children or the money, or has driven while intoxicated. The patient may allow her resentment at this to fuel her drinking, and it may need months to help her to see how this has come about.

Low self-esteem is very common in such women, even in those who were confident before the drinking became problematic. The partner, while remaining firm about the unacceptability of her drinking, may need help to be more caring and positive, to show interest in what concerns her, and to show appreciation.

When helping women with alcohol dependence to abstain some of the following may be relevant:

- Help her to stop feeling taken for granted, and to know that she has a right to set limits on what others expect of her.
- Although guilt may be proportional to what she has put her family through by her drinking, it may not help. It may prevent her from asking for the conditions at home or work that would make it easier for her to stop drinking.
- Help her let go of resentments.
- Help her find ways of recharging her batteries by, for example, taking up new interests or exercise.
- Talk with the partner, both alone and with her present. He may want to know that she acknowledges the strain on him. While still accepting complete responsibility for her drinking, she can let him know what he can do to help her.
- Self-help literature is available in many languages to help women improve self-confidence and self-assertion.[57]

Treatment of coexisting disorders

Affective disorder

Depression is common in patients who are dependent on alcohol. The drinking may have alienated friends, family, or employer, with resulting feelings of hopelessness, guilt, and lack of direction. Alcohol can reduce appetite, energy, and sexual drive. The drinker wakes in the small hours of the night feeling anxious owing to the rebound wakefulness of alcohol withdrawal. Those signs and symptoms suggesting depressive illness commonly clear with abstinence and help in tackling or tolerating personal problems and improving relationships.

Sometimes (more often in women than in men) a depressive episode precedes the alcohol dependence, the patient begins to use alcohol as self-medication. Sometimes depressive symptoms continue despite abstinence. In these cases, antidepressants should be offered in the usual way.[58,59] Relapsing alcoholism, secondary to depressive illness, is an indication for long-term antidepressants. Lithium is not a treatment for alcohol dependence itself, but is effective if alcohol dependence is secondary to manic–depressive disorder.

General practitioners and general psychiatrists often prescribe antidepressants to patients with alcohol dependence who are still drinking, because the patient has complained of low mood, insomnia, or anxiety. There is no evidence that this will improve the drinking problem, and the period of alcohol withdrawal under benzodiazepine cover can be an occasion to withdraw the antidepressant. Most depressive symptoms experienced while alcohol-dependent patients are drinking are alleviated with abstinence. Early-onset alcohol dependence, marked by novelty seeking and impulsivity, can be exacerbated by SSRIs.[60,61]

Anxiety and panic disorder

Some patients have had panic attacks for years before discovering that alcohol can end or prevent them. Others have a first panic attack during alcohol withdrawal, but the attacks continue independently even during sustained abstinence. In this case, cognitive behavioural therapy and/or medication are indicated. Anxiety symptoms, which persist are predictive of relapse in the coming year.[62] However, the majority of anxiety symptoms reported by alcohol-dependent patients resolve with abstinence[63,64] and the weight of evidence is that adding specific psychological therapy aimed at the anxiety symptoms does not improve the drinking or the anxiety outcomes beyond that achieved by the treatment for the alcohol dependence.[65,66] In Project MATCH, male patients with social phobia allocated to 12-step facilitation (i.e. encouragement to attend AA) improved their drinking as much or even slightly more than those patients allocated to cognitive behaviour therapy (CBT) who would have received specific treatment for their phobia, though an advantage to CBT showed in female socially phobic patients.[67]

One explanation for these findings could be that attending to the anxiety might, for some patients, distract attention from the drinking, or could even seem to 'justify' their continuing to drink. It is also the case that some phobic patients report that attending AA helped them to overcome their social phobia.

Three studies suggest that the serotonin agonist buspirone can help reduce both drinking and anxiety.[68] Tricyclic antidepressants and selective serotonin-reuptake inhibitors (**SSRIs**) are prescribed to patients whose anxiety disorder persists despite abstinence. Some patients with long histories of alcohol dependence and severe panic disorder fail to respond to these medications or to CBT. For these patients the risk of complications from a prescription for a long-acting benzodiazepine such as chlordiazepoxide may be less than the harm that might accrue if bouts of excessive drinking persisted. If prescribed (and to do so is controversial), the benzodiazepine should be dispensed in limited amounts. The prescription should be conditional on abstinence from alcohol, perhaps aided by disulfiram, if necessary. 'As-required' use (e.g. for travelling on public transport) helps to limit the development of tolerance, even though in theory it may perpetuate phobic beliefs. This method probably commits the patient to long-term use and an enduring risk of escalation.

Treating alcohol-dependent patients with antipsychotic medication when there is no psychotic illness may increase their drinking and should be avoided.[69,70]

Residential and inpatient treatment

It is debatable whether a period of inpatient treatment can improve the eventual outcome. Some studies have compared outcomes after patients have been randomly allocated to either inpatient or outpatient treatment. Usually no difference has been found. However, the interpretation of these results and their extrapolation to clinical reality has been debated. Finney *et al.*[71] concluded that the studies often lacked statistical power. Furthermore, the more seriously affected patients had sometimes been excluded before randomization.[72,73] While evidence that it is inpatient treatment rather than intensity of treatment which improves outcome is lacking,[74,75] admission to hospital can provide valuable respite for the drinker and the family when life is severely disorganized because

drinking is out of control. Perhaps such respite need not be offered in a relatively expensive medical environment. However, if the patient has become suicidal as difficulties increase or has developed serious medical complications, then hospital admission may be indicated, ideally to specialized facilities. Longer stays in hospital are not supported by research. For example, Trent[76] found no evidence of worse outcome when the United States Navy reduced the length of its inpatient alcoholism treatment programme from 6 to 4 weeks. The role of inpatient treatment is considered further in Chapter 4.2.2.5.

Matching patients to treatments

It is recognized that people with alcohol dependence present a range of problems, come from various backgrounds, and have different personality characteristics. Some have no accompanying emotional disturbance; others have a psychiatric disorder. The poor outcomes of treatment for alcohol dependence have been attributed to their use with unsuitable patient, and better matching of patients to treatments has been sought. A North American study of 1726 outpatients (Project MATCH) set out to test hypotheses about matching treatments to patients. Three treatments were studied, each established in previous randomized controlled trials as more effective than 'supportive therapy': motivational enhancement therapy, cognitive behavioural therapy, and instruction in the AA approach with encouragement to take part in AA meetings ('12-step facilitation').

Few matching effects reached statistical significance. In patients recruited from outpatient clinics, those who scored high on anger at initial assessment averaged 85 per cent of abstinent days if they had been allocated to motivational enhancement therapy compared with 75 per cent if they had been allocated to 12-step facilitation or cognitive behavioural therapy.[77] In the first year of follow-up, patients with initially less severe psychiatric symptoms had more abstinent days after the 12-step facilitation than after cognitive behavioural therapy. Patients with critically high psychiatric severity did no better with cognitive behavioural therapy.[77]

Another marker of who benefits most from AA emerged in the 3-year Project MATCH data. Patients who came from a social milieu where they mixed a lot with other drinkers owing to family, neighbourhood, or work influences did better if they had received 12-step facilitation than with either cognitive behavioural therapy or motivational enhancement therapy.[34]

There are several reasons for the absence of evidence of other powerful predictors of treatment outcome in the Project MATCH data. Perhaps the key behaviour—not taking the first drink—can be arrived at in different ways.

Some clinical situations

Morbid jealousy

This is discussed in Chapter 4.4.

The homeless alcohol-dependent person

It is difficult to conduct randomized controlled studies with adequate follow-up to test the efficacy of interventions to reduce drinking and improve social conditions for the homeless, and few answers have been found. A brief hospital admission to 'dry out' and assessment for transfer to residential care may result in transient improvement in physical health and is more humane than prison. However, supporting evidence is lacking. The structured intensive outpatient intervention, 'community reinforcement approach', has been shown in a North American study to reduce drinking (corroborated by improvement in serum γ-glutamyl transferase) and increase the number of clients at work and in satisfactory housing.[78] The community reinforcement approach combined an offer of free housing, a place at a 'job club' to assist with finding employment, training in problem-solving skills, communication, goal-setting, refusal of drinks, and independent living. Patients had access to an alcohol-free social club. The housing offer was contingent on sobriety and some evidence of saving money. Continuation in the housing was contingent on sobriety checked by breathalyser. Disulfiram had been shown to improve the effects of the community reinforcement approach.[15,79]

Young people

There is a dearth of evaluation of programmes to help young people with alcohol problems. AA groups may have teenage members. When education or employment is in jeopardy, young people may accept disulfiram, supervised perhaps by the family. However, without the support of a non-drinking peer group (which they would have in AA), most young people will try again and again to resume 'social drinking'. Job or marriage commitments sometimes alter the pay-off matrix sufficiently for recovery to be sustained. Otherwise, it may not be until age 30 that the young person is sufficiently convinced that he or she cannot control drinking and takes serious steps to seek help.

Employment referrals

It is common for individuals to seek help when their drinking has put their job in jeopardy. Having a job helps recovery, and for the person to lose employment while paying only lip-service to treatment is common and disheartening for all. The psychiatrist should find out whether disciplinary procedures are in motion or threatened. It can be helpful if the psychiatrist and the patient are told this directly by the employer. If the consultation is part of an undertaking under a company 'alcohol and drugs policy', the patient may have given permission for the psychiatrist to answer the employer's request to know whether he or she is attending and following advice.

Patients who are on the point of dismissal may offer to take disulfiram supervised in the company's occupational health or welfare department. This can bring about recovery and employment for as long as the threat of dismissal remains, and sometimes afterwards.[80]

The liver transplant candidate

Some transplant centres require a demonstration of months of abstinence, to show commitment, before offering transplant to a patient with alcoholic liver disorder. Other centres have no such restrictions. From 6 to 80 per cent of transplant recipients, varying between centres, have recommenced drinking and exceeded safe limits by the end of the first year. Their eventual outcome in terms of quality of life and psychiatric health is no worse than for other transplant patients, and there is no evidence to support demanding lengthy preoperative abstinence. However, patients who relapse to problematic drinking are more likely to have had a history of definite alcohol dependence, and/or depressive illness.[81,82]

Physicians as patients

Alcohol dependence is commoner among doctors than among most other occupational groups, other than those groups who are employed in the alcohol beverage manufacturing or retailing. Doctors' outcome, once in treatment, tends to be good if they can return to their practice. This is probably partly due to the requirement by the licensing body that 'impaired physicians' accept monitoring by an independent specialist to corroborate that they are following advice and continuing to progress.[83,84]

Doctors' reluctance to accept help for their illnesses, and their tendency to treat themselves, is well known and true for substance misuse. Initial denial often means that problems escalate until there are disciplinary or Court proceedings and attempts to treat their own alcohol dependence may result in dependence on other substances. In some instances, where there is any risk to safety of the doctor's patients, the professional licensing body should be informed if not already involved.

The alcoholic doctor should be treated in the same way as a lay person. The partner should be invited to the interview. Ideally, information should be obtained from the employer or from a colleague about the nature of any problems at work or any disciplinary action, actual or threatened.

In some countries there are support groups for recovering doctors and dentists who meet together and are ready to offer advice and encouragement to individuals and their families.

Follow-up

Systematic follow-up has been shown to improve outcomes.[17,85] Early detection of relapse is important, and is aided by regular contact with the family or the workplace, a breathalyser test at interview, and tests for blood markers of drinking (γ-glutamyl transferase or carbohydrate-deficient transferrin).[86] Objective markers are required when a patient requests a report for a Court, the driving licence authority, or an employer.

Some guiding principles

Research into alcoholism spanning 50 years has shown that the attitudes of the agency and the therapist influence patients' outcome, as they may do for many illnesses. The therapeutic alliance is a strong predictor of outcome in the treatment of alcohol dependence.[87] However, agencies must also be prepared to set limits on drunken behaviour at the clinic and telephone calls when intoxicated. And for patients who repeatedly relapse, resumption of treatment should sometimes be made conditional on complying with a new treatment plan, such as supervision of medication.[88]

Showing respect, enhancing dignity, conveying accurate empathy, adopting objective and not moral criteria, involving the family, and reducing hurdles to seeking help have been shown to improve compliance, and often outcome, for alcohol dependence.

4.2.2.5 Services for alcohol use disorders

D. Colin Drummond

A spectrum of disorders needing a range of services

The provision of services for alcohol use disorders has been driven by the prevailing view of their nature and prevalence. Following the Second World War, the disease concept of alcoholism gained increasing support in both the United States (US) and the United Kingdom (UK).[1] According to this concept, alcoholism is an all-or-nothing phenomenon affecting a relatively small subgroup of the population, and requires intensive specialist treatment. In the UK this led to the development of specialist alcohol treatment centres with an emphasis on intensive inpatient treatment involving group therapy, often with close affiliation to the Alcoholics Anonymous (**AA**) fellowship. Such programmes tended to be targeted at relatively socially stable men, and catering for the more severely alcohol dependent.[2]

In the 1970s and 1980s came a recognition that there existed a much wider range of alcohol-related problems in the population than would meet the narrow criteria of alcoholism or alcohol dependence, but which might nevertheless benefit from intervention. Research began to show that alcohol problems existed on a continuum of severity and thus might not necessarily require intensive specialist treatment with a lifelong goal of complete abstinence from alcohol. Screening and brief intervention with presymptomatic heavy drinkers in the primary care or general hospital medical ward setting could be effective in reducing excessive alcohol consumption and alcohol-related harm.[3,4] This led to the proposal that greater benefit could be accrued from less intensive

approaches aimed at the large number of hazardous drinkers, than more intensive and expensive interventions catering for the minority of very heavy drinkers: the 'preventive paradox'.[5]

In a ground-breaking report, the US Institute of Medicine advocated 'broadening the base of treatment for alcohol problems'.[6] Recognizing the potential for increased prevention and treatment activity in health care personnel without specialist addiction training (e.g. general practitioners, physicians, social workers), and the limitations of expanding specialist treatment given the high prevalence of alcohol misuse, the report emphasized the need for an expanded range of locations and methods of intervention, across the spectrum of alcohol use disorders (see Fig. 4.2.2.5.1). Importantly however, the report also recognized that alcohol use disorders are heterogeneous, and different types of disorders are likely to require different types or intensities of treatment, that is, the need to match treatments to the nature of the presenting problem.

Since this report there has been some progress made towards increasing the range and accessibility of treatment. However, in some cases this has been disappointing. This chapter describes the range and organization of treatment approaches and explores the barriers to implementation of a comprehensive system of care for alcohol use disorders. The evidence suggests that we have a long way to go to deliver an optimal level of access to alcohol treatment for those in need. The evidence on the cost-effectiveness of alcohol treatment is discussed, and consideration is given to the needs of special groups in the population who may find access to treatment more difficult. The main conclusion is that on the basis of the existing research evidence there remain considerable opportunities to expand and improve treatment services for alcohol use disorders. This will require further training and dissemination initiatives and the political will and funding to achieve this throughout the health system.

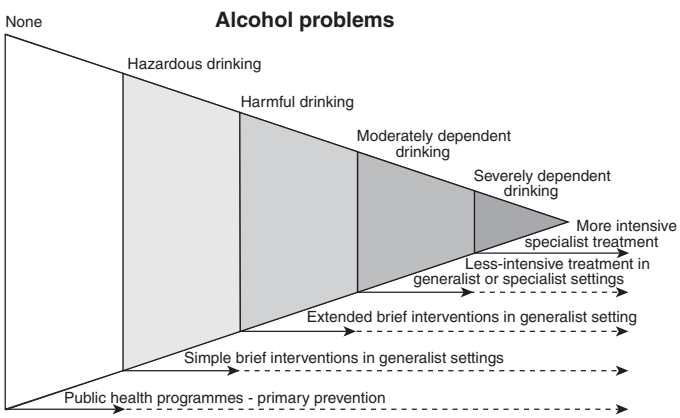

Fig. 4.2.2.5.1 A spectrum of responses to alcohol problems. (Reprinted from D. Raistrick, N. Heather, and C. Godfrey, (2006), *Review of the effectiveness of treatment for alcohol problems*, National Treatment Agency for Substance Misuse, London © 2001–2008 National Treatment Agency.) The triangle represents the general population, with the spectrum of alcohol problems experienced by the population shown along the upper side of the figure. Responses to these problems are shown along the lower side. The dotted lines suggest that primary prevention, simple brief intervention, extended brief intervention and less-intensive treatment may have effects beyond their main target area. Although the figure is not drawn to scale, the prevalence in the population of each of the categories of alcohol problem is approximated by the area of the triangle occupied; most people have no alcohol problems, a very large number show risky consumption but no current problems, many have risky consumption and less serious alcohol problems, some have moderate dependence and problems and a few have severe dependence or complicated alcohol problems.

Location and intensity of treatment

Brief interventions

There has been considerable research interest in the potential of brief interventions in primary care, and to a lesser extent in the general hospital.[7] There are several potential advantages in conducting treatment interventions in primary care. Patients with alcohol use disorders consult their general practitioner more frequently than other patients. Excessive drinkers identified by screening in primary care are largely at an earlier stage in their drinking career and are potentially more likely to benefit from brief early intervention than more severely dependent drinkers presenting to specialist treatment services. Further, primary care is often seen as less stigmatizing than a specialist clinic. Brief interventions typically involve opportunistic screening using tools such as the AUDIT questionnaire[8] or other shorter variants,[9] followed by 5–30 min. of brief intervention conducted by a practitioner who does not have training in specialist alcohol treatment.

Several studies have demonstrated the effectiveness of screening and brief intervention in hazardous drinkers in primary care. In a large randomized controlled trial, Wallace *et al.*[4] found that brief intervention was more effective than a control treatment in reducing alcohol consumption and γ-glutamyl transferase at 1-year follow-up. Similar findings were obtained in a large World Health Organization multicentre trial.[10]

Fewer screening and brief intervention studies have been conducted in the general hospital setting. A recent meta-analysis of this literature showed no difference between intervention and control in this setting.[11] However, some recent studies have shown benefits of screening and brief intervention in accident and emergency departments. One UK study showed reduced alcohol consumption and fewer reattendances in A&E attenders identified by screening and referred to an alcohol health worker.[12] Another UK study in young men with alcohol-related facial injuries found that brief intervention significantly reduced alcohol consumption and alcohol-related problems.[13]

Meta-analyses of brief interventions have mostly found advantages of brief intervention over control treatments with effect sizes of 10–20 per cent on reduced alcohol consumption at 1 year.[14–16] Some earlier reviews concluded that brief interventions are at least as effective as more intensive specialist treatments. However, the populations studied in brief intervention trials are heterogeneous.[17] Most trials have been conducted with opportunistic screening in non-treatment seeking populations in primary care. A smaller number have compared brief interventions to more intensive treatments in specialist alcohol treatment settings. A recent review found that brief interventions are effective only in less severe alcohol disorders in the context of opportunistic screening.[15]

There are barriers to implementation of brief intervention in non-specialist settings, which may limit its effectiveness. In a UK national survey,[18,19] it was found that general practitioners and

primary care practice nurses were reluctant to engage in screening and brief interventions because of a perceived lack of training and support to carry-out this work. Effective implementation of large-scale screening and brief intervention programmes will require attention to the training and support needs of non-specialist personnel. Further, screening programmes will identify more severely alcohol dependent drinkers who may not respond to brief interventions alone. Thus, effective working arrangements between generalists and specialists are needed. Drummond[20] has also questioned the generalizability of brief intervention research findings in the typical clinical setting, given the large number of exclusions in research studies and a lack of pragmatic trials.

Specialist treatment in inpatient settings

The main treatment response to alcohol use disorders continues to be delivered by specialists, although this is mostly delivered in the community rather than in inpatient settings. There has been extensive research on the location and intensity of specialist treatment. An early influential study was that of Edwards *et al.*[21] in which 100 alcohol-dependent men referred to the Maudsley Hospital in London were randomized to receive either intensive specialist treatment, including specialist inpatient care, or a single session of counselling. At 1-year follow-up there was no difference in outcome between the two treatments. It was concluded that the reliance on intensive treatments up to that time was called into question by the findings. This controversial study gave rise to considerable debate and several studies have subsequently investigated the same issues. Another British study attempted to replicate the Edwards study and found only modest differences between advice only and extended treatment in a randomized controlled trial at 2 years' follow-up.[22] There were, however, no differences between treatments in abstinence rates or alcohol consumption level during follow-up. However, a later follow-up of the Edwards cohort found that more severely dependent drinkers benefited more from intensive treatment.[23]

In a larger study in the US, employees who were identified as drinking excessively were randomized to one of the three options: compulsory inpatient treatment, compulsory AA attendance, or a choice of these two options.[24] At 2-year follow-up there were no differences between the groups in terms of work-related outcome measures. However, drinking-related measures the inpatient group had the best, and the AA group the poorest outcome, with the choice group having an intermediate outcome. The compulsory AA group was more likely than the others to require subsequent inpatient treatment. However, the length of inpatient treatment does not appear to influence outcome significantly.[25,26]

Studies comparing inpatient versus outpatient alcohol detoxification have generally found the two approaches to be equally effective. For example, Hayashida *et al.*[27] randomized male military veterans to inpatient and outpatient detoxification. At 6 months' follow-up no differences in outcome were found between the two groups. Indeed, outpatient detoxification is generally regarded as the treatment of choice for the majority of patients. It should be noted, however, that studies comparing inpatient and outpatient treatment (including detoxification) have tended to exclude patients with particularly poor prognosis (e.g. poor social circumstances, severe psychiatric or physical comorbidity, those at risk of harm to themselves or others). Hence, the clinician needs to interpret the research evidence with caution in applying it to patients in the typical clinical setting. However, it is probably safe to assume that in less complicated alcohol dependence there is no evidence of an advantage of inpatient over outpatient treatment.

A recent randomized trial by Rychartic *et al.*[28] assigned alcohol dependent patients to inpatient, intensive outpatient, or standard outpatient treatment. Following treatment inpatients had reduced jail and subsequent inpatient episodes, and those with greater alcohol dependence or impaired cognitive function had better outcomes with inpatient treatment.

Overall, the majority of studies that have compared intensive specialist treatment with less intensive treatment have not supported the use of more intensive approaches. However, most of these studies excluded patients with more complex needs. Few studies have examined the interaction between treatment setting and problem severity. The emerging evidence now is that alcohol dependent patients with more complex needs (more severe alcohol dependence, psychiatric comorbidity, cognitive impairment, poor social circumstances, or support) are more likely to benefit from inpatient treatment.[9]

Community-based specialist treatments

The growth of studies questioning the value of specialist inpatient treatment and a move towards cost containment in health care have led to a shift in resources to treating alcohol use disorders in community settings. In the US for example 87 per cent of specialist alcohol treatment is delivered on an outpatient basis.[29] A similar survey in England found that 69 per cent of specialist alcohol treatment agencies were community based.[30]

Apart from the potential advantage of lower cost, community-based treatment provides the least social disruption for the individual and offers the opportunity to mobilize existing community resources to support sustained recovery. In the UK, the past 30 years have seen the widespread development of the community alcohol team (CAT) model of treatment following the original Maudsley Alcohol Pilot Project.[31] The main principle of the CAT model is that the specialist multi-disciplinary team (typically consisting of specialist medical, nursing, social work, and psychology staff) work to train and support generic teams, mainly in primary care, to manage alcohol use disorders more effectively. In practice, CATs have tended to find difficulty in avoiding becoming involved in a more traditional specialist role, often providing direct care for alcohol use disorders in the face of reluctance on the part of primary care personnel to take on this work.[32]

There has been remarkably little research conducted to evaluate the CAT model. One study randomly allocated 40 problem drinkers referred to the specialist alcohol treatment clinic at the Maudsley Hospital to receive either routine specialist treatment or 'shared care'.[33] Following specialist assessment, the shared care group was returned to the care of their general practitioner, who was then supported by the specialist CAT. Shared care within this model included advice and training for the general practitioner, a shared treatment plan, regular phone contact between specialist and general practitioner, and the offer of further specialist care should the patient remain unchanged or deteriorate. At 6 months' follow-up the specialist and shared care groups both showed significant improvements, but there was no difference in outcome between the two groups.

Another study in Scotland evaluated the efficacy of a home detoxification service compared with minimal intervention in a

randomized controlled trial in 95 patients referred by their general practitioner.[34] At 6 months' follow-up the home detoxification group remained abstinent twice as long after treatment than the minimal intervention group.

The 'community reinforcement approach' has been demonstrated to have benefits in the treatment of alcohol dependence in the US.[35] This approach aims to provide reinforcers for abstinence from alcohol including positive family support, help in finding employment, membership of an alcohol-free social club, and alcohol counselling. The specialist treatment input aims to ensure that these supports are put in place. There is some evidence from small-scale controlled trials[35,36] that this approach is effective in reducing alcohol consumption and improving social adjustment compared to standard treatment, but it has not so far been fully evaluated, and has never been tested in the UK.

Another variant on the CAT approach has been the evaluation of community psychiatric nurse (CPN) aftercare following specialist inpatient treatment.[37] One study in the UK evaluated the effectiveness of regular CPN follow-up consisting of weekly 1 to 2 h visits to the patient's home for a period of 6 weeks post-discharge from inpatient care, followed by less frequent visits up to 1 year. The home-based sessions involved advice, support, counselling, partner involvement, and encouragement to attend AA. This was compared to routine 6-weekly hospital appointments. The study, which involved a non-randomized design, found significant improvements in abstinence and engagement in support in the CPN approach compared to the routine aftercare group.

There is growing interest in the potential application of Assertive Community Treatment (ACT) approaches for alcohol dependence, particularly for patients with more severe, complex and chronic problems who are difficult to engage in standard treatment approaches. This borrows from the experience of ACT in severe mental illness[38] and acknowledges that for some patients, alcohol dependence is a chronic disorder that in these cases may be more suited to a 'disease management' model of care, commonplace in treatment of many physical illnesses such as diabetes or hypertension. Assertive approaches appear promising in alcohol dependence,[39] but a definitive trial of ACT is needed.

In summary, the CAT model of alcohol service delivery has been widely implemented in the UK in advance of clear evidence of its effectiveness. Evidence is emerging showing at least the equivalence, and in some cases, the superiority, of outcome from community-based services compared with more traditional inpatient treatment approaches. However, the CAT approach is implemented in a range of ways in the UK, and encompasses many different models and specific interventions. More research is needed to evaluate the cost-effectiveness of community alcohol team approaches and to identify the specific elements and methods that contribute to treatment effectiveness.

Matching and stepped care

The Institute of Medicine report emphasized the need to match the level of intervention to the severity and nature of the presenting problems.[6] There is some empirical evidence of matching effects in relation to both inpatient and outpatient treatment.[40] Up until recently, however, matching effects have generally been explored in *post hoc* analyses in studies that lacked sufficient statistical power. The Project MATCH study in the US aimed to assess a wide range of matching hypotheses in a prospective design, but found no strong matching effects[42] (see Chapter 4.2.2.4). However, it should be noted that most controlled trials, including MATCH, excluded the more complex patients, including those with limited social support and those with severe psychiatric comorbidity. This tends to work against finding matching effects as the study sample lacked clinical heterogeneity.[43] Further, many of the patient and treatment programme characteristics likely to mediate treatment matching and treatment effectiveness, remain largely unresearched. The matching results of a similar trial in the UK are awaited.[43]

Stepped care is an alternative method of matching treatments to patient needs that has become accepted in the fields of smoking intervention and general medicine. Until now it has received relatively scant attention in the alcohol field. In essence, stepped care involves initially providing relatively low-intensity treatments, and only offering more intensive treatments to those who fail to respond.[44] This provides a potentially resource-efficient means of delivering treatment, and provides clinicians with clinical algorithms. A recent trial of alcohol screening in primary care compared stepped care intervention with minimal 5 min of advice delivered by a practice nurse.[45] In the stepped care group received an initial 40 min session of Behaviour Change Counselling delivered by a trained practice nurse who then followed up the patients (Step 1). Those who did not respond to Step 1 were referred to four sessions of Motivational Enhancement Therapy delivered by trained alcohol counsellors (Step 2). Finally those not responding to Step 2 were referred to more intensive treatment delivered by a CAT (Step 3). The study found no significant difference in alcohol consumption at 6 months, which may in part be due to a small sample size. However, the stepped care intervention was more cost-effective than minimal intervention, mainly through reduced health care and criminal justice costs.

Overall, few community-based studies have found significant treatment matching effects. But this may be in part due to exclusion of the most severe cases. Some studies have found advantages of inpatient compared with community treatment for patients with more severe and complex needs as described above. A more promising approach is stepped care, which is effectively pragmatic matching: that is patients not responding to less intensive treatments receive more intensive treatments. This now forms an important principle of the national framework for alcohol services in England.[46]

Cost-effectiveness of alcohol treatment

With a trend towards containment of health care costs in industrialized societies, there has been an increase in the application of health economic research in the alcohol treatment field. It has been estimated that the annual cost to society of alcohol misuse is in the region of US$184 billion in the US[47] and £20 billion in the UK.[48] In comparison, the direct treatment costs of alcohol use disorders by specialist treatment agencies amounted to approximately US$7.5 billion in the US and about £217 million in the UK.[47,30] Thus there is a need to demonstrate the cost-effectiveness of treatments for alcohol use disorders.

Until recently, research on cost-effectiveness has been largely speculative and not based on direct estimates of cost benefits. In a landmark study, Holder *et al.*[49] provided a 'first approximation' of the cost-effectiveness of treatment. In their analysis they

used a combination of findings of efficacy from clinical trials, typical costs of different treatments, and recommendations from experts and treatment providers about appropriate treatment approaches. While noting the lack of studies directly assessing the cost-effectiveness of treatments, they concluded the cost of care was inversely correlated with evidence of effectiveness. They also noted that those treatments with the highest cost and lowest evidence of effectiveness were amongst the most prevalent in the North American treatment system. While this review has been criticized on methodological grounds, it has stimulated an important debate and has contributed to an increasing number of clinical trials including a health economic component in outcome evaluation.

Cost-effectiveness analysis, which takes a societal perspective rather than a narrow intervention cost perspective, provides a better measure of the overall impact of an intervention. These wider costs include patient out-of-pocket costs, lost productivity, unplanned health care utilization (e.g. admissions with alcohol-related physical and mental illnesses, primary care utilization), criminal justice costs, accidents, premature deaths, social work involvement, childcare costs, and costs associated with illnesses in relatives and carers.[50]

Also important in cost-effectiveness analysis is the estimation of improvements in quality of life following an intervention. This is beginning to be studied in the alcohol treatment field. Quality of life can be measured in a variety of ways (e.g. Euroqol, Short Form 36). In a randomized controlled trial an estimate of the difference in Quality Adjusted Life Years (QALYs) can be compared between treatment and control groups. The National Institute of Clinical Excellence (NICE) in the UK determines which treatments should be funded by the National Health Service (NHS) based on the available evidence. NICE regards a net cost per QALY, taking into account the costs of treatment and the savings to society, of £20 000 or less to be the maximum cost acceptable to implement the treatment in the NHS. Alcohol misusers typically have a much lower quality of life than non-alcohol misusers. One study compared quality of life in alcohol dependent drinkers before treatment with controls. Mean quality of life measured by the Euroqol (EQ5D) was 0.57 in the alcohol dependent group compared to age matched controls: 0.9 (1.0 being the best possible quality of life and 0 being death).[43] However, a recent review found that while treatment significantly reduces alcohol consumption and societal costs, it has a limited impact on quality of life.[9]

A recent review of cost-effectiveness examined the available literature on alcohol interventions.[9] In terms of intensive specialist alcohol treatment it was estimated that providing evidence-based alcohol interventions would result in a saving of £5 for the public sector for every £1 spent. However, it was noted that several studies showed an initial increase in costs in people newly entering alcohol treatment. This is likely to be because people not in treatment and in an active drinking phase find it harder to access services, and specialist alcohol services assist patients to address outstanding health and social care needs. Cost savings as a result of treatment therefore need to be examined over the longer term (>1 year). Comparing individual specialist interventions including pharmacotherapies and psychosocial interventions one review found the net health cost per death averted ranged from –£3073 to £2076 for most of the interventions that also provided significant clinical improvements.[51]

There is now good evidence that brief intervention in hazardous/harmful drinkers is highly cost-effective. Fleming *et al.*[52] found that, as well as reducing excessive drinking, there was a reduced length of hospitalization during the 12-month follow-up period. In addition, while brief intervention cost more than minimal intervention, this cost was more than offset by reductions in subsequent health care, criminal justice, and road traffic accident costs (US$56 000 savings per US$10 000 intervention costs). An analysis of several brief intervention studies found the cost per life year gained was approximately £2000, well within the NICE definition.[53]

There is considerable scope for further development of health economic research in the alcohol field. This will prove important in providing health care commissioners with appropriate information to make rational decisions in the provision of cost-effective evidence-based services for alcohol use disorders. (For a further account of cost-effectiveness analysis, see Chapter 7.7.)

The availability of alcohol services

The availability of alcohol services is likely to affect the overall impact of treatment at a whole population level. There is some evidence that the availability of alcohol treatment services is related to the prevalence of alcohol use disorders at a population level. Mann *et al.*[54] found that increased treatment services in Ontario, Canada, were associated with decreased hospital discharges for liver cirrhosis. A similar study in North Carolina examining the 20-year period between 1968 and 1987 found an association between increased alcohol treatment admissions and decreased cirrhosis mortality. Further, Mann *et al.*[55] found a relationship between AA membership and alcohol-related problems including cirrhosis mortality rates in the US, Canada, and other countries. They estimated that a 1 per cent increase in AA membership was associated with a 0.06 per cent decrease in cirrhosis mortality. These studies of course demonstrate associations rather than causal links between treatment availability and prevalence, but do provide support to the hypothesis that access to treatment could have an impact at a population level.

The National Drug and Alcohol Treatment Utilization Survey (**NDATUS**), which is a national census of public and private treatment programmes in the US, provides a unique data set to study treatment availability. It has been conducted intermittently since 1979 and provides a method to study trends over time. An analysis by the Institute of Medicine found large regional variations in the availability of treatment places.[6] There was no association found between treatment place availability and prevalence of alcohol misuse across states in the US. This points to the importance of 'needs assessment' in the rational allocation of public resources to fund treatment services. This involves a variety of data sources as indicators of alcohol use disorder prevalence in a particular locality, including general population surveys, mortality statistics (e.g. deaths from alcoholic liver disease), crime statistics (e.g. public drunkenness and driving whilst intoxicated arrests), and alcohol-related hospital admissions. Such indicators provide measures of relative 'need' in different localities, gaps between need and access to treatment, and can be used to direct resource allocation.

Examining data from NDATUS surveys between 1982 and 1993, Weisner *et al.*[56] found an increase in activity over this period of 147 per cent. In the US the impact of managed care organizations, which aim to limit access to treatment on the basis of individual

need and cost, has yet to be fully established in relation to overall access to alcohol services. Such measures are likely to reduce the availability of inpatient services and to reduce the rate of readmission for those with chronic alcohol problems.

A recent national needs assessment in England examined *inter alia* the regional variation in the prevalence of alcohol use disorders and access to specialist alcohol treatment services.[30] The prevalence of alcohol dependence in adults was 3.6 per cent overall (men: 6 per cent; women: 2 per cent), varying from 1.6 per cent to 5.2 per cent across regions. The overall level of access to treatment also varied across regions. In England overall, 1 in 18 people with alcohol dependence gained access to treatment per annum (the Prevalence–Service Utilization Ratio). But this varied from 1 in 12, to 1 in 108 between the best and worst served regions. A ratio of 1 in 10 is regarded as a 'low' level of access and 1 in 5 a 'high' level in North America.[57] Factors associated with better access included a greater number of treatment agencies, greater overall spending on treatment, and shorter waiting times.

Special groups

Specialist alcohol treatment services typically attract younger, male, single patients of lower socio-economic and educational background, with more severe alcohol dependence. Relative to the prevalence of alcohol use disorders in the general population, women, older people, and people from ethnic minorities are typically under-represented, as are the homeless. Further, there are limited specialist alcohol services for young people. This is of particular concern as the prevalence of alcohol use disorders is increasing in young people in the UK.

Women

Thom and Green have identified three main factors that may account for the under-representation of women in alcohol treatment.[58] Women tend to perceive their problems differently from men, less often identifying themselves as 'alcoholic'. This may in part be related to negative public stereotypes of female drinking and negative attitudes towards female problem drinkers amongst professionals. Women have also been found to perceive the 'costs' of entering treatment differently from men. This is particularly in relation to the perceived social stigma as well as other costs, both financial, in relationships, and in terms of losing their children into the care system. Finally, women often find the services offered to be less appropriate in meeting their needs than do men. Often specialist alcohol services do not offer childcare or 'women-only' facilities. However, an increasing number of women are seeking help for alcohol use disorders, both in the US and the UK on the basis of general population surveys and surveys of treatment populations. In England we found that women with alcohol dependence were 1.6 times more likely to access treatment than men.[30] This suggests that some of the barriers to access identified by Thom and Green have been overcome. Nevertheless, more still needs to be done to provide alcohol treatment services that are sensitive to women's needs. Further, there is a need to develop services catering for pregnant women.[59]

Ethnic minority groups

The evidence concerning help-seeking in ethnic minority groups is complex (see Chapter 7.3). Harrison *et al.*[60] have provided a review of the evidence. In the US, Hispanics tend to be under-represented and African–Americans are over-represented in alcohol treatment compared with the general population prevalence. However, interpretation of the evidence is complicated by the fact that household surveys tend to under-represent socially disadvantaged individuals from ethnic minorities. Marmot *et al.*[61] found that cirrhosis mortality rates were elevated compared to the national average for men from the Asian subcontinent and from Ireland, but lower than average for African–Caribbean men. In women, cirrhosis mortality was lower than average in Asian and African–Caribbean women but higher in Irish women. However, there were few cirrhosis deaths in total in ethnic minorities, which may lead to large errors in extrapolation to the whole population alcohol misuse estimates. In terms of alcohol treatment populations, studies have tended to find higher rates of admission (per 100 000 population) in Indian-, Scottish- and Irish-born people than in those born in the Caribbean or Pakistan. Differences in culturally related health beliefs and help-seeking, as well as service factors such as the availability of interpreters or treatment personnel from appropriate ethnic minority groups, may account for some of these differences. There remain few specific services for people from ethnic minorities, although some examples of good practice exist in the UK.[60]

The homeless

There is a high prevalence of alcohol use disorders (as well as mental and physical health and social problems) amongst the homeless population, a group that is not typically well catered for by mainstream alcohol services (see Chapter 7.10.2). The prevalence of alcohol problems in the homeless has been found to be as high as 38 per cent in the UK[62] and between 2 and 86 per cent in the US; typically the prevalence is between 20 and 45 per cent in North American studies.[59] This has contributed to the development of specific alcohol services for the homeless and street drinkers, notably 'wet' hostels. In the 'wet' hostel, residents are able to continue drinking but are cared for in an environment that is designed to minimize the harm associated with heavy drinking and to tackle issues associated with homelessness.[59,62] Such facilities tend to be restricted to large urban centres and have restricted places compared to the number of street drinkers. Similarly, outreach services and 'crisis centres' have been developed to attract alcohol-misusing homeless people into treatment facilities.[63] Often those entering 'wet' hostels can subsequently be persuaded to undergo alcohol detoxification and progress to 'dry' (or alcohol-free) supported accommodation.

Young people

The prevalence of alcohol use disorders is increasing in young people, particularly young women in the UK.[48] The young are over-represented in alcohol-related road traffic accidents, and alcohol is a leading cause of accidental death in this group. Alcohol misuse is also associated with unprotected sexual activity. Nevertheless, there are few specialist alcohol services for young people. Most initiatives have been directed at prevention and health promotion in this group, but the evidence to support these is lacking. This has led to the proposal that individually targeted interventions, for example by the primary health care team or in accident and emergency departments, are more likely to be effective.[64]

Relatives and carers

Relatives and carers of people with alcohol use disorders often experience significant social and psychological problems related to the drinking of a 'significant other'. Alcohol use disorders are associated with a high level of domestic violence and child neglect and abuse. Many specialist treatment programmes provide help and support to relatives and carers, and Al-Anon (for adult carers and relatives) and Alateen (for the young), which are affiliates of AA, provide a widely available source of mutual aid for these groups.

Services for individuals with comorbidity

There is an increasing recognition of the problems associated with alcohol and other drug misuse and mental illness (see Chapter 4.2.2.3). Often alcohol misuse is complicated by multiple substance misuse. For example, in the Epidemiologic Catchment Area Study half of all patients with schizophrenia also had a substance use disorder,[65] and a recent British survey of psychiatric inpatients found that half had an alcohol use disorder.[66] However, there is currently no consensus on the most appropriate treatment services for patients with comorbidity.[67] Alcohol and substance misuse can be particularly problematic in the context of mental illness, and is associated with higher rates of violence and poor treatment outcome. Such patients are often poorly engaged with, and disruptive in mental health services, and typically have difficulty in engaging in alcohol or drug services. Assertive community outreach and integrated service models, covering both mental illness and substance misuse, have been advocated, but more research is needed to evaluate the cost-effectiveness of these approaches.

Conclusions

The alcohol treatment field has seen considerable change over the past 30 years. Some of this has been evidence based, and some has been largely politically driven, particularly in the pursuit of containing health care costs. On the positive side, a shift in policy from a limited number of treatment services catering only for the small minority of severely dependent drinkers, to more community orientated services with a greater emphasis on early identification and intervention, is to be broadly welcomed. However, in some places a move towards services catering for early stage 'at-risk' drinkers has been at the expense of losing services for those with more severe alcohol problems.[40] While the evidence in favour of matching treatments to individual needs is still at a relatively early stage of development, and clear evidence of matching effects is not yet available, clinical practice needs to be guided by pragmatic principles by which more intensive treatments are provided to more complex patients, and/or in a stepped care paradigm. It must be concluded that, despite a large research effort in evaluating intensive versus less intensive alcohol interventions, there is still a long way to go in developing pragmatic clinical trials that evaluate effectiveness and cost-effectiveness of treatment in a way that can best advise practitioners in the typical treatment setting.

On the positive side, research has begun to address fundamental health economic issues that are highly relevant to the rational funding of treatment services. Important in this is the development of health economic analysis in randomized controlled trials. The assessment of the impact of treatment availability on the prevalence of alcohol-related harm also represents a significant advance.

Health services research that does not influence clinical practice fails in its fundamental aim. For example, while there is a now considerable evidence base in support of brief intervention in the primary care setting, there is a resistance within primary care to adopt such approaches, often despite exhortations from governments and professional bodies. Part of the problem may lie in the disparity between the priorities of public health, which is directed towards population level benefits of an intervention, and the priorities of the individual practitioner, whose first duty is to the patient in his or her care.[17] If the individual practitioner remains unconvinced about the value of a particular intervention for the patient, such public health policies are likely to fail even if they are supported by research evidence.

Similarly, as Holder *et al.*[49] have pointed out, often treatment programmes continue to provide alcohol services that are not supported by research evidence. On occasions, but not exclusively, this criticism is levelled at private for-profit agencies, with the implication that their motivation is financial rather than being principally for the benefit of their patients. In many cases, however, the evidence base is lacking because the fundamental research has not yet been conducted. Or, as in the case of self-help organizations such as AA, the methodology necessary adequately to evaluate an intervention would be extremely complex, or perhaps impossible, to conduct to the standard typically expected in evidence-based medicine (i.e. a randomized controlled trial).

Nevertheless, treatment research cannot occur in a vacuum. Research needs to take account of the funding environment in which treatment takes place. Further, treatment research needs to provide answers to the key issues facing commissioners of health care. With the gradual improvement in the quality of treatment research over the past three decades[68] and the development of more advanced health economic methods to evaluate treatment, the treatment research community is in a much better position than ever before to provide evidence to guide the rational development of treatment services for alcohol use disorders.

While many differences between health care systems exist in different countries, the evidence points to the need for a wide spectrum of services to cater for different needs. The development of low-threshold community-based services should not occur at the expense of more specialized services for more severe alcohol use disorders. Similarly, a treatment system that provides only specialist services for the minority of severe cases misses a significant public health opportunity to reduce the prevalence of alcohol use disorders through early, brief interventions.

4.2.2.6 Prevention of alcohol-related problems

Robin Room

Alcohol consumption is widely distributed in the population in most parts of the world, with abstainers in a minority among adults in most developing societies but in a majority in many less developed societies.[1,2] Those qualifying to be diagnosed with an alcohol use disorder are usually a relatively small minority of drinkers.

On the other hand, alcohol is causally implicated in a wide variety of health and social problems. The WHO *Global Burden of Disease* (*GBD*) study for 2000 estimated that alcohol accounted globally for 4 per cent of the total health-related loss of disability-adjusted life years (DALYs), for 6.8 per cent in developed societies like those in Western Europe and North America, and for 12.1 per cent in Eastern Europe and Central Asia.[3] In terms of where this burden appears in the health system, while psychiatric conditions (including dependence) and chronic physical disease are both important, casualties often play a predominant role. The *GBD* 2000 study calculated that injuries accounted for 40 per cent of the DALYs lost worldwide due to alcohol.[3]

The public health importance of acute effects of a particular episode of intoxication underlies what is often described as the 'prevention paradox'. In many societies, a fairly substantial proportion of the population (particularly of males) gets intoxicated at least occasionally, and by that fact is at risk of experiencing and causing social and health harm from drinking.[4] Preventing alcohol problems thus requires looking beyond the considerably smaller segment of the population diagnosable with an alcohol use disorder, or the even smaller segment receiving treatment for such a disorder.

A complication in preventing alcohol problems is that there is also evidence of a health benefit from drinking in terms of reduced cardiovascular disease. This benefit is, however, important mainly for men over 45 and women past menopause, and can be attained with a pattern of very light regular drinking, as little as a drink every second day.[5] There is thus little potential conflict between taking alcohol as a preventive heart medication and any prevention policy short of total prohibition.

Simplifying somewhat, there are seven main strategies to minimize alcohol problems. One strategy is to educate or persuade people not to use or about ways to use so as to limit harm. A second strategy, a kind of negative persuasion, is to deter drinking-related behaviour with the threat of penalties. A third strategy, operating in the positive direction, is to provide alternatives to drinking or to

drink-connected activities. A fourth strategy is in one way or another to insulate the use from harm. A fifth strategy is to regulate availability of the drug or the conditions of its use. Prohibition of supply may be regarded as a special case of such regulation. A sixth strategy is to work with social or religious movements oriented to reducing alcohol problems. And a seventh strategy is to treat or otherwise help people who are in trouble with their drinking. We will consider in turn these strategies and the evidence on their effectiveness in reducing rates of alcohol problems in the population.

Education and persuasion

In principle, education can be offered to any segment of the population in a variety of venues, but it is usually education of youth in schools, which first comes to mind in the prevention of alcohol problems. Community-based prevention programmes, which may be also directed at adults, often also include an educational component.

Education offers new information or ways of thinking about information, and leaves it to the listener to draw conclusions concerning beliefs and behaviour. However, most alcohol education programmes go beyond this. A commonplace of the North American evaluative literature on alcohol education is that 'knowledge-only' approaches do not result in changes in behaviour.[6] School-based alcohol education has thus usually had a persuasional element, aiming to influence students in a particular direction.

Persuasion is directly concerned with changing beliefs or behaviours, and may or may not also offer information. Mass-media campaigns aimed at persuasion have been a very common component of prevention programmes for alcohol-related problems, but persuasion can be pursued also through other media and modalities.

In most societies, public health-oriented persuasion about alcohol must compete with a variety of other persuasional messages, including those intended to sell alcoholic beverages. The evidence that alcohol advertising influences teenagers and young adults towards increased drinking and problematic drinking is becoming stronger.[7,8] Even where alcohol advertising is not allowed on the mass media, these messages are conveyed to consumers and potential consumers in a variety of other ways.

Evidence on effectiveness

The literature on effectiveness of educational approaches is dominated by studies from the United States on school-based education. This means that the alcohol education has usually been in the context of drug and tobacco education, and that the emphasis has been on abstention,[9] or at least on delaying the start of drinking, in cultural circumstances where the median age of actually starting drinking is about 13, while the minimum legal drinking age is 21. In general, despite the best efforts of a generation of researchers, this literature has had difficulty showing substantial and lasting effects.[10] There is a good argument from general principles for alcohol education in the context of consumer and health education, but there is little evidence from the formal evaluation literature at this point of its effectiveness beyond the short term.

Persuasional media campaigns have also been a favourite modality in many places in recent decades for the prevention of alcohol problems. In general, evaluations of such campaigns have been able to demonstrate impacts on knowledge and awareness about substance use problems, but little effect on drinking behaviour. As with school education approaches, there are hints in the literature that success may come more from influencing the community environment around the drinker—in terms of attitudes of significant others, or popular support for alcohol policy measures—than from directly persuading the drinker him/herself. Thus, media messages can be effective as agenda-setting mechanisms in the community, increasing or sustaining public support for other preventive strategies.[11]

Deterrence

In its broadest sense, deterrence means simply the threat of negative sanctions or incentives for behaviour—a form of negative persuasion. Criminal laws deter in two ways: by general deterrence, which is the effect of the law in preventing a prohibited behaviour in the population as a whole, and specific deterrence, which is the effect of the law in discouraging those who have been caught from doing it again.[12] A law tends to have a greater preventive effect and to be cheaper to administer to the extent it has a strong general deterrence effect.

Prohibitions on driving after drinking more than a specified amount are now in effect in most nations.[13] In many societies, there have also been laws against public drunkenness (being in a public place while intoxicated), and against obnoxious behaviour while intoxicated. Other common prohibitions are concerned with producing or selling alcoholic beverages outside state-regulated channels, and with aspects of drinking under a specified minimum age.

Evidence on effectiveness

Drinking-driving legislation, such as 'per se' laws outlawing driving while at or above a defined blood-alcohol level, has been shown to be effective in changing behaviour and reducing rates of alcohol-related problems (Babor *et al.*,[14] pp. 157–72). The effect is through both general and specific deterrence. The quickness and certainty of punishment, as well as its severity, are important in the deterrent value (too much severity tends to undercut its quickness and certainty). Drinking driving is an ideal area for applying general deterrence, since the gains from breaking the law are limited, and automobile drivers typically have something to lose by being caught.

Many English-speaking and Scandinavian countries have had a tradition of criminalizing drinking in public places or public drunkenness as such, but the trend has been to decriminalize public drunkenness. Though there are few specific studies, criminalizing public drunkenness is not very effective in changing behaviour, particularly of those who have little to lose (Parliament of Victoria, Drugs and Crime Prevention Committee,[15] pp. 309–20).

Providing and encouraging alternative activities

Another strategy, in principle involving positive incentives, is to provide and seek to encourage activities, which are an alternative to drinking or to activities closely associated with drinking. This includes such initiatives as making soft drinks available as an alternative to alcoholic beverages, providing locations for sociability

as an alternative to taverns, and providing and encouraging recreational activities as an alternative to leisure activities involving drinking. Job creation and skill development programmes are other examples.

Evidence on effectiveness

'Boredom' and 'because there's nothing else to do' are certainly among the reasons that are given for drinking by some drinkers. And there are often good reasons of general social policy for providing and encouraging alternative activities. But it has been noted that the problem with alternatives to drinking is that drinking combines so well with so many of them. Soft drinks are indeed an alternative for quenching thirst, but they may also serve as a mixer in an alcoholic drink. Involvement in sports may go along with drinking as well as replace it. The few evaluation studies of providing alternative activities, again from a restricted range of societies, have generally not shown lasting effects on drinking behaviour,[16,17] though they undoubtedly often serve a general social purpose in broadening opportunities for the disadvantaged.[18]

Insulating use from harm

A major social strategy for reducing alcohol-related problems in many societies has been measures to separate the drinking, and particularly heavy drinking, from potential harm. This separation can be physical (in terms of distance or walls), it can be temporal, or it can be cultural (e.g. defining the drinking occasion as 'time-out' from normal responsibilities). These 'harm reduction' strategies, as they are called in the context of illicit drugs, are often built into cultural arrangements around drinking, but can also be the object of purposive programmes and policies (Moore and Gerstein,[19] pp. 100–11).

A variety of modifications of the driving environment affect casualties associated with drinking and driving, along with other casualties. These include mandatory use of seat belts, airbags, and improvements in the safety of road vehicles and roads. Many other practical measures tending to separate intoxication episodes from casualties and other adverse consequences have been put into practice, though usually without formal evaluation.

The main focus for self-conscious strategies of alcohol harm reduction in recent years has been on modifying the drinking environment, particularly in public drinking places, primarily by modifying the behaviour of alcohol servers through server training and enforcement of bans on serving those under age or already intoxicated (Babor *et al.*,[14] pp. 141–47).

Evidence on effectiveness

Drinking-driving countermeasures are a prime example of an approach in terms of insulating drinking behaviour from harm, since they seek to reduce alcohol-related traffic casualties without necessarily stopping or reducing alcohol use. There is substantial evidence of the success of a range of such countermeasures (Babor *et al.*,[14] pp. 159–68). Environmental measures which reduce road casualties in general—e.g. requiring wearing of seat belts in cars, providing sidewalks separated from the road—may prevent casualties associated with intoxication at least as much as other casualties. While there is also evidence for the effectiveness of some other harm reduction approaches, there are also many examples of well-meaning efforts which proved ineffective (Room *et al.*,[2] pp. 186–92).

Regulating the availability and conditions of use

In terms of the substantial harms to health and public order they can cause, alcoholic beverages are not ordinary commodities. Governments have thus often actively intervened in the markets for such beverages, far beyond usual levels of state intervention in markets for commodities.

Total prohibition can be viewed as an extreme form of regulation of the market. In this circumstance, where no one is licensed to sell alcohol, the state has no formal control over the conditions of the sales, which nevertheless occur, and there are no legal sales interests, controlled through licensing, to cooperate with the state in the market's regulation.

With a general prohibition, typically the consumption of alcohol does fall in the population, and there are declines also in the rates of the direct consequences of drinking such as cirrhosis or alcohol-related mental disorders.[19,20] But prohibition also brings with it characteristic negative consequences, including the emergence and growth of an illicit market, and the crime associated with this. Partly for this reason, prohibition is not now a live option in any developed society, although it is in some other societies.

The features of alcohol control regimes, regulating the legal market in alcohol, vary greatly. Special taxes on alcohol are very common, imposed often as much for revenue as for public health considerations. Many societies have minimum age limits forbidding sales to underage customers, and regulating forbidding sales to the already intoxicated. Often the regulations include limiting the number of sales outlets, restricting hours and days of sale, and limiting sales to special stores or drinking places. Rationing of alcohol purchases—limiting the amount individuals can buy in a given time-period—has also been used as a means of regulating availability. Regulations restricting or forbidding advertising of alcoholic beverages attempt to limit or channel efforts by private interests to increase demand for particular alcoholic beverage products. Such regulations potentially complement education and persuasion efforts. State monopolization of sales of some or all alcoholic beverages at the retail and/or wholesale level has also been commonly been used as a mechanism to minimize alcohol-related harm.[21]

The effectiveness of specific types of regulation of availability

The last 25 years have seen the development of a burgeoning literature on the effects of alcohol control measures. Specific types of regulation of the alcohol market, and the evidence on their effectiveness, are discussed below.

(a) Minimum age limits

A minimum age limit is a partial prohibition, applied to one segment of the population. There is a strong evaluation literature showing the effectiveness of establishing and enforcing minimum age limits in reducing alcohol-related problems (Babor *et al.*,[14] pp. 127–28). However, this literature has been primarily North America based, focuses mostly on youthful driving casualties, and mostly evaluates reduction from and increases to age 21 as the limit, a higher minimum age limit than in most societies. The applicability of the literature's findings in other societies and where youth cultures are less automobile-focused has been little tested.

(b) Taxes and other price increases

Generally, consumers show some response to the price of alcoholic beverages, as of all other commodities. If the price goes up, the drinker will drink less; data from developed societies suggests this is at least as true of the heavy drinker as of the occasional drinker (Babor *et al.*,[14] pp. 110–11). Studies have found that alcohol tax increases reduce the rates of traffic casualties, of cirrhosis mortality, and of incidents of violence.[22,23]

(c) Limiting sales outlets, and hours and conditions of sale

There is a substantial literature showing that levels and patterns of alcohol consumption, and rates of alcohol-related casualties and other problems, are influenced by such sales restrictions, which typically make the purchase of alcoholic beverages slightly inconvenient, or influence the setting of and after drinking (Babor *et al.*,[14] pp. 125–42). Enforcing rules influencing 'house policies' in drinking places on not serving intoxicated customers, etc., has also been shown to have some effect (Babor *et al.*,[14] pp. 142–45).

(d) Monopolizing production or sale

Studies of the effects of privatizing retail alcohol monopolies have often shown some increase in levels of alcohol consumption and problems, in part because the number of outlets and hours of sale typically increase with privatization.[24] From a public health perspective, it is the retail level which is important, while monopolization of the production or wholesale level may facilitate revenue collection and effective control of the market.

(e) Rationing sales

Rationing the amount of alcohol sold to an individual potentially directly impacts on heavy drinkers, and has been shown to reduce levels both of intoxication-related problems such as violence, and of drinking-history-related problems such as cirrhosis mortality.[25,26] But while a form of rationing—the medical prescription system—is well accepted in most societies for psychoactive medications, it has proved politically unacceptable nowadays for alcoholic beverages in developed societies.

(f) Advertising and promotion restrictions

Many societies have regulations on advertising and other promotion of sales of alcoholic beverages.[13] As noted, the evidence on the effects of advertising and promotion on overall demand has become stronger in the recent literature.[27] However, studies of the effects of advertising and promotion restrictions on alcohol consumption have so far found at best weak effects, at least in the short term (Babor *et al.*,[14] pp. 180–83).

Social and religious movements and community action

Substantial reductions in alcohol-related problems have often been the result of spontaneous social and religious movements, which put a major emphasis on quitting intoxication or drinking. In recent decades, there have also been efforts to form partnerships between state organizations and nongovernmental groups to work on alcohol problems, often at the level of the local community. There has been an active tradition of community action projects on alcohol problems, often using a range of prevention strategies.[28–31] School-based prevention efforts have also moved increasingly to try to involve the community, in line with general perceptions that such multifaceted strategies will be more effective.[32]

While some of the biggest historical reductions in alcohol problems rates have resulted from spontaneous and autonomous social or religious movements, support or collaboration from a government can easily be perceived as official cooptation or manipulation.[33] Thus there is considerable question about the extent to which such movements can or should become an instrument of government prevention policies.

Evidence on effectiveness

In the short term, movements of religious or cultural revival can be highly effective in reducing levels of drinking and of alcohol-related problems. Alcohol consumption in the United States fell by about one-half in the first flush of temperance enthusiasm in 1830–1845 (Moore and Gerstein,[19] p. 35). Rates of serious crime are reported to have fallen for a while to a fraction of their previous level in Ireland in the wake of Father Mathew's temperance crusade.[34] The enthusiasm which sustains such movements tends to decay over time, though they often leave behind new customs and institutions with much longer duration. For instance, though the days when the historic temperance movement in English-speaking societies was strong are long gone, the movement had the long-lasting effect of largely removing drinking from the workplace in these societies.

There are some good examples of well-evaluated community action projects with demonstrated effectiveness.[30,31] However, the strategies used in such projects should be guided by evidence on effectiveness; good intentions and effort in themselves offer no guarantee of effectiveness.

Treatment and other help

Providing effective treatment or other help for drinkers who find they cannot control their drinking can be regarded as an obligation of a just and humane society. The help can take several forms: a specific treatment system for alcohol problems, professional help in general health or welfare systems, or non-professional assistance in mutual-help movements. To the extent such help is effective, and it is also potentially a means of reducing rates of alcohol-related problems.

Treatments for alcohol problems need not be complex or expensive. The evaluation literature suggests that brief outpatient interventions aimed at changing cognitions and behaviour around drinking are as effective in most circumstances as longer and more intensive treatment.[35,36] Positive results from such interventions in a primary health care settings were shown in a WHO study including a number of countries.[37]

Evidence on effectiveness

In terms of the effects of treatment on those who come for it, there is good evidence of effectiveness of treatment for alcohol problem. Typically, the improvement rate from a single episode of treatment is about 20 per cent higher than the no-treatment condition. Further treatment episodes are often needed. Brief treatment interventions or mutual-help approaches usually result in net savings in social and health costs associated with the heavy drinker (at least where health care is not self-paid), as well as improving the quality of life.[38,39] However, evaluations of brief interventions

by medical general practitioners have not always found effects.[40] Getting general practitioners to use the methods on a sustained basis has not proved easy,[41] and their patients are often unreceptive[42] or recalcitrant.[43] It remains to be seen whether and in what sociocultural circumstances making brief interventions for problematic drinking a routine part of general medical practice is a feasible and effective strategy.

The effectiveness of providing treatment as a strategy for reducing rates of alcohol problems in a society is more equivocal. In a North American context, it has been argued that the steep increase in alcohol problems treatment provision and mutual-help group membership in recent decades has contributed to reducing alcohol problems rates.[44] But the strength of the evidence for this contention is disputed.[45,46] A treatment system for alcohol problems is an important part of an integrated national alcohol policy, but as an instrument of prevention—of reducing societal rates of alcohol problems—it is probably not cost-effective.

Building an integrated societal alcohol policy

Often the different strategies for preventing alcohol problems appear to be synergistic in their effects.[47] Controls of availability, for instance, are more likely to be adopted, continued, and respected when the public has been successfully persuaded of their effects and effectiveness. But strategies can also work at cross-purposes: a prohibition policy, for instance, makes it difficult to pursue measures which insulate drinking from harm.

In a society where alcohol is a regular item of consumption, in view of the resulting rates of alcohol-related social and health problems, there is a strong justification for adopting a comprehensive policy concerning alcohol, taking into account production, marketing and consumption, and the prevention and treatment of alcohol-related problems. But while the adoption of overall alcohol strategies or policies has become common,[48] governments often tend to shy away from the most effective strategies.

In terms of strategies we have reviewed for managing and reducing the rates of alcohol problems in the society, there is clear evidence for effectiveness and cost-effectiveness of measures regulating the availability and conditions of use, and some such evidence for some measures which insulate use from harm. With respect to some aspects of alcohol problems, notably drinking-driving, deterrence measures also fall in the same category. The literature has begun to move beyond the question of effectiveness of these measures, and to consider questions of the relative cost-effectiveness of different measures in different societies.[49]

Despite their perennial popularity, evidence of the effectiveness of education/persuasion and treatment strategies in reducing societal rates of problems is limited at best. Education and treatment are good things for a society and a government to be doing about alcohol problems, but they do not constitute in themselves a public health policy on alcohol. These strategies will be nevertheless be pursued in most societies, and they can best pursued with attention to using cost-effective methods, and to integrating targets and messages with other aspects of alcohol policy.

Physicians and other health workers observe the adverse effects of alcohol in their daily practice, and are well-positioned to argue for public health approaches to reducing the burden of alcohol problems. Reports by colleges of psychiatrists and other physicians have played an important role in such countries as Britain[50] and Sweden[51] in putting a public health response to alcohol problems on the societal agenda.

4.2.3 Other substance use disorders

Contents

4.2.3.1 Opioids: heroin, methadone, and buprenorphine

Soraya Mayet, Adam R. Winstock, and John Strang

Opium is derived from the seed of the opium poppy (Papaver somniferum) and has been used for thousands of years for its analgesic and euphoriant effects.

What are opioids?

Opioids are drugs which mimic endogenous opioid peptides (e.g. endorphins and enkephalins) and activate opioid receptors. Opioids include both naturally occurring opiates extracted from opium (morphine and codeine) and synthetic opioids (heroin and methadone). Heroin is the most common opioid to be misused partly because of its distinctive euphoriant effects.

Neurobiology of opioids

Opioid receptors are widely distributed throughout the central nervous system. Activation of opioid receptors inhibits activity of the dorsal horn. The three most important opioid receptors are μ-receptor, δ-receptor, and κ-receptor. The μ-receptor is concentrated in brain areas and is mostly involved in nocioception (pain sensation). μ-receptor and δ-receptor activation cause hyperpolarization of neurones by activating K+ channels involving G-proteins. Exogenous opioids such as heroin and methadone act at all opioid receptors but particularly at μ-receptors. Opioid receptor antagonists such as naloxone reverse the effects of opioid agonists.[1]

The precise mechanisms of tolerance and dependence to opioids are not clear. Short term use of opioids causing intoxication may not lead to neuroadaption of opioid receptors. However, continued use of opioids may lead to opioid receptor desensitization and dependency. Acutely, opioids lead to the inhibition of adenylate cyclase with reduced conversion of ATP to cAMP, resulting in reduced firing at noradrenergic neurones located on the locus coeruleus. Chronic opioid administration leads to compensatory upregulation of cAMP, returning levels towards baseline. On cessation of opioid use (or following opioid receptor antagonism), withdrawal ensues, characterized by a massive surge in unopposed noradrenergic activity (termed the 'noradrenergic storm') from the locus coeruleus. This noradrenergic hyperactivity is thought to underlie many symptoms of opioid withdrawal, and explains some of the efficacy of the presynaptic α2 agonists in the treatment of the symptoms of acute opioid withdrawal. Opioid receptors can readapt back to normal in the absence of opioids.[2]

Both glutamate and γ-aminobutyric acid (GABA) are also likely to be involved. Positive reinforcement is thought to be mediated via the dopaminergic mesolimbic system. In the ventral tegmental area, GABA inhibits dopaminergic neurones, which in turn are inhibited via μ-opioid receptor activation. Consequently, opioid use leads to increased dopaminergic activity which is thought to mediate the drive to use and its positive reinforcement.

Route of administration

Heroin may be administered by a number of routes including injecting (intravenous, intramuscular and subcutaneous 'skin popping'), snorting and 'chasing the dragon' (inhaling after heating on tin foil).[3] These different routes of administration have profound effects on bioavailability, speed of onset, severity of dependence and physical complications. Different types of heroin may be preferentially used by different routes of administration.[4] Brown heroin is poorly water soluble with a high oil content which 'runs' well on a heated foil making it better for 'chasing'. In contrast, white heroin tends to be more water soluble and better suited for intravenous use, although it may still be snorted or smoked after preparation.

Whilst smoking heroin ('chasing the dragon') is probably the most commonly used route of self-administration, it is not as effective or efficient as injecting. Consequently, as heroin users develop tolerance, many subsequently change to the intravenous route. Injecting heroin use is also associated with a greater risk of fatal overdose and hence reducing the transition from smoking to injecting may be associated with reduced harms. Although injecting in the upper limbs is the most common site for administration, as venous access becomes compromised increasingly risky sites such as the groin or neck my be used. However, non-injecting routes of administration are not without risks and may still result in dependence and similar treatment outcomes.

Opioid metabolism

The oral bioavailability of heroin (Diacetylmorphine) itself is poor due to complete first pass metabolism, which is the reason it is often administered by alternative routes. Following administration, heroin is rapidly metabolized to 6-monoacetylmorphine (6-MAM), which is the only metabolite that specifically indicates that heroin has been used. 6-MAM is metabolized to morphine, which is catalyzed in the liver. Morphine (either as a metabolite of heroin or given as a drug) is mostly metabolized by UDP-glucuronosyltransferase (UGT) to the inactive metabolite morphine-3-glucuronide (M3G) and in lesser amounts to the active morphine-6-glucuronide (M6G). Morphine is also ***N***-demethylated to normorphine by hepatic CYP3A4 and CYP2C8 enzymes (Fig. 4.2.3.1.1). Heroin and its metabolites can be monitored in the blood, hair, saliva and urine. 6-MAM is detectable up to 12 h post administration, whilst morphine can be detected in the urine for several days after use.[5] Methadone is primarily metabolized in the liver by CYP3A4 to the inactive metabolite 2-ethylidine-1,5-dimethyl-3,3-diphenylpyrrolidine (EDDP), then to 2-ethyl-5-methyl-3,3-diphenylpyraline (EMDP). Buprenorphine is metabolized to norbuprenorphine and to conjugated buprenorphine and norbuprenorphine. Codeine (3-methylmorphine) is synthesized from morphine and metabolized to codeine-6-glucuronide. Additionally codeine is

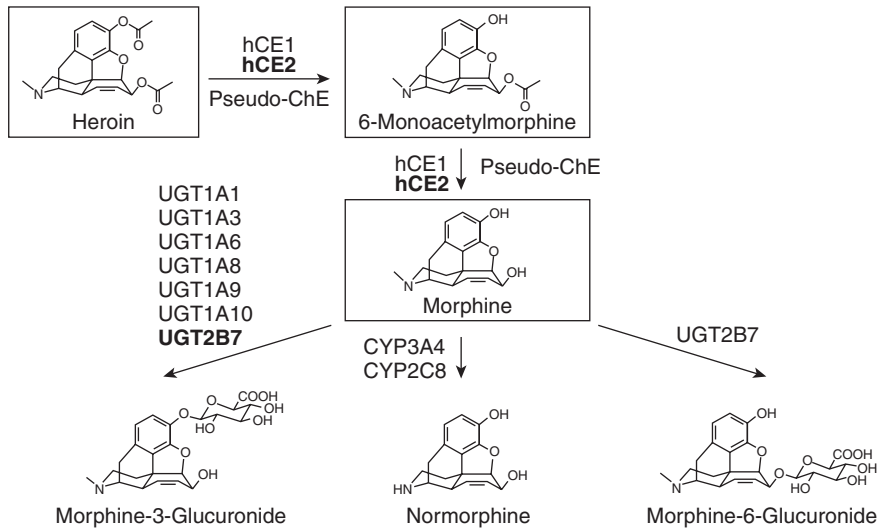

Fig. 4.2.3.1.1 Major metabolic pathways of heroin and morphine in humans.[6] Reproduced from Maurer, H.H., Sauer, C., Theobald, D.S. (2006). Toxicokinetics of drugs of abuse: current knowledge of the isoenzymes involved in the human metabolism of tetrahydrocannabinol, cocaine, heroin, morphine, and codeine. The Drug Monit. 2006 June; **28**(3), 447–53, copyright 2006, Lippincott Williams & Wilkins

metabolized to morphine by CYP2D6. Therefore a morphine positive result is possible after consuming codeine only.[5] Dihydrocodeine is metabolized to nordihydrocodeine and dihydromorphine and cannot normally be metabolized to codeine or morphine.

Epidemiology

The illicit nature of opioid use means that it is often difficult to estimate the exact prevalence. The European Monitoring Centre for Drugs and Drug Addiction reports that heroin use in the general population is less than one per cent.[6] Gender differences in opioid use have been reported with women accounting for approximately one third of all opioid users. Non-dependent recreational heroin use has been reported, but is rare. Dependence will often develop gradually over the first few years, most commonly in the late teens and early twenties. Treatment can alter the course of opioid dependence, by prolonging periods of abstinence and improving outcomes (see later sections). The risk of death from heroin dependence is approximately 12 times that of the general population, with most deaths occurring in males (> 80 per cent). Opioid use has a major effect on crime and it has been estimated that half of all crime is drug related, with estimated costs within the UK criminal justice system at £1 billion per annum in 1996.

The effects of opioids

The effects of opioids are outlined in Table 4.2.3.2.1. The effects vary depending on dose and route.

Opioid dependence and withdrawal

Opioid dependence may be classified according to the ICD-10 criteria (see appendix). Continued use of heroin (or other opioids) tends to lead to physiological dependence with the development of tolerance and withdrawal symptoms on discontinuing heroin. Tolerance occurs when the same dose gives a reduced effect or conversely, an increased opioid dose is required to have the same effect. Once physiological dependence is established, abrupt cessation or a marked reduction in dose will result in a withdrawal syndrome. During this time there is an 'undoing' of the neuroadaptation which had occurred during the development of tolerance. Withdrawal leads to 'gooseflesh' (piloerection) of the skin (which is the reason behind the term 'cold turkey'). Insomnia (with increase in Rapid Eye Movement sleep) and craving for the drug may persist for weeks. Most withdrawal symptoms appear within 4–12 h and peak at 48–72 h lasting 7–10 days. Longer acting opioids such as methadone may result in a more prolonged withdrawal. Opioid withdrawal is not usually considered to be life threatening.

Complications from opioid use

Complications may be biological, psychological, or social (Table 4.2.3.1.2).

Biological complications

Opioid overdose is the most common cause of death among opioid users, while blood-borne virus infection and other injecting related complications also contribute to increased morbidity and premature deaths.

(a) Opioid overdose

Opioid overdose occurs when the opioid dose exceeds the individual's tolerance to the respiratory depressant effect of the drug.

Table 4.2.3.1.1 Effects of opioids

Mood change (euphoria)
Analgesia
Drowsiness/Sleep
Respiratory depression
Cough reflex depression
Sensitization of the labyrinth with nausea and vomiting
Decreased sympathetic outflow (bradycardia and hypotension)
Lowering of the body temperature
Pupillary constriction
Constipation

Table 4.2.3.1.2 Complications of opioid use

Biological	Psychological	Social
Infections – hepatitis and HIV – bacterial endocarditis – septicaemia – abscesses – cellulitis Cardiorespiratory – pulmonary emboli – aspiration – cardiac arrthymias – respiratory depression – overdose death	Psychiatric complications – depression – suicide	Criminal behavior – fund dependence Loss of housing Unemployment Loss of family – family breakdown

It is more common when other Central Nervous System depressants are concurrently consumed. Respiratory depression is caused by the opioid action on the brain stem nuclei and death can follow within minutes of injecting excessive amounts. Risk factors for opioid overdose are injecting use, return to opioid use following recent abstinence (such as following detoxification and release from prison), during the early stages of dependence and starting opioid substitution treatment.[7] In addition, variability in opioid purity, increased central depressant effects following polysubstance use and high levels of psychiatric co-morbidity may increase the vulnerability for accidental or intentional overdose. Opioid overdose can be rapidly reversed if naloxone (opioid antagonist) is administered to the person who has overdosed. The management of an opioid overdose is described later in the chapter.

(b) Blood borne virus transmission

The risk of viral transmission is high among injecting drug users, and routine testing with counseling should be available to those at risk. Transmission of blood borne viruses is primarily related to sharing injecting equipment and involvement in the sex industry. Needle sharing appears to occur less frequently than sharing of spoons and filters, but any shared equipment may pose the risk of viral transmission. The prison population is particularly at risk, as injecting is more common likely to involve sharing injecting equipment.

Opioid substitution treatment is one of the most effective interventions for reducing the extent of injecting, thereby also reducing both the spread of and morbidity from blood borne viruses. Stabilization on methadone/buprenoprehine with abstinence from injecting, needle and other injecting equipment sharing, and unprotected sex should be encouraged among all dependent heroin users. Blood borne virus testing and referral to specialists for treatment is important. In addition, close liaison with medical and psychiatric services is important for improving outcomes and compliance with treatment.

(i) Human immunodeficiency virus (HIV)

Rates of HIV seropositivity amongst current injecting drug users in England and Wales although low, have recently increased, with an incidence of 1.5 per cent reported in 2004 (the highest since 1992), with higher rates reported in London.[8] The relatively low levels of HIV within the UK and elsewhere in Europe is believed to be due to the widespread availability of 'needle-exchange' services and provision of services focused towards 'harm minimization'.[9]

(ii) Hepatitis B & C

Screening of drug users in treatment has revealed prevalence rates of 20 per cent for Hepatitis B and more than 50 per cent for Hepatitis C. Intravenous drug users are likely to have higher rates estimated at 30 to 50 per cent (Hepatitis B) and up to 90 per cent (Hepatitis C).[10] Prognosis is worsened by high levels of alcohol consumption and therefore liaison with hepatitis/gastroenterology services is important. Screening for Hepatitis B and C and targeted vaccination for Hepatitis B, in addition to education and harm-reduction provision, should be provided.

Psychological complications

Numerous large epidemiological studies have identified that co-morbid psychiatric illness is common among those with opioid dependence, with prevalence rates of about 50 per cent.[11] Concurrent use of benzodiazepines, alcohol, and especially stimulant drugs increases psychiatric morbidity in addition to female gender, poor physical function, and difficulties in personal relationships.[12] Many of those with opioid dependence will have had childhood behavioural problems such as conduct disorder which may be a marker for subsequent drug use.[13] The rate of suicide among heroin users is estimated at 14 times that of age matched peers with reports of 3–35 per cent of deaths related to suicide. Risk factors include a history of depression, poly substance use in addition to generic risk factors.[14]

At entry into treatment, it may be difficult to make an accurate determination of an opioid user's psychiatric diagnosis and generally assessment should be repeated once stability on a substitution medication or detoxification has been achieved. Waiting to review a patient's mental health once they are out of crisis can prevent early misdiagnosis since much of psychiatric distress dissipates rapidly on cessation of illicit use and stabilization. In one follow up study of opioid users entering treatment, baseline levels of depression fell from 25 per cent at baseline to 11 per cent at 12 month follow up, with the observed decline being strongly related to treatment exposure.[15] Follow-up and provision of treatment for co-morbid disorders are thus essential. Enhancing compliance with prescribed medications through supervised dispensing or engagement of carers is useful. Treatment can be effective in reducing psychiatric distress observed on entry to treatment in this group. However, in a significant proportion, even on cessation of use or abstinence, major psychiatric illnesses can persist. If left untreated, co-morbid conditions can lead to a poorer prognosis particularly in respect to relapse and suicide.

Social complications

The ramifications of heroin dependence upon individual functioning and that individual's ability to relate and function within their family and community are immense. Although high rates of socioeconomic disadvantage often precede entry into heroin use, it is the other associated problems of relatively poorer premorbid functional and educational attainment that frequently compound later efforts at rehabilitation. High rates of criminal activity, homelessness, and unemployment are associated with opioid addiction, although treatment can improve socio-economic status.

Treatment of opioid dependence

Opioid maintenance treatment

Opioid maintenance treatment generally involves substituting heroin for an oral long-acting opioid, thereby reducing the plasma level variability and stopping injecting drug use. Oral methadone and buprenorphine have been licensed in several countries for use in the treatment of opioid dependence and both are approved in the UK.[16] The decision regarding whether methadone or buprenorphine is used should be based on individual factors estimating the risks and benefits and following discussion with the patient. If both drugs are equally suitable, cost-effectiveness examination by the National Institute of Clinical Excellence (NICE) concludes that methadone should be prescribed as the first choice.[16]

(a) Methadone maintenance treatment

Methadone is a synthetic orally active full opioid agonist with a half-life of 24–36 h, making it suitable for daily administration. This is an effective treatment for heroin dependence and has significantly better outcomes than non pharmacological substitution for retaining patients in treatment, decreasing heroin use, reducing crimes, reducing overdose deaths, reduced injecting and sharing of injecting equipment and consequent reduced risk behaviours leading to transmission of HIV.[17] Higher doses of methadone (60 to 120 mg/day) have been shown to be more effective than lower dosages[18] and doses greater than 80 mg daily are believed to provide a reasonable level of opioid receptor blockade such that euphoria from illicit opioids is diminished.

Methadone steady state plasma levels take approximately 4 to 5 days and so there is potential for methadone accumulation (and overdose) when initiating treatment. Deaths have been recorded during the induction phase onto methadone especially when the recipient is not as tolerant as believed or is using other opioids or substances.[19] Therefore, confirmation of the patient's dependent status is paramount as described in the chapter and it is safer to start treatment at low doses (not more than 30 mg daily). Treatment should be initiated under supervision with oral methadone liquid where consumption can be easily monitored. Doses should generally be increased slowly, and titrated against withdrawal symptoms. As methadone can accumulate, there should be increased observation over the first few weeks of treatment. Doses can then gradually be increased to within therapeutic levels (60–120 mg daily). Prescribing should follow the guidelines outlined later in the chapter.

(b) Buprenorphine maintenance treatment

Buprenorphine (Subutex) is a synthetic partial opioid agonist which is given as a sublingual tablet and has a high affinity at μ-opioid receptors. It is an effective treatment for use in maintenance treatment for heroin addiction, but is not more effective than methadone at adequate dosages.[20]

Buprenorphine undergoes extensive first metabolism. Therefore, it is administered as sublingual tablets (2 mg and 8 mg) with bioavailability of between 30–40 per cent. Optimizing sublingual absorption while minimizing diversion is a practical challenge that supervised dispensing points still need to address. Taking 5–7 minutes to dissolve, buprenorphine reaches a plateau on most physiological subjective effect at a daily dose of 4–16 mg. At higher doses, the duration of action increases, permitting less than daily dosing in about one-third of patients. Because of its high affinity for the opioid receptor, buprenorphine will precipitate withdrawal if administered to someone with an opioid agonist on board (typically within 8 h of heroin use or 24–36 h of methadone use). Therefore, patients are advised to wait until they are in mild withdrawal before commencing treatment. Finally, it is thought to be safer in overdose (with a 'ceiling' in the respiratory depression, unlike with full opioid agonists) and so induction can be quite rapid aiming for doses of between 8–16 mg by day 3.

It is an effective analgesic but may be less suitable than methadone for those with chronic pain. Although safer in overdose than methadone, fatal overdose can occur especially when taken in combination with other substances. As with methadone dose, reduction in someone stable on maintenance should be done gradually (typically 2 mg ever 2 weeks) and only supported when there is evidence of continued abstinence from illicit opioid use. Continued dose reduction in the face of return to illicit use is likely to further destabilize the patient. In some countries (e.g. many European countries since 2007), another preparation has become available (Suboxone), in which buprenorphine has been combined with naloxone in a ratio of 4:1 to reduce the desirability of injecting diverted medication. When taken as directed (sublingual), the bioavailability of naloxone is very poor, whereas when injected by a dependent opiate user, a severe withdrawal reaction may be precipitated.

(c) Other opioid maintenance treatments

Injectable methadone and injectable heroin are rarely prescribed in the United Kingdom and at present there is insufficient evidence to guide this use.[21] However, it may be considered in some patients as a 'second-line' treatment option for whom an adequate trial (e.g. at least 6 months) of optimized methadone maintenance treatment (e.g. doses > 80 mg daily, regular supervised dosing, regular appointments and appropriate management of medical or psychiatric co-morbidity) is ineffective in controlling illicit injecting heroin use. This should only be initiated by a specialist. Both long-acting morphine and dihyrocodeine have been compared to methadone in two randomized controlled trials which have revealed broadly equivalent outcomes between the groups.[23,23]

Opioid detoxification

Detoxification may be based on suppression of the 'nor-adrenergic storm' that accompanies opioid withdrawal, by prescribing either α2-receptor agonists or a gradual reduction of an opioid agonist. When a patient is stable and motivated, a gradual reduction in the dose of opioid maintenance dose can be an effective means for attaining abstinence. However, it must be noted that detoxification is generally associated with poor long term rates of abstinence and retention in treatment.

(a) Buprenorphine detoxification

Buprenorphine has been found to be more effective than clonidine (below) for the management of opioid withdrawal. In addition, there is no significant difference between buprenorphine and methadone in terms of completion of treatment, but withdrawal symptoms may resolve more quickly with buprenorphine.[24] This can be undertaken as an inpatient or outpatient. Buprenorphine should only be taken after cessation of heroin use as it can precipitate withdrawal. Withdrawal may be achieved by the burpenorphine dose being stabilized according to withdrawal over

a 24–48 h period, after which a gradual dose reduction should occur over 5–21 days in the inpatient or outpatient setting.

(b) Methadone detoxification

Methadone detoxification can be used for pharmacologically assisted opioid detoxifications. A review revealed that withdrawal programs vary widely with regard to duration, design and treatment objectives. This review confirmed that slow tapering with temporary substitution of methadone accompanied by medical supervision and ancillary medications can reduce withdrawal severity. Nevertheless, the majority of patients relapsed to heroin use.[25]

(c) α2-Agonist assisted detoxification

α2-agonists, such as lofexidine and clonidine, reduce pre-synaptic nor adrenaline release alleviating many withdrawal symptoms associated with opioid withdrawal. The dose is titrated against the symptoms and signs of withdrawal whilst also avoiding hypotensive episodes. Detoxification can occur in both outpatient and inpatient settings. Lofexidine that has a lower incidence of hypotension than clonidine is the preferred non-opioid method of assisting opioid withdrawal. A review has concluded that there is no significant difference in efficacy for treatment regimes based on clonidine and lofexidine, compared to reducing doses of methadone over a period of around 10 days, for the management of opioid withdrawal.[26]

(d) Naltrexone assisted detoxification

Some research has been published suggesting that withdrawal may also be completed more quickly by additionally administering the long-acting opioid antagonist naltrexone. However, further research is still needed to confirm effectiveness and safety of this treatment.

Naltrexone for relapse prevention

Oral naltrexone has recently been recommended in the UK for the management of opioid dependence. Naltrexone is relevant for highly motivated patients who have completed an opioid detoxification. This may be combined with arrangements for supervision and should be given as part of a programme of supportive care. Regular reviews of effectiveness of naltrexone should be undertaken by the clinician and discontinuation of treatment should be considered if there is evidence of continued opiate misuse.[27]

Psychosocial interventions for opioid dependence

There are numerous psychosocial approaches that are currently used in the management of substance misuse. Treatment based on a holistic approach encompassing biological, psychological and social aspects of care is likely to improve outcomes. Psychosocial treatments such as relapse prevention, motivational interviewing and contingency management are often used in the addiction setting. Cognitive behaviour therapy and other types of psychotherapy are also used particularly for those with a specific psychiatric disorder such as depression and can be referenced elsewhere in the book.

Relapse Prevention looks at identification of triggers for craving (e.g. people, places, or moods) and uses learning techniques (distraction, relaxation) to handle high-risk situations.[28] Motivational interviewing techniques can help patients move along a 'cycle of change' from pre-contemplation (no interest in changing behaviour) to contemplator, to determination and action without confrontation.[29] This is based on five key principles (Table 4.2.3.1.3) which are often used in both addiction and eating disorders, but may also be used in any aspect of the doctor-patient relationship where the patient is ambivalent about change.[30] Although used rarely in the UK, Contingency Management (CM) has a stronger evidence base. This behavioural treatment uses rewards or other reinforcers to promote abstinence or other selected goals. Narcotics Anonymous is based on the 12-step program (the philosophy behind Alcoholics Anonymous) where the individual accepts they have a drug problem and uses 12 steps (Table 4.2.3.1.4) within the group setting, to attain abstinence.[31]

Table 4.2.3.1.3 Principles of motivational interviewing[30]

- express empathy
- help the client to see discrepancies in their behaviours
- avoid argument
- roll with resistance
- support the patient's sense of self-efficacy.

Reproduced from Miller, W. and Rollnick, S. Motivational Interviewing, copyright 1991, Guildford Press NY.

Psychosocial interventions alone have not been shown to be more effective than no treatment.[32] However psychosocial interventions combined with pharmacological interventions have been shown to lead to better outcomes.[33]

Educating the drug user about safe practices (including safer injecting, not sharing equipment) and harm-reduction techniques is important, as is appropriate liaison with other agencies such as social services or voluntary sector supports. Therapeutic communities, residential rehabilitation and 'concept houses' based on a religious or abstinent theme offer longer-term care.

Management of opioid dependence

The treatment plan should be made jointly between the clinician and patient. The actual management plan depends on whether the person has opioid dependence, the amount of opioids used, and the outcome of the mutually agreed treatment objectives and

Table 4.2.3.1.4 12 Steps of Narcotics Anonymous[31]

1. We admitted that we were powerless over our addiction, that our lives had become unmanageable.
2. We came to believe that a Power greater than ourselves could restore us to sanity.
3. We made a decision to turn our will and our lives over to the care of God as we understood Him.
4. We made a searching and fearless moral inventory of ourselves.
5. We admitted to God, to ourselves, and to another human being the exact nature of our wrongs.
6. We were entirely ready to have God remove all these defects of character.
7. We humbly asked Him to remove our shortcomings.
8. We made a list of all persons we had harmed, and became willing to make amends to them all.
9. We made direct amends to such people wherever possible, except when to do so would injure them or others.
10. We continued to take personal inventory and when we were wrong promptly admitted it.
11. We sought through prayer and meditation to improve our conscious contact with God as we understood Him, praying only for knowledge of His will for us and the power to carry that out.
12. Having had a spiritual awakening as a result of these steps, we tried to carry this message to addicts, and to practice these principles in all our affairs.

treatment plan. Opioid dependence management is sometimes based on 'abstinence', where the person refrains from taking drugs, but also needs to be based on the principles of harm reduction. Harm reduction aims to reduce harms from opioid use often in terms of reducing deaths, spread of blood-borne viruses or improving psychosocial outcomes. This may optimally be achieved through cessation of injecting illicit opioid use by stabilizing the person on an opioid replacement.

Assessment of opioid use and dependence

A comprehensive assessment of opioid use patterns and associated risks forms the basis of any treatment plan. A suggested plan of enquiry that allows both accurate diagnosis and risk assessment is outlined below.

(a) Clinical assessment

1 **Current consumption:** How much heroin (or other opioid) is consumed on a typical day, in terms of either weight or money spent, and for how long has consumption been at this level? Are opioids taken daily? What happens when no opioids are taken? The route of use (smoking, intravenous injection), number of administrations per day, and the minimum amount of opioid required each day to avoid withdrawal symptoms should also be assessed. Enquiry should be made to determine if more than one type of opioid is being used (e.g. prescribed medication or street methadone). All other substances being used should be identified (e.g. cocaine, benzodiazepines and alcohol) and their patterns of use.

2 **Typical day:** A systematic enquiry of the person's typical day and the use of opioids and other substances is particularly important for assessing evidence of withdrawal. This can also be useful for identifying risk activities that the user engages in to support their ongoing use, including criminal activity, high risk sex, or injecting practices.

3 **Drug use history:** A careful enquiry needs to be made to determine the temporal relationship between the onset of drug use and any psychological behaviors. The age of first use and the psychosocial precipitants of use should be established, as should the development of tolerance and craving through increased frequency of use, escalating dose, and where relevant, the onset of injecting.

4 **Biopsychosocial complications:** This should assess episodes of overdose (intentional or accidental), viral screening status and injecting behaviour including use of needle exchanges, sharing equipment and use of high-risk injection sites such as the groin and neck. Effects on family relationships, employment and criminal activity, and co-morbid psychiatric conditions related to opioid use should be assessed.

5 **Past treatments and abstinent periods:** Have they ever been in contact with treatment services, maintained on substitute medication or undertaken a detoxification? What was their longest period of abstinence? What has helped in the past? When and why did relapses occur? What are high-risk situations and other triggers for use?

6 **Motivation for change:** Why seek treatment now? What support is needed? Thinking of **L**ivelihood (financial), **L**ife (physical health), **L**ove life, **L**egal problems and **L**osing it (loss of control) can be helpful as these are often precipitants for seeking treatment and can be used to encourage behavioural change.

(b) Confirmation of dependence

Although a diagnosis of opioid dependence can be made by taking a full history; dependence and tolerance to opioids should be corroborated before commencing substitute treatment. Confirmation of dependence and tolerance prior to commencing treatment is important since the greatest risk associated with prescribing methadone is the possibility of overdose following consumption of methadone by a non-tolerant individual. Corroborative information may come from urine drug screens and other health care practitioners such as the GP or criminal justice worker. Physical examination is essential and may reveal stigmata of injecting drug use such as evidence of recent intravenous injection sites or the more long-term 'track marks' (linear scarring along veins from repeated intravenous use) on the drug user's limbs. All patients should be asked where they usually inject and recent injection sites should be examined. In those with poor upper limb veins, with evidence suggestive of ongoing illicit use, it may be appropriate to examine groin or neck sites.

Urines tests are supportive of use but not confirmatory of dependence. Sequential urine testing over a few days may allow the confirmation of regular opioid (although not necessarily heroin) consumption. Measurement of withdrawal by using withdrawal scales (Table 4.2.3.1.5) in addition to examining for presence of tachycardia and hypertension, following a period of abstinence, is helpful in confirming withdrawal. The Objective Opiate Withdrawal Scale (Table 4.2.3.1.5) is useful when assessing whether a person is in withdrawal before commencing opioid substitution treatment and useful after commencing treatment to aid assessing whether the opioid substitute dose is adequate. Partial or full reversal of withdrawal following a measured dose of opioids administered on site will provide some information of the patient's level of tolerance.

Table 4.2.3.1.5 Objective opiate withdrawal scale[27]

This is to be completed by clinician. A score should be given for each observation within a 5 minute observation period.

Observations	Scoring
1. Yawning	0 = no yawns 1 = ≥ 1 yawns
2. Rhinorrhoea	0 = <3 sniffs 1 = ≥3 sniffs
3. Piloerection (observe arm) 'gooseflesh'	0 = absent 1 = present
4. Perspiration	0 = absent 1 = present
5. Lacrimation	0 = absent 1 = present
6. Tremor	0 = absent 1 = present
7. Mydriasis	0 = absent 1 = ≥ 3mm
8. Hot and cold flushes	0 = absent 1 = shivering / huddling for warmth
9. Restlessness	0 = absent 1 = frequent shifts of position
10. Vomiting	0 = absent 1 = present
11. Muscle twitches	0 = absent 1 = present
12. Abdominal cramps	0 = absent 1 = Holding stomach
13. Anxiety	0 = absent 1 = mild – severe
TOTAL SCORE

Investigations for patients with opioid dependence

Heroin dependence is associated with high rates of physical and psychiatric morbidity. Since access to primary health care may be difficult, basic physical health checks should be a fundamental part of all drug treatment. The core assessment should include history, physical examination, routine blood tests, blood borne virus screening and vaccination where appropriate, and assessment of nutritional status, mental and dental health. Referral to appropriate specialist services should be facilitated through coordinated care planning which should form the cornerstone of structured drug treatment delivery.

Management options for opioid dependence

Following a careful and thorough assessment which allows confirmation of dependence as outlined above, there are several treatment options. In the short term, opioid substitution treatments with methadone or buprenorphine may be offered. Opioid substitution treatment should be monitored closely, especially during the initial phase of treatment. Initiation of opioid substitution treatment usually takes place in the community setting, but may occur in an inpatient setting if there is a complicated history involving medical or psychiatric morbidity. Opioid maintenance treatment is continued in the community setting and can be continued as maintenance for the long term, with some patients continuing treatment for over 50 years. Treatment for opioid dependence is likely to be improved when framed within a comprehensive treatment package including psychosocial and pharmacological interventions.[32] Relapse prevention and motivational interviewing can be carried out during regular appointments with health professionals. Community substance misuse teams often use keyworking as a model of care for opioid dependent patients. This is where one healthcare professional looks after the patients care and provides the main source of contact, often following up referrals and ensuring medical and psychosocial needs are met. Opioid maintenance treatment within the community substance team may continue in the long term or be a prelude to starting abstinence based treatments, with the aim of stopping all illicit heroin use.

Abstinence can be achieved by pharmacologically assisted withdrawal from the opioid via a detoxification with either lofexidine or an opioid substitute such as methadone or buprenorphine (as above). This usually takes 10–21 days but may be longer if withdrawal from a longer acting opioid is required. Opioid detoxification may take place in the inpatient or community setting, depending on the level of medical and psychiatric morbidity. Following opioid detoxification patients may benefit from treatment within a therapeutic community or residential rehabilitation centre where life skills for dealing with a world without opioids may be developed. For patients who do not enter rehabilitation centres, regular sessions with keyworkers using relapse prevention and motivational interviewing may also be beneficial. Highly motivated patients may also benefit from naltrexone to prevent relapse (described above).

Prescribing opioids for opioid dependence

In the United Kingdom, all doctors may prescribe methadone or buprenorphine for the treatment of dependence, although prescribing should generally be initiated by a specialist or special interest general practitioner. Prescriptions for opioid dependence should ideally be dispensed daily with supervised doses, particularly for the first three months of treatment. After about three months, if a patient is stable (based on psychosocial outcomes and illicit substance use) the number of dispensings per week and level of supervision may be reduced, although this may be varied when there are extenuating circumstances. UK guidelines advocate that no more than a week's medication is dispensed at a time.

Liaison between the pharmacist, the general practitioner and the specialist is important to prevent double scripting, reduce diversion and improve safety. Clinicians in all specialties should be aware of the potential for all opioid-containing analgesics to be diverted for abuse or develop into iatrogenic dependence. Repeat prescriptions of such analgesics should be carefully reviewed. Prescriptions for controlled drugs can only be for 28 days in total and the total prescribed amount must be written in words and figures. It is recommended that the prescription should state the name of the pharmacy where the prescription is to be dispensed, how often the prescription should be dispensed and whether the dose should be consumed under supervision. Installment prescriptions for daily dispensing are available in the UK for burpenorphine and methadone. Only doctors in possession of a Home Office license are able to prescribe heroin for the treatment of opioid dependence.[34]

Opioid overdose management

Opioid overdose management training is particularly important as early recognition (Table 4.2.3.1.6) of an opioid overdose and prompt action (Table 4.2.3.1.7) can save lives. The antidote to heroin is naloxone and this should be given if an opioid overdose is suspected. Although intravenous naloxone is quicker acting, venous access may be difficult and therefore, intramuscular injection may be preferable and also results in a more gradual reversal of the overdose which may be less likely to provoke aggression. Hospital monitoring should always be recommended, since the plasma half-life of naloxone is shorter (<1 h) than the physiological effects of heroin (4–6 h) and methadone (24–36 h). In addition many overdoses are a result of concomitant substance use—the effects of which will not be reversed by naloxone alone. Opioid overdoses involving buprenorphine (partial agonist) will not be readily be reversed by naloxone; however buprenorphine is believed to have much less respiratory depressant effects.

The supply of 'take home' emergency naloxone may help reduce opioid related overdose deaths. It has, therefore, been advocated that providing take-home naloxone in combination with opioid overdose management training to opioid using patients and their families may help reduce deaths.[35]

Table 4.2.3.1.6 Recognition of an opioid overdose

Recognition
Respiratory Arrest with a pulse
Pinpoint pupils (unreactive to light)
Snoring giving way to shallow respiration
Respiratory Depression (<8 breaths per min)
Bradycardia and hypotension
Varying degrees of unconsiousness

Table 4.2.3.1.7 Management of an opioid overdose

Check area safe, then try to rouse overdose victim
If unrousable - Call for help/ambulance
Check airway and breathing a. If not breathing, give 2 rescue breaths b. If breathing — place in recovery position
Administer 0.4 mg Naloxone Intramuscularly — Increase dose until adequate reversal achieved
Consider use of high flow oxygen
Patient to have medical monitoring after naloxone, as opioid overdose may re-emerge. Patients may need additional doses of naloxone

Table 4.2.3.1.8 Aims of managing the pregnant drug user

- Engage and maintain contact with the patient and partner.
- Aim to reduce risk-taking behaviours (sharing needles, prostitution).
- Stabilize on oral methadone maintenance treatment (or extremely slow detoxification, if required).
- Ensure that other drug and alcohol use are assessed routinely.
- Provide health and psychosocial care including blood borne virus screening.
- Close liaison with multi-agency teams including possible social work assessment.
- Social stability and provisions for motherhood.

Special groups

Young people

Young people with opioid problems often have other emotional and/or behavioural problems, and frequently fall between the adult and child psychiatric services as well as addiction services, compounding the difficulties in providing effective services to this group. Increasingly dedicated services have recently been developed and these integrated services focus as much on the family and re-integration with education as they do on substance use issues. Approaches effective for the adult population may be less effective in a group with less developed emotional and cognitive abilities. Separation of such a service from adult providers would also assist in preventing experienced drug users from influencing more naive users. Ultimately, a tiered approach would appear appropriate, since it would allow maximum utility of current services and focused development of new services. Generic services in primary health care could provide accurate screening with initial referral to youth-oriented services within existing departments. Beyond this, referral to specialist and super-specialist regional services could be employed to provide secure environments with the option of residential rehabilitation and therapeutic communities. Once engaged they may benefit from a range of possible therapies from family work and cognitive behavioural therapy to pharmacotherapy and self-help groups.

Pregnancy and breastfeeding

Maternal opioid use poses a risk to both the mother and foetus. Pregnancy can be a specific point when women try to address their opioid use problem. The management of the pregnant opioid user should follow the same guiding principles as for other opioid users; additionally, there should be close liaison between addictions and maternity services, the general practitioner and other relevant agencies (Table 4.2.3.1.8).

Women who are already on methadone maintenance treatment can remain on methadone but should be encouraged to stop illicit opioid use. For women who are not prescribed methadone, the first step is to initiate stabilization on methadone. Methadone maintenance may continue at a stable dose throughout pregnancy. During the third trimester, maternal metabolism may increase the need for methadone and so the dose may need to be increased or alternatively the daily dose could be split. Methadone increases the risk of respiratory depression in the neonate and should always be pre-considered for the delivery plan. Women prescribed opioids may also need increased pain relief during delivery. The long-term outcome in women who enter methadone treatment programmes during pregnancy is better in terms of their pregnancy, childbirth, and infant development, irrespective of continuing illicit drug use.[36] Methadone is not contraindicated for breast feeding.

Some women prefer to be abstinent from opioids during pregnancy. These women will often need a gradual pharmacologically assisted detoxification, which should be avoided in the first trimester, ideally undertaken in the second trimester and undertaken with caution in the third trimester. Detoxification is best undertaken within a dedicated inpatient facility, however, this may not always be possible and therefore community detoxification can be undertaken. During stabilization on methadone or detoxification, it is important to prevent the pregnant woman experiencing opioid withdrawal as this is dangerous for both mother and fetus.

Currently, there is insufficient evidence regarding the use of buprenorphine during pregnancy or breastfeeding to be able to define its safety profile. However, women well maintained on buprenorphine prior to pregnancy refusing alternative pharmacotherapy could be kept on buprenorphine following full informed consent.

Forensic

It has been estimated that up to two-thirds of people arrested have taken substances prior to arrest, whilst approximately 15–50 per cent of the prison population were previously dependent on drugs or alcohol. It is difficult to estimate exact opioid use and dependence, but approximately one-fifth of the prison population injects drugs. Access to illicit substances is not prevented by imprisonment; indeed some users may increase or start using drugs whilst imprisoned.[37] Improving identification of drug users before sentencing is important. In addition, identification of drug related crimes and offering court diversion schemes with drug treatment interventions can be an alternative to a custodial sentence. Prisoners will benefit from education, good primary health care, blood borne virus testing, and hepatitis vaccination. In addition, prisoners can undertake opioid detoxification or commence/continue opioid maintenance treatment whilst in prison. Release from prison is associated with extremely high risk of opioid overdose death, particularly in the first few weeks, and therefore quick access to drug services following release (or prior to release) may reduce deaths.

Accessing treatment and the range of services

Those who experience problems with opioids may present to a wide range of professionals within the health-care, social, and legal systems. The range of treatment options available from statutory and non-statutory agencies in any particular area will vary, as will the provision of either maintenance or detoxification for opioid dependents depending upon differing treatment philosophies and treatment settings.

Outcomes

Heroin dependence is a chronic relapsing condition and opioid use reduces morbidity and mortality more than any other drug use.[38] Treatment saves lives and improves psychosocial function as well as reducing risk to both the individual and the community. Outcomes are broadly comparable to those seen with other chronic medical conditions.[39] Abstinence rates following treatment vary widely, but 10 to 40 per cent of treated patients are still drug free at 6 months.[40] The majority of those who relapse following treatment do so within 3 months of discharge. Longer treatment is associated with better outcomes and greater pre-treatment severity of psychopathology is associated with worse outcomes. Long-term follow-up studies suggest that successful and lasting cessation of opioid use can be a very slow process and becomes increasingly unlikely if users continue into their late thirties.

Results from three longitudinal studies ranging from 3–5 years based in the United Kingdom, Australia and United States of America have shown that treatment leads to better outcomes against all parameters as compared to no treatment.[41,42,43] Patients who enter drug treatment are more likely to significantly reduce use of heroin and other illicit drugs and longer treatment times have been associated with better treatment outcomes. Reductions in heroin use have also been mirrored by reductions in heroin overdose rates. Therefore opioid treatment increases morbidity and mortality in opioid users.

The Australian Treatment Outcome Study (ATOS) reported that half the number of opioid overdoses occurred in the participants in treatment at 1 year as compared to the same participants prior to entering treatment. In addition this study showed that levels of psychopathology reduced, physical health improved and crime rates in this population reduced following treatment.[43] The National Treatment Outcome Research Study (NTORS) based in the UK had increased rates of abstinence, reduced heroin use and reduced injecting and sharing of injecting related equipment with both residential and community treatment.[42] Findings from the Drug Abuse Treatment Outcome Studies (DATOS) based in the USA were similar to both the UK and Australia studies.[41]

Longer term outcomes have been observed in a study following up 581 male heroin users since 1962. At the 33-year follow up, 284 subjects were dead and 242 were interviewed. Over a fifth were still using heroin and 40.5 per cent admitted to using heroin in the last year. There were high rates of health problems, mental health problems, and criminal justice system involvement. Heroin abstinence was associated with improved outcomes in all these domains. Deaths increased steadily over time with a relatively stable pattern of heroin use in the subjects.[44] A further analysis of the results assessed years of life lost through heroin use and concluded that on average, 18.3 years of potential life were lost before the age 65, which is significantly higher than that of US population.[45]

Conclusion

Opioid dependence is a chronic relapsing and remitting disorder affecting a large proportion of people throughout the world with severe physical, psychological, and social consequences. Opioid overdose and spread of blood borne viruses are major causes of morbidity and mortality. Assessment of opioid use and dependence should be systematic and confirmation of dependence is of paramount importance before initiating treatment. The prescription of substitute opioids should be managed carefully to prevent harm, diversion to others and improve safety. Management of opioid dependence can greatly improve outcomes and may be based on opioid maintenance stabilization or detoxification combined with psychosocial interventions.

4.2.3.2 Disorders relating to the use of amphetamine and cocaine

Nicholas Seivewright and Robert Fung

Introduction

Amphetamine and cocaine are classed as stimulant drugs, although the distinction between stimulants and depressants can be criticized on the grounds that the same drug may have both actions in turn. This does indeed occur with amphetamine and cocaine, but the initial desired effects are increased energy and activity, and elevation in mood. These appear to be mainly due to enhanced central transmission of dopamine and noradrenaline (norepinephrine), with a similar enhancement of serotonin playing a less certain role.

Pharmaceutical preparations of amphetamine were previously widely used for treatment of depression and obesity, with some misuse of these occurring. In the period since the 1970s of increasing recreational drug use, the powder preparation of 'street'

amphetamine (commonly known as 'speed' or 'whizz') has largely displaced the pharmaceutical forms to become a common drug of misuse in many countries. The powder is typically very impure and constitutes a racemic mixture of d- and l-isomers, with the l-form being relatively inactive. A stronger street preparation is the 'base', sometimes more a moist paste, and both these forms of the drug may be swallowed (either on their own or in a drink), snorted, or injected. (For the methylated forms 'ecstasy' and 'crystal meth', see Chapter 4.2.3.5.)

The coca shrub is indigenous to countries in South America, where the leaf is chewed, and use of the derived cocaine powder has spread extensively to the United States and elsewhere. The powder may be injected, sometimes along with heroin, by polydrug users, or snorted, the image of which is sometimes linked with executive lifestyles. Cocaine has become more dangerous as usage has gradually transferred in many countries to the 'crack' form, which is made from cocaine hydrochloride powder in a simple chemical process, and is more potent in its effects and withdrawal effects. Very rapid increases in blood levels of the drug can be achieved by smoking crack, and this is the usual route, although it is injected by committed intravenous drug users.

Clinical features

The effects and withdrawal effects of amphetamine and cocaine can be considered together, as the main features are equivalent. However, amphetamine has a slower onset of action than cocaine and longer elimination half-life, while crack is the most quickly absorbed of the cocaine preparations. This is reflected not only in the generally more intense effects of cocaine than amphetamine, but in the timescales involved. Thus an amphetamine user may experience desired effects, unwanted mental effects, and withdrawal features over the course of a few days, while a crack user can report the same sequence occurring in a matter of hours or even less. The main effects and withdrawal effects of these two stimulant drugs are shown in Table 4.2.3.2.1.

The list of effects can be seen as merging from the desired to the undesired. These drugs are typically taken in situations where stimulation is the aim, with sleep and eating regarded as hindrances. Mood is elevated, but characteristically this progresses to suspicion, in which true paranoid symptoms may be experienced. This is usually recognized by the individual as indicating that the episode of use should be terminated, but if use persists symptoms may become severe, or a more confused state develop. After stopping the drugs there are typically withdrawal effects of depressed mood, hyperphagia, and hypersomnia; no consensus exists as to whether such features are best viewed as 'rebound' symptoms, a truer withdrawal syndrome, or simply users catching up on sleeping and eating after a period without either.

Table 4.2.3.2.1 Effects and withdrawal effects of amphetamine and cocaine

Effects	Withdrawal effects
Increased energy	Depression
Hyperactivity	Irritability
Euphoria	Agitation
Reduced appetite	Craving
Insomnia	Hyperphagia
Paranoid symptoms	Hypersomnia
Confusion	

Such withdrawal features have been delineated most closely in relation to cocaine. A three-stage process has long been recognized[1]: initially agitation, anorexia, and acute craving; second, excessive tiredness, depression, and hyperphagia; finally, a normalization of most features, but a return of craving when triggered by environmental cues. This description is from before the escalation in crack use, and depression, craving, and agitation especially are often much more severe with this form of the drug. While environmental cues are clearly relevant in precipitating the use of any drug, a powerful surge of craving on encountering situations associated with previous use appears particularly characteristic of cocaine and crack.[2] The three-stage description of withdrawal features suggests that this phenomenon may occur after months or even years of abstinence.

Are amphetamine and cocaine addictive?

It is commonly observed that amphetamine and cocaine are non-addictive, or cause psychological but not physical dependence. Such observations rest on a distinction in which the condition of addiction, or physical dependence, requires visible bodily withdrawal symptoms, but critics claim this is of limited meaning now that there is an understanding of the neurobiological basis of drug withdrawal states. The current classification systems do retain some distinctions between physical and psychological dependence, and the issue is largely one of definition and semantics. The credibility of the label 'non-addictive' is certainly tested by individuals who have injected amphetamine 10 or more times every day for many years, or who spend vast amounts of money using crack in a highly compulsive manner.

Classification

Table 4.2.3.2.2 shows the classification within ICD-10 and DSM-IV-TR of disorders that may relate to the use of cocaine. In both systems the same diagnoses can be applied to amphetamine, in ICD-10 within a category 'other stimulants'.

Importantly, the list of diagnoses in ICD-10 is a standard one to be used across all psychoactive substances, with the second digit of the code number simply changed according to substance, and so does not imply that all those conditions can be caused by amphetamine or cocaine. The DSM-IV-TR listing is somewhat more specific, in that the diagnoses are selected from a wider general list of conditions which can apply to the range of substances. In this way the DSM-IV-TR classification recognizes that cocaine and amphetamine can produce states of dependence and withdrawal, as well as psychosis, affective disorders, and the other conditions included.

Diagnosis

The use of amphetamine or cocaine can be detected by drug screening of a plain urine sample, in laboratory testing or with instant kits. The importance of urine testing as a relatively simple procedure to employ, in any setting, in cases where drug use is suspected must be emphasized, as it is surprisingly often neglected. The two main limitations are possible doubts about authenticity, where mouth swabs for oral mucosal transudate can be a useful

Table 4.2.3.2.2 Classification of disorders relating to cocaine in ICD-10 and DSM-IV-TR

ICD-10		DSM-IV	
F14.0	Acute intoxication	292.89	Cocaine intoxication
		292.81	Cocaine intoxication delirium
F14.1	Harmful use	305.60	Cocaine abuse
F14.2	Dependence syndrome	304.20	Cocaine dependence
F14.3	Withdrawal state	292.0	Cocaine withdrawal
F14.4	Withdrawal state with delirium		
F14.5	Psychotic disorder	292.11	Cocaine-induced psychotic disorder, with delusions
		292.12	Cocaine-induced psychotic disorder, with hallucinations
		292.84	Cocaine-induced mood disorder
		292.89	Cocaine-induced anxiety disorder
		292.89	Cocaine-induced sexual dysfunction
		292.89	Cocaine-induced sleep disorder
F14.6	Amnesic syndrome		
F14.7	Residual and late-onset psychotic disorder		

alternative, and the short time for which drugs remain detectable in urine—as little as 24 h for cocaine. By contrast drugs remain in hair from the head or other parts of the body for the whole period of growth, but this technique which gives much longer-term information is a specialized one.

Obtaining a history and compliance with sampling may be particularly problematic in psychotic states. In such conditions it is also important to recognize that detected drug use may be incidental rather than necessarily causative.

Epidemiology

In most countries, the use of illicit drugs is commonest among young males of lower socio-economic status. Stimulant use overall reflects this, although of the various drugs of misuse, cocaine powder has been exceptional in the extent of usage also by more affluent individuals.

The biggest epidemic of cocaine use outside South America has been in the United States, where it peaked in the mid-1980s.[3] Household surveys at that time estimated that approximately one-tenth of the population had used the drug; the same epidemiological method has charted the subsequent general decline in occasional use, but an increase in more dependent use of crack. Cocaine use in other countries has not generally spread as widely as was predicted from the United States experience. In Europe the population lifetime prevalence of cocaine use has remained in low single-figure percentages,[4] much of it among inner-city polydrug users, although snorting cocaine powder is seemingly increasing among young people, rather displacing the recreational use of 'ecstasy'.

Even in areas where stimulant use is common, such users tend to present relatively rarely to treatment services. Priority is generally given to opioid substitution treatment of heroin addicts, and so service statistics will nearly always underestimate stimulant problems.

Aetiology

Broadly the same familial, social, and psychological factors are relevant in the aetiology of amphetamine and cocaine misuse as in other forms of drug misuse. Approximately half of the drug misusers are deemed in studies to have an underlying personality disorder,[5] usually of the antisocial type, although the figure has sometimes been found to be lower for stimulant misusers than for those dependent on opiates. This may be partly methodological, to do with the difficulty in distinguishing true personality characteristics from behaviours inherent in the activity of highly dependent drug misuse, but is probably also a reflection of the use of stimulant drugs by a generally broader population.

Course and prognosis

Course

A far greater proportion of amphetamine and cocaine misuse than opiate misuse is recreational in nature, with few significant complications if the medical harms are avoided. It is assumed that the vast majority of those who are identified in school and teenage surveys as having used stimulants simply give them up in due course, although little systematic data is available. Complications and involvement with treatment services are more likely where there is dependent usage, and there may be psychiatric contact in episodes of psychosis. A very small proportion of amphetamine injectors progress to high-dose daily usage, while the heavy use of cocaine appears to be less sustainable and is therefore usually periodic in nature.

Other drug use

After being stimulated with amphetamine or cocaine, many individuals will use sedatives such as alcohol, benzodiazepines, or cannabis to 'come down' from their drug. Increasingly heroin is being used for this purpose, sometimes to the point of becoming dependent on the opiate and requiring substitution treatment. The use of cocaine in particular is commonly encountered as a secondary form of drug misuse in methadone patients,[6] with some individuals undoubtedly switching their preferred illicit drug from heroin to cocaine when treatment is established.

Prognosis

The drug misuse literature in general would suggest that stimulant use is more likely to progress and become problematic in individuals with associated personal or social difficulties or psychiatric disorder. Usage by individuals with severe mental illness, which often contains an element of 'self-medication' of distress even though in the long run stimulants will render symptoms worse, can be particularly entrenched.[7]

Complications

Many of the complications of amphetamine and cocaine misuse are complications of drug misuse in general, including those related to injecting. The range includes general physical decline,

weight loss, dental problems, infective complications ranging from abscesses to hepatitis and infection with the human immunodeficiency virus (HIV), reduced foetal growth in pregnancy, mood disturbances, and various social problems. Complications in the following areas are somewhat more specific to stimulant misuse:

- Cardiovascular—hypertension, arrhythmias, myocardial infarction, cerebrovascular accident
- Obstetric—premature labour, placental abruption
- Psychiatric—anxiety, depression, aggressive behaviours, psychosis
- Other—perforation of nasal septum (cocaine snorting)

The cardiovascular problems relate to increased catecholamine secretion, and represent the most serious hazard of cocaine abuse.[8] With obstetric complications, it is difficult to separate the effects of drugs from other risk factors such as poor diet, smoking, or adverse social conditions, but there appears to be a particular link between stimulants and placental abruption.

There are also various psychiatric disorders that are particularly associated with amphetamine and cocaine misuse. Anxiety as a symptom is common in relation to the agitation produced by the drugs, while depression is a classic withdrawal effect. An assessment of the true clinical significance of these features therefore requires withdrawal from drugs, while in acute presentations both can be extremely distressing. Aggressive behaviour may be due to an underlying personality disorder, but it is also characteristic of withdrawal from crack cocaine when severe craving is experienced. Paranoid psychosis, sometimes indistinguishable from an acute schizophrenic episode, is the best-known complication of stimulant misuse. The earliest descriptions were of cases where symptoms quickly subsided after withdrawal of the drugs, but it is now recognized that through mechanisms which represent a kind of sensitization, symptoms which are drug-induced can persist and recur even with avoidance of substance use.[9]

Treatment

Evidence

A very large number of medications have been investigated in cocaine misuse, mainly compounds which through actions on catecholamines or serotonin could be expected to alleviate withdrawal effects. After decades of such work the evidence is very discouraging, with no medications consistently found to reduce stimulant abuse.[10] Inpatient programmes and psychological treatments basically represent modifications of those approaches used across all forms of drug misuse, although cocaine abuse appears particularly amenable to the 'contingency management' approach of providing material incentives for abstinence.[11]

Management

Faced with the limitations in treatment for these forms of drug misuse that have high morbidity and mortality, drug services have had to consider how best to achieve some benefits in terms of very practical management.[12] The factors that appear important in such provision are:

- specific outreach programmes
- harm-reduction approaches
- rapid response where necessary
- targeted use of treatments
- admission in severe cases

To engage stimulant users at all can require outreach aimed at the subcultural groups in whom usage is common. Basic harm-reduction measures must be offered, including drug information, education about health risks, advice to reduce damaging injecting practices, and the provision of clean equipment. Counselling of a supportive or more behavioural kind may be provided by various types of agency.

The periodic nature of stimulant problems means that rapid response can be important, for instance in states of acute crack withdrawal or psychiatric disturbance. Use of tranquillizers and antipsychotic medications may be necessary for some presentations, while fluoxetine appears to be increasingly favoured over other antidepressants, due to a possible anticraving effect and good acceptability. Inpatient admission can be required in cases where no long-term measure is able to make much impact between acute crises. The possibility of any substitute prescribing in stimulant misuse is highly controversial, with some services seeing a role for oral dexamphetamine in heavily dependent amphetamine users experiencing extreme problems from injecting.[13]

Drug-induced psychosis

The two aspects of management of this complication are the treatment of psychotic symptoms and the withdrawal of the drug which is thought to be causative. The latter can be very problematic other than as an inpatient, and is not guaranteed even then. In practice, ongoing low-grade psychotic states in individuals who have not completely stopped drug use are common, and treatment may have to be attempted in such circumstances. The use of antipsychotic medications does not differ significantly from that in psychoses not produced by drugs.

Prevention

The prevention of drug misuse lies largely outside the clinical domain, in the areas of education, enforcement and social improvement. A more biological development in cocaine misuse of vaccination, whereby limited exposure produces antibodies to subsequently block the drug's effects, remains experimental.

4.2.3.3 Disorders relating to use of PCP and hallucinogens

Henry David Abraham

PCP

Introduction

Phencyclidine (PCP, 'angel dust') is an arylcyclohexylamine dissociative anaesthetic. It was first abused in the United States in New York and San Francisco in the 1960s, but abuse declined when a broad range of adverse complications was noted.(1)

Epidemiology

While use of the unadulterated drug occurs, PCP is more frequently mixed with LSD or cannabis. The drug may be ingested or injected, but is more commonly smoked or snorted. Data suggest use in the United States and Europe. In the United States, a stable trend of 3 per cent of high school seniors have tried PCP at least once.(2) It traffics under a long and colourful list of street names. It has been suggested that any illicit smoked drug with an unrecognized street name (dust, mist, THC, embalming fluid, *inter alia*) should be considered PCP until proven otherwise.

Acute physiological effects

The drug has a delayed onset of activity when taken orally. Unlike the major hallucinogens, PCP requires doses in milligrams to be effective, a factor facilitating toxicological identification. When smoked, the onset of its main effects occurs immediately. The drug has particular affinity for the sigma opioid receptor, and non-competitively blocks the *N*-methyl-D-aspartate-type excitatory amino acid receptor. Other effects appear to be mediated indirectly by catecholamine release, cholinergic stimulation, and serotonergic receptors.

DSM-IV lists as criteria for acute PCP intoxication the following:

- agitation
- belligerence
- impaired judgement
- nystagmus
- hyperacusis
- hypertension
- tachycardia
- numbness
- ataxia
- dysarthria
- rigidity
- salivation
- seizures
- coma

It is clear from this daunting inventory that impaired judgement is likely to be present beforehand in any person intentionally choosing to abuse this drug.

Adverse effects

PCP affects not only adults, but fetuses and nursing infants.(3) Neurological consequences in infants include poor attention, hypertonia, and depressed neonatal reflexes.(4) *In vitro* studies show that PCP causes inhibited axon outgrowth, degeneration, and death in human fetal cerebral cortical neurones.(5)

In adults signs of severe PCP toxicity include:

- hyperthermia
- opisthotonus
- cardiac arrhythmia
- stroke

PCP is capable of provoking extreme muscular agitation, rhabdomyolysis and renal failure in 2.5 per cent of users.(6) DSM-IV lists psychiatric effects of PCP including intoxication, delirium, PCP-induced psychotic, mood, and anxiety disorders, and PCP abuse and dependence. A criterion for diagnosis is the emergence of the disorder within a month of drug use.

PCP delirium

Unlike acute intoxication with other hallucinogens, PCP delirium is associated with neurological disturbances. A continuum of effects is noted depending on dose.(7) Psychiatric symptoms occur early in

drug use, with stupor and coma occurring later. Shortly after drug use, patients appear confused and ataxic. Analgesia in fingers and toes may be described. PCP can produce complex hallucinations resembling LSD intoxication. Differentiating the two drugs in emergencies is important, since high-potency neuroleptics, which are useful in PCP toxicity, may exacerbate LSD, while the use of benzodiazepines, helpful in acute LSD toxicity, may disinhibit an assaultive PCP patient. Unlike LSD, PCP is readily identified in routine toxicological screening of blood and urine, but such data may not be readily available. One rapid bedside technique to differentiate the two drugs is the palm sign. The examiner asks the patient to describe the names of all the colours seen in the examiner's outstretch palm. A typical LSD patient reports a vision of multiple colours and images. A PCP patient simply attacks the hand. Dexterity of the examiner is suggested. Unfocused aggression makes PCP delirium a particularly dangerous disorder. The spectrum of violence includes both suicide and homicide.[8] The technique of 'talking down' acutely toxic patients is contraindicated. Environmental stimuli should be minimized, and the patient provided with protective supervision. The use of physical restraints is relatively contraindicated because of the potential for rhabdomyolysis.

Specific treatments involve:

- intravenous naloxone to rule out narcotics overdose
- activated charcoal
- acidification of the patient's urine with vitamin C, ammonium chloride, cranberry juice
- diuresis with frusemide (furosemide, Lasix)
- antihypertensives
- high-potency neuroleptics or barbiturates

PCP has mixed agonist and antagonist effects at cholinergic receptors. Anticholinergic drugs may precipitate a synergistic reaction with PCP, worsening delirium. Thus, low-potency neuroleptics, tricyclic antidepressants, and the anticholinergic antiparkinsonian drugs should be avoided.

PCP-induced psychotic disorder

PCP delirium may evolve into a chronic PCP psychosis that is differentiated from schizophrenia only with difficulty. Alternatively, a PCP delirium may clear, only to be replaced by the insidious onset of a post-PCP psychotic disorder. Certain features of PCP psychosis, namely neurological abnormalities, dose-related severity of symptoms, and regularity of the length of illness, are not noted with other psychedelic drugs, leading to the suggestion that PCP psychosis is a toxic drug effect rather than a functional illness. Four classes of agents are reported to help PCP psychosis:

- benzodiazepines
- neuroleptics
- acetylcholinesterase inhibitors (physostigmine)
- catecholamine depleters (reserpine)

Otherwise, treatment considerations are those for PCP delirium. The long-term prognosis for this disorder appears to be poor, according to data from an 8-year follow-up of 10 patients.[9]

PCP abuse, dependence, and organic mental disorder

Rhesus monkeys will self-administer PCP in a dose-dependent way,[10] suggesting that repeated abuse in humans may be associated with psychophysiological dependence. This in turn is likely to be associated with a decline in social and occupational function characteristic of other forms of addiction. Because of its widespread neuropsychological effects, any intentional, informed use of PCP should be considered maladaptive. For the habituated patient, long-term treatment is indicated. Issues that should be addressed in the process are:

- emotional lability
- cognitive defects
- depression
- possible PCP withdrawal
- nutritional status

Many of the treatments applicable to patients addicted to the opiates, alcohol, and cocaine apply to this population. Several aspects of treating the PCP patient depart from the more conventional addiction treatments. A triad of confusion, decreased cognitive function, and assaultiveness mark an organic mental disorder associated with PCP use. Reduced cognition is a barrier to recovery that must be recognized and addressed in any prospective treatment plan. Neuropsychological assessment is helpful in this regard. Secondly, there is murine evidence that PCP is sequestered in fat and by melanin for at least 3 weeks following a single exposure.[11] Conditions associated with weight loss are likely to release long-held PCP into the blood and brain.

Hallucinogens

Introduction

Agents that alter perception and mood without disorientation typify hallucinogenic drugs. They have been known and used for millennia for purposes ranging from magical to medical. Anthropologists trace back the earliest use of hallucinogens to Paleolithic Europe, although 80 per cent of extant hallucinogenic plants are to be found in the New World. Galen (AD 130–200) wrote that it was customary to give dinner guests hemp seeds to promote the evening's proceedings. The ergot-bearing fungus *Claviceps purpurea* infected rye in tenth-century France and claimed 40 000 lives. Despite such calamities, ergot continued to be used by midwives in medieval Europe. In search of a benign ergot derivative for use in childbirth, Albert Hofmann synthesized lysergic acid diethylamide (LSD-25) in 1938, described in his classic monograph, *LSD: my problem child*.

In 1947, Stoll in Switzerland published the first experimental use of LSD in psychiatry. Intelligence agencies worldwide seized on the misnomer of LSD as an instrument of 'mind control'. Academicians including Sandison and Elkes in England, Cohen and Eisner in the United States, Leuner in Germany, and Grof in Czechoslovakia engaged in human studies. But within a decade the drug the genie was out of the bottle, as the drug moved from the hands of scientists to clinicians, clergy, curious professors, and a widening number of students on both sides of the Atlantic. Military investigators in the United States gave the drug surreptitiously to recruits. By the late 1960s LSD and cannabis led the way to a pandemic of drug abuse among the young.

Drug preparations

Hallucinogenic drugs comprise not so much a single class of compounds, but a multiple classes affecting different neuronal receptors. Hofmann and Schultes describe 11 classes of hallucinogenic compounds which can be isolated from botanicals.[12] Hallucinogens are readily available. Botanicals are easily grown. Indole and phenethylamines can be easily synthesized, especially with the rise of the Internet. Chemically pure hallucinogens are psychoactive in microgram quantities, and are easily concealed, transported and sold, accounting for their enduring role as abusable substances.

LSD is psychoactive in a single droplet of solvent. The drug is easily dissolved in an aqueous solution. Drops of the drug are placed on sugar cubes or blotting paper stamped with coloured cartoon figures to mark the drug's location. Sheets of the paper are then distributed, and the figures ingested. Dosages commonly range from 25 to 100 µg. A hallucinogenic trip can occur after 75 µg. Other hallucinogens, such as dimethyltryptamine, are injected. The serotonin-2A receptor has been shown to bind strongly to many hallucinogenic drugs, and these drugs appear to act as partial agonists.[13]

Common **botanical hallucinogens** include fungi and angiosperms (flower-bearing plants), of which approximately 100 are recognized with hallucinogenic properties. Ibogaine is derived from the root of the *Tabernanthe iboga* plant cultivated in Gabon and eaten as a rite of passage. Ayahuasca is a tea of dimethyltryptamine from the Amazon vine, *Banisteriopsis*, potentiated by beta-carbolines which inhibit monoamine oxidase. Mescaline is a predominant hallucinogen in the cactus *Lophophora williamsii*. Strips of cactus are cut from the plant, dried, and eaten. The Mexican mint, *Salvia divinorum*, contains a diterpene kappa-opioid agonist. *Salvia* is easily bought from the Internet from scores of Websites in the United States and Europe.[14]

Hallucinogenic mushrooms contain psilocybin and psilocin, which are phosphorylated hydroxylated congeners of dimethyltryptamine. Mushrooms are ingested for their effect, or brewed first and the broth consumed. Responses vary widely between individuals and occasions. The American psychologist William James reported ingesting several dozen hallucinogenic mushrooms and only experiencing headache. Shulgin has synthesized and tested 179 phenylethylamines for hallucinogenic properties. Their effects on the human brain are complex and largely unknown.

Epidemiology

Annual surveys in United States college students indicate that LSD use fell from 1995 to 2005 from a lifetime prevalence of 11.5 to 3.7 per cent. This was offset by an increase in the lifetime use of psilocybin mushrooms, from 6.5 to 10.6 per cent. This increase in the use of non-LSD hallucinogens is reflected across secondary grades and young adults between 19 and 28 as well,[1] and follows a period of rising LSD use in Germany, the United Kingdom, and the United States in the 1990s. Factors which may explain this decrease in LSD use include student reports of less availability, greater perceptions of risk, and the substitution of psilocybin and MDMA for LSD. A cross-sectional study of 904 women from 14 to 26 found that LSD users were more often Caucasian, victims of physical abuse, and suffering depression.[15]

Acute effects

The characteristic LSD trip comprises:

- autonomic arousal
- marked mydriasis
- sensory disturbances
- emotional lability

Progressive modulations of visual imagery appear to be generated both from external objects and distortions of eidetic sources. Ordinarily benign objects may take on new emotional meanings. Geometric imagery may rise and fall before one's eyes. A prevalent feeling one experiences is a sense of helplessness to control one's streaming images and emotions, hence the hippie advice of 'going with the flow'. The loss of cognitive, perceptual, and affective control for some users leads to panic, which in turn results in the so-called 'bad trip'. As these effects decline, they may be replaced with a sense of oceanic well-being or residual paranoia.

Adverse effects

Adverse reactions to hallucinogens include panic reactions associated with a bad trip, hallucinogen persisting perception disorder, and prolonged psychoses.

(a) Panic reaction

Panic may arise during the acute drug experience. It is characterized by a crescendo of rising anxiety accompanied by autonomic arousal in the context of streaming emotions and imagery. Mydriasis is greater than that seen in non-drug-induced panic. The use of an oral benzodiazepine such as diazepam 20 mg is utterly effective in stopping the panic within minutes.

(b) Hallucinogen persisting perception disorder (HPPD)

It became apparent within the first few years of experimentation with LSD that this class of drugs was capable of inducing visual disturbances days to weeks following drug exposure. Subsequent research found that these disturbances, dubbed 'flashbacks' because of their evanescent visual appearance, appeared to be an intermittent form of post-drug visual disorder that in its extreme form was experienced continually. Thus, HPPD patients are capable of describing a range of visual disturbances that fluctuate in intensity, but are observable from moment to moment (Abraham, 1983). Such imagery includes:

- geometric hallucinations
- false perceptions of movement
- afterimagery
- the perception of trails behind moving images
- pinpoint dots in the air (aeropsia)

Symptoms drawn by HPPD patients have been published on the Internet.[16] Patients also describe derealization and depersonalization. Symptoms are intensified by stimulation from:

- emergence into a dark environment
- marijuana
- amphetamines
- cocaine

- anxiety
- the stress of intercurrent illnesses

While recovery may occur over months and years following last drug use, approximately half of the patients so afflicted appear to develop a permanent alteration of the visual apparatus. Studies of psychophysics in HPPD patients reveal quantified prolongations in afterimagery.[17] Neurophysiological studies confirm cerebral disinhibition involving those regions of the cortex processing visual information.[18]

Management: Because the disorder is exacerbated by psychological and physiological conditions of arousal, benzodiazepines have been helpful for management of visual symptoms.[19] The results of these efforts are palliative at best, and complicated by the prospect of treating a drug abuser with an abusable substance. Recent case reports of treatment with sertraline, naltrexone, and clonidine are encouraging.

In addition to pharmacotherapy, HPPD patients often require supportive psychotherapy to deal with the issues of learning to cope with what may be a permanent alteration in perception. Therapy is also indicated to educate the patient, and prevent the development of common comorbid disorders in HPPD. These are:

- major depression
- panic disorder
- alcohol dependence from self-medication

(c) Psychosis

Evidence supporting the hypothesis that the use of potent hallucinogens can trigger prolonged psychotic episodes is found in multiple longitudinal, cross-sectional, and case studies (Abraham *et al.* 1996). Psychiatric patienthood appears to be a risk factor for the development of psychosis following LSD. The clinical picture of post-LSD psychosis resembles schizoaffective disorder more than it does schizophrenia, with the commonly added feature of chronic visual disturbances. Clinically such patients resemble those with good-prognosis schizophrenia, since they possess more affect than those with poor prognosis, have less thought disorder, are more socially related, and appear to have fewer signs of negative schizophrenia. Mystical preoccupations reminiscent of acute drug experiences can predominate. Visual hallucinations often are of the variety that are seen in HPPD, although in contradistinction to such patients, psychotic patients may describe delusions and auditory hallucinations as well.[20]

Management: Atypical pharmacotherapies appear to have an important role in treatment, and in selected cases are preferable to dopamine-blocking neuroleptics. Reports in the literature describe cases responding to electroconvulsive therapy, lithium, anticonvulsants, and the serotonin precursor, l-5-hydroxytryptophan. Long-term supportive psychotherapy is almost always indicated to help the patient and his family make painful adjustments to the patient's chronic disappointments in relationships and employment, frequently made all the more poignant by the illness' propensity to preserve the patient's insight as it progresses. This last factor may partially explain the apparently high risk for suicide.

Human experimentation with hallucinogens

The discovery of the effects of LSD in 1943 led to a flurry of experimental activity with the drug in humans, at its worst with dubious methodology and indifferent to the protection of human subjects. But the ability of this unique class of drugs to alter perception, cognition, and affect has prompted a new wave of research with selected hallucinogens with regulatory oversight. Studies have examined the safety of peyote in religious use[21]; the psychological effects of psilocybin, dimethyltryptamine, and ketamine[22]; their use as a tool in modelling the pathophysiology of psychosis,[23] and possible therapeutic uses.

Hallucinogens have been used as experimental psychoses. Vollenweider *et al.* have found increased metabolic activity in the frontal cortex of subjects on the dissociative anaesthetic ketamine,[24] and in subjects during an experimental psychosis from psilocybin, increased serotonin-2 agonist activity.[25] Finally, the study of treatment with hallucinogens for psychiatric disorders has cautiously reemerged. In a randomized trial of ketamine for depression, Zarate *et al.* found that the drug had benefits for a week following a single dose.[26]

4.2.3.4 Misuse of benzodiazepines

Sarah Welch and Michael Farrell

Epidemiology and patterns of use

The rise in benzodiazepine prescribing in the United Kingdom in the 1960s and 1970s was a development that followed the previous period of prescribing of barbiturates and other sedatives. Concerns about the obvious toxicity of barbiturates, and previously other sedatives, in overdose, together with knowledge of their dependence-inducing characteristics, led to their replacement with the safer benzodiazepines as the commonly prescribed anxiolytic and hypnotic drugs. Case reports of patients who escalated their dose of benzodiazepines above the recommended dose, and who experienced convulsions and confusional states on stopping them, began to appear in the 1970s.[1,2] In the mid-1970s and onward, regulatory bodies in the United Kingdom and United States began to recognize the abuse potential of benzodiazepines even in therapeutic doses. Dependence on benzodiazepines was well described in the early literature on the development of these drugs but surprisingly clinical dependence was not reported in the medical literature until the early 1980s.[3,4] Dependence on therapeutic doses of prescribed benzodiazepines is covered in Chapter 6.2.2. In this chapter we are concerned with abuse of and dependence on high doses of benzodiazepines.

The upsurge in the drug epidemic in the 1980s was associated with an increase in misuse of hypnosedatives, and in the late 1980s there was a series of reports on the intravenous use of benzodiazepines, in particular temazepam.[5,6] Because benzodiazepines are the most commonly prescribed anxiolytics and hypnotics it is not surprising to find that they are also reported to be commonly misused. However, patterns of misuse vary, from episodic use of non-prescribed medication with up to 15 per cent of young people reporting some experience with benzodiazepines, to continuous high-dose use. Since the mid-1980s there has been a substantial drop in the prescription of benzodiazepines as anxiolytic agents but use as hypnotics has remained relatively steady with the concentration of long-term use being in the elderly population. Changes in prescribing practices are likely to influence diversion of benzodiazepines to the illicit market.

Reports indicate that supra-therapeutic dose misuse and dependence is strongly associated with polydrug and alcohol abuse and dependence.[7,8] This pattern of benzodiazepine misuse and dependence is probably much less common than iatrogenic benzodiazepine dependence. However, it presents a substantial problem to many clinicians in primary care and specialist settings. In particular, high-dose misuse is likely to be associated with 'doctor shopping' and efforts to extract additional medication on top of that already prescribed. The high doses used present a particular risk because they are often used in combination with other substances such as alcohol, opiates, and stimulants. High-dose use may be intermittent in nature (in a 'binge' pattern), and not associated with dependence (in which case the initiation of a prescription may change a pattern of intermittent binge use to daily dependent use in a manner that entrenches polydrug use; see the section below on guidelines for management). Drug misusers use benzodiazepines in a non-dependent fashion for a variety of reasons. For example, benzodiazepines may be used to enhance the effect of other drugs (such as boosting the euphoria with heroin), or to alleviate unwanted effects from other drugs (to 'cushion' the 'come-down' from cocaine), or to help alleviate withdrawal symptoms when drugs such as heroin are unobtainable, or in attempts at self-detoxification from other drugs. Misuse of benzodiazepines may also arise from injudicious patterns of prescribing for the treatment of alcohol dependence, or from attempts at self-treatment for alcohol dependence. Some drug users will also develop a dependent pattern of use of benzodiazepines in their own right. Benzodiazepine dependence may be a factor contributing to poor outcome for patients who are attempting opiate detoxification.

High-dose use is associated with substantial tolerance to the sedating effects of the medication but some of the other effects may not be equivalently protected by tolerance. Thus, some individuals may consume extraordinarily high doses, and not appear sedated, but experience profound amnesia for their actions. Such effects of

amnesia may also be associated with the reported high rates of risk-taking behaviour, and amnesia may be more pronounced in injecting benzodiazepine users, although there are no good data to confirm this.

The potential of different benzodiazepines for misuse and dependence

In view of the frequency of prescribing of benzodiazepine drugs, it is an important question as to whether some benzodiazepines are more likely to be misused, or to lead to dependence, than others. The similarities between different benzodiazepines are much greater than the differences. Patients may maintain that they need a specific named benzodiazepine, but there is marked cross-tolerance, and patients changed to an equivalent dose of a different benzodiazepine under double-blind conditions show almost complete cross-dependence (i.e. no difference in withdrawal symptoms from those whose medication has been unchanged).[9] However, this cross-dependence was shown for patients who were already benzodiazepine dependent. It is possible that the properties of certain benzodiazepines lead to a stronger motivation for people to desire their effects, to escalate the dose, and to persist with their use.

Factors that have been considered to influence the liability to misuse and development of dependence include the relative potency of the drug, and its elimination half-life.[10] Triazolam, a very short-acting benzodiazepine prescribed for insomnia, was withdrawn from the British market following concerns about the severity of rebound anxiety experienced even after a single dose. Triazolam is a very potent benzodiazepine that binds very readily to benzodiazepine receptors, and experience with its use suggested that it had a more euphoriant effect than other benzodiazepines, resulting in greater potential for misuse and for the development of dependence. Other benzodiazepines that have high potency and have caused concern include flunitrazepam and lorazepam. Flunitrazepam is relatively rarely prescribed in the United Kingdom, but frequently reported as one of the most common benzodiazepines misused in many European countries and in Australia. It is not marketed in the United States. Concerns about its availability on the illicit market continue.[11,12] It has attracted media attention as a drug used to facilitate 'date rape'; it is unclear why this particular benzodiazepine should have this image, although it is a potent drug. Lorazepam, also a potent benzodiazepine, is much more widely prescribed in the United Kingdom, and alprazolam is used in the United States. Some studies suggest that lorazepam and alprazolam may be associated with an earlier and more difficult withdrawal process than diazepam.[9,13] In one European study, triazolam and lorazepam were found to feature more highly among individuals dependent on high doses of benzodiazepine drugs than among those dependent on low or 'therapeutic' doses.[14] In summary, it appears that potency is a contributory factor in the abuse and dependence-inducing potential of benzodiazepine drugs. However, this picture is somewhat complicated by the fact that drugs such as lorazepam tend to have been marketed at higher equivalent doses than some other benzodiazepines. The elimination half-life influences the nature of withdrawal; if it is short, withdrawal symptoms appear more rapidly and may appear more severe, although withdrawal of more insidious onset in longer-acting benzodiazepines may be just as problematic.

As well as properties of the drugs themselves, the abuse potential of different benzodiazepines is also associated with broader prescribing patterns which affect the potential for diversion to illicit market. Diazepam and temazepam have been the most widely prescribed benzodiazepines in the United Kingdom, and are therefore the most likely to be obtained by drug users and problem drinkers. Drugs such as clonazepam which tend to be prescribed much less widely, and generally for epilepsy rather than for anxiety or insomnia, seem infrequently to raise concerns about misuse[10] but are frequently requested as the treatment of choice for those who are both epileptic and drug dependent. In other parts of Europe where flunitrazepam is more commonly prescribed, there are reports of its high levels of misuse among the illicit drug-using population.

The potential for misuse by injecting

Over time, there have been reports of misuse of various benzodiazepines by injection.[7] A number of factors have influenced this practice. These include the availability of the drug, its short-acting nature, and also the formulation of the drug. In the 1980s temazepam was marketed as a liquid-filled capsule, which enabled easy extraction of the contents to put into a syringe for injecting. The later gel formulation was also injected, by heating to liquidize the gel, resulting in very damaging injecting complications. Some medications that come in easily soluble form can also be converted into a form for injecting, such as liquid diazepam.

The injection of benzodiazepine drugs is associated with substantially more harmful drug misuse in a number of respects,[15] with increased rates of reported sharing of injecting equipment,[9,16] increased risks of overdose, and poorer general health.[8]

Evidence-base for management of benzodiazepine misuse

The literature on management of 'ordinary dose' benzodiazepine dependence, relating mainly to patients prescribed benzodiazepines for treatment of psychiatric disorders, is far more extensive and systematic than that concerning illicit drug users. At the time of writing, there are no meta-analyses or indeed well-conducted randomized controlled trials specifically addressing this problem. In practice, the applicability of the 'ordinary dose' dependence literature is affected not only by clinical differences, but also by concerns about abuse and diversion of prescribed supplies by illicit drug users. So far, no clear guidelines for management have been produced, and the management principles covered in the section below are based on expert clinical consensus statements: these involve some extrapolation from the 'ordinary dose' benzodiazepine dependence literature, and some from established evidence-based principles for management of misusers of other drugs such as opiates.[17] For example, unlike the established evidence that supervised substitute prescribing of methadone reduces injecting in intravenous heroin users, there is no clear evidence that substitute prescribing of benzodiazepines reduces injecting behaviour in injecting misusers of these drugs. Nevertheless, prescribing of oral benzodiazepines with daily supervised consumption is sometimes instituted for this group of patients, especially if they are already established in supervised treatment for concurrent intravenous heroin use (see section on concurrent opioid dependence below).

Guidelines for management of misuse of non-prescribed benzodiazepines

These are a complex group of patients to manage and in general such patients should be referred for specialist assessment.

Assessment

Assessment should attempt to confirm evidence for benzodiazepine dependence. Assessment over a number of visits should involve obtaining urine specimens to determine objectively the regularity (or intermittent nature) of benzodiazepine consumption. Part of the initial assessment process should identify underlying psychiatric disorders that may have been the trigger for a doctor initiating a prescription or for the patient obtaining drugs for the purpose of self-medication. High levels of psychiatric morbidity have been found among samples of patients with severe benzodiazepine dependence.[18] The commonest conditions are probably anxiety disorders for which anxiolytics have been prescribed injudiciously; however, in some instances major depressive disorders may be treated or self-medicated with benzodiazepines. Thorough assessment should explore for evidence of major depression and if identified, consideration should be given to the use of antidepressant medication combined with cognitive behavioural therapy.

Treatment

In the presence of polydrug abuse or dependence, caution needs to be exercised about initiating a prescription for benzodiazepines (see section on opioid drug users). Where dependence is established, dose titration should aim to ameliorate withdrawal symptoms rather than to match the large doses of medication that the patient reports consuming. Long-acting benzodiazepines such as diazepam are preferred (Chapter 6.2.2), and doses should rarely exceed 40 to 60 mg daily. Where large doses are prescribed these should ideally be dispensed on a daily pick-up basis from the community pharmacist. The prescribing doctor should avoid succumbing to pressure from the patient to increase the dose without a thorough dose assessment and evidence of withdrawal symptoms. Prescriptions issued on a routine 'repeat' basis should be avoided, and the patient should be informed that lost medication will not be replaced. Requests for replacement medication or additional medication should encourage the doctor to review the overall care plan and to consider reducing and stopping the benzodiazepine prescription. Virtually all benzodiazepine prescriptions should be time limited and part of a detoxification plan with gradual reduction over a clearly stated and negotiated time period. Alternatively, inpatient detoxification, perhaps with longer admissions, may be the best course of action where reduction regimens fail in the community setting. Reduction regimens with benzodiazepines are very variable and many clinicians opt for a very gradual withdrawal with small dose reduction at wide intervals. There is no evidence to indicate that such a gradual approach is any more effective than 20 to 25 per cent reductions over a shorter, more clearly defined time (such as 6 weeks). Carbamazepine can also be effective in ameliorating withdrawal symptoms and in seizure prevention, and may be used as an adjunct in withdrawal management in high-dose benzodiazepine dependence,[19] though drug interactions need to be considered for patients who are also prescribed opioid substitute drugs for treatment of heroin dependence (see section on concurrent benzodiazepine and opioid dependence).

Special considerations for managing concurrent benzodiazepine and alcohol dependence

There are high reported rates of alcohol dependence among the homeless, and there are substantial reports of benzodiazepine abuse and dependence in this population also. Cross-tolerance between benzodiazepines and alcohol permits individuals who are alcohol dependent to tolerate high doses of benzodiazepines. Patients may be prescribed benzodiazepines to manage alcohol withdrawal, but injudicious prescribing that is not targeted towards the management of alcohol withdrawal symptoms may result in iatrogenic benzodiazepine dependence.

The extensive research on pharmacological interventions for management of alcohol withdrawal in alcohol-dependent patients has been examined in a meta-analysis by Mayo-Smith, who subsequently produced a systematic review with treatment guidelines.[20] This review supports the use of benzodiazepines as the treatment of choice for managing withdrawal symptoms for patients whose symptoms are of sufficient severity to warrant medication, and is consistent with a more recent Cochrane review.[21] However, carbamazepine is established as an acceptable alternative to benzodiazepine drugs in treatment of alcohol withdrawal, and is effective both in reducing withdrawal symptoms and in seizure prevention.[17] Agents such as clomethiazole and the barbiturate phenobarbital, are less well-supported by controlled trials than benzodiazepines, and carry higher risks of adverse effects.

The potential for misuse of benzodiazepines must be considered in alcohol-dependent patients. However, this is not an adequate reason for avoiding the use of benzodiazepines in the management of withdrawal in view of their superiority in effectiveness, and possibly in potential for harmful misuse, over other treatments. Benzodiazepines with a slower onset of action such as chlordiazepoxide, appear to have less potential for misuse. The prolonged use of benzodiazepines in withdrawal is rarely necessary or helpful, and evidence for benefits of 'substitute prescribing' of benzodiazepines for alcohol users in the longer term is lacking. Use of benzodiazepines to manage phobic and anxiety disorders associated with alcohol dependence should be avoided. For alcohol-dependent patients with a history of benzodiazepine misuse, especially where the patient wishes to avoid further benzodiazepine use, management of withdrawal using carbamazepine alone should be explored.

Special considerations for managing concurrent benzodiazepine and opioid drug dependence

Currently there is no evidence base for long maintenance prescribing of benzodiazepines for those who are high-dose injecting polydrug abusers. However, this intervention has not been subject to any structured evaluation and merits further study in the face of the difficulties of managing such patients. There are two particular areas of concern in managing opioid drug users who also misuse benzodiazepines. The first is the potential for toxicity and overdose when combining illicit or prescribed opioid drugs with benzodiazepines, particularly because of the sedative and respiratory

depressant effect of both. Two studies comparing the effects of benzodiazepine use in conjunction with either methadone or buprenorphine treatment have reported higher subjectively reported opioid toxicity symptoms[22] and greater peak effects on objectively assessed performance measures[23] for patients on methadone than for patients on buprenorphine. Where substitute prescribing for heroin or other opioid drug dependence is to be undertaken, the patient needs clear information about the effects of combining opioid and benzodiazepine drugs. Close supervision of prescribed medication (such as daily supervised consumption in the clinic or pharmacy) should be maintained in the early stages of treatment. As many opioid drug users use benzodiazepines somewhat erratically, for example as a substitute when heroin is not available, then stabilization on either methadone or buprenorphine as a regular dose may allow them to stop benzodiazepine use without any other intervention. Initiation of any prescribing intervention addressing benzodiazepine dependence is usually best delayed until it is clear that dependent use has continued despite well-established treatment for opioid dependence. The second area of concern is the potential poor prognosis of opioid withdrawal programmes for patients with concurrent benzodiazepine dependence. Opioid withdrawal symptoms may be more pronounced in patients with both problems, and treatment protocols may need to be adjusted to address this.[24]

Conclusion

There is a valuable role for benzodiazepines, and a need for vigilance and care in their use, as well as active recognition and management of those who are dependent. However, there is a need for greater awareness of the risks of polydrug dependence with misuse of high doses of benzodiazepines in conjunction with both alcohol dependence and opiate dependence. Caution needs to be used in assessing patients, and benzodiazepine prescribing should be restricted to those where there is clear evidence of dependence.

The risk of synergistic effects with other drugs and consequent overdose should be explained to all patients who are identified as being involved in such behaviour. Community detoxification or inpatient detoxification is the best option based on the evidence of available research and evaluation of current interventions.

4.2.3.5 Disorders relating to the use of ecstasy and other 'party drugs'

Adam R. Winstock and Fabrizio Schifano

Introduction

Participation in the dance music/rave scene has been associated with an ever-growing range of primarily stimulant and hallucinogenic drugs since its inception in the Balearic Islands in the mid-1980s. The last two decades have seen the globalization of the dance music scene and the gradual adoption of these and other drugs by mainstream drug using populations. Although 'Ecstasy' (**MDMA**, 3,4-methylenedioxymethamphetamine) was the archetypical dance drug inducing both stimulant and empathogenic effects, dance drug use is polydrug use with cocaine, amphetamine, nitrates, ketamine, and GHB all being common.[1] The use of this diverse group of drugs is now no longer confined to either young adults or the dance floor with use common for example, at house parties or other more intimate social gatherings.[2] Although not typically identified as dance drugs, alcohol and cannabis are of course highly prevalent among this group.

Ecstasy (3,4-methylenedioxymethamphetamine)

Background

Incorrectly termed a designer drug (a drug whose chemical structure is modified to avoid being included within a list of drugs/chemical structures prohibited by legislation), MDMA was first synthesized in 1912 by Merck Pharmaceuticals. It was never marketed and remained largely ignored until the 1950s when the United States Army explored its military potential. It was not until the late 1960s and early 1970s however that drug users on the west coast of America began to popularize its recreational use along with MDA (methylenedioxymethamphetamine).

Although MDMA may claim its place as the mother of dance drugs and possessor of the best branding in terms of name, MDMA is only one of a large number of synthetic amphetamine type drugs possessing varying degrees of stimulant, hallucinogenic, and empathogenic effects that are used within the dance scene. Characterized by its stimulant and prosocial effects the sought after experiences of disinhibition, euphoria, energy, and empathy are ideally suited to the 'dance scene' where energetic and prolonged dancing is commonplace. Indeed it may be that dancing offsets the psychomotor agitation that stimulants can induce or that MDMA-like drugs may enhance enjoyment and ability to dance to dance music. In the United Kingdom MDMA is classified as a Class B drug.

Preparations, purity, and routes of use

MDMA is most commonly taken orally though it may be snorted or injected. MDMA is most commonly sold as branded tablets ('pills'), with different tablets being identified by an imprinted logo (for example of a cartoon character, car manufacturer, or animal), but may also be found as capsules or powder. The average dose of an ecstasy tablet containing MDMA is about 70 mg (range 50–150 mg). The cost has reduced markedly over the last 20 years from £20/tablet in 1985 to as little at 50 pence/tablet when bought in bulk (typical price in the United Kingdom for a single tablet would be 2–5).[3]

Because of the illicit nature of MDMA production, variation in precursor availability, and the large number of possible synthetic pathways for its production, tablets sold as ecstasy may contain a wide range of substances other than MDMA. In the United Kingdom and Europe especially in the 1990s, ecstasy tablets were often found to contain substances (usually psychoactive) other than MDMA. These included analogues of MDMA, such as methylenedioxyamphetamine (**MDEA**), *N*-methyl-1-(1,3-benzodioxol-5-yl)-2-butanamine (**MBDB**), and methylenedioxyethylamphetamine (**MDEA**), or combinations of stimulants such as ephedrine or amphetamine and hallucinogens such as LSD or ketamine.[4] While these other psychoactive substances may be marketed as distinct substances with their own branding (e.g. 4-Bromo-2, 5-dimethoxyphenethylamine sold as 2CB and 4 MTA as 'flatliners') more commonly they and the MDMA analogues MDEA, MBDB, and MDA, which broadly share the effects of MDMA, are sold under the generic term 'ecstasy'. More recent evidence would suggest that the proportion of tablets sold as ecstasy that contains MDMA in the United Kingdom is very high, with purity levels of 80–90 per cent not being uncommon.[5]

Pill testing

Some users utilize various pill testing methods (such as the Marquis test which gives colorimetric result by mixing the substance with a reagent) and websites (www.EcstasyData.org) which provide the contents of different pills following more elaborate analytical methods. Although it may be the case that these approaches may have some role in getting users to consider risks and promote the uptake of harm reduction practices, it is only on very few occasions that such methods have identified potentially far riskier psychoactive contents such as paramethoxyamphetamine (PMA).[6] In such cases, early warning through such websites may be potentially helpful. However, even with more sophisticated analytic processes (e.g. GMS, HPLC), knowing the content of your tablet never guarantees the user a positive experience and does not guarantee that they will not experience severe adverse effects.[4] In addition, most ecstasy-related deaths have involved tablets containing MDMA. Most deaths have not been related to dose and would have been unpredictable from knowing the content of the tablet.[3]

Prevalence and patterns of ecstasy use

British population studies show that 54 per cent of 20- to 22-year-olds have been offered ecstasy at some time and 15 per cent have tried it at least once.[7] The prevalence of use appears higher in those associated with the dance music drug scene with over 90 per cent reporting ever use. Similar findings have been reported from Europe,[8] Australia,[9] and the United States.

The typical pattern of use in the United Kingdom and Europe is one to four tablets a night, though many users will often consume larger number of tablets during a binge session especially when holidaying in summer dance resort destinations. Regular users will use between once or twice a week to once every fortnight, though there has been increasing recognition of a minority of users who take very large numbers of tablets (20 or 30) over a single session,

or with the availability of very cheap 'pills' extended periods of low-level daily use. Ecstasy, especially within the context of dance clubs is rarely taken in isolation and polydrug use is the norm, with different adjunctive substances taken at different times over the course of a night.[1] For example, alcohol is taken with ecstasy at the beginning of the night to get a stronger/better high.[10] Cocaine, amphetamines, and/or additional ecstasy tablets are taken to maintain arousal and a state of alertness (the MDMA enactogenic effects fade away in 2–4 h). Finally depressants such as cannabis, alcohol, benzodiazepines, and more rarely opiates, may be taken in the last part of the night to calm down before going home, since the untoward after-effects of ecstasy (namely irritability, insomnia, and restlessness) may persist well beyond its 'pleasurable' effects. With a chronic high dosage, ecstasy users develop tolerance and experience a decrease in the desired effects over time, which could lead to exploration of use of other stimulants and hallucinogens.[1]

Physical effects and complications

Physiologically sympathomimetic properties similar to amphetamine predominate including tachycardia, anorexia, increased respiratory rate, blood pressure, increased motor activity, tremor, mydriasis, increased temperature, and sweating. Jaw tightening (bruxism), xerostomia, teeth grinding with molar erosion, may also be seen (see Table 4.2.3.5.1). Sleep architecture modification[11] and sexual activity alteration[12,13] have also been described.

After MDMA intake a number of untoward effects may commonly occur including nausea, vomiting, diarrhoea, tachycardia, and palpitations. Pathologies less commonly seen include arrhythmias, hypertension as well as potentially life-threatening, metabolic acidosis, cerebral haemorrhages, convulsions, coma, rhabdomyolysis, thrombocytopenia, disseminated intravascular coagulation, SIADH, acute kidney failure, acute liver failure, dehydration, and malignant hyperthermia.[14–18]

Hyperthermia although enhanced by exertional activity and poorly ventilated environments may be somewhat independent from the setting in which the drug is taken, with MDMA having thermal dysregulation effects in its own right. Dehydration is common and thirsty clubbers naturally tend to replace body fluids lost during sweating sensibly with fruit juices, other isotonic fluids or water, or less sensibly but quite commonly with alcohol. Very rarely excessive intake of hypotonic fluids, coupled with an increase in vasopressin levels, has led to the occurrence of lethal hyponatraemia.[19] Deaths as a result of SIADH are very rare but can be fatal in association with excessive hypotonic fluid consumption with MDMA potentially impairing judgement or stimulating repetitive compulsive behaviours. In normal subjects who take ecstasy and do not develop SIADH there does appears to be an increase in both ADH and oxytocin levels,[20] the latter perhaps responsible for the drug's prosocial effects. MDMA is a potentially damaging cardiac stimulant;[21] with reports suggesting long-term MDMA use may possibly lead to a fenfluramine-like valvular heart disease condition. All users of ecstasy develop a (mild, in most cases) serotonin syndrome after acute drug intake.[13,22] Unfortunately although being reported by almost half ecstasy users, Verheyden and Henry[23] found that concerns about physical health are not perceived as important as concerns about mental health.[23]

Table 4.2.3.5.1 Psychological and physical effects of MDMA

Physical	Psychological
Increase in physical and emotional energy	Relaxation/euphoria
Dilated pupils, dry mouth	Feelings of well-being
Tachycardia, hypertension, increased respiratory rate	Enhanced closeness and sociability
Increased sweating, dehydration	Heightened perceptual awareness
Increased motor activity, tremor	Disinhibition
Blurred/double vision	Increased response to touch/empathy
Anorexia, nausea, weight loss	Anxiety/panic/paranoia
Teeth grinding, jaw clenching	Agitation and restlessness

MDMA psychological effects and problems (see Table 4.2.3.5.1, adapted from Liester *et al.*[24])

Being structurally related to both amphetamine and mescaline, 'empathogens' or 'entactogens'[25] like MDMA possess both stimulant and hallucinogenic properties which allow them to be discriminated from other related substances. After MDMA ingestion, enhanced mood, increased energy, openness, heightened sensory perception, and mild perception alterations are reported[15,17] (Table 4.2.3.5.1).

MDMA is described as evoking 'an easily controlled altered state of consciousness with emotional and sensual overtones',[26] with the substance's appeal resting in its 'dramatic and consistent ability to induce in the user a profound feeling of attachment and connection'. With this in mind it is perhaps not surprising that the Los Angeles dealer who coined the street name 'ecstasy' for MDMA would have preferred the name 'empathy' but he did not feel that his typical customer would know what it meant. It was also these qualities that led to the enthusiasm of a small number of physicians and therapists in the United States to explore its use within a clinical psychotherapeutic setting and more recently led to its approval as a research agent in the treatment of PTSD.[27]

Acute psychological problems associated with MDMA use

There have been reports of acute episodes of anxiety, panic, paranoia, and rarely brief psychotic episodes following consumption of MDMA by some users. Many users of MDMA report 'midweek blues', with some individuals reporting clinically borderline levels of depression in the days following MDMA[28] which could reflect depletion of serotonin following the acute elevation that follows ingestion of MDMA. This could be seen as a parallel to the 'crash' reported after abstinence of cocaine use or as a hangover effect from all night dancing, excessive alcohol, and minimal sleep. Although depression, anxiety, and mood fluctuations attributed to ecstasy are reported to be strongly related to the number of occasions of MDMA use,[29,30] Morgan *et al.*[31] found that higher depression scores among current heavy ecstasy users, in comparison to drug-naïve and polydrug controls, were no longer significant after treating cannabis use as a covariate.

Other consequences of use

(a) Neurotoxicity and evidence for 5-HT disruption in humans (see Table 4.2.3.5.2)

Although, in humans, the relationship between MDMA intake, putative 5-HT neurotoxicity, and persistent functional consequences is somewhat controversial,[32] the average single dose size consumed by humans approaches levels found to be neurotoxic in animals.[10] Core ambient temperature and hydration status have been implicated as key factors in the development of neurotoxicity.[13]

Although Colado *et al.*[33] suggested that MDMAs ability to produce neurodegeneration of dopamine nerve endings is open to debate, MDMA is generally considered to be a selective 5-HT neurotoxin. After administration of MDMA, animals have reduced levels of 5-HT, 5-hydroxyindole acetic acid, and tryptophan hydroxylase. Abnormal 5-HT regrowth has been reported after MDMA-induced damage with a decrease in 5-HT terminal density, suggestive of a 'chemical axotomy'. Pathological investigations suggest that 5-HT nerve terminals arising from the dorsal raphe nucleus are specifically involved. Duration and magnitude of these neurotoxic effects are dose dependent and are followed by differential rates of recovery, with 5-HT damage persisting for up to a year in the rat, and dopaminergic damage for up to 3 years in the rhesus monkey. These changes appear to be species specific with primates being more sensitive to the neurotoxic damage than rodents.

Markers for 5-HT damage may be sought either by direct assessment of metabolite levels or indirectly by assessing those functions thought to be dependent on an intact 5-HT system (see Table 4.2.3.5.2). MDMA users may show reduced brain 5-HTT (serotonin transporter) levels; there might be an association between degree of MDMA exposure and degree of reduction in 5-HTT ligand binding.[34]

Further evidence for disruption of the 5-HT system comes from blunted neuroendocrine responses (cortisol and prolactin) to d-fenfluramine in former MDMA users;[13] from cognitive disturbances in former MDMA users and from PET studies showing a decrease in a structural component of 5-HT neurones.

(b) Neuropsychological impairment and psychiatric presentation of ecstasy users

MDMA users as a group demonstrate a range of cognitive deficits in comparison to alcohol users, non-drug controls, and MDMA-naïve polydrug controls, including cannabis users.[31,35] Although the issue is somewhat controversial the most consistent neuropsychological finding in former MDMA users is a deficit in verbal memory under both immediate- and delayed-recall conditions.[36] Deficits in other areas of cognitive function, such as verbal fluency, executive function, impulse control, reaction time, and processing speed have been reported as well.[31] Evidence for attentional deficits varies depending on the task employed.[37] MDMA use may be associated with longer visual scanning times, reaction times, or planning times. Interpretation of these data is somewhat complicated by the fact that MDMA users typically use other drugs which may exert independent or interactive effects on cognitive performance.[37]

MDMA intake may put users at significant risk for developing psychiatric problems,[23] although some have suggested that this may occur only in vulnerable individuals.[39] Studies suggest that ecstasy users may report both childhood emotional/physical abuse[40] and history of familial depression, anxiety, and panic attacks[41] more frequently than ecstasy-naïve controls.

Thus although fraught with confounders, especially other drug use and premorbid functioning, there does appear to be an association between MDMA use and increased rates of anxiety,[24] panic, major depressive disorder,[38] prolonged depersonalization, psychosis, flashbacks, and even craving for chocolate.

(c) Depression and its management in ecstasy users

In the case of a patient presenting with psychological problems who has a history of MDMA use, the crucial assessment issues are the identification of any premorbid disorders, where in the cycle of use/post use they are, and the persistence of any symptoms beyond a 2–4 week period following cessation of use. As with amphetamine use, in the days after taking MDMA there is a period characterized by symptoms attributable to monoamine depletion and subsequently repletion. A period of acute 5-HT depletion due to vesicular monoamine depletion (Tuesday blues), is likely to be the most potent cause for the relative reduction in monoamine neurotransmitters. Repeated use of MDMA over several days will be associated with markedly diminished effects. Recovery is delayed further by inhibition of the rate-limiting enzyme (tyrosine hydroxylase in the case of MDMA) and the relative absence especially in chronic users, of a good source of monoamine precursors following stimulant-induced anorexia and malnutrition. It is likely that, as with other stimulant drugs, including cocaine, a period of extended but less intense withdrawal symptoms (mood, sleep) may be seen with persistent abstinence which may take weeks or months to recede and are associated with the more gradual reversal of neuroadaptive changes in dopaminergic receptor sensitivity/expression.[42]

History taking should specifically endeavour to identify any pre-existing/persistent depressive/other disorders and to ascertain the functionality of the use of MDMA and the consequences on underlying mood and functioning in days following use. Antidepressant treatments should usually not be commenced until 2–4 weeks after cessation of MDMA use in order to allow for reassessment and confirmation of any disorder. In addition, resolution of symptoms with cessation of use may also act as powerful reinforcer of continued abstinence if an individual's mood recovers. Reassessment and treatment where necessary, is important since being depressed is associated with an enhanced initial response to stimulant drugs and higher relapse risk.

Table 4.2.3.5.2 Clinical signs of intoxication with amphetamine

Physical	Psychological	Behavioural
Elevated P, BP, temperature	Euphoria/energized	Motor hyperactivity
Increased respiratory rate	Anxious/irritable	Restless/twitching
Sweating/dehydrated	Rapid thoughts	Talkative, pressured speech
Dilated pupils	Paranoia	Aggressive
Tremor/shakiness	Perceptual disturbance	Stereotyped movements

In prescribing an antidepressant to a client with a previous history of MDMA use, confining prescribing to only abstinent users is recommended since their effectiveness during a period of current use would be expected to be poor both as a result of poor compliance and monoamine depletion. In addition there are at least theoretical causes for concern over potentially fatal interactions between MDMA and selective serotonin reuptake inhibitors (SSRIs) that have very rarely been reported, possibly because some SSRIs (i.e. citalopram) can inhibit the CYP2D6 enzyme.[22] The precise effects of combining SSRIs and MDMA appears to be related to whether use of the SSRI was before or after the MDMA and whether SSRI dosing is acute or chronic. For example, SSRIs given acutely after MDMA (taken by users to intensify the ecstasy effects) may theoretically increase the risk of precipitating a serotoninergic syndrome. It is probable that SSRIs and other classes of antidepressant can be used effectively in this group if a diagnosis of responsive affective/anxiety disorder is confirmed and abstinence is maintained. CBT may be useful in this group both to address their underlying drug as well as to address any coexisting anxiety/depressive disorders.

Dependence with the development of heavy regular use patterns is possible, though there are unlikely to be any specific signs or symptoms that differentiate diagnosis of management significantly from other forms of stimulant dependence.

Methamphetamine-'crystalline methamphetamine hydrochloride' ice, crystal, shabu, yaba, meth, tina

Background

Methamphetamine is one of number of synthetic amphetamine type stimulants that includes dex-amphetamine. Whilst its use has been problematic in SE Asian countries such as Thailand, Japan, and Korea for many years it is only in the last decade that it has become a significant problem in eastern Europe, America, Australia, and elsewhere. In the United Kingdom methamphetamine was reclassified as Class A drug in 2007.

Preparation, purity, and routes of use

Unlike illicit amphetamine sulphate powder (speed), methamphetamine is often of very high purity. Crystalline methamphetamine hydrochloride (known as ice-because it can resemble shards of glass) can be up to 80% pure. Base amphetamine (sometimes known as paste), is an oily, waxy intermediate product on the way the manufacture of the crystalline hydrochloride salt of methamphetamine and has a lower purity of about 40–50 per cent. Methamphetamine is a versatile drug and can be smoked, snorted, injected, and taken orally.

Mechanism of action and metabolism

Methamphetamine closely resembles amphetamine sulphate (commonly referred to as speed) in structure and mechanism of action but is considerably more potent in its sympathomimetic effects and has a longer duration of action (half-life about 12 h). Methamphetamine has both direct sympathomimetic effects secondary to disruption of vesicular storage of monoamines and inhibition of their breakdown by MAOIs and indirect actions through inhibition of central presynaptic reuptake of catecholamines.

Prevalence and patterns of use

In the United Kingdom reports of its use are becoming more common, particularly in association with the gay and dance music scene but compared to the use of cocaine in all its forms, the prevalence of methamphetamine use at present is still low.[43]

Physical effects and complications

Sympathetic arousal induced by methamphetamine produces rapid and sometimes irregular heartbeat, sweating, pupillary dilation, hypertension, dry mouth, tremor and blurred vision, and increased body heat. Occasionally, serious medical complications arise including coronary artery syndrome, seizures, and cerebral bleeds (see Table 4.2.3.5.2).

Psychological effects and complications

Acute sought after-effects are similar to those of amphetamine and include euphoria, enhanced stamina, confidence, disinhibition, reduced appetite, improved coordination, and heightened alertness and awareness.

Other consequences of use

(a) Dependence and withdrawal

Dependence may occur and is more common among heavy male users and in those who smoke or inject the drug. Although dependent users may use every day to avoid withdrawal, more typically users tend to consume a large amount of the drug (often several grams) over several days going out without sleep (a binge) before ceasing use through physical exhaustion or an exhaustion of funds. 'Crashing' refers to the period following a binge, which is characterized by fatigue, hypersomnia, hyperphagia, and low mood due to acute monoamine depletion. The crash and subsequent comedown period may last 2–7 days. If abstinence persists a longer term withdrawal period may be seen, characterized by craving, low mood, anergia, irritability, sleep, and appetite disturbance. Similar neurobiological mechanisms involving alterations in the function and activity of the monoamine neurotransmitters are responsible for the overlap between the symptoms of depression and those of stimulant withdrawal.[42,44] Typically the withdrawal gradually diminishes over 2–4 weeks though dysphoric symptoms may persist for up to 10 weeks.

(b) Withdrawal, depression, and management

The frequency of depressive symptoms is highest during the withdrawal period. As with alcohol, there are a far fewer number of people who present with depression symptoms outside of stimulant use or withdrawal. Management of withdrawal is largely supportive and with a safe, well-supported home environment. In patient admission is rarely required other than in those with severe mental or physical illness. The patient should be placed in quiet surroundings for several days and allowed to sleep and eat as much as is needed. Because a significant component of the withdrawal syndrome is probably related to neurotransmitter depletion, recovery may be delayed because of anorexia associated with amphetamine use. It may be useful in some to provide nutritional supplements or a well-balanced diet rich in monoamine precursors: phenylalanine, tyrosine, l-tryptophan for example, pumpkin seeds, chocolate, marmite, bananas. Benzodiazepines may be prescribed

on a short-term basis for agitation. Some patients may become markedly despondent during withdrawal and a suicide assessment may be necessary.

Since antidepressants have no specific anti-craving effects, and the efficacy of antidepressants in reducing depression is confined to those stimulant users who are depressed, it is useful to wait until after they have stopped using for 2–4 weeks and reassess them for depressive symptoms. The advantages of waiting are improved diagnostic accuracy, avoidance of potentially unnecessary medication, and probably an improvement in compliance and efficacy. However the persistence of depressive symptoms beyond 2–4 weeks after stopping amphetamine use may suggest that there is an underlying depressive illness and this should be treated[42] since left unmanaged its presence represents a high risk for relapse. Psychosocial treatments for stimulant abuse and dependence have been found to be effective in reducing levels of use,[45] but to date, no reliably effective pharmacological treatments have been identified and there are currently no widely accepted evidence-based pharmacotherapy regimes for the treatment of psychostimulant withdrawal.[46]

(c) Stimulant-induced psychosis

The use of high doses of methamphetamine may lead to the induction of a temporary psychotic state that may be clinically indistinguishable from paranoid schizophrenia. First recognized in 1938 in association with Benzedrine nasal inhalers, it was not until Connell's classic 1958 study that the syndrome was well described. Acute transient psychotic episodes (typically characterized by suspiciousness, unusual thought content, or hallucinations) occur in about 10–15 per cent of users. Psychotic episodes are more common in dependent users, men, injectors, and smokers, polydrug users, those with past history and following a binge in association with prolonged insomnia.[47]

Characterized by persecutory delusions and hallucinations which are typically auditory but may be visual or tactile (which can be associated with secondary delusion of parasitic infestation) amphetamine-induced psychosis typically remit within few days or at most a few weeks. Little has changed in the way of management since Connell's time who recommends 'removal of the drug and appropriate sedation'. Often, patients present with high levels of hostility and violence secondary to persecutory delusions or hallucinations, and safe containment and management of the disturbed individual can require enormous levels of both physical and chemical restraint. Benzodiazepines (often required in very high doses) should be the first-line medication with antipsychotics used only where additional tranquilization is required. A diagnosis of a possible underlying or persistent psychotic disorder must be deferred until a reassessment can be made in a drug-free state. These often florid psychoses usually remit within a few days and the user returns to normal functioning, although some retain a vulnerability to such episodes.[48] Only a minority (1–15 per cent) persist beyond 1 month and many of these patients will have underlying psychiatric disorders.[47]

The prognosis is variable with those who have experienced stimulant-induced psychotic episodes being more vulnerable to future episodes (possibly through behavioural sensitization) on re-exposure to the drug often at lower levels. Recent positron emission tomography (PET) imaging studies in chronic methamphetamine users have demonstrated a reduction in dopamine transporter concentration and this reduction was significantly associated with the duration of methamphetamine use and closely related to the severity of persistent psychiatric symptoms. Moreover, the severity of psychiatric symptoms was significantly correlated with the duration of methamphetamine use. Cessation is still potentially important since there does however appear to be some recovery of dopamine transporter function with abstinence.

Gamma hydroxy butyrate, GHB, GBH, fantasy, G, liquid ecstasy, and GBL

Background

GHB is an endogenous short-chain fatty acid found in the CNS and elsewhere in the body. A putative neurotransmitter, its precise role is yet to be identified although specific binding sites have been identified in hippocampus (linked to DA neurones). Trace amounts may also be found in certain fruits such a guava. In the United Kingdom GHB is classified as Class C drug.

Like ketamine, GHB was originally developed as an anaesthetic though the high incidence of tonic clinic seizures dampened enthusiasm among surgeons for its routine use. Subsequently it found clinical utility as a sedative, a treatment for narcolepsy, as a detoxification agent (it is effective in the management of alcohol withdrawal) and as a putative muscle growth enhancer for body builders (through its effect on increasing slow wave sleep). Since the 1990s however it has become best known for its place among the smorgasbord of drugs commonly used by those involved in the dance/rave scene. It has a reputation as a cheap stimulant drug of short duration with marked aphrodisiac properties but a narrow therapeutic threshold carrying a significant risk of overdose especially in combination with alcohol.[49]

Preparation (pro drugs), purity, and routes of use

Until the late 1990s GHB and its precursors including the psychoactive pro compounds GBL (gamma butyl-lactone) and 1,4 butanediol were widely available over the Internet. Because of its relative ease of manufacture attempts at home production were common, resulting in preparations of widely varying concentrations. The resultant formulations were sometimes caustic, resulting in gastrointestinal discomfort, vomiting, aspiration, and coma.

GHB is sold most commonly as a free acid (a colourless and odourless liquid in its pure form, with a slightly salty, acidic taste) or as a sodium salt (usually a white powder). Although varying widely in concentration typically doses are sold in plastic vials holding 5–10 ml.

Mechanism of action and metabolism

GHB readily cross the BBB and acutely leads to a transient decrease followed by increase in dopamine levels (accompanied by increase in endogenous opioid release). Increases in other neurotransmitters such as GABA, Ach, and 5-HT are also seen. At higher doses it exhibits some partial GABA-b activity (epileptogenic). GHB is usually taken orally often mixed in fruit juice or alcoholic beverage. It has a very rapid onset of action with noticeable effects occurring within 15 min of administration it has a relatively short duration of action ($t_{1/2}$ 27 min) with effects peaking at 30–60 min and being over within 2–4 h, being eliminated though its breakdown to CO_2 and H_2O.

Physical effects and complications

GHB exhibits a very narrow therapeutic index and as a result of wide interpersonal variation in tolerance and significantly enhanced toxicity (depressant effects) when combined with alcohol, overdose with GHB has been reported more widely than for any other dance drug,[50,51] overdose should be suspected in someone who presents with nystagmus, ataxia, nausea, vomiting, sedation, weakness, bradycardia, hypotension, and the rapid onset of unconsciousness (quite similar to severe alcohol intoxication but without alcohol on the breath). Management should include placing the person in the recovery position, airway management and pulse oximetry. GCS scores may be very low (<7). If oxygen saturation drops or they are so unconscious that they can tolerate a Guedels airways then ventilation should be considered. Overdoses are short lived and most awake somewhat aroused and disorientation after a few hours. Other clinical presentations include agitation, anxiety, coma, amnesia, and collapse. These patients when in coma may require ventilation and typically suddenly emerge from their coma with high levels of agitation, arousal, and violence.

Although there have been press reports of GHB being commonly used as 'date rape drug', such cases are very rare and it is still the case that the most common drug used for such purposes is alcohol alone.

Psychological effects and complications

Consumption of GHB results in a dose-related euphoria and stimulation which gives way to sedation at higher doses. In combination with stimulant drugs there may be an increase of precipitating a brief psychotic reaction, whilst with alcohol the risk of fatal overdose is the primary concern. There has been a single case report of Wernicke Korsakoff syndrome.

Other consequences of use

(a) Dependence and withdrawal

More recently there have been number of reports describing GHB dependence and withdrawal. The later may present as a rapid onset, prolonged alcohol withdrawal picture. Although associated with lower levels of autonomic arousal and seizure risk, patients may exhibit marked confusion, delirium, and hallucinations. Management may require doses of diazepam markedly in excess of those typically used to manage alcohol withdrawal with a waxing and waning clinical progression that may last 2 weeks.[52]

Ketamine (K, Special K, Super K, Vitamin K, Green, Mean Green, Jet)

Background

Ketamine (2-(2-chlorophenyl)-2-(methylamino)-cyclohexanone) and PCP (angel dust) are very similar drugs, the main difference being ketamine's shorter half and less problematic 'emergence phenomena'. Ketamine has a range of useful clinical applications. It is used across several areas of medicine including paediatric analgesia and anaesthesia, emergency anaesthesia, obstetrics, and battle-zones[53] and benefits from having a wide margin of safety in overdose. Ketamine is an NMDA antagonist and is almost unique as an anaesthetic in its ability to produce a 'dissociative' state, which results in higher brain structures in the brain centres being prevented from perceiving auditory, visual or painful stimuli leading to 'a lack of responsive awareness'. Overall the effect has been described as somato-aesthetic sensory blockade with amnesia and analgesia. In recent years its non-medical use as a psychedelic has become more common. In the United Kingdom ketamine is classified as Class C drug. For a recent review see Wolff and Winstock.[54]

Mechanism of action and metabolism

Ketamine has multiple actions at numerous receptor sites particularly affecting glutaminergic and monoaminergic neurotransmission. The most significant pharmacological action of ketamine is the non-competitive antagonist binding at the cation channel of the NMDA receptor and consequent interference with excitatory amino acid transmitters—glutamate and aspartate. As a research probe in the study of schizophrenia, ketamine has given increasing prominence to the role of glutamate in the aetiology of psychotic illness. Ketamine also enhances monoaminergic transmission resulting in marked sympathomimetic effects as well as modulating activity at opioid receptors, thought to be responsible for its analgesic and dysphoric effects.

Ketamine undergoes marked first-pass metabolism and is fairly ineffective when taken orally (bioavailability may be <20 per cent). However, oral consumption does result in a two-fold higher concentration of its primary metabolite norketamine compared to, for example, intramuscular dosing. Norketamine is pharmacologically active with anaesthetic potency approaching one-third that of the parent compound. Hence although the onset of effects following ingestion may be somewhat slower than by parental routes the duration of effects would almost certainly be longer. The majority of the parent drug will be eliminated from the body within 24 h, although prolonged effects due to the presence of active metabolites may occur.

Preparations, purity, and routes of use

Ketamine may be sold illicitly in a number of preparations; as crystalline powder for intranasal use (dose-100–400 mg), in liquid, tablet, powder, or capsular form (dose-350–500 mg) for ingestion. When obtained from diverted licit sources, the formulation of the drug is a solution prepared for intravenous use. This solution may be injected or swallowed, but more typically the solution is dried and taken intranasally.[54] However, this process of desiccation may reduce the purity of the crystalline residue, and is an obvious point at which, via contamination, purity may be altered. Ketamine may be adequately absorbed via the intranasal, intravenous, subcutaneous, intramuscular, and intrathecal routes, with snorting and injecting being the most common recreational routes of use. Reports of clinical use via the rectal and transdermal routes have also been described.

Prevalence and patterns of use

Far less common in the general population than MDMA, ketamine none the less has become increasingly popular among those associated with the dance scene with a prevalence of about 20 per cent being reported among clubbers. Whilst ketamine maintains a good safety record within clinical settings, the increase in its unregulated use outside such controlled environments is a cause for concern

Table 4.2.3.5.3 Ketamine, psychological and physical effects

Psychological	Physical
Rapid onset, short duration of action (1 h), wide safety margin	
Dissociative anaesthesia 'somatosensory blockade' analgesia	Dilated pupils
Perceptual distortion/hallucinations/near death	Tachycardia
Out of body experience	Hypertension
Though disorder/synaethesia	Ataxia
Emergence phenomena	Paralysis
Cognitive impairment	Sweating
Amnesia	Hypersalivation
Derealization/depersonalization	Little effect on cough reflex

with its effects being highly sensitive to age, dose, route, set, and setting (see Table 4.2.3.5.3). Outside clinical settings ketamine is most commonly snorted or injected, with typically administered doses being small fractions of a gram (an eighth). Because of its short half-life (17 min) the psychedelic effects experienced are generally short-lived with effect duration of about 1–2 h. The short duration of effect and rapid onset of action when taken by intranasal or intravenous routes often leads recreational users to administer repeated doses over the course of an evening (session) in order to maintain a desired psychoactive effect.

Physical effects and complications

Because of its fast urinary excretion (within 2 h) the ability to identify ketamine in urine screens is almost impossible and thus a level of clinical suspicion is required especially if a history of its use is not forthcoming.[55] Detection by clinical examination relies on identifying mydriasis, moderate tachycardia, elevated BP, slurred speech, blunted affect, ataxia, delirium, nystagmus (less commonly than with PCP). Tachycardia is the most common finding on physical examination. Its short half-life of 17 min (see Table 4.2.3.5.3).

Admissions to hospital are most commonly for complaints related to sympathetic over activity with chest pain, palpitations and taccycardia, nausea, vomiting, difficulty breathing, ataxia, temporary paralysis/inability to speak, blurred vision, no awareness of pain as well as derealization/depersonalization, and amnesia. Other risks associated with its use include accidents, trauma, and risky sexual behaviours. Rarely more severe complications are reported including severe agitation and rhabdomyolysis. Although relatively safe in overdose, in combination with ethanol or other CNS depressants the use of ketamine can result in death.

Clinical findings and detection

(a) Psychological effects and complications

At low doses marked elevation in mood predominate. At higher doses intense psychedelic effects commence with sensory and perceptual distortion, euphoria, and out of body and floating experiences (see Table 4.2.3.5.3). The Harvard academic, Timothy Leary, described it as 'the ultimate psychedelic journey'. Users describe entering the 'K hole' where they experience—visits to god, aliens, their birth, past lives and the 'experiences of evolution'. Some users report taking issues of set and setting into careful consideration prior to using ketamine such preparation cannot be performed if the drug is consumed unwittingly when it has been marketed under the guise of another drug such as ecstasy. Being an amnestic it may become difficult to remember the total doses consumed.

Ketamine can also produce a psychotic picture that can briefly mimic schizophrenia. Both positive and negative symptoms of schizophrenia can be transiently seen in normal users and its use can exacerbate symptoms in those with pre-existing psychotic disorders. Other adverse effects can include frightening hallucinations/out of body experiences, thought disorder, confusion, and dissociation. Such episodes tend to be short-lived, resolving in a few hours or at the most a few days. In many respects these are similar to those adverse effects seen LSD, though with ketamine they come on after a shorter period following use and recede more quickly.

Management is by supportive monitoring (cardiovascular) in a quiet low stimulation room with symptomatic treatment with benzodiazepines if needed. Unusually, the effects of benzodiazepines are inconsistent varying between compounds and dose. For instance, whilst lorazepam may reduce emotional distress, it appears to have little impact upon the psychosis or perceptual changes observed. Midazolam, on the other hand, is able to negate ketamine's effect on thought process and perceptual disorder but has little impact upon mood problems. Interestingly haloperidol also has little effect upon the psychosis associated with ketamine, suggesting a role for receptors other than D2. Chlorpromazine should be avoided (anticholinergic effects).

Other consequences of use

(a) Ketamine dependence and long-term cognitive impairment

Animal studies demonstrate the ability for intravenous ketamine to produce dependence in rat models, with disruption of operant behaviour on withdrawal. Ketamine demonstrates reinforcing efficacy in animal self-administration models and is found to be a discriminative stimuli in operant tasks. Its effects are thus readily distinguishable from other drugs and may have abuse liability. However, ketamine is somewhat unusual in its pharmacodynamics, almost acting as a partial antagonist with regard to brain reward enhancements, being stimulatory at low doses, and inhibiting brain reward centres at higher doses.

Clinically ketamine dependence has been described, with compulsive use as primary symptom. Heavy habitual use has been described by Jansen (1990), and cases of dependence have also been reported among anaesthetic staff. Although tolerance develops there are only a few case reports of a withdrawal syndrome occurring.

Longer-term follow-up studies suggest that any impairment of semantic memory may be reversible upon cessation of use but persistent deficits may be seen in episodic memory and in subjective experience with one study suggesting persistence of schizotypal and perceptual changes after cessation of use.[56]

(b) New class of drugs

Tryptamine (1H-indole-3-ethanamine) is a naturally occurring metabolite of tryptophan. It forms the parent nucleus of a wide

range of hallucinogenic drugs, some entirely synthetic (LSD, *N*,*N*-dimethyltryptamine) but many naturally occurring in plants, fungi (psilocybin—the psychoactive component of 'magic mushrooms'), and occasionally animals. It seems unlikely that many tryptamines other than LSD and psilocybin will be used unduly in dance clubs because they possess few stimulant properties, and need to be smoked or injected because most are inactive by mouth unless taken with a monoamine oxidase inhibitor.An example of the latter is the combination of *N*,*N*-dimethyltryptamine (the hallucinogen) and harmine (the activator) in the hallucinogenic drink ayahuasca or caapi used in rituals by South American Indians. Drugs such a *N*,*N*-dimethyltryptamine may have adverse effects upon both the cardiovascular system and on temperature regulation. They may induce unpleasant hallucinogenic experiences.

As described earlier the analogues MBDB, MDEA, and MDA all share similar properties with MDMA and at times have been marketed as distinct drugs. More recently 4-Bromo-2, 5-dimethoxyphenethylamine (also known as 2C-B, Nexus) a drug with similar hallucinogenic properties as psilocybin and mescaline has become available within the dance scene in Europe. Others such a 2C-T2 (2,5-dimethoxy-4-ethylthio-β-phenethylamine) suggest that new additions to an expanding street pharmacy are unlikely to become a thing of the past any time soon. Newer drugs are likely to be less easily detected by toxicologist and may have unfamiliar or atypical clinical manifestations.

Conclusion

MDMA, methamphetamine, GHB, and ketamine are all capable of producing acute adverse psychological experiences in normal users and exacerbating symptoms in those with underlying psychological disorders. They also to varying degrees pose the risk of long-term neuropsychiatric consequences. Although dependent patterns of use are not commonly seen with this group of drugs, methamphetamines certainly can result in the very rapid development of severe dependence. Most acute presentations are typically short-lived and self-limiting and are only very rarely life-threatening. The precipitation of an underlying psychiatric disorder or an exacerbation of premorbid traits may well be one of the longer term consequences of heavy use of these drugs. In those who present with acute drug-related psychological symptoms there should be an emphasis on follow-up since in some cases the symptoms will represent the onset of a persistent independent disorder which requires treatment. Users who have experienced acute psychological problems should be encouraged to make the attribution that there may be something inherent in them that makes them susceptible to experiencing the unpleasant reactions with a drug and that they are likely to remain vulnerable to those adverse experiences. This may be difficult to accept for potentially vulnerable young people who may prefer to think that the experience was not enjoyable because the drugs were not good – 'it was a bad pill'.

4.2.3.6 Disorders relating to the use of volatile substances

Richard Ives

Introduction

Volatile substance abuse (**VSA**)—also known as 'solvent abuse' and 'inhalant abuse'—is the deliberate inhalation of any of a range of products (see Table 4.2.3.6.1[1]), to achieve intoxication. Amyl (pentyl) and isobutyl nitrites ('poppers') have different patterns of misuse, and are not discussed here.[2]

VSA has dose-related effects similar to those of other hypnosedatives. Small doses rapidly lead to 'drunken' behaviour similar to the

Table 4.2.3.6.1 Some products which can be abused by inhalation

Product	Major volatile components
Adhesives	
Balsa wood cement	Ethyl acetate
Contact adhesives	Butanone, hexane, toluene, and esters
Cycle tyre repair cement	Toluene, and xylenes
Woodworking adhesives	Xylenes
Polyvinylchloride (PVC) cement	Acetone, butanone, cyclohexanone, trichloroethylene
Aerosols	
Air freshener	LPG, DME, and/or fluorocarbons
Deodorants, antiperspirants	LPG, DME, and/or fluorocarbons
Fly spray	LPG, DME, and/or fluorocarbons
Hair lacquer	LPG, DME, and/or fluorocarbons
Paint sprayers	LPG, DME, and/or fluorocarbons and esters
Anaesthetics/analgesics	
Inhalational	Nitrous oxide, cyclopropane Diethyl ether, halothane, enflurane, isoflurane
Topical	FC 11, FC 12, monochloroethane
Dust removers (air brushes)	DME, FC 22
Commercial dry cleaning and degreasing agents	Dichloromethane, FC 113, methanol, 1,1,1-trichloroethane, tetrachloroethylene, toluene, trichloroethylene (now rarely carbon tetrachloride, 1,2-dichloropropane)
Domestic spot removers and dry cleaners	Dichloromethane, 1,1,1-Trichloroethane, tetrachloroethylene, trichloroethylene
Fire extinguishers	Bromochlorodifluoromethane, FC 11, FC 12
Fuel gases	
Cigarette lighter refills	LPG
'Butane'	LPG
'Propane'	Propane and butanes
Nail varnish/nail varnish remover	Acetone and esters
Paints/paint thinners	Acetone, butanone, esters, hexane, toluene, trichloroethylene, xylenes
Paint stripper	Dichloromethane, methanol, toluene
'Room odorizer'	

(Reproduced from B. Flanagan and R. Ives Volatile substance abuse, *Bulletin on Narcotics*, **XLVI**, 49–78, copyright 1994, UNODC.).

effects of alcohol, and may induce delusions and hallucinations. Some heavy misusers inhale large quantities; 6 l of adhesive weekly have been reported.

Long-term effects include listlessness, anorexia, and moodiness. The hair, breath, and clothing may smell of the substance(s) used, and empty product containers (e.g. glue cans, cigarette lighter refills, and aerosol spray cans), and bags used to inhale from, may be found.

Being readily available, volatile substances are, along with alcohol and tobacco, the first intoxicating substances some children try. However, most VSA is experimental and does not lead to the use of other psychoactive substances; problematic misusers have other difficulties in their lives.[3]

History

Inhaling substances to achieve intoxication is not new. Inhaling ether and nitrous oxide ('laughing gas'), as well as commercially available volatile products, has a long history.

Public concern is more recent. In the United States during the 1950s and 1960s there was much publicity about glue sniffing; this helped to publicize the possibilities of glue as an intoxicant.[4] Only in the 1970s did public concern about VSA emerge in the United Kingdom, to reach a peak in 1983 when there were more press cuttings on the subject than on all other drugs.[5] Public anxiety has since waned, although the problem has not disappeared.

Prevalence of VSA

VSA is a worldwide problem. For an overview, see a WHO report,[6] and a National Institute on Drug Abuse (NIDA) report.[7] The European Schools survey Project on Alcohol and other Drugs (ESPAD) report provides 2003 data from 35 European countries: lifetime experience of VSA (i.e. whether *ever* tried VSA) among 15- to 16-year-olds varied from 2 per cent (in Romania) to 22 per cent (in Greenland). In the United Kingdom (and Iceland) 12 per cent reported trying VSA—nine countries had a higher prevalence. There was little difference between boys' and girls' lifetime prevalence.[8] Although young people from all socio-economic groups experiment with volatile substances, for some among the poor and the dispossessed, VSA is the drug of choice.[9] VSA is a particular problem among people living on the street. Chronic VSA is associated with poor socio-economic conditions, with delinquency and illegal drug use,[10] disrupted families, and other social and psychological problems.[11]

VSA deaths

Even for first-time experimenters, death from VSA is an ever-present risk. Death may ensue from convulsions and coma, inhalation of vomit, or direct cardiac or central nervous system toxicity. Sudden deaths of young people should be thoroughly investigated, as VSA-related deaths can be overlooked. Post-mortem examination usually reveals little, except perhaps acute lung congestion and possibly cold-induced burns to the mouth and throat. Toxicological examination of blood and tissue specimens is used to confirm a diagnosis of VSA-related death.[12]

A long-term study in the United Kingdom identified 2152 VSA-related deaths between 1971 and 2004.[13] The death rate peaked in 1990 with 152 deaths, declining since, with 47 deaths being recorded in 2004. Under-18s make up half the deaths, although the age of death is increasing. Most are male, although the overall proportion of female deaths has risen and in the first 5 years of the new millennium females comprised 22 per cent of the deaths (Table 4.2.3.6.2). Volatile-substance-related deaths occur in all social classes in the United Kingdom. However, ' . . . in deaths of

Table 4.2.3.6.2 VSA-related deaths in the United Kingdom—selected years

Year	1983	1985	1987	1989	1990	1993	1996	1998	1999	2000	2001	2002	2003	2004

Reproduced from Field-Smith, M.E., Butland, B.K., Ramsey, J.D. and Anderson, H.R. Trends in deaths associated with abuse of volatile substances 1971–2004, copyright 2006, St. George's University of London, London.

those under 16, there was a marked difference in mortality between social classes I and V, with nearly four times as many deaths occurring in social class V . . . compared with social class I'.[14]

Health issues

Health effects of volatile substances include the following:

- A sensitization of the heart—so that cardiac arrhythmias may occur if VSA is followed by exertion or fright.
- Cooling of the throat tissues—caused by spraying substances directly into the mouth, which may causing swelling and suffocation.
- A risk of fire—especially when combined with smoking; many products are inflammable.
- Suffocation—a particular danger if large plastic bags are used.
- Most products are mixtures of chemicals, and manufacturers do not list the constituents. Changing product formulations make the dangers unpredictable.
- Using alone in an isolated place presents special hazards.
- When combined with alcohol or other drugs, the effects can be unpredictable.
- Intoxication itself has potential dangers, for example, greater recklessness, doing bizarre things in response to hallucinations, becoming unconscious, and choking on vomit.

Apart from the real risk of death, VSA rarely causes long-term damage. However, some products contain poisonous substances, such as lead in some petrol or *n*-hexane in some glues. Chronic abuse of toluene-containing products and of chlorinated solvents such as 1,1,1-trichloroethane sometimes causes damage to the liver and kidneys. Damage to the lungs, bone marrow, and nervous system is also known, but is uncommon and generally reversible. Some people are more vulnerable (genetically or otherwise) than others to certain harmful effects. However, the long-term effects of sniffing have not been thoroughly studied, and virtually all reports of chronic toxicity are case studies, so the actual morbidity from VSA is not known.

A review article looking at the possibility of cognitive impairments concluded that: 'the possibility that permanent structural brain damage, with accompanying psychiatric manifestations, results from solvent abuse remains inconclusive'.[15]

Users develop tolerance. Although no dependence syndrome exists, a few young people develop a more compulsive and long-term habit. The UK Advisory Council on the Misuse of Drugs suggested that: 'There are . . . pharmacological reasons for suspecting that persistent exposure to volatile substances might be able to induce a dependence of the so-called depressant type'.[16]

Many volatile substance misusers are also users of other drugs, both legal and illegal. Poly-drug use may potentiate the effects of individual drugs and make it difficult to assess the risks of individual substances.[17]

VSA during pregnancy is associated with increased maternal and foetal morbidity.[18] Paternal exposure to volatile substances may also have deleterious effects on their offspring.[19] But the complexities of the chemicals involved—and the complexities of people's lives—make it difficult to identify specific causes of foetal damage difficult.

Treatment of VSA-related disorders

Emergency treatment

The immediate treatment of an intoxicated person needs a calm and firm approach. The product being misused should be removed; although not if this would lead to conflict—exertion or high emotion may raise adrenaline to dangerous levels for an over-sensitized heart. Therefore, an intoxicated person should be kept calm and never chased. It is unlikely that it will be possible to have a serious conversation with an intoxicated misuser, but calming and reassuring talk may help. After 5 to 20 min without inhalation the abuser will sober up (unless alcohol or other drugs have also been used). Subsequently, medical help might be needed; a check-up may identify particular health problems.

Cessation

No special regime is necessary when stopping misusing volatile substances. Although, being lipid-soluble, the chemicals may be detectable in the body tissues for some weeks after cessation of use, they do not have any psychoactive effect. There is no clearly defined withdrawal syndrome and special detoxification regimes are unnecessary, but rest, sleep, and good food may aid recovery.

Dealing with experimental misuse

Most teenagers never even try misusing volatile substances; those who do, do so only a few times, and even those who do so more frequently do not continue for long. Experimental or the occasional misuse of volatile substances occurs mainly from curiosity or as part of peer group activity. Appropriate intervention may simply involve a warning of the dangers, plus increased supervision. Specialist treatment is not required, and may be counterproductive, entrenching an otherwise transient activity.

Dealing with dependent misuse

Biology may predispose to dependent use, but chronic VSA is connected with other problems. As group of United Kingdom professionals put it:[20]

> Persistent misuse of volatile substances is a complex behaviour . . . frequently associated with low self-esteem, family problems, isolation and psychological difficulties. These are factors that may also be associated with the problematic use of legal and illegal drugs, and indeed,

> a large proportion of people who misuse volatile substances also misuse other drugs. Chronic VSA is thus intertwined with social and psychological problems and with the misuse of illegal drugs. Therefore, counselling services for young people should not be narrowly focused on volatile substances, but should be able to deal with VSA in the context of a range of problematic behaviours.

Often, these other problems need attention first, and until these are dealt with, the misuser—even while recognizing the harm—may not give up. Consequently, generic services, which can deal more effectively with these broader problems, should lead on care, supported where necessary by specialist agencies. Mental health services, as well as drugs' services, have an important role in giving this support, for example, in the treatment of psychiatric comorbidity (dual diagnosis). Specialist services can also help to identify areas for intervention; implementation should take account of social and cultural patterns of the misuser's life. Female volatile substance misusers may not readily present for treatment and can suffer additional stigmatization. Services for young people need to be specifically designed for their needs and cognizant of issues such as confidentiality and consent. Families who struggle unaided with problematic VSA by a young family member may also need help.

The Modified Social Stress Model, developed by the WHO Street Children Project, gives a framework for understanding substance use.[21] Potential for change can be assessed using Prochaska and DiClemente's 'revolving door' model of stages of change.[22] Jumper-Thurman and colleagues point out that the treatment of volatile substance misusers:[23]

> has presented a particularly difficult challenge . . . given the general lack of direction for effective treatment strategies. In addition to the physiological, neurological, and emotional challenges abusers face . . . [they] bring with them a multitude of other problems—academic, legal, social, and family issues.

Some groups (such as people living on the street, and indigenous peoples) have special problems with substance use that require different, more holistic, attention. Treatment should work 'with the grain' of the culture, rather than imposing inappropriate 'alien' treatment models. Indigenous peoples are beginning to insist that their cultures have useful perspectives and approaches that can be utilized in the treatment of people with drug and volatile substance problems.[24]

Follow-up

After-care, long-term rehabilitation, social reinsertion, relapse management, and follow-up of discharged patients are important aspects of the treatment process.

Relapse, which is common, should be treated non-judgementally; not as 'failure' but as an opportunity for learning. Support in maintaining improvements may be helpful; for example, events for ex-users of volatile substances to help them to maintain abstinence and to utilize group support.

Harm minimization

Because of the unpredictable dangers of VSA, harm minimization advice should not be routinely given. However, very entrenched misusers may benefit from careful individual guidance on minimizing the risks, such as avoiding spraying gases directly into the mouth.

Wider aspects

Chronic VSA is not an individual problem: it arises not only from individual pathology, but also from failures in social structures. Treatment, in the broadest sense, needs to help the healing of the family, the community, and to assist in making changes in society.

Measuring outcomes

Evaluation and monitoring need careful thought and planning. But treatment interventions have multiple aims and varied outcomes. Aims may alter and be adapted as the work develops, so that outcomes will be difficult to assess in relation to the original aims. Evaluation should handle this complexity: identifying 'success' requires measures beyond the simple calculation of reduction in, or abstention from, substance use.

Building evaluation in from the start, and using it to inform the intervention throughout, makes it part of the process of intervention; the reflection that monitoring and evaluation encourages can increase the effectiveness of the intervention.

Prevention

There are many different sniffable products, many possibilities for substitution of one product for another, many different chemicals involved, and insufficient information about the relative harm of various products and practices. Volatile substance misusers are generally young, and VSA-related deaths are sudden and unpredictable. All these factors make prevention difficult.

Tackling the supply of products

This can be approached in several ways:

- Product elimination—while it is not possible to eliminate all volatile substances, some products are particularly dangerous, and have satisfactory substitutes.
- Product modification—there are three possibilities (a review paper gives more details:[25])
  - changing the formulation of the product to remove the intoxicating substance. There has been great success in Australian indigenous communities through substituting petrol with unsniffable 'Opal', an unleaded fuel with low levels of aromatics[26,27]
  - adding a chemical to make the product unpalatable (experiments with the bittering agent, *Bitrex*, have been inconclusive)
  - and modifying the container to make misuse difficult.
- Warning labels—these may be helpful, although labelling draws attention to the potential for misuse. Many sniffable products in the United Kingdom carry the 'SACKI' warning, 'Solvent Abuse Can Kill Instantly'.[28]
- Education for suppliers—retailers need information and advice about a product's potential for misuse. This is difficult, as the various products are sold through many retail outlets.
- Legal controls on the sale and supply of misusable products—these exist in many countries but are difficult to enforce.

Tackling the demand for products

- Legal controls—in Japan, Singapore, and the Republic of Korea, VSA is an offence. However, this is not so in most countries because the criminalization of misusers of volatile substances is considered counterproductive.
- Information and education—this can be provided through public advertising, leaflets, helplines, in schools and informal education. Early education about volatile substances is essential; these products are in most people's homes and therefore (unlike illegal drugs) they can be accessed by very young children. Because many parents are unaware of the misuse potential of household products, information should also be targeted at parents.

All these strategies should be considered; as the Advisory Council on the Misuse of Drugs pointed out, 'good practice' will constitute a layered series of alternative or multiple strategies rather than any one master stroke.[29]

4.2.3.7 The mental health effects of cannabis use

Wayne Hall

Cannabis the drug

Cannabis products are derived from the female plant of *Cannabis sativa* and contain the psychoactive constituent delta-9-tetrahydrocannabinol (**THC**).[1] Marijuana (THC content typically 0.5–5 per cent) is prepared from the dried flowering tops and leaves of the plant. Hashish (THC content typically 2–20 per cent) consists of dried cannabis resin and compressed flowers.[1]

Cannabis is usually smoked in a 'joint', like a tobacco cigarette, or in a water pipe, often mixed with tobacco. Although marijuana and hashish may be eaten, cannabis is usually smoked because this is the most efficient way to achieve the desired effects.[2]

THC acts on a widely distributed, specific receptor in brain regions that are involved in cognition, memory, reward, pain perception, and motor coordination.[1] These receptors respond to an endogenous ligand, anandamide, which is considerably less potent and has a shorter duration of action than THC.[1]

Patterns of cannabis use

Cannabis has been tried by many young adults in Europe, the United States, and Australia.[3] Most cannabis users in these countries start in their mid to late teens and stop in their middle to late 20s.[3,4] In the United States and Australia, about 10 per cent of those who ever use cannabis become daily users, and another 20 to 30 per cent use weekly.[3] This pattern of use differs from that found in traditional cannabis-using countries, such as Egypt and India, where recreational cannabis use is uncommon and heavy cannabis use is confined to small, marginalized groups.[3]

'Heavy' cannabis use is usually defined as daily or near-daily use.[5] This pattern of use places users at the greatest risk of experiencing adverse psychological and physical consequences.[2,3] Daily cannabis users are also more likely to be regular users of alcohol and tobacco and to use amphetamines, hallucinogens, psychostimulants, sedatives, and opioids.[2,3]

Acute psychological effects of cannabis use

Cannabis produces euphoria and relaxation, perceptual alterations, impaired short-term memory and attention, and intensification of ordinary sensory experiences.[2] The most common unpleasant psychological effects are anxiety and panic reactions,[2] that are most often reported by naive users and are a common reason for discontinuing use.[2] Cannabis produces dose-related impairments in cognitive and behavioural functions that may impair ability to drive an automobile.[6]

Chronic psychological effects of cannabis use

Cannabis dependence

Animals and humans develop tolerance to the effects of THC,[1] and some heavy users experience withdrawal symptoms on the abrupt cessation of cannabis use.[7] During the 1990s there was an increase in the number of persons in the United States, Australia, and Europe seeking help to stop their cannabis use.[3]

A cannabis-dependence syndrome occurs in heavy chronic users of cannabis who report problems in controlling their cannabis use, but who continue despite experiencing adverse personal and social consequences.[8] The lifetime prevalence of cannabis abuse and dependence (as defined in DSM-IIIR) in the United States has been estimated at 4.4 per cent of adults.[9] Around 10 per cent of those who ever use cannabis will meet criteria for dependence at some point in their lives.[2,9]

It is not clear how cannabis dependence is best managed. Roffman and Stephens,[10] in summarizing the results of controlled trials of cognitive behavioural, relapse prevention and other psychological approaches to treatment, report low rates of abstinence at 12 months but substantial reductions in cannabis use and problems among those who continue to use cannabis.

Cannabis psychosis

High doses of THC have been reported to produce visual and auditory hallucinations, delusional ideas, and thought disorder in normal volunteers.[2] In traditional cannabis-using cultures, such as India, a 'cannabis psychosis' has been reported in which the symptoms are preceded by heavy cannabis use and remit after abstinence[11] but the existence of a 'cannabis psychosis' in Western cultures is still a matter for debate.[11]

Cannabis and schizophrenia

Cannabis use and schizophrenia are associated[12,13] and there is consistent evidence from a series of prospective studies in a number of different countries suggesting that cannabis use can precipitate schizophrenia in persons who are vulnerable because of a personal or family history of this disorder,[12,13] and possibly a genetic vulnerability.[14] This hypothesis is consistent with the stress-diathesis model of schizophrenia[15] and it is also biologically plausible because psychotic disorders involve disturbances in the dopamine neurotransmitter systems and cannabinoids, such as THC, increase dopamine release.[1]

Individuals with psychotic symptoms who use cannabis should be encouraged to stop or, at the very least, to reduce their frequency of use. The major challenge is in finding ways to persuade individuals with psychoses to stop doing something they enjoy and to help those who want to stop using cannabis but find it difficult to do so. Psychological interventions for cannabis dependence in individuals without psychoses produce modest rates of abstinence and many individuals with schizophrenia lack social support, may be cognitively impaired, are often unemployed, and may not comply with treatment. A recent Cochrane review[16] found no clear evidence that supported any type of substance abuse treatment in schizophrenia over standard care. The development of more effective pharmacologic and psychological methods of treatment for cannabis dependence in persons with psychoses is a research priority.

Other disorders

Cognitive impairment

Cannabis use acutely impairs cognitive functioning but long-term heavy use of cannabis does not appear to produce severe or grossly

debilitating impairment of cognitive function that is comparable to the impairments found in chronic heavy alcohol drinkers.[17] There is evidence that the long-term use of cannabis produces more subtle cognitive impairment in the higher cognitive functions of memory, attention and organization, and the integration of complex information.[16] This evidence suggests that, longer the period of heavy cannabis use, the more pronounced is the cognitive impairment.[17] But it remains to be decided whether these cognitive impairments antedate cannabis use, reflect poorer learning in non-academically oriented young people, or reflect neurotoxic effects of cannabis use that can be reversed after an extended period of abstinence.[18]

An 'amotivational syndrome'

Anecdotal reports that chronic heavy cannabis use impairs motivation and social performance have been described in societies with a long history of cannabis use, such as Egypt, the Caribbean, and elsewhere.[2] A similar pattern of behaviour among young Americans who were heavy cannabis users in the early 1970s was described as an 'amotivational syndrome'.[19] Field studies of chronic heavy cannabis users in societies with a tradition of such use, for example Costa Rica and Jamaica,[2] have produced evidence that has usually been interpreted as failing to demonstrate the existence of the amotivational syndrome. Critics have argued that these studies are unconvincing because the chronic users studied have come from socially marginal groups, so that the cognitive and motivational demands of their everyday lives were insufficient to detect any impairment caused by chronic cannabis use.[2]

The status of the amotivational syndrome remains contentious. Many clinicians find the cases of 'amotivational syndrome' compelling, while many researchers are more impressed by the largely negative findings of the field and epidemiological studies. Regular cannabis users can experience a loss of ambition and impaired school and occupational performance[2] and former cannabis users report that impaired occupational performance was their reason for stopping.[2] It may be more parsimonious to explain impaired motivation as a symptom of chronic cannabis intoxication and dependence than to invent a new syndrome.[2,3]

Flashbacks

There are case reports of users experiencing cannabis 'flashbacks', i.e. symptoms of cannabis intoxication days or weeks after the individual last used cannabis.[20] Because of their rarity, and the fact that many affected individuals have also used other drugs, it is difficult to decide whether these are rare events that are coincidental with cannabis use, the effects of other drugs that are often taken together with cannabis, rare consequences of cannabis use that only occur at much higher than usual doses, experiences that require unusual forms of personal vulnerability, or the results of interactions between cannabis and other drugs.[2]

Behavioural effects in adolescence

There has been understandable societal concern about the effects of rising rates of cannabis use among adolescents on their school performance, mental health and adjustment, and their use of other more hazardous illicit drugs.[3,21]

There is a strong cross-sectional association between heavy cannabis use in adolescence and the risk of discontinuing a high-school education and experiencing job instability in young adulthood.[20,22] However, in longitudinal studies the strength of this association is reduced but not eliminated when statistical adjustments are made for the fact that heavy cannabis users have lower academic aspirations and poorer high-school performance prior to using cannabis than their peers.[22]

There is some evidence that heavy cannabis use has adverse effects upon family formation, mental health, and involvement in drug-related crime.[3] In each case, the strong associations in cross-sectional studies are more modest in longitudinal studies after statistically controlling for associations between cannabis use and other pre-existing characteristics which independently predict these adverse outcomes.[22] It remains uncertain to what degree these modest relationships represent residual confounding[22] or real relationships.

A consistent finding in the United States[23] has been the regular sequence of initiation into drug use, in which cannabis use has typically preceded involvement with 'harder' illicit drugs such as stimulants and opioids. The interpretation of this sequence of events remains controversial.[24] There is support for two hypotheses: (i) there is a selective recruitment into cannabis use of non-conforming adolescents who have a propensity to use a variety of other illicit drugs and (ii) once recruited to cannabis use, it is the social interaction with drug-using peers and greater access to illicit drug markets that increases the likelihood of using other illicit drugs.[23]

A major public health challenge will be finding effective ways of explaining the mental health risks of cannabis use to young people. In addition to a possible increased risk of psychosis, young people also need to be informed about the risks of developing dependence on cannabis, impairing their educational attainment, and possibly increasing their risk of depression.[21]

School-based drug education programmes produce small, statistically significant reductions in cannabis use but their primary effect is on knowledge rather than behaviour change and most reductions in use occur among less frequent users rather than the heavier users who are at greater risk of adverse mental health effects.[25,26]

Summary

The major adverse acute psychological effects of cannabis use are as follows:

- Anxiety, dysphoria, panic, and paranoia, especially in naive users
- Impairment of attention, memory, and psychomotor performance while intoxicated
- An increased risk of accident if an intoxicated person attempts to drive a vehicle.

The major psychological effects of daily heavy cannabis use over many years remain contested but probably include the following:[3]

- A cannabis-dependence syndrome
- Subtle forms of cognitive impairment that affect attention and memory and which persist while the user remains chronically intoxicated
- Impaired educational achievement in adolescents with a history of poor school performance, whose achievement may be limited

by the cognitive impairments produced by chronic intoxication with cannabis

- Among those who initiate cannabis use in the early teens, a higher risk of progressing to heavy cannabis and other illicit drug use, and becoming dependent on cannabis.

4.2.3.8 Nicotine dependence and treatment

Mª Inés López-Ibor

Introduction

Tobacco use is the single most important preventable health risk in the developed world, and an important cause of premature death worldwide.(1) Smoking causes a wide range of diseases, including many types of cancer, chronic obstructive pulmonary disease, coronary heart disease, stroke, peripheral vascular disease, and peptic ulcer disease.(2) According to the World Health Organization (WHO) smoking prevalence is estimated at around 28.6 per cent (40 per cent among males and 18.2 per cent among females),(3) it is therefore the most prevalent form of drug dependence in the world.

Tobacco causes around 13 500 deaths per day, currently, approximately 5 million people are killed annually by tobacco use. In the last few years the standardized death rate for lung cancer among men across the European region has fallen but it has increased in women.(3) By 2030, estimates based on current trends indicate that this number will increase to 10 million, with 70 per cent of deaths occurring in low- and middle-income countries.(4)

Tobacco remains the leading contributor to the disease burden in the majority of the developed countries. According to the WHO tobacco-related health care costs between 1 per cent and 1.1 per cent of Gross Domestic Product (GDP) in many countries.(5,6)

Despite the considerable efforts made to fight smoking in the last few decades, there are still substantial number of people who, in full knowledge of the health hazards, begin smoking or continue smoking. Since 2002 many countries have implemented smoke-free policies, strengthening product regulation, restrictions on smoking in public places and in work places, which for the first time are extended to bars and restaurants.(7)

Traditionally, experimentation with and the initiation of the smoking habit were related to issues such as rebellious adolescent behaviour, a need to affirm maturity, challenging authority, imitating idols, peer group pressure (from friends or relatives who are smokers) and associating smoking with being successful from a professional, financial, or sexual point of view. More recently, other perspectives, such as the specific personality pattern typified by the search for challenges (sensation seeking behaviour) and the characteristics of neuropsychological development, also began to be considered.(8)An other important issue is that smokers are much more likely than non-smokers to use or even to abuse other psychoactive drugs. Over 90 per cent of alcoholic persons smoke, drink more coffee, or take other drugs like cannabis, cocaine, or amphetamines. The reasons that smokers have such difficulty in ceasing smoking are probably similar to those of organic dependence.(9–11)

Cigarette smoking and nicotine dependence

Approximately one-third of those individuals who experiment with cigarettes become regular smokers.(12) Once dependence develops, tobacco addiction can become a chronic relapsing disorder with direct and serious medical consequences.(13)

Nicotine dependence explains why approximately 70 per cent of smokers who want to quit smoking do not succeed. Of these, approximately one-third succeed for only 1 day and less than 10 per cent remain abstinent for 12 months.(13) The definitive cessation of smoking generally occurs only after various attempts, and the relapse rate is very high, 88 per cent.(14) The percentage of smokers in which relapse occurs is similar in almost all social classes, even when including individuals, such as health care professionals, who are more informed about tobacco-related diseases.

On the other hand, only a portion of smokers develop such dependence. Why is it that not all smokers follow the same course? This question about smoking relates to the wider one of why only some people exposed to drugs become addicted to them.(15)

Why is nicotine so addictive?

The psychoactive component of tobacco is nicotine, which has its central nervous system effects by acting as agonist at the nicotine subtype of acetylcholine receptors. About 25 per cent of the nicotine inhaled when smoking a cigarette reaches the blood, and reaches the brain in about 15 s. The half-life of nicotine is about 2 h.(13)

Nicotine is believed to have positive reinforcing and addictive properties because it activates the dopaminergic pathway projecting from the ventral tegmental area to the cerebral cortex and the limbic system, the system that is affected by cocaine and amphetamine. In addition to activating the reward system, nicotine causes an increase in the concentrations of circulating norepinephrine and epinephrine, and increased release of vasopressin, β-endorphin, adrenocorticothropine, and cortisol.(16)

The development of dependence is enhanced by strong social factors that encourage smoking in some settings.(17)

Other central effects

The stimulatory effects of nicotine result in improved attention, learning, reaction time, and problem-solving ability. Nicotine also decreases psychological tension and lessens depressive feelings.

The effects of nicotine in the cerebral blood flow (CBF) have been studied and results suggest that short-term nicotine exposure increases the CBF without changing cerebral oxygen metabolism but that long-term nicotine exposure is associated with decrease in the CBF.(18)

Genetic issues

Epidemiological studies have shown that the genetic component can play a significant role in the smoking habit, being responsible for 40 per cent to 60 per cent of the variability in the risk of addiction.(19,20) The first studies relating genetics to smoking date from 1958(21) when it was suggested that there were genes that, in

youth, predispose individuals to become smokers and, later, to present with lung cancer.[21]

Many twin concordance studies have indicated that genetic inheritance plays a role in smoking addiction.[22] Such studies have demonstrated a higher concordance rate in relation to smoking among monozygotic twins than among dizygotic twins, whether raised together or separately.[23,24] More recent studies with larger study samples, a better classification of phenotypes, and more sophisticated statistical models, point to a rather significant influence of the genome in determining the smoking phenotype.[25]

The most extensively studied genes of the dopaminergic pathway are those that regulate the flow of dopamine in the central nervous system. Five different dopamine receptors are known, and the genes that encode them have been cloned (DRD1, DRD2, DRD3, DRD4, and DRD5). Among those, the DRD2 receptor has been studied most widely, because of its association with other addictive behaviours, and because nicotine has a dopamine-releasing effect.[26–28]

Smoking in psychiatric patients

Nicotine has been said to provide anxiety relief, oral gratification, and self-medication of psychotic symptoms in psychiatric patients.[29] Patients with schizophrenia and severe mental illness smoke cigarettes at rates that well exceed the general population.[30] Little is known about the correlates and sequels of increased smoking severity on persons with severe mental illness. Greater smoking severity has however been associated with greater perceived stress, poorer overall subjective quality of life, and lower satisfaction with finances, health, leisure activities, and social relationships, results that may lend support to a self-medication hypothesis.[31]

Nicotine intoxication and withdrawal symptoms

The primary addictive substance in cigarette smoking is nicotine. Cigarette smoking is very efficient nicotine delivery system because nicotine is nebulized and subsequently absorbed through the extensive pulmonary lung vessels. Consequently, smoking produces high arterial nicotine concentrations.[12] These high arterial concentrations, higher than venous concentrations, deliver a bolus of 1–3 mg of nicotine rapidly to the brain, a few seconds after smoking. With nicotine receptor activation, neurotransmitters are released including dopamine, norepinephrine, serotonin, and endogenous opioids. The immediate positive reinforcing effects of smoking include a reduction in anxiety and increased alertness and concentration.[32]

Nicotine's half-life is 2 h; therefore, repeated administration is needed through the day to maintain its effects. Consequently smokers usually smoke at frequent intervals to maintain narrow range of nicotine concentration in the blood. Paradoxically, chronic administration of nicotine results in an increase in the number of nicotine receptors. This paradoxical effect is probably due to a chronic nicotine receptor desensitization and inactivation. An increased number of receptors may play a role in the withdrawal symptoms that many smokers experience with prolonged cigarette abstinence.[33]

Nicotine is a highly toxic chemical; doses of 60 mg in adults are fatal secondary to respiratory paralysis (an average cigarette has an average dose of 0.5 mg). At low doses, symptoms of toxicity are nausea, vomiting, salivation, pallor due to peripheral vasoconstriction, weakness, abdominal pain, diarrhoea, dizziness, headache, increased blood pressure, tachycardia, tremor, and cold sweats. Toxicity is also associated with inability to concentrate, confusion, and sensory disturbances. During pregnancy, smoking is associated with an increased incidence of low-weight-birth babies.[32]

DSM-IV does not have a diagnostic category for nicotine intoxication; however, it has a category for nicotine withdrawal.[34] ICD-10 does have a category for nicotine intoxication (F17.0, mental and behavioural disorders due to use of tobacco, acute intoxication).[35] Withdrawal symptoms can develop within 2 h after having smoked the last cigarette. Withdrawal symptoms include dysphoria and depressed mood, insomnia, irritability, anxiety, frustration, difficulty in concentration and increase in appetite, and weight gain. Withdrawal symptoms peak within 24–36 h after cessation and usually diminish after 1 week of abstinence but can last for much longer. Some individuals continue smoking to avoid the negative symptoms of withdrawal.[36,37]

Nicotine dependence

The cumulative findings of more than 2500 scientific papers were summarized in the *1988 Surgeons General's Report on the Health Consequences of Smoking: Nicotine Addiction*.[38] Nicotine has a pronounced effect on the major stress hormones, and the dose-related effects of nicotine on neuroendocrine responses appear to constitute a critical component of its pharmacological action. Hypothalamic corticotrophin-releasing factor (CRF) is stimulated by nicotine, and levels of hypophyseal hormones including ACTH and arginine-vasopressin are increased in a dose-related manner. At higher doses, growth hormone (GH) and prolactin are entrained, and corticosteroid levels are related to plasma nicotine levels.[15,39,40]

Treatment for tobacco dependence

Many of the adverse health effects of smoking are reversible, and smoking cessation treatments represent some of the most cost-effective of all health care interventions. Although the greatest benefit accrues from ceasing smoking when young, even quitting in middle age avoids much of the excess health care risk associated with smoking.[41–43]

In order to improve smoking cessation rates, effective behavioural and pharmacological treatments, coupled with professional counselling and advice, are required. Since smoking duration is the principal risk factor for smoking-related morbidity, the treatment goal should be early cessation and prevention of relapse.[44,45]

The health benefits are various: smoking cessation has a major and immediate health benefit for persons with or without smoking-related diseases; former smokers live longer than those who continue to smoke; smoking cessation decreases the risk of lung cancer, myocardial infarction, cerebrovascular diseases, and chronic lung diseases.[46]

Non-pharmacological treatment

Physician counselling and pharmacotherapeutic interventions for smoking cessation are among the most cost-effective clinical interventions. Several strategies can be used for smoking cessation, counselling differs according to the patient's readiness to quit. For smokers who do not intend to quit smoking, physicians should

inform and sensitize them about tobacco use and cessation. For smokers ready to quit, the physician should show strong support, help set a quit date, prescribe pharmaceutical therapies for nicotine dependence, if needed.[47,48]

There is insufficient information to know which elements of behavioural support are effective or whether one approach, such as motivational interviewing or cognitive behavioural therapy, is more effective than another. There is some evidence to suggest that group support may be more effective in general than one-to-one support[49] and that it should involve multiple sessions.[50] There is also evidence that such sessions can be effective even if conducted over the telephone.[51]

Of the many web-based support packages available on the Internet, only two have been evaluated in randomized controlled trials,[52,53] these trials of tailored programmes enrolled smokers who were using nicotine replacement. Both trials showed significant benefits 10–12 weeks after the quit date.

There are a few adequate studies examining complementary therapies in smoking cessation. Meta-analysis of trials of acupuncture and hypnotherapy showed no benefit but could not exclude small effects.[54,55]

Nicotine replacement therapies

Nicotine replacement therapies (NRTs) were designed in order to enhance efficacy rates during smoking cessation by replacing some of the nicotine usually delivered by smoking. All replacement therapies have shown to have high rates of efficacy. The choice of NRT depends on patient's preference, side effects, presence of concomitant medical conditions, and a history of previous success or failure.[56,57]

(a) Nicotine gum and nicotine lozenge

Nicotine gum was the first NRT marketed for smoking cessation, contains nicotine bound to an iron resin. The nicotine is slowly released into the mouth and is absorbed through the mucosa of the mouth, only 50 per cent of the nicotine in a piece of gum is systemically absorbed and concentrations reach a maximum peak in 30 min after onset of chewing.[12] The staring dose for individuals who smoke 20 cigarettes a day should be 2 mg. The gum should not be prescribed in patients with temporo-mandibular joint disease and those with dental or oral problems. The nicotine lozenge contains nicotine bound to a prolacrilex ion-exchange resin, does not require chewing and therefore is preferable to the gum for patients with dental problems.[58]

(b) Transdermal nicotine

Transdermal nicotine, commonly known as the nicotine patch, produces a constant delivery of nicotine that is very useful for patients with poor treatment adherence. Eight weeks of treatment are generally sufficient for smoking cessation.[59]

Transdermal nicotine is available in a variety of formulations and dosing schedules (i.e. 15 mg/16 h; 7, 14, 21 mg/24 h). Peak nicotine concentrations for the various systems are reached 2–6 h after application and steady state conditions occur 2–3 days after continued patch use.[59]

(c) Nicotine nasal spray and inhaler

Nicotine nasal spray delivers nicotine through the nasal mucosa. One advantage is that it relieves tobacco cravings quickly. It is available only by prescription. One spray to each nostril constitutes a dose, approximately 1 mg nicotine. Patients should use one or two doses per hour; the nasal spray delivers nicotine rapidly, with venous nicotine peaking at 5–10 min after administration.[60] Side effects include some initial irritation of the nasal mucosa should be avoided in patients with rhinitis, nasal polyps, or sinusitis.

Nicotine vapour inhaler is used by puffing through a cartridge inhaler, and may be useful for smoking cessation in some patients because its use is similar to the smoking ritual, and it delivers nicotine rapidly. It is only available by prescription. The recommended treatment period is up to 24 weeks.[45]

Pharmacological treatments

Considering that not all smokers respond well to nicotine replacement therapies and some smokers have comorbid symptoms there has been considerable interest in non-nicotine medications to treat nicotine dependence. The observations that some antidepressant-like bupropion and other selective serotonin-reuptake inhibitors (SSRIs) are useful as a treatment for smoking cessation, led to intensive research to study dopamine, serotonin, norepinephrine, glutamate, gamma-aminobutyric acid (GABA), nicotine, cannabinoid, and opiod receptors.[61,62]

Sustained-released bupropion

The sustained-released bupropion is currently considered as a first-line treatment for cigarette smokers. The mechanism of action of this antidepressant in the treatment of nicotine dependence likely involves blockade of dopamine and norepinephrine reuptake as well as antagonism of high-affinity nicotine acetylcholine receptors.[63]

The goals of bupropion therapy for nicotine dependence are (1) cessation of smoking behaviour and (2) reduction of nicotine withdrawal symptoms. In addition, bupropion SR may delay cessation-induced weight gain.[64]

A study by Hurt *et al.*[65] established the efficacy and safety of bupropion SR for treatment of nicotine dependence, and led to its approval for this indication by the FDA in 1998. Bupropion treatment also reduces weight gain associated with smoking cessation and significantly reduced nicotine withdrawal symptoms at a dose of 150–300 mg/day. Major side effects are headache, dry mouth, nausea, vomiting, and insomnia.[65]

Nortrityline

This tricycle antidepressant appears to have efficacy rates similar to bupropion in smoking cessation.[66] The mechanism of action is thought to be related to its noradrenergic and serotoninergic reuptake blockade. Side effects are those of the typical tricyclic antidepressants and include dry mouth, blurred vision, constipation, and orthostatic hypotension. Nortryptiline has been recommended as a second-line treatment.[61,67]

Clonidine

Because clonidine appears to have some efficacy for alcohol and opioid withdrawal, it has been evaluated for the treatment of nicotine withdrawal. However, it has not proved to be as effective as other therapies. Several clinical trials used oral or transdermal clonidine in doses of 0.1–0.4 mg/day for 2–6 weeks with or without behaviour therapy. Most common side effects of clonidine are dry mouth, sedation, and constipation, postural hypotension, and depression.[61]

Selective serotonin reuptake inhibitors

The available evidence provides little support for the use of SSRIs to assist in smoking cessation, either alone or in combination with other therapies. Placebo-controlled trials of fluoxetine or paroxetine failed to show an increase in smoking cessation.[61]

Varenicline

Varenicline is a selective alpha (4) beta (2) nicotinic acetylcholine receptor partial agonist and the first non-nicotine-containing medication developed with the sole purpose of treating nicotine addiction.[68]

Varenicline seems to be more efficacious than bupropion 24 weeks after randomization to a 12-week treatment course and 1 year after randomization in an identical trial. There are no contraindications except hypersensitivity and the drug is generally well tolerated. Varenicline, which is recently approved for smoking cessation, offers an option to patients who cannot tolerate the adverse effects associated with nicotine-replacement therapy and bupropion. It is also an alternative to consider for patients with contraindications to such therapies. Varenicline is completely absorbed orally and not affected by food. Steady state is reached within 4 days of administration.[69,70]

Other pharmacological treatments

Several new therapies are emerging as possible treatment options for smoking cessation. Rimonabant, a selective cannabinoid antagonist, blocks dopamine release in the nucleus accumbens, a primary reward centre for the brain. Studies have found that Rimonabant may not only be effective as a smoking cessation aid but may also assist in the maintenance of nicotine abstinence. Rimonabant has also demonstrated a weight-loss benefit, which may be attractive to smokers concerned with weight gain associated with smoking cessation.[71–73]

Three nicotine vaccines are currently in development, each acting to sequester nicotine from the bloodstream, thereby preventing its penetration of the central nervous system. Ongoing studies will evaluate their use as established therapies for smoking cessation.[74,75]

Conclusions

Despite the reality that smoking remains the most important preventable cause of death and disability, most clinicians underperform in helping smokers quit. Nearly 70 per cent of smokers want to quit, and 42.5 per cent attempt to quit each year. The most effective smoking cessation programmes involve a combination of pharmacotherapy and behavioural and/or cognitive counselling to improve abstinence rates. Ways to counter clinicians' pessimism about cessation include the knowledge that most smokers require multiple attempts before they succeed in quitting.

4.2.4 Assessing need and organizing services for drug misuse problems

John Marsden, Colin Bradbury, and John Strang*

Introduction

In the present decade, there has been substantial investment in drug misuse treatment thereby expanding the workforce, the capacity of the treatment system and leading to reduced waiting times and better integration of local services. In 2006–07, an in-treatment population of approximately 200 000 individuals were recorded by the National Drug Treatment Monitoring System (NDTMS). Capture-recapture estimates suggest that there are approximately 327 000 users of opioids and/or crack cocaine.

About two-thirds of adults entering drug misuse treatment services are dependent on illicit heroin—a clinical presentation complicated by between 20 per cent to 50 per cent of admissions by concurrent dependence on cocaine and other substances such as the misuse of pharmaceutical medications (such as benzodiazepines). Cannabis is reported as the main problem drug for younger patients under 18 years of age. Overall, treatment services for clients of all ages are able to assess and provide interventions across all illicit drugs including amphetamine-type stimulants, sedative/hypnotics, cannabis, hallucinogens and volatile substances (solvents and inhalants). Hazardous and harmful alcohol use characterizes a significant, but priority group of drug misuse treatment seekers.

In 2006, a revised national drug misuse treatment effectiveness strategy stressed the need for better local partnerships to commission and organize local services and promote reintegration of treated patients into the community. A core component of the strategy was the creation of Criminal Justice Integrated Teams (CJITS) who were given the role of treatment case coordination for individuals involved in the justice system with identified drug misuse. Nevertheless, improvements to the reach, operation, and effectiveness of treatments remains a priority—particularly tackling high-risk behaviours linked to the acquisition and transmission of blood-borne infections and ensuring that all service users receive good quality assessment and care coordination.

Local coordination of treatment

Drug Action Teams (DATs) were originally set up in 1995 under a Government white paper on drug misuse. The purpose of the DAT was to co-ordinate the activity and spend of local statutary commissioning agencies who have an interest in reducing the harm caused by illicit drug use to individuals, their families, and the community. DATs and their membership typically consists of senior commissioning representatives from local Police, Health, Local Authority and Probation services. Increasingly, the Prison Service are represented following the announcement of a new Integrated Drug Treatment System for prisoners which seeks to ensure that the same appropriate and evidenced drug treatment interventions are available to individuals regardless of whether they are in prison or in the community. Under the Police Reform Act (2002), the process of combining the activity of DATs with their equivalent bodies for crime (Crime and Disorder Reduction Partnerships (CDRPs) was started. Local areas organize their activity in differing ways, but the concept of co-ordination of action between the DAT and CDRP is now universal.

DATs are charged with consulting with and involving local communities, stakeholders, treatment providers, and crucially—users and carers—in the development of their local commissioning strategies. DATs are allocated a hypothecated fund for improving capacity and quality of drug treatment services for their residents. This Pooled Treatment Budget is typically banked by a partner agency (usually the PCT) but is intended to be commissioned jointly (along with mainstream monies that partner agencies allocate for drug treatment) via the DAT Partnership structure. DAT Partnerships typically have a sub-group know as the Joint Commissioning Group (JCG) which seeks to operationalize the DAT's agreed strategy for the locality.

The National Treatment Agency for Substance Misuse (NTA) is a Special Health Authority set up in 2001 to oversee and performance manage the commissioning of effective drug treatment.

* The views expressed in this chapter are those of the authors and do not necessarily reflect the views of the National Treatment Agency. The commissioning, performance management and planning of drug treatment varies significantly across the United Kingdom. Unless stipulated to the contrary, the following text applies specifically to England.

DAT Partnerships submit a treatment plan on an annual basis which is signed off by the NTA and other regional partners and performance monitored on a quarterly basis. Since 2005–06, the NTA has issued guidance on conducting a Needs Assessment for the local population and increasingly assessment of need is being seen as the centrepiece of DAT Partnership commissioning activity. DAT Partnerships are encouraged to set up expert groups which (in combination with available local data sources of prevalence and treatment) should be used to carefully consider available information and intelligence in order to inform the local Joint Commissioning Group of assessed levels of unmet need, therefore enabling them to set and update commissioning priorities on a cyclical basis.

Types of treatment

In the UK, treatment for substance use disorders vary on several core dimensions, as follows: (a) setting (outpatient/community or inpatient/residential), modality (pharmacological or behavioural); (b) content (e.g. cognitive behavioural therapy, motivational approaches, contingency management; couples therapy); (c) goals (harm reduction, partial or complete abstinence); (d) intensity (brief interventions or intensive therapeutic contact); (e) extent of external contingency (e.g. self-referral or criminal justice mandate); and (f) type of provider (NHS, non-governmental organiztion and private/commercial). In 2002, the NTA promulgated a national service framework for drug misuse services and updated this four years later. The framework uses a practical framework to aid rational and evidence-based commissioning of drug treatment in England with services for drug misusers grouped into four broad bands, or tiers.

Tier 1 interventions

This first tier involves the provision of information, advice, screening and referral to drug users by generic medical and social care services (e.g. Accident and Emergency Departments, community retail pharmacies). It includes liaison and partnership working with specialist drug treatment services to provide specific interventions (e.g. treatment of patients with health problems caused by Hepatitis C infection).

Tier 1 services for adults are not structured drug or alcohol treatment, but can be part of the local substance misuse treatment system. These services work with a wide range of clients including drug and alcohol misusers, but their sole purpose is not drug or alcohol treatment. Tier 1 services comprise a range of interventions which are not drug-specific, but offer a variety of generic health and social care interventions. In this context, the role of Tier 1 includes the provision of their own services plus, as a minimum, screening drug misusers and referral to local drug and alcohol treatment services in Tiers 2 and 3. Tier 1 provision for drug and alcohol misusers may also include assessment, services to reduce drug-related harm, and liaison or joint working with Tiers 2 and 3 specialist drug and alcohol treatment services. Tier 1 services are crucial to providing services in conjunction with more specialized drug and alcohol services (e.g. general medical care for drug misusers in community-based or residential substance misuse treatment, or housing support and aftercare for drug misusers leaving residential care or prison).

Tier 2 interventions

The second tier describes interventions involving specific drug-related information and advice to help drug users reduce or avoid hazardous and harmful patterns of use or attain and maintain abstain harm. Services are delivered from dedicated community locations as well as outreach and may also include brief, structured psychosocial interventions, various harm minimization interventions (including syringe and needle exchange) and aftercare support. Tier 2 services may also provide triage assessment and linked referral to structured drug treatment and in this respect may operated independently or in the same setting as a Tier 3 intervention team. Tier 2 interventions for adults provide accessible drug and alcohol specialist services for a wide range of drug and alcohol misusers referred from a variety of sources, including self-referrals. This tier is defined by its low threshold to access services, and limited requirements on drug and alcohol misusers to receive services. Often drug and alcohol misusers will access drug or alcohol services through Tier 2 and progress to higher tiers. Tier 2 interventions include advice and information, drop-in services, needle exchange and motivational interviewing.

Tier 3 interventions

In terms of the volumes of people receiving treatment, this tier is at the centre of the system. It includes specialized care-planned pharmacotherapy (opioid agonist and antagonist and adjunctive medication prescribing to treat dependence) and a broad array of psychosocial interventions delivered by combined or separate teams in the community and primary care. There is an emphasis on high-quality assessment, care planning, liaison and review and regular contact with a clinical keyworker and other team members. The frequency of scheduled contact varies widely across Tier 3 services but is particularly indented to be intensive among users attending 'structured day programmes'. Tier 3 interventions for adults are provided solely for drug and alcohol misusers in structured programmes of care. Tier 3 structured services include psychotherapeutic interventions and structured counselling (e.g. cognitive behavioural therapy, motivational interventions), methadone maintenance programmes, community detoxification, or day care provided either as a drug- and alcohol-free programme or as an adjunct to methadone treatment. Community-based aftercare programmes for drug and alcohol misusers leaving residential rehabilitation or prison are also included in Tier 3 interventions. There is interest in developing behaviour therapies to treatment drug dependence on contingency management. Psychoactive substances can exert unconditioned reinforcing effects and repeated administration produce several conditioned responses. For example, voucher-based reinforcement therapy uses vouchers of increasing value for goods and services with various bonus incentives to subjects who can provide drug-free urine tests. The National Institute for Health and Clinical Excellence (NICE) has produced guidelines for the effective delivery of various psychosocial treatment interventions tailored to the needs of drug misusers, including brief motivational interventions, contingency management and behavioural couples therapy.

Tier 4 interventions

The fourth tier of the treatment system denotes specialist inpatient (and general ward) inpatient services providing stabilization and

medically supervised withdrawal (detoxification), residential rehabilitation programmes (providing psychosocial and practical, vocational supports designed to maintain abstinence and promote long-term recovery) and a range of halfway houses and supportive accommodation. Some inpatient and residential programmes are directly linked. These services vary in duration from brief (<10 days), short-term (<3 months) and long-term (>3 months). Tier 4 services are highly structured interventions underpinned by assessments and close monitoring of clinical progress. Rehabilitation programmes have been pioneered and then sustained chiefly in the voluntary sector. Some adhere to or have adopted a therapeutic philosophy (e.g. 12-Step based on the Minnesota Model of addiction recovery developed in the USA) or therapeutic community model, while others operate as 'general houses'—which seek to foster responsible communal living and community reintegration. Tier 4 substance misuse interventions for adults are aimed at individuals with a high level of presenting need and usually require a higher level of commitment from drug and alcohol misusers than is required for services in lower tiers. Tier 4 services are rarely accessed directly by clients. Referral is usually from Tiers 2 or 3 services or via community care assessment.

NICE has produced guidelines for the delivery of psychosocial interventions in residential rehabilitation services and also for the organization and delivery of opioid detoxification services.

Commissioning treatment services

The national drugs strategy requires Crime and Drug Partnerships to commission services (or ensure access to) structured treatment (Tiers 3 and 4). The balance of l*f*ocal drug misuse treatment services and their detailed delivery mechanisms should be tailored to fit the needs of the local population; commissioners are encouraged to think systemically rather than focusing on putting in place individual services. Poorly defined care pathways between services and the lack of a joined-up care planned approach is clearly an unsatisfactory situation. Many individuals may require the provision of several different types of treatment service over time. It is quite common for an individual receiving treatment from one provider to receive additional welfare support and other social inclusion services which are provided by other agencies (e.g. housing support, legal advice). These supports are important elements in an effective package of care services that can evolve over the course of an individual's treatment. Together, the four tiers are meant to imply a continuum of care. Generic service providers and state agencies can refer an individual both up and down the four tiers to access appropriate treatment or support services.

Needs assessment

In the following section, we use an epidemiologically-based conceptualization of population treatment needs to discuss the organization of treatment services and methods for assessing need. Needs assessment occupies an importance place in the evidence-based planning process for the design and delivery of substance misuse services. It is the systematic collection of information about a geographically defined population and then applying this to make changes that will be beneficial to health. In the drug misuse field, there is a specific focus on two groups in the community: (a) those that are not in contact with services and treatment agencies and have unmet need; (b) those in contact with inefficient, ineffective or inappropriate health care services who have unmet need or for whom outcomes could be improved. Good needs assessment practice involves the application of epidemiological (and sometimes spatial geographical) techniques to estimate the number of people in the two groups above, clear understanding of the costs and benefits of interventions, a close collaboration with clinical services and the range of community stakeholders, and a planning and evaluation process to effect change. There is active encouragement for drug misuse partnerships and commissioners to undertake comprehensive needs assessments in the area of drug misuse with a specific target to assess the needs of young people. However, there have been few systematic quantitative and qualitative studies conducted in the drug misuse field in the UK. In fact, most studies in the mental health service field have been mainly or exclusively qualitative, relying on focus group discussion material. Multiple indicator methods and capture-recapture techniques have enabled estimates to be derived of the number of problem drug users in local areas.

Target groups

At the level of the individual patient, several headline factors may be influential in the assessment and treatment planning process: age, gender, race, and culture; pregnancy; familial pattern; quantity, frequency, and route of administration of psychoactive substances used; acute intoxication (overdose liability); extent of impairment and complications; social and occupational environmental supports and stressors—including acute housing need, training, and education. Complex cases will usually (but not always) be characterized by drug-related impairment, dependence, regular injecting, high tolerance levels and co-morbid problems across physical, psychological and personal/social functioning domains. At the population level, we identify six, non-independent groups. The prevalence of these groups and their case-mix at the local level will have ramifications for the assessment of health care needs and the planning, commissioning, delivery and monitoring of treatment services.

(a) Non-dependent, hazardous substance users

This group comprises individuals who are experiencing drug-related problems but they do not meet the criteria for dependence. This group may include large numbers of younger users who have begun to use drugs relatively recently. Because members of this group (both adults and particularly young people) are at risk of advancing their drug involvement to more serious levels they may be ideal clients for early intervention services.

(b) Drug injectors

This group comprises individuals who are injecting drugs and who may be at risk of acquiring and transmitting blood borne diseases. Community surveys suggest that less than 1:3 drug injectors share needles and syringes but 1:2 share injecting equipment (filters, spoons and flushing water). Research Individuals who inject drugs are much more likely to be dependent and experience drug-related harms. They constitute a priority group to be attracted to appropriate harm reduction and structured treatment programmes and retained in treatment as appropriate.

(c) Acutely intoxicated drug users

The specific needs of this group are identified because of the morbidity and mortality risks to health due to adverse reactions and drug overdose. This sub-group may overlap with sub-group B

(the IDU). There is evidence that some two-thirds of heroin users have experienced an overdose. Risk of overdose is increased for opiates users who have also consumed other central nervous system depressants—commonly other opiates, alcohol and benzodiazepines. Preventing drug overdose and overdose mortality is a specific priority area. Acute intoxication is a discrete event although an individual's needs may advance to those associated with dependence, co-morbidity and withdrawal management and support. Most services provided to the intoxicated drug user will be found outside specialist drug or mental health services (e.g. accident and emergency departments, police custody). All services, which have contact with opiate users, should have prompt access to the injectable opiate antagonist naloxone which may be administered intravenously, intramuscularly or subcutaneously and can be life-saving in the event of an opiate overdose. There is now widespread recognition of the problem of drug dependence among the prison population and evidence from database linkage studies showing that newly released prisoners are at substantial risk of fatal overdose. In a study of 48 771 male and female sentenced prisoners in England and Wales released during 1998–2000, there were 442 recorded deaths (59 per cent drug-related) in year following release. There were 342 observed male deaths (45.8 expected in the general population) and 100 observed female deaths (8.3 expected). Drug-related male deaths were relatively more likely to involve heroin and female deaths were relatively more likely to involve benzodiazepines, cocaine and tricyclic antidepressants.

(d) Dependent drug users

This group comprise individuals who have drug-related problems and meet ICD/DSM dependence criteria. Dependence ranges in severity and is characterized by substantial impairment in the ability to control the frequency and amount used and various neuro-adaptational aspects. The majority of people presenting to specialist drug misuse services are in this group. They will require carefully planned community (and often residential treatment) together with the offer of aftercare support and access to social inclusion services to assist problems with housing, employment and training.

(e) Drug users with psychiatric co-morbidity

There is widespread concern about improving services and outcomes for people who have co-morbid psychiatric and substance use disorders. There is currently no research and clinical evidence-base for the effective management and care of patients in psychiatric inpatient units with psychoactive substance misuse co-morbidity and this is an important development area. There is some evidence that people with substance use problems and co-morbid psychiatric disorders appear to have a relatively high contact with medical services and may require more intensive treatment. However, it would appear that substance use disorders amongst people admitted for psychiatric treatment are of a less severe nature than those entering treatment for primary substance use problems. It is also important to consider and plan for the possibility that people with drug misuse and severe mental illness will not respond well or comply with traditional care plans and arrangements. In terms of client attributes, the presence of psychiatric co-morbidity in drug users entering treatment has been linked to poorer outcomes. Pre-treatment psychiatric severity has been found to be predictive of outcome and this should be taken into account when selecting appropriate treatments. The importance of providing social inclusion and reintegration services, particularly in the first three months of treatment has been advocated for community-based treatment services. However, the intensity or comprehensiveness of services *per se* is not consistently associated with improved outcome. The matrix of client attributes and treatment factors and processes has important implications for referral, assessment and client treatment-placement activities.

(f) Drug users in recovery

This group denotes individuals who have achieved a state of abstinence from their main problem drug (or all drugs), usually through successful completion of a health care treatment episode. This group may require residential rehabilitation services or community based aftercare programmes and other supports.

The process and techniques of needs assessment

Service commissioners should follow a sequence of steps to inform the needs assessment for their population requirements. The overarching goal is to produce a strategic commissioning framework which can be agreed across the health, social, and criminal justice partners. This remains an evolving area with guidance available from the NTA to assist the commissioning and implementation of work in this area. The usual steps when conducting a needs assessment are as follows:

- Allocation of resources and establishment of an agreed plan/methods.
- Prevalence estimation of target population and identification and profiling of sub-groups.
- Mapping of treatment services provided in the locality and an audit of treatment commissioning purchasing from services located outside the geographical boundary of the drug misuse partnership (e.g. Social Services purchasing of residential rehabilitation) to determine the extent to which demand is being met elsewhere.
- Audit of the demand profile of treatment services (capacity; number of episodes; estimated number in need).
- Personal interviews with key informants across commissioning, provision and advocacy sectors.
- Focus group discussions with key stakeholders (commissioners, clinicians, treatment providers, service users, carers of service users) to explore what they want from services.
- A 'gaps' analysis of current and desired profile of service provision (often qualitative exercise involving estimation of desired range of services to increase coverage for specific special groups).
- Recommendations for increasing treatment coverage, purchasing efficiency, and service effectiveness based on available evidence.
- Assessment of reactions to recommendations from strategists, commissioners, purchasers, services providers, and service users.
- Development of an implementation plan based on the identification of activities, resources, and timetables.

People in the seven sub-groups summarized above are not all the same and it is necessary to characterize each group on the basis of

the severity of their problems (and extent of any complications). It is important to note that the above sub-categories are not mutually exclusive. Indeed, it is likely that an individual patient will occupy more than one category at any particular point in time (e.g. the injecting dependent heroin user with co-morbidity of HBV infection). The multiple occupation of different categories may also vary over time. In addition to these six primary groups, there is a further category which can be labelled 'at risk'. There is particular concern about segments of the younger population (see below) thought to be at risk; prevention initiatives and general educational programmes are Drug misuse services and treatment modalities.

The appraisal of the healthcare needs of the target populations and commissioning of strategic service responses should be flexible and adaptive to changing circumstances in each locality, including: variations and new trends in drugs use and consumption patterns; the geographical distribution and concentration of drug use; variations in demand for services; the changing relationship between drug use and other conditions (notably HIV infection, and blood borne viral hepatitis); changes in the organization of health services and monitoring the evidence-base for current and new treatment services.

Needs assessment activities are potentially costly activities. Intensive surveys of the resident population in most areas will be time consuming and expensive. It is quite likely that most partnerships will employ alternative (and less precise) estimation methods with which to inform the direction and success of commissioning strategies. A qualitative approach to needs assessment can be undertaken relatively quickly and can answer important questions concerning what commissioners, purchasers, service providers and service users want from treatment services and supports. Service user satisfaction surveys may be a useful means of gathering information about the extent to which a programme is perceived to have met an individual's treatment wants and needs. A range of issues has been examined including the accessibility, adequacy, content, and impact of services received. In addition to serving a simple monitoring function for treatment service providers and their commissioners, treatment satisfaction is argued to be a valuable indicator of treatment experience. Treatment satisfaction can act as a moderator of treatment outcome, since it is reasonable to assume that less satisfied clients may leave treatment prematurely or have different responses to interventions. Both users and carers should be routinely involved and consulted on service development and the setting of commissioning activities. Many DAT Partnerships (and the services they commission) now have good user/carer involvement mechanisms and guidance exists to enable the development of these mechanisms where they are still lacking.

Monitoring the impact of interventions

Drug interventions are from identical in their structure and operation, and outcome studies show that their level of effectiveness varies widely. Many service providers have been interested in monitoring their own outcomes reflecting organizational learning and quality values. The National Treatment Agency has now further developed the NDTMS as a national outcomes monitoring system. There are several benefits from collecting assessment and outcome information. Firstly, many patients perceive that a structured approach to assessment and recording outcome is a reflection of a service that is committed to providing the best care.

The feedback of information describing during-treatment changes to the patient (and his/her spouse/partner or carers) by clinical staff can be a powerful motivational influence to reinforce progress and assist in personal treatment goal setting. Secondly, clinical staff can monitor the characteristics and outcomes of their caseloads and identify areas of priority work. Thirdly, service managers can aggregate information across staff as an indicator of how well the agency is serving its patients. Fourthly, information on samples of cases of aggregate summaries across services can be provided to funding bodies and other government agencies to show the overall impact of treatment provision for a particular area.

In 2007, the NTA launched a national outcome monitoring system for substance misuse treatment services. A brief, outcome monitoring instrument—the Treatment Outcomes Profile (TOP) has been validated for this purpose. The TOP contains 30 items in four domains and is shown in Table 4.2.4.1. From these, a subset of 20 items are compiled at a national level to assess the overall effectiveness of the treatment system.

Case mix and performance analysis

Prognostic models of treatment outcome have been developed in our health care arenas with some success but the approach is in its infancy in the substance use disorders field. Essentially, a set of variables which predict a health or other outcome are identified using a statistical technique. Various methods can then be used to rank individual treatment provider's outcome performance can then be ranked against this averaged outcome. Having adjusted for

Table 4.2.4.1 The Treatment Outcomes Profile (TOP)

Domain/section	Item—in past 28 days
Substance use	Number of days used the following substances alcohol; opiates; cocaine; crack cocaine; amphetamines; cannabis; other (named) Typical quantity consumed on typical day (recorded as units, grams or amount spent) Number of days injected drugs in past 28 days Whether shared needles and syringes (direct receptive sharing); Yes/No Whether injected using a spoon, water or filter used by someone else (indirect receptive sharing; yes/no)
Crime	Days committed shop theft; days sold drugs Whether committed theft from or of vehicle (yes/no) Whether committed other property theft (yes/no) Whether committed fraud, forgery handling stolen goods (yes/no) Whether committed assault or violence (yes/no)
Health and social functioning	Had acute housing need (yes/no) Was at risk of eviction (yes/no) Number of days had paid work in past 28 days Number of days attended college or school in past 28 days Subjective rating of physical health (0 [poor] to 20 [good]) Subjective rating of psychological health (0 [poor] to 20 [good]) Subjective rating of quality of life (0 [poor] to 20 [good])

patient case mix differences, the objective is then to isolate the characteristics of very successful service providers as well as the correlates of less successful delivery of care. The results of this process can then be used to guide the development of the local treatment system.

4.3

Schizophrenia and acute transient psychotic disorders

Contents

4.3.1 Schizophrenia: a conceptual history

Nancy C. Andreasen

We know that psychotic disorders have been present and publicly recognized at least since classical times because of their portrayals in literature: the madness of Medea, the frenzied behaviour in *The Bacchae*, or the paranoia of Othello. Perhaps the most 'valid' portrayal from a modern clinical perspective is the feigned madness of 'Poor Tom' in King Lear. Poor Tom is a 'bedlam beggar' who encounters Lear during the great scenes of madness, portrayed while the world itself is also in the midst of a terrible storm. Tom's speech is a classical example of schizophrenic thought disorder, but he also experiences delusions and visual hallucinations:

> Who gives anything to poor Tom? Whom the foul fiend hath led through fire and through flame, and through ford and whirlpool, o'er bog and quagmire, that hast laid knives under his pillow, and halters in his pew; set ratsbane by his porridge; made him proud of heart, to ride on a bay trotting-horse over four-inch'd bridges, to course his own shadow for a traitor. Bless thy five wits! Tom's a-cold, –O, do de, do de, do de. Bless thee from whirlwinds, star-blasting, and taking! Do poor Tom some charity, whom the foul fiend vexes. There could I have him now, –and there, –and there again, and there. (*King Lear*, III. iv. 51–60)

However, the definition and delineation of schizophrenia as a discrete disorder is a relatively recent phenomenon.

The founding fathers of the concept: Kraepelin and Bleuler

The earliest academic formulations of the concept of schizophrenia occurred in the mid-nineteenth century in the work of Bénédict-Auguste Morel and Karl Kahlbaum.[1] Morel coined the term 'démence precoce' to refer to a disorder that he observed in young people that was characterized by cognitive impairments and progressive degeneration. He did not develop the concept fully, however. Instead, under the influence of Darwinian thinking, he became preoccupied with the general concept of hereditary

degeneration, which he described in disorders ranging from intellectual disability to alcoholism. This general concept was highly influential throughout the nineteenth and early twentieth century, which led to some of the earliest studies of the familiality of mental illnesses, and laid early foundations for later efforts to examine the role of genetic factors in schizophrenia. Kahlbaum's seminal contribution was an emphasis on using course of illness (as opposed to symptoms) to define discrete disorders. He objected to the concept that there was only one form of severe mental illness ('unitary psychosis' or 'einheitspsychose') and argued that various kinds of psychotic disorders could be differentiated from one another based on changing patterns of symptoms and long-term outcome. Kahlbaum identified one type as 'hebephrenia'.

Our modern concept of schizophrenia primarily derives, however, from the interaction between two great clinicians early in the twentieth century: Emil Kraepelin and Eugen Bleuler.

Although his ideas were presaged by Morel and Kahlbaum, Emil Kraepelin was clearly the first to give a detailed description of this syndrome and a compelling justification for its delineation. Kraepelin highlighted his concept of the key features of the disorder in the name that he chose for it: It was an illness that tended to begin at an early age ('praecox') and to have a relatively chronic course characterized by significant cognitive and social impairment ('dementia'). Alois Alzheimer was a member of Kraepelin's department in Munich and used the tools of neuropathology to study a similar dementia that began at a later age; examination of the brains of these individuals at post-mortem revealed a characteristic neural signature—plaques and tangles. Kraepelin began to call this disorder Alzheimer's disease and thus gave it its current name, as well as its differentiation from dementia praecox. A similar neuropathological signature was sought for dementia praecox, but it was never found, although Kraepelin hypothesized that it must be a disease involving prefrontal and temporal regions[2]:

> If it should be demonstrated that the disease attacks by preference the frontal areas of the brain, the central convolutions and the temporal lobes, this distribution would in a certain measure agree with our present views about the site of the psychic mechanisms which are principally injured by the disease. (p. 219)

Kraepelin did not select any specific clinical feature as pathognomic, but he did stress the importance of several symptoms as characteristic:

> . . . there are apparently two principal groups of disorders which characterise the malady. On the one hand we observe a *weakening of those emotional activities which permanently form the mainsprings of volition*. In connection with this, mental activity and instinct for occupation become mute. The result of this part of the morbid process is emotional dullness, failure of mental activities, loss of mastery over volition, of endeavor, and of ability for independent action.
>
> The second group of disorders . . . consists in the *loss of the inner unity* of the activities of intellect, emotion, and volition in themselves and among one another … the near connection between thinking and feeling, between deliberation and emotional activity on the one hand, and practical work on the other is more or less lost. Emotions do not correspond to ideas. The patients laugh and weep without recognizable cause, without any relation to their circumstances and their experiences, smile while they narrate the tale of their attempts at suicide . . . (pp. 74–5).

Thus, for Kraepelin, what we now refer to as negative symptoms and fragmenting of thought were two key features of the disorder.

Bleuler was a near contemporary of Kraepelin. During their two long careers they maintained a dialogue between their native countries of Germany and Switzerland. Kraepelin was a thoroughgoing empiricist with a keen eye for detail, while Bleuler was primarily a high-level conceptualizer, although he clearly also had vast clinical experience. Bleuler chose to highlight fragmenting of thinking as the most fundamental feature of schizophrenia and designated it as the pathognomonic symptom. That is, he explicitly stated that this particular symptom ('loosening of associations') was present in all patients with schizophrenia and did not occur in other disorders. Because of the importance that he gave to this particular symptom, he renamed the illness after it (schizophrenia = fragmenting of mind). To this symptom, he added several others that he also considered to be of high importance. These included loss of volition, impairment in attention, ambivalence, autism, and affective blunting. He regarded these symptoms as basic or fundamental and the other symptoms observed in the disorder, such as delusions or hallucinations, as secondary or accessory. He pointed out that these accessory symptoms tended to occur in a variety of other conditions, such as manic-depressive illness, delirium, or dementia.

> Certain symptoms of schizophrenia are present in every case and in every period of the illness even though, as with every other disease symptom, they must have attained a certain degree of intensity before they can be recognized with any certainty . . . Besides the specific permanent or fundamental symptoms, we can find a host of other, more accessory manifestations such as delusions, hallucinations, or catatonic symptoms . . . As far as we know, the fundamental symptoms are characteristic of schizophrenia, while the accessory symptoms may also appear in other types of illness (p. 13).

Bleuler's conceptualization of the disorder captured the imagination of clinicians and investigators throughout the world, and the name he chose for the disorder eventually became the one that is now universally used. The prophecy of Kraepelin's tombstone came true: 'though his name will be forgotten, his work will live on'. During the much of the twentieth century, Bleuler's conceptualization and terminology prevailed. Although he drew on Kraepelinian concepts, very few people were aware of the magnitude of Kraepelin's contributions. Students of schizophrenia used Bleuler's name for the disorder and defined it in terms of 'the four A's' (associations, autism, affect, and ambivalence).

Schneiderian symptoms, psychosis, and the dominance of diagnostic criteria

The Bleulerian emphasis slowly began to change, however, beginning in the late 1960s and 1970s. This change in emphasis arose primarily from an interest in improving diagnostic precision and reliability. Because they are essentially 'all or none' phenomena, which are relatively easy to recognize and define, florid psychotic symptoms such as delusions and hallucinations were steadily given greater prominence and indeed even placed at the forefront of the definition of schizophrenia. Bleuler's secondary or accessory symptoms began to be treated as the pathognomonic symptoms.

The emphasis on florid psychotic symptoms arose because of the influence of Kurt Schneider and the interpretation of his thinking

by influential British psychiatrists. Schneider was greatly influenced by the work of Karl Jaspers, who explored phenomenology and created a bridge between psychiatry and philosophy. Jaspers believed that the essence of psychosis was the experience of phenomena that were 'nonunderstandable'—i.e. symptoms that a 'normal' person could not readily imagine experiencing. Schneider, like Bleuler, wished to identify symptoms that were fundamental. He concluded that one critical component was an inability to find the boundaries between self and not-self and a loss of the sense of personal autonomy. This led him to discuss various 'first-rank' symptoms that were characterized by this loss of autonomy, such as thought insertion or delusions of being controlled by outside forces.[3–5]

Schneiderian ideas were introduced to the English-speaking world by British investigators and began to exert a powerful influence on the concept of schizophrenia. An emphasis on Schneiderian first-rank symptoms satisfied the fundamental need to find an anchor in the perplexing flux of the phenomenology of schizophrenia. Schneiderian symptoms were incorporated into the first major structured interview developed for use in the International Pilot Study of Schizophrenia, the Present State Examination (PSE).[6] From this major base, they were thereafter introduced into other standard diagnostic instruments such as the Schedule for Affective Disorders and Schizophrenia (SADS),[7] Research Diagnostic Criteria (RDC),[8] and the *Diagnostic and Statistical Manual* (*DSM-III*).[9]

The emphasis on positive symptoms, and especially Schneiderian symptoms, derived from several concerns. The first was that Bleulerian symptoms were difficult to define and rate reliably. They are often continuous with normality, while positive psychotic symptoms were clearly abnormal. In addition to concerns about reliability, work with the IPSS and the US/UK study also had indicated that in the United States the concept of schizophrenia had broadened to an excessive degree, particularly in the Northeastern parts of the United States. Thus, in the United States, there was clearly a need to narrow the concept of schizophrenia. Stressing florid psychotic symptoms, particularly Schneiderian symptoms, was a useful way to achieve this end, since it appeared that schizophrenia was often being diagnosed on the basis of mild Bleulerian symptoms. When diagnostic criteria such as the RDC and later *DSM-III* were written, these placed a substantial emphasis on positive symptoms and minimized negative symptoms.

While there have been many good consequences of this progression and of the interest in Schneider's work, there have also been problems.

From a Schneiderian perspective, Schneider's work and point of view has been oversimplified and even misunderstood. As a Jasperian phenomenologist, Schneider was in fact deeply interested in the subjective experience of schizophrenia—in understanding the internal psychological processes that troubled his patients. For him, the fundamental core of the illness was not the specific first-rank symptoms themselves, but rather the internal cognitive and emotional state that they reflected. It is somewhat ironic that he has become the symbol of objective quantification and reductionism. He himself was a complex thinker who was concerned about individual patients.

The development of diagnostic criteria for schizophrenia has also had both advantages and disadvantages. When *DSM-III* was originally developed, it was intended only as a 'provisional consensus agreement' based on clinical judgement. The criteria were created by a small group of individuals who reached a decision about what to include based on a mixture of clinical experience and research data available up to that point. The criteria were chosen to serve as a gatekeeper that would include or exclude individual cases, and they were not intended to be a full description of the illness. Unfortunately, they are now sometimes treated as a textbook of psychiatry. Further, the criteria have become reified and given a power that they originally were never intended to have.

Diagnostic criteria have substantial and undeniable advantages, they improve reliability, provide a basis for cross-centre standardization both nationally and internationally, improve clinical communication, and facilitate research. However, they may also have potential disadvantages and even abuses: they provide an oversimplified and incomplete view of the clinical picture, discourage clinical sensitivity to individual patients and comprehensive history-taking, lead students and even clinicians to believe that 'knowing the criteria is enough', reify an agreement that was only intended to be provisional, and discourage creative or innovative thinking about the psychological and neural mechanisms of schizophrenia.

The concept of positive and negative symptoms

Neither Kraepelin nor Bleuler actually used the terms 'positive symptoms' or 'negative symptoms', although the concepts are embedded in their writings. While various sources for this term can be cited,[10] one of the earliest and most prominent was Hughlings-Jackson.[11] Although Jackson's work was not published until much later, in the late nineteenth century Jackson speculated about the mechanisms that might underlie psychotic symptoms:

> Disease is said to 'cause' the symptoms of insanity. I submit that disease only produces negative mental symptoms, answering to the dissolution, and that all elaborate positive mental symptoms (illusions, hallucinations, delusions, and extravagant conduct) are the outcome of activity of nervous elements untouched by any pathological process; that they arise during activity on the lower level of evolution remaining.

Thus Jackson believed that some symptoms represented a relatively pure loss of function (negative symptoms answer to the dissolution), while positive symptoms such as delusions and hallucinations represented an exaggeration of normal function and might represent release phenomena. Jackson presented these ideas at a time when Darwinian evolutionary theories were achieving ascendance, and his concepts concerning the mechanisms that produced the various symptoms were clearly shaped by a Darwinian view that the brain is organized in hierarchical evolutionary layers. Positive symptoms represent aberrations in a primitive (perhaps limbic) substrate that is for some reason no longer monitored by higher cortical functions. Thus Jackson's concept of negative versus positive symptoms rather closely resembles those which are currently discussed. Although today most investigators do not necessarily embrace the specific mechanism that he proposed, they accept his view that they must be understood in terms of brain mechanisms, as well as his basic descriptive psychopathology.

References to positive and negative symptoms occurred sporadically during the 1970s, sometimes making clear references to Jackson's ideas and sometimes simply presenting notions about the clinical meaning of the distinction. Notable examples include the descriptions of Fish,[3] a reference to the terms by Strauss and others,[12] and Iowa work on affective blunting and on thought disorder, classifying it as positive versus negative.[13, 14]

In 1980, Crow published an influential paper describing a two syndrome hypothesis of schizophrenia using the terms 'positive' and 'negative' symptoms.[15] He proposed that schizophrenia could be divided into two different syndromes, which he referred to as Type I and Type II. Type I schizophrenia was characterized by prominent positive symptoms, an acute onset, good premorbid adjustment, a good response to treatment, intact cognition, intact brain structure, and an underlying mechanism that was neurochemical (dopaminergic) and therefore reversible. Type II schizophrenia was characterized by prominent negative symptoms, an insidious onset, poor premorbid adjustment, a poor response to treatment, impaired cognition, structural brain abnormalities (i.e. ventricular enlargement as visualized by Computerized Tomography [CT]), and an underlying mechanism that was characterized by neuronal loss and therefore irreversible. This proposal was highly generative for research in schizophrenia during the 1980s, primarily because it combined speculations about clinical presentation and about underlying neural mechanisms within a single hypothesis.

Two major problems were inherent in Crow's presentation of this hypothesis, however, which initially limited its empirical testing. One problem was its failure to specify a clear method for measuring positive and negative symptoms, and the second was its failure to indicate which of the broad array of variables associated with each of the two syndromes should be considered dependent or independent. Which symptoms of schizophrenia should be considered to be positive and which negative? Which variable—or group of variables—should be used to define the separate syndromes and test whether the hypothesized relationships were present?

Solutions to these problems were proposed by the investigative team at the University of Iowa.[16] Reliable methods for defining and differentiating positive and negative thought disorder and other negative symptoms such as affective blunting had already been developed at Iowa[13, 14] and the research group there also had a long tradition of developing diagnostic criteria. Consequently, we developed structured scales for the assessment of both positive and negative symptoms, the Scale for the Assessment of Negative Symptoms (SANS) and the Scale for the Assessment of Positive Symptoms (SAPS).[16–18] These scales were intended to provide a more comprehensive, reliable, and well-anchored set of measurements for the evaluation of psychopathology in schizophrenia than had been provided by standard instruments such as the Brief Psychiatric Rating Scale (BPRS).[19] They were subjected to rigorous assessment of their psychometric properties, including internal consistency, reliability, and validity. They were quickly translated into a variety of languages and widely used throughout the world.

In addition, a solution to the second problem was implemented by using a standard strategy in the study of psychopathology: the core clinical syndrome would be treated as the independent variable, while the various associated features would be (somewhat arbitrarily) designated as dependent. To this end, criteria were developed that could be used to classify schizophrenic patients as positive, negative, or mixed. Initial work with these criteria suggested that this strategy could be quite useful.[16, 17] As Crow hypothesized, negative patients differed from positive patients in the predicted direction: larger ventricular brain ratio (VBR), poorer premorbid adjustment, lower educational achievement, and poorer cognitive performance. Many subsequent studies continued to explore the two syndrome hypothesis, with the majority confirming at least some aspects of it. However, other problems with this hypothesis also became evident. Perhaps the most vexing for the hypothesis, and for the application of criteria to categorize patients based on clinical presentation, was the large number of patients with a mixture of positive and negative symptoms. The hypothesis had difficulty in explaining how patients who were both positive and negative could have both reversible and irreversible abnormalities, good and poor premorbid adjustment, and other counterintuitive and contradictory findings. For these reasons, most investigators have regretfully abandoned this appealingly simple and heuristic hypothesis during recent years.

However, the clinical distinction between positive and negative symptoms has remained relatively robust. The tendency to distinguish between these two classes of symptoms has become widespread, and the terms have passed into standard clinical usage. The alacrity with which the terms have been adopted suggests that they fill a useful linguistic and conceptual niche. Negative symptoms are an important component of schizophrenia, and the use of the 'positive' and 'negative' terminology gives them recognition and even equal weight. As the Bleulerian symptoms received de-emphasis because of concerns about reliability, they left a void in the descriptive lexicon. Patients were designated as having 'recovered' when their delusions and hallucinations were no longer present or prominent; yet many remained unemployed, unable to return to school, or socially isolated. What might explain this outcome if their symptoms were genuinely absent? Upon reflection, it became evident that only some of their symptoms were absent, and that a group of 'no name' symptoms were the likely explanation. If these symptoms could be named 'negative', grouped together, measured objectively and reliably, and related to outcome and treatment, an important mechanism for clinical description and communication was restored. Although the oversimplified distinction between positive and negative implied in the two syndrome hypothesis might be misleading, it was useful to recognize that some symptoms tend to get patients hospitalized and to call these 'positive' and that other symptoms tend to lead to psychosocial morbidity and to call these 'negative'. Thus the distinction at the level of symptoms (as opposed to syndromes or disease categories) is helpful descriptively.

The distinction has also persisted because standardized and reliable methods have been developed for assessing these symptoms and placing them in broad general classes. Instruments such as the SANS and SAPS have facilitated the persistence of the terminology because they have provided the tools for rating and measuring. Although tools were at hand for most positive symptoms, no scale was available at all for negative symptoms prior to the SANS. The extensive and repeated documentation of its reliability has quieted concerns that negative symptoms are too 'soft' to be assessed precisely, accurately, and objectively. Furthermore, other simpler scales, targeted primarily for use in

clinical drug trials, have also been developed.[20] By the time that *DSM-IV*[21] and *ICD*-10[22] were written, the concept of positive and negative symptoms was so widely accepted that negative symptoms were included in their diagnostic criteria for the first time.

Beyond diagnostic criteria and the search for fundamental mechanisms

As the present moves towards the future, corrective readjustments are continuing to occur. Paradoxically, these often occur by returning to the past and coming back full circle to the work of Kraepelin, Bleuler, Jackson, and Schneider.

Clinically, the emphasis on negative as well as psychotic symptoms is leading to increased interest in the full range of symptoms of schizophrenia and in developing methods for treating that full range. In particular, there has been a growing interest in developing improved treatments for negative symptoms. The interest in negative symptoms has been complemented by a return to an interest in cognitive aspects of schizophrenia. Many negative symptoms are cognitive in nature—alogia (poverty of thought and speech), avolition (inability to formulate plans and pursue them), and attentional impairment. While their assessment may emphasize objective aspects of behaviour in order to achieve reliability, their underlying essence is in the domains of thought and emotion. Increasingly, therefore, investigators are returning to the original insights of Kraepelin and Bleuler that the core symptoms of schizophrenia represent a fundamental deficit in cognition and emotion.

Several prominent investigators have turned from a focus on explaining and 'localizing' the specific symptoms of schizophrenia to a search for more fundamental underlying cognitive mechanisms.[23] Examples include Frith's hypotheses concerning an inability to think in 'metarepresentations',[24] Goldman-Rakic's studies of working memory,[25] our descriptions of cognitive dysmetria Andreasen,[26] or the work of Holzman,[27] Braff,[28] Swerdlow and Geyer,[29] and Freedman[30] on information processing and attention. These cognitive models provide a general theory of the disease that is consistent with its diversity of symptoms, permit testing in human beings with a variety of convergent techniques (e.g. imaging, neurophysiology), and even permit modelling in animals. This efficient and parsimonious approach offers consider hope for the future because it facilitates the search both for improved treatments and for molecular mechanisms.

4.3.2. Descriptive clinical features of schizophrenia

Peter F. Liddle

The clinical features of schizophrenia embrace a diverse range of disturbances of perception, thought, emotion, motivation, and motor activity. It is an illness in which episodes of florid disturbance are usually set against a background of sustained disability. The level of chronic disability ranges from a mild decrease in the ability to cope with stress, to a profound difficulty in initiating and organizing activity that can render patients unable to care for themselves.

Disorders of thought and perception

Delusions

Although there are no features that provide an unambiguous distinction between the delusions of schizophrenia and those of other psychotic illnesses, the delusions most typical of schizophrenia have an enigmatic character rarely seen in other disorders. In contrast to the delusions of affective psychosis, which usually have content consistent with the prevailing emotional state, in schizophrenia delusions often appear to reflect a fragmented experience of reality. This fragmentation is manifest in several ways.

- There is a lack of logical consistency between the components of the belief, or between the belief and common understanding of what is possible. For example, a patient was very distressed by the belief that he had no head and also that there was blood all over his face.
- Behaviour bears an unpredictable relationship to the delusional belief. In some instances, the patient believes he has a special role or identity, yet for the most part, lives a life that is scarcely influenced by the belief. In the words of Bleuler[1]: 'Kings, Emperors, Popes, and Redeemers engage for the most part, in quite banal work, provided they still have any energy at all for activity'.
- In the chronic phase of the illness, patients might acknowledge that a former delusion was not justified, yet in the same interview they reiterate the delusional belief. Bleuler[1] reported: 'sometimes the patients even produce thoughts which are only understandable if it is assumed that the delusions still retain some reality for these patients even though consciously they may reject them'.

The mental mechanism of schizophrenic delusions remains to be ascertained. It is not a lack of capacity for logical thought; rather it appears that certain ideas acquire an attribute that exempts them from the normal processes of validation. This phenomenon is illustrated by the historic case of Daniel Schreber,[2] a high-ranking judge from Leipzig, who suffered a late-onset schizophrenic illness. After obtaining a court order for discharge from his second hospital admission he published his memoirs[3] in a volume that includes his own account of his beliefs, and also the report prepared by the asylum director, Dr Weber, opposing his discharge. For the purpose of understanding the nature of delusions in schizophrenia, Schreber's account is of special value because we have access to his own perceptions of his condition in addition to detailed accounts by his physician. Dr Weber reported that Schreber exhibited lively interest in his social environment, a well-informed mind, and sound judgement, while nonetheless maintaining his delusional beliefs in a manner that would accept no contrary argument. Schreber himself agreed that his beliefs were unchangeable. He believed that he had a mission to redeem the world and restore humankind to its lost state of bliss. His system of delusions included the belief that he was being transformed into a voluptuous female partner of God. He considered that his beliefs belonged to a domain that was exempt from normal logic: 'I could even say with Jesus Christ: My kingdom is not of this world; my so-called delusions are concerned solely with God and the beyond'. Furthermore, he maintained total conviction in his core beliefs despite recognizing that his experiences earlier in his illness had been unrealistic. He stated:

> Having lived for months among miracles, I was inclined to take more or less everything I saw for a miracle. Accordingly, I did not know whether to take the streets of Leipzig through which I traveled as only theatre props, perhaps in the fashion in which Prince Potemkin is said to have put them up for Empress Catherine II of Russia during her travels through the desolate country, so as to give the impression of a flourishing countryside.

Thus, in the stable phase of his illness, Schreber recognized that his earlier experiences were unrealistic and that his current beliefs defied normal logic, but appeared to regard them as exempt from the need for validation. The late onset of his illness and his high level of professional achievement are unusual for an individual with schizophrenia, and raise questions about the diagnosis. However, the fact that he eventually suffered a marked deterioration in function during his third episode of illness strongly supports the diagnosis of schizophrenia.

In many instances, the delusions of schizophrenia appear to arise from an altered experience of self. The phenomena identified by the German psychiatrist, Kurt Schneider[4] as first-rank symptoms of schizophrenia (discussed in greater detail below) include several symptoms that entail an aberrant experience of ownership of one's own thought, will, action, emotion, or bodily function, which the patient attributes to alien influence. In some cases, delusions might arise from a delusional mood, i.e. an altered sense of reality in which the current circumstances acquire an indefinable transcendental quality.

Although the delusions most characteristic of schizophrenia have an incongruous quality, it is not uncommon for schizophrenic patients to have coherent delusions that are internally consistent and produce predictable behavioural responses. In particular, coherent persecutory delusions are common, and can lead to defensive actions such barricading oneself in one's room with blinds drawn. Ideas of reference and delusions of reference are also prevalent. For example, a patient might report that television

programmes refer specifically to him or her. In the International Pilot Study of Schizophrenia[5] conducted by the World Health Organization, ideas of reference were reported in 70 per cent of cases, suspiciousness in 66 per cent, and delusions of persecution in 64 per cent.

Hallucinations

Hallucinations in any modality can occur, but auditory hallucinations are the most prevalent in schizophrenia. Hearing voices speaking in the third person is the most specific. This experience is listed among the Schneiderian first-rank symptoms. Sometimes the content is mundane, as in the instance when a patient of Bleuler[1] heard a voice saying 'Now she is combing her hair' while she was grooming in the morning. In other instances there is an implied criticism, as in the case reported by Schneider[4] of a woman who heard a voice saying 'Now she is eating; here she is munching again', whenever she wanted to eat.

Second-person auditory hallucinations are also common. In the International Pilot Study of Schizophrenia,[5] voices speaking to the patient were reported in 65 per cent of cases. Voices might issue commands that the patient obeys. In some instances, the patient engages in a dialogue with the voices.

During the acute phase of illness, auditory hallucinations usually have the same sensory quality as voices arising from sources in the external world. In some instances the voice is attributed to a radio-transmitter implanted in the body, especially in the teeth. In the chronic phase, the voices are often recognized as coming from within the person's own mind. Kraepelin[6] reports: 'at other times they do not appear to the patient as sense perceptions at all; they are 'voices of conscience'; 'voices which do not speak with words". These experiences are pseudohallucinations, but nonetheless they are a significant feature in many cases.

In schizophrenia, visual hallucinations are less common than auditory hallucinations, but do occur. Somatic hallucinations are also relatively common, and often are associated with a delusional misinterpretation. For example, a young man reported sensations in his belly that he attributed to a snake, which he believed had crawled up his anus.

Schneiderian first-rank symptoms

Kurt Schneider[4] identified a set of phenomena that he considered were strongly indicative of schizophrenia in the absence of overt brain disease. These symptoms, listed in Table 4.3.2.1, have become known as first-rank symptoms. Schneider did not consider that the diagnosis could be made simply on the presence of one such symptom; on the contrary, he warned,[4] 'a psychotic phenomenon is not like a defective stone in an otherwise perfect mosaic'. Schneider did not define the phenomena precisely, and clinicians have interpreted his writings differently. Mellor[7] formulated a precise set of definitions and found that, according to these strict criteria, 72 per cent of patients with schizophrenia exhibited at least one first-rank symptom. Applying the same criteria, O'Grady[8] found that in a series of cases assessed at admission to hospital, 73 per cent of schizophrenic patients exhibited at least one first-rank symptom, while no cases of affective psychosis did. However, applying less strict criteria, O'Grady found more broadly defined first-rank symptoms in 14 per cent of patients with affective psychosis.

Table 4.3.2.1 Schneiderian first-rank symptoms

Voices commenting—a hallucinatory voice commenting on one's actions in the third person
Voices discussing or arguing—hallucinations of two or more voices discussing or arguing about oneself
Audible thought—hearing one's thoughts aloud
Thought insertion—the insertion, by an alien sources, of thoughts that are experienced as not being one's own
Thought withdrawal—the withdrawal of thoughts from one's mind by an alien agency
Thought broadcast—the experience that one's thoughts are broadcast so as to be accessible to others
Made will—the experience of one's will being controlled by an alien influence
Made acts—the experience that acts executed by one's own body are the actions of an alien agency, rather than oneself
Made affect—the experience of emotion that is not one's own, attributed to an alien influence
Somatic passivity—bodily function is controlled by an alien influence
Delusional perception—the attribution of a totally unwarranted meaning to a normal perception

Three of the first-rank symptoms (voices commenting, voices discussing, and audible thoughts) involve auditory hallucinations, while the remainder entail delusional attributions to experiences or perceptions. Although Schneider himself avoided speculating on the theoretical implications of these phenomena, it is notable that most of them involve a disorder of the sense of ownership of one's own mental or physical activity. Thought broadcast, thought withdrawal, and thought insertion reflect the experience of loss of autonomy over thought, while made will, made acts, made affect, and somatic passivity reflect loss of autonomy over action, will, affect, and bodily function.

Mellor[7] emphasizes that there are two aspects to these phenomena: the experience of loss of autonomy and the delusional attribution to alien influence. As an illustration of made acts, Mellor reports a patient who reported that his fingers moved to pick up objects 'but I don't control them … I sit there watching them move, and they are quite independent, what they do is nothing to do with me. I am just a puppet … I am just a puppet who is manipulated by cosmic strings'. To illustrate made affect, Mellor quotes a young woman: 'I cry, tears roll down my cheeks and I look unhappy, but inside I have a cold anger because they are using me in this way, and it is not me who is unhappy, but they are projecting unhappiness into my brain'.

Delusional perception, in which an entirely unwarranted conclusion is drawn from a normal perception, illustrates the incongruity between a delusional idea and concurrent mental activity, which is characteristic of schizophrenia. However, the way in which delusional perceptions often crystallize from a delusional mood indicates that it is not merely a matter of illogical inference; the delusional idea is more like a divine revelation. Mellor[7] gives the example of an Irishman who experienced a sense of foreboding

while seated at the breakfast table in a lodging house. When another lodger innocently pushed the salt cellar towards him, he suddenly knew this meant that he must return home to greet the Pope who was visiting his family to thank them because Our Lord was to be born again to one of the women.

Disorders of the form and flow of thought

The speech of schizophrenic patients is often difficult to understand because of abnormalities of form of the underlying thought. However, the clinical assessment of thought form disorder remains a major challenge. This is due in part to the fact the essential features of formal thought disorder in schizophrenia have yet to be defined in a fully satisfactory manner. Furthermore, thought disorder is usually manifest during spontaneous speech, making it difficult to create circumstances in which the phenomena can be elicited reliably.

Bleuler[1] coined the term loosening of associations to describe the weakening of the connections between words and ideas that bind thoughts into a coherent whole. While this term is a useful label for one of the major types of disorder of the form of speech and thought, it does not encompass the entire range of such disorders. In addition to disordered connections between words and ideas, there are oddities in the use of language. One of the most comprehensive catalogues is the Thought, Language, and Communication Scale compiled by Andreasen.[9] This scale includes several items that involve different aspects of the loosening of associations:

- Derailment—wandering off the point during the free flow of conversation
- Tangentiality—answers to questions that are off the point
- Incoherence—a breakdown of the relationships between words within a sentence so that the sentence no longer makes sense
- Loss of goal—failure to reach a conclusion or achieve a point.

The Thought, Language, and Communication Scale also includes several items that refer to unusual use of language:

- Metonyms—unusual uses of words (e.g. hand-shoe instead of glove)
- Neologisms—new words invented by the patient.

The various aspects of loosening of associations and peculiarities of language use are commonly regarded as positive thought disorder. The Thought, Language, and Communication Scale also include negative thought disorders that entail impoverishment of thinking:

- Poverty of speech—a disorder of the flow of speech in which the rate of speech production is reduced
- Poverty of content—the amount of information conveyed is relatively little in proportion to the number of words uttered.

The Thought, Language, and Communication Scale has proved to be one of the most successful of recent attempts to define and quantify formal thought disorder, but it has several limitations. Most important of these is that the positive thought disorder items defined in the scale do not discriminate well between manic thought disorder and florid schizophrenic thought disorder.[10] Secondly, the scale is not sensitive to the subtle thought form disorders that occur in first-degree relatives of schizophrenic patients.

These limitations are dealt with, at least partially, in the Thought Disorder Index devised by Holzman.[11] This scale employs ratings based on thought and speech elicited by the Rorschach inkblot figures and during an assessment of IQ. Two categories of disorder, disorganization (comprising vagueness, confusion, and incoherence) and idiosyncratic verbalizations, appear to discriminate fairly well between schizophrenic and manic thought.[11] Unfortunately, this scale is too cumbersome for routine clinical use.

Positive formal thought disorder is usually a transient feature of acute episodes of illness. Nonetheless, after resolution of the acute episode there is often a subtle residual thought disorder that is manifest as vague, wandering speech, or minor idiosyncrasies of word usage or ideas. Negative formal thought disorder has a greater tendency to be persistent. Chronic poverty of speech is associated with impairment in several domains of cognition[12] including abstract reasoning. It leads to impaired social relationships,[13] although it is also influenced by the social milieu. Transient poverty of speech can occur during acute episodes of illness. At its most severe, the patient is mute.

Insight

Lack of insight is one of the defining characteristics of psychotic illness. Lack of insight entails a failure to accept that one is ill and to appreciate that symptoms are due to illness. In the International Pilot Study of Schizophrenia[5] lack of insight occurred in approximately 90 per cent of cases. Insight is often partial. In particular, even in instances in which a patient acknowledges suffering from an illness, he or she might fail to accept that psychotic symptoms such as delusions or hallucinations are a manifestation of that illness. Lack of insight is one factor that contributes to unwillingness to accept treatment. However, the clinician should be aware that other factors, including lack of appropriate education about the illness and justified fear of side-effects of treatment, can also impede the development of a therapeutic collaboration between physician and patient.

Impaired cognition

In addition to delusions and disorders of thought form, a wide range of cognitive deficits occur in schizophrenia. These are discussed in Chapter 4.3.3. This chapter focuses on the relationship between cognitive impairment and other features of the illness.

In the acute phase of the illness, attentional impairment is common and is often associated with psychomotor excitation and/or formal thought disorder. It might also reflect preoccupation with delusions and hallucinations.

During the chronic phase of illness, many schizophrenic patients exhibit persistent cognitive impairments. Longitudinal studies of individuals who subsequently develop schizophrenia reveal that the deficits are discernible during childhood, suggesting that these deficits are an aspect of the predisposition to schizophrenia. The major cognitive impairments are in the realm of executive function, working memory, and long-term memory. Executive dysfunction includes impaired ability to initiate and select self-generated mental activity. Impaired ability to form and initiate plans is associated with chronic poverty of speech, blunted affect, and lack of spontaneous activity, while impaired ability to inhibit inappropriate responses is associated with chronic formal thought disorder.[12]

Disorders of emotion

An extensive range of disorders of emotion occur in schizophrenia. Blunted affect and inappropriate affect are the most characteristic, and also tend to be the most persistent, but transient excitation, irritability, lability, and depression are also common.

Blunted affect

Blunting of affect is manifest as decreased responsiveness to emotional issues, loss of vocal inflection, and diminished facial expression. These objective signs of affective blunting are sometimes accompanied by awareness of loss of emotional tone that, paradoxically, patients find to be distressing. More commonly, there is a lack of concern and even a lack of awareness of the problem. Affective blunting is one of the hallmarks of chronic schizophrenia. Bleuler[1] remarked that when the affects disappear, the illness becomes chronic. While blunted affect is usually chronic, it can also be a feature of acute episodes of the illness that resolves as the acute episode resolves.

Inappropriate affect

Inappropriate or incongruous affect is the expression of affect that is inappropriate in the circumstances. At its most severe it takes the form of hollow laughter that is unrelated to any apparent stimulus.

Excitation and depression

During acute exacerbations of schizophrenia, excitation, manifest as irritability, sleeplessness, agitation, and motor overactivity, is common. Depression is also common around the time of an acute episode of schizophrenia,[14] and is often a feature of the prodromal phase of the illness.

Depression also occurs during the chronic phase of the illness. The cross-sectional rate is approximately 10 per cent in the chronic phase,[15] while in a longitudinal study, Johnson[16] found that 65 per cent of schizophrenic patients exhibited an episode of depression in a period of 36 months after a florid psychotic episode.

Motor disorders and catatonia

Subtle disturbance of motor co-ordination is common. Home videos of children who subsequently develop schizophrenia demonstrate that even in infancy they are noticeably more clumsy than their siblings, suggesting that disturbed motor co-ordination is an aspect of the predisposition to schizophrenia.[17]

Catatonia is a term embracing disorders of the initiation or organization of voluntary movement or posture. The most characteristic catatonic phenomena are:

- *Immobility*—absence of motor activity
- *Posturing*—adopting an unusual body posture
- *Waxy flexibility*—allowing an examiner to adjust one's posture, yielding like a warm candle
- *Negativism*—resisting manipulation by an examiner, with force proportional to that applied by the examiner
- *Stereotypy*—aimless repetitive motor behaviour
- *Mannerisms*—apparently purposeful actions that appear odd because they are exaggerated in form or occur out of the usual context
- *Echo phenomena*—repetition of an examiners utterances or movements
- *Excitement*—excessive motor activity, usually accompanied by excessive mental activity.

These disorders can occur not only in schizophrenia, but also in other psychiatric or neurological disorder such as bipolar mood disorder or encephalitis, or alone as a primary disorder of motility.

Kahlbaum[18] provided the classic description of catatonia. He emphasized not only the typical phenomena but also a characteristic time course, in which a prodromal phase dominated by melancholic symptoms evolved into a fluctuating disorder in which episodes of diminished motility typically lasting for several weeks or months, were interspersed in periods of near normal function, but with a tendency towards eventual dementia in many cases. Episodes were often accompanied by confusion and in some instances, a state of stupor. In some cases, episodes of excitation occurred as well. While Kahlbaum's emphasis on both characteristic phenomena and time course laid a foundation for the subsequent delineation of major mental illnesses at the end of the nineteenth century and in particular, for Kraepelin's delineation of schizophrenia,[7] it is probably best to regard catatonia as a cluster of clinical features that can occur within various different illnesses.

Two major forms are retarded catatonia, characterized by slowed or diminished activity; and excited catatonia in which the dominant feature is excessive motor activity. Many variants of catatonia differing in the relative prominence of the characteristic features; or in the associated features such as autonomic instability; or in time course, have been reported in the past 150 years. Fink and Taylor[19] argue on the grounds similarity of clinical features and response to treatment (with benzodiazepines and/or ECT) that the variants of catatonia share a common brain pathophysiology, though different predisposing or precipitating factors might lead to variation in clinical features and time course. The variants include malignant catatonia, in which there is a sudden onset of excitation, associated with fever and autonomic instability, leading to fatal outcome in a substantial proportion of cases. The relationship between malignant catatonia and neuroleptic malignant syndrome (NMS), which is characterized by features very similar to malignant catatonia, but is triggered by antipsychotic medication, is an issue of practical clinical importance. A careful review nine cases of NMS and 17 cases of malignant catatonia by Carroll and Taylor[20] failed to find differences in clinical features, supporting the conclusion that NMS is a form of catatonia.

Disorders of volition

Among the most disabling of the clinical phenomena of schizophrenia are disruptions of motivation and will. Voluntary activity can be disjointed or weakened. Disjointed volition is manifest in poorly organized ill-judged activities which appear to be prompted by impulse. For example, an artistic, intelligent young woman felt cold so she lit a fire on the carpet in her bedroom, even though she was able to appreciate that this was a dangerous thing to do.

Weakened volition results in prolonged periods of underactivity. The patient might lie in bed or sit in an armchair for hours.

Anxiety and somatoform disorders

Various forms of anxiety and somatic symptoms are common in schizophrenia. Huber[21] described a non-characteristic defect state which is dominated by anxiety and asthenia. Coenesthesia, in which the patient suffers unusual or debilitating bodily experiences that do not have an apparent somatic cause, occurs frequently.

Dimensions of psychopathology in schizophrenia

Schizophrenia is heterogeneous in its clinical presentation, suggesting that several different pathophysiological processes might contribute to the illness.

Positive and negative symptom dimensions

Positive symptoms are those that reflect the presence of an abnormal mental process, and include delusions, hallucinations, and formal thought disorder. Negative symptoms reflect the diminution or absence of a normal mental function. They include poverty of speech and blunted affect. In schizophrenia, positive symptoms tend to be transient, while negative symptoms tend to be chronic. In an influential hypothesis, Crow[22] proposed that positive symptoms arise from dopaminergic overactivity, while negative symptoms reflect structural brain abnormality. While this hypothesis is consistent with a substantial body of evidence, it does not account adequately for the complexity of the heterogeneity of the clinical features in schizophrenia.

Three dimensions of characteristic symptoms

The preponderance of evidence[12, 13, 23] from factor analysis of schizophrenic symptoms indicates that the characteristic symptoms of schizophrenia segregate into three syndromes, as shown in Table 4.3.2.2. These syndromes do not reflect separate illnesses, but different dimensions of illness, in the sense that a patient might exhibit more than one of the syndromes.

The three syndromes embrace only the characteristic symptoms that are given weight in making a diagnosis of schizophrenia. In addition, there are two affective syndromes, depression and psychomotor excitation, which are prevalent in schizophrenia,[12] despite being more characteristic of mood disorders. These affective syndromes are usually transient.

Table 4.3.2.2 Three syndromes of symptoms characteristic of schizophrenia

Reality distortion
Delusions
Hallucinations
Disorganization
Thought form disorder
Inappropriate affect
Bizarre behaviour
Psychomotor poverty (core negative symptoms)
Poverty of speech
Blunted affect
Decreased spontaneous movement

An accumulating body of evidence[12] from brain imaging studies indicates that the three characteristic syndromes are associated with three distinguishable patterns of cerebral malfunction involving the areas of association cortex and related subcortical nuclei, which serve higher mental functions. In an individual case, several of these neural systems might be involved.

Although many details of the relationships between the diverse clinical features of schizophrenia remain uncertain, a growing understanding of the neural pathways involved is beginning to provide the foundation for understanding the protean manifestations of this disorder.

4.3.3 The clinical neuropsychology of schizophrenia

Philip D. Harvey and Christopher R. Bowie

Introduction

Impairments in a variety of cognitive functions are found in patients with schizophrenia. These impairments affect a wide array of different cognitive abilities and are often quite severe, when compared to standards based on healthy individuals of the same age, education levels, and gender. Cognitive impairments appear to be present across the lifespan, detectable at the time of the first treatment episode, if not before, and to manifest a generally stable course over time. Although the current knowledge base regarding cognition in schizophrenia is quite broad, additional research information is constantly accruing. The main purpose of this chapter is to provide a broad overview of the domains, severity, and course of cognitive impairments in schizophrenia, with a focus on functional relevance and treatment possibilities.

History

Cognitive impairments were reported by both Emil Kraepelin and Eugen Bleuer, both of whom noted that they believed that cognitive impairments were amongst the core features of the illness. The conception of dementia praecox introduced by Kraepelin focused on the cognitive and functional deficits in the illness and likened the condition to a condition such as Alzheimer's disease with an earlier onset age. Over the first half of the twentieth century research on cognition in schizophrenia focused on a variety of different topics, including memory, attention, and language skills.[1]

Clinical neuropsychology and schizophrenia

The development of clinical neuropsychology and formalized neuropsychological (NP) tests led to a substantial increase in interest in cognition in schizophrenia. Classical NP ability domains, as well as the types of tests typically used to assess them are presented in Table 4.3.3.1. Clinical NP assessments develop an understanding of areas of relative strength and weakness, comparing current functioning following illness or injury to evidence or estimates regarding prior functioning.[2] Then a profile can be developed, contrasting better or more poorly performed ability areas. Performance across these ability areas can be converted to standard scores, considering demographic factors that influence performance such as age, education level, and sex.[3] Thus, the results of a clinical NP assessment provide a summary of relative strengths and weaknesses. Clinical NP assessment has moved away from earlier efforts to anatomically localize deficits through test performance or to distinguish 'functional' versus 'organic' impairments. The current conception of neuropsychological performance is largely based on the concept of functional neural networks, which link cortical and subcortical regions through patterns of linked activation during task performance.[4]

Table 4.3.3.1 Important cognitive ability domains and tests

Ability areas	Tests
Perceptual skills	Pattern recognition
Motor skills	Manual dexterity
Attention	
Sustained attention	Continuous performance tests
Selective attention	Resistance to distraction
Working memory	
Spatial working memory	Spatial delayed response tests
Verbal working memory	Measures of verbal memory span
Episodic memory	
Verbal memory	List learning; paragraph recall
Non-verbal memory (spatial memory)	Object learning tests
Procedural memory	Pursuit rotor; mirror writing
Long-term semantic memory	Word recognition reading
Executive functions	
Concept formation	Comprehension tests
Reasoning	Proverb interpretation
Problem-solving	Wisconsin card sort; Tower of London
Inhibition	Stroop test
Processing speed	Trail-making; digit symbol
Verbal skills	
Naming	Object naming test
Verbal fluency	Animal naming

Cognitive impairment in schizophrenia

Severity

Patients with schizophrenia demonstrate impaired performance on NP tests measuring a variety of ability areas. As shown in Table 4.3.3.2, impairments across abilities range from mild to severe.[5] Further, aspects of spared functioning are quite rare, with patients performing at levels worse than population means on nearly all domains other than reading skills, object naming, and recognition memory. These impairments are not due to poor motivation or the presence of psychosis[6]; it is well understood that patients demonstrate persistent NP impairments following recovery from acute psychotic episodes and that cognitive impairments are quite stable over time.

Profile

It is important to consider that patients with schizophrenia show considerably smaller overall decline in intelligence than in some specific ability areas.[7] The majority of these impaired domains are often seen to be those that are associated with the functions of the frontal lobe. However, the notion that the whole array of cognitive impairments seen in schizophrenia could originate from a single localized lesion is implausible, as impairments in cognitive functions that are impaired individuals with medial temporal-hippocampal lesions are also quite profound in patients with schizophrenia.[8]

Table 4.3.3.2 Level of impairment in cognitive abilities in schizophrenia

	Mild	Moderate	Severe
Perceptual skills	X		
Motor skills	X		
Attention			
Sustained attention			X
Selective attention		X	
Working memory			
Spatial working memory		X	
Verbal working memory			X
Episodic memory			
Verbal learning			X
Non-verbal memory (spatial memory)		X	
Delayed recall		X	
Delayed recognition	X		
Procedural memory		X	
Long-term factual memory	X		
Executive functions		X	
Processing speed			X
Verbal skills			
Naming	X		
Verbal fluency		X	

See Heinrichs and Zakzanis[5] for a description of the methods used to evaluate these levels of impairment.

There has been considerable debate about the structure of cognitive deficits in schizophrenia. This debate has focused on whether the profile of relative deficits is generalized, with similar severity across all components, or specific.[9] Proponents of the specific profile argument often site evidence of regional brain dysfunction detected with neuroimaging procedures[10] or more extreme deficits on certain NP tests such as episodic memory.[8] There have been recent factor analytic studies that found complex solution with up to six factors[11] and other studies that found a single factor characterized all of the cognitive data in large samples.[12] It does seem that tests requiring cognitive capacity and processing speed are amongst the most poorly performed and that tests examining the ability to use information acquired prior to the onset of schizophrenia are performed best.

Onset

At the time of the first treatment for schizophrenia, either inpatient or outpatient, people who receive the diagnosis perform in a manner that is nearly as impaired as more chronic patients, with a similar profile of impairment.[13] These data support the idea that cognitive impairment is not continuously progressive over the entire course of illness.[14] It is clear, however, that cognitive impairments may also be detectable in at least some people who are destined to develop schizophrenia. In population-based studies of apparently healthy individuals being screened for induction into compulsory military service, there are clear group differences in performance between individuals who eventually develop schizophrenia and those who do not.[15] These impairments have some level of sensitivity and specificity, but are clearly not diagnostic indicators at that stage. Findings of impairments in cognition prior to the patient's meeting formal diagnostic criteria for the illness do provide additional suggestions that cognitive deficits are central features of the illness.

Cognitive decline in schizophrenia?

While the course of cognitive impairments in schizophrenia appears generally stable over the lifespan, there is a substantial minority of patients with schizophrenia who manifest considerable cognitive impairments that worsen over time. The patients who show these changes tend to be older and with a chronic course of treatment-refractory positive symptoms, often accompanied by a lifetime of institutional care.[16] Longitudinal studies have suggested that younger institutionalized patients with similarly severe positive do not show declines during similar follow-up periods,[17] suggesting that there may be age-associated vulnerability to decline. Studies from multiple research sites have found a low prevalence of neurodegenerative changes at post-mortem in older schizophrenia patients,[18] suggesting that these abnormalities cannot be fully explained by degenerative conditions. At present, there is no information on whether these changes could be due to the experience of institutionalization alone, but studies of patients who were released from chronic psychiatric care have not shown evidence of reversal of these cognitive impairments. As patients with schizophrenia have evidence of considerable reduction in their 'cognitive reserve', based on the lower levels of premorbid functioning, it would expected that a variety of risk factors could lead to cognitive changes, including subclinical neurodegenerative pathology, vascular abnormalities, or other factors which can influence cognitive impairments in older individuals.

Presence in relatives and individuals with 'spectrum' conditions

Cognitive impairments are present in the relatives of people with schizophrenia and these impairments have evidence of heritability. Longitudinal studies have suggested that some aspects of cognitive impairment, such as attentional deficits, predict the development of psychotic symptoms in high risk children with at least one schizophrenic parent.[19] Further, individuals with schizophrenia spectrum conditions such as schizotypal personality disorder (SPD) show evidence of cognitive deficits similar in profile, yet reduced in severity compared to people with schizophrenia.[20] As patients with SPD do not have a markedly increased risk for schizophrenia, some aspects of cognitive functioning may represent a stable correlate of some aspects of the predisposition to schizophrenia. While studies have been in process to identify candidate cognitive processes as potential genetically mediated intermediate phenotypes,[21] specific gene-performance correlations are not large enough in magnitude yet to demonstrate that any cognitive impairment is clearly related to specific susceptibility genes for schizophrenia.

Functional relevance

One of the reasons for the increased interest in NP impairment in schizophrenia over the past decade is the developing understanding of the functional relevance of NP impairment. In specific, NP impairment in schizophrenia is the single strongest correlate of impairments in everyday living skills, in social outcomes, and in seeking and maintaining employment or other productive activities. This realization was spurred by several high-profile reviews of the literature[22] and a developing interest in both disability reduction and the direct measurement of disability. While the correlations between impairments in individual NP ability areas and specific aspects of everyday disability are only moderate in size, correlations between composite measures of multiple NP domains and global measures of outcome are often fairly substantial, in the range of Pearson correlations of $r = 0.7$ (reflecting 50 per cent shared variance). In contrast, in similar studies, the cross-sectional correlation between the severity of psychotic (i.e. positive) symptoms is often closer to $r = 0.1$, reflecting about 1 per cent shared variance.[12] This difference in correlations is likely accentuated by the unstable and episodic nature of positive symptoms, in contrast to both functional disability and NP performance, which are both known to be quite stable over time.

Studies of the ability to perform skilled acts (i.e. independent living and social skills) in analogue situations have found that the correlation between impairment on NP tests and deficits in 'functional capacity' is greater than the correlation between NP performance and real world functional performance.[23] This difference in correlations is probably due to the fact that there are multiple factors other than ability that determine everyday outcomes. Opportunities, disability compensation, environmental support, and familial resources are all factors that could lead to discrepancies between what a person can do (i.e. their competence) and what they actually do (i.e. their everyday performance). The fact that disability, in terms of reduced competence, can be measured directly with performance-based tests is quite important, as some of these measures could actually be used in everyday clinical practice or as outcomes in treatment studies.

Treatment of cognitive impairment in schizophrenia

Although antipsychotic medications have been shown for years to be effective in reducing psychotic symptoms in about 70 per cent of patients with schizophrenia, effects on cognitive impairments are much smaller. Although cognitive impairments are apparently not worsened by conventional antipsychotic treatments, their beneficial effects are small and limited to a subset of cognitive domains. Atypical antipsychotic treatment appears to have a somewhat greater effect, suggested by meta-analyses and large-scale studies to be about 0.25 standard deviations.[24] Given the substantial magnitude of impairments in the illness, this level of improvement does not come close to normalization for most patients.

Targeted treatments aimed at cognitive functioning have come from both pharmacological and cognitive remediation domains. Most pharmacological interventions have had quite modest effects, while the results of recent cognitive remediation interventions have been more promising. At least three different interventions, using computerized interventions in randomized trials have shown both cognitive improvements and generalization of improvement to functionally relevant aspects of everyday outcome.[25] Concurrent antipsychotic treatments may be responsible for the poor outcomes of pharmacological interventions, as some of these treatments that have shown minimal benefits in patients with schizophrenia receiving antipsychotic treatments have shown beneficial effects in healthy individuals and in persons with schizotypal personality disorder. This is an issue that will require further study.

Conclusion

Cognitive impairments in schizophrenia are related to the functional disability in the illness and may produce much of the morbidity associated with the condition. These impairments are wide ranging and are found in multiple important domains, with onset at the time of, or in many cases, prior to the first episode of illness. No single focal lesion appears responsible for the array of deficits seen. Relatives of people with schizophrenia and individuals with non-psychotic schizophrenia-spectrum conditions are also affected by these cognitive deficits. Cognitive impairments have proven difficult to treat, but multiple initiatives are underway to improve treatment success. Both pharmacological and cognitive remediation interventions are being studied in detail at this time.

4.3.4 Diagnosis, classification, and differential diagnosis of schizophrenia

Anthony S. David

The diagnosis of schizophrenia

Until the early 1970s, the diagnosis of schizophrenia was one of the most contentious and fraught issues in the whole of psychiatry. Since then a massive international effort has been put in motion out of which explicit diagnostic criteria emerged. Some achieved widespread and even multinational agreement, allowing the painstaking process of calculating diagnostic specificity, sensitivity, reliability, and (perhaps) validity to begin. Although criticism of the diagnosis of schizophrenia continues, mostly from outside psychiatrists, the vast majority of psychiatrists look upon the major sets of diagnostic criteria with weary acceptance, seeing them as flawed but useful and possibly 'as good as it gets' given our current state of knowledge/ignorance.

Throughout the 1970s and early 1980s there was an overabundance of criteria including the St. Louis criteria[1] and the Research Diagnostic Criteria,[2] followed by the Present State Examination (PSE-CATEGO), the ICD-9, and the DSM-III. Perhaps because of the 'cookbook' explicitness of the DSM-III or the pervasive influence of American psychiatric practice, dubbed by some 'neocolonial', the DSM, in its fourth revision with a fifth due in 2010, is the mostly widely used. The ICD-10 is also used throughout the world, but seldom in North America.

Diagnostic criteria

The signs and symptoms of schizophrenia and related disorders are discussed in detail in Chapter 4.3.2. Also, the diagnostic process is described in general in Chapter 1.8.1. As noted, the signs and symptoms, weighted in terms of their typicality or specificity, combined with additional clinical factors such as onset, duration, social consequences, etc., are used to make a diagnosis of schizophrenia and subsequently to classify the disorder into subtypes. The DSM and ICD criteria are described below (Tables 4.3.4.1–4.3.4.3).

Table 4.3.4.1 Major diagnostic criteria for schizophrenia

	DSM-IV	ICD-10
Characteristic symptoms		
One or more for 1 month	1. Bizarre delusions	1. Thought echo/insertion/ withdrawal/broadcasting
	2. Commenting voice or voices conversing	2. Delusions of control
		3. Hallucinatory voices
		4. Persistent delusions
Or two or more	1. Delusions	1. Persistent hallucinations
	2. Hallucinations	2. Thought block/disorder
	3. Disorganized speech	3. Catatonia
	4. Grossly disorganized or catatonic behaviour	4. Negative symptoms
	5. Negative symptoms	5. Significant personality change
Time course	1 month ('significant proportion') for symptoms listed plus 6 months social/occupational disturbance	1 month (most of the time)
Exclusions	Schizoaffective disorder or brief mood disturbance Direct effect of drugs of abuse/ medication or general medical condition	Extensive depressive/manic symptoms or diagnosis of schizoaffective disorder Overt brain disease; drug intoxication/withdrawal

Another group of psychotic disorders which may be distinguished on the basis of formal phenomenological properties are the delusional disorders[3, 4] formally known as paranoia (see Chapter 4.4).

Basis of classification

Atheoretical: Schneider's first-rank symptoms

These are still important for the diagnosis of schizophrenia using the ICD-10 frame of reference. They are too rare to achieve high levels of sensitivity and their specificity has been challenged. Nevertheless, first-rank symptoms perform creditably on these parameters when compared to negative symptoms.[5,6] On the other hand, the lack of aetiological and prognostic significance of first-rank symptoms has undermined the prominence claimed for them.[7,8] The negative[9] or so-called deficit syndrome[10] relates more consistently to outcome/prognosis and shows more stability over time. The constituent symptoms such as social withdrawal, apathy, lack of initiative, and self-care, have rather poor diagnostic specificity in isolation and must be distinguished from depression and parkinsonism, chronic drug dependence, and organic brain damage.

Theoretical

Attempts at a theoretical classification have been made. The first in the modern era was Crow's Type I and Type II distinction,[11]

Table 4.3.4.2 Criteria for the diagnosis of schizophrenia subtypes

Schizophrenia subtypes	DSM-IV	ICD-10
Paranoid	One or more delusions plus frequent auditory hallucinations; no prominent thought disorder, catatonia, or negative symptoms	Delusions, hallucinatory voices, hallucinations in other modalities; disturbances of affect, volition, and speech 'inconspicuous'
Disorganized DSM Hebephrenic ICD	Prominent disorganized speech behaviour and flat/inappropriate affect; no catatonia	Prominent disturbances of affect, volition, and thought; 2–3 months duration; adolescents/young adults only
Catatonic	Two of motoric immobility, excessive activity, negativism, peculiar voluntary movements, echolalia/ praxia	One or more of stupor, excitement. posturing, negativism, rigidity, waxy flexibility, automatic compliance and perserveration
Undifferentiated	Meets criteria for schizophrenia but none of the above subtypes	Meets criteria for schizophrenia but none of the above subtypes plus residual
Residual	Absence of prominent characteristic symptoms (but two or more must be present in attenuated form); continuing evidence of disturbance including negative symptoms	Prominent negative symptoms; clear-cut episode(s) in past; at least 1 year history; no dementia or depression etc.
Simple	Slowly progressive negative symptoms without other psychotic symptoms	(See schizoid personality disorder)

Table 4.3.4.3 Terminology used to describe the course of schizophrenia in the DSM-IV and ICD-10 classifications

DSM-IV	ICD-10
Continuous	Continuous
Episodic with residual symptoms	Episodic with stable deficit
Episodic with no interepisode symptoms	Episodic remittent
Single episode in partial remission	Incomplete remission
Single episode in full remission	Complete remission
Other	Other Episodic with progressive deficit

[a]Course specifiers in both DSM-IV and ICD-10 require 1 year of observation.

although it echoes older notions of 'process'-chronic and deteriorating versus 'reactive' (relapsing and remitting) typologies. The innovation was to link the distinction with proposed differences in dopamine receptor hyperactivity (Type I), associated with positive symptoms and good response to dopamine antagonist drugs, and on the other hand, to neurological damage (Type II) as evidenced by ventricular enlargement on Computerized Tomography (CT) brain scans, associated with chronicity, poor premorbid functioning, and poor response to treatment.

Building on this was the 'aetiological classification' proposed by Murray *et al.*[12] which contrasted cases with a presumed genetic aetiology and those who had other putative risk factors such as early brain damage (see Chapter 4.3.6.1). Although these attempts have served as useful stimuli for research, they have not been found to aid clinical decision-making and in fact now appear to support a blurring of diagnostic boundaries rather than a sharpening or subdivision.[13] In fact the search for 'biological markers' often called 'endophenotypes', which might validate diagnostic distinctions continues. Take for example, the presence of ventricular enlargement or cortical thinning, first detected using CT and now magnetic resonance imaging (**MRI**). Meta-analyses have confirmed that indices of 'cerebral atrophy' are strongly associated with schizophrenia but the effect sizes are small.[14] Medial temporal lobe structures are the region of most grey matter volume loss. However, there is substantial overlap between normal controls and schizophrenia cases and MRI cannot be considered a useful diagnostic test. A host of genetic markers have been identified in the last 5 years, each of small effect and some showing overlap between the major schizophrenic and affective syndromes.[15]

Positive family history remains an important finding in the psychiatric history of an individual patient. Although none of the diagnostic criteria permits the influence of family history, in clinical settings, 'odd' or withdrawn behaviour takes on a very different meaning if seen in the first-degree relative of someone with a firm schizophrenia diagnosis.

Early diagnosis?

The premorbid personality in schizophrenia is typically described as emotionally and socially detached. Such people have few friends, are often cold and aloof, and engage in solitary occupations. Their behaviour may be eccentric and they are indifferent to praise or criticism. Recent studies, including United Kingdom national cohort studies[16] and a Swedish conscript cohort study[17] indicate that children who later develop schizophrenia are more likely to have lower IQs and educational achievements than other children. They are also more likely to have interpersonal and behavioural difficulties. Parents recognize 'preschizophrenic' children as being different from their other siblings. However, such characteristics are very common in the general population so have virtually no positive predictive value.

Early diagnosis is only successful when based on psychotic symptoms. Here the diagnosis of schizophreniform psychosis (DSM-IV) and the acute schizophrenia-like psychotic disorder of the ICD-10 are relevant. The former must last for more than 1 but less than 6 months (otherwise the diagnosis is brief reactive psychosis). Hence the disorder is substantial by any common-sense definition, and unsurprisingly many cases (70 per cent) go on to develop full-blown schizophrenia, affective disorder, or schizoaffective disorder.[18] The temporal stability of the diagnosis is poor, with around 30 per cent recovering over follow-up periods averaging 16 months in one study.

New services have built up around ever earlier diagnosis with the explicit aim of secondary or even primary prevention. Criteria have been developed for the diagnosis of high-, ultra-high, or so-called 'at-risk' mental states based on transient psychotic experiences—even briefer than schizophreniform or more persistent disturbances in the sense of self ('basic symptoms') which fall short of true psychosis.[19,20] One impetus to this being the discovery that most patients when first ill endure a long duration—months or years—of untreated psychosis (DUP).

Differential diagnosis

Other psychiatric disorders

(a) Other psychoses

It could be argued that distinguishing schizophrenia from schizoaffective disorder, schizophreniform disorder, delusional disorder, etc. is an academic exercise. Despite passing enthusiasms, treatment in psychiatry is largely symptom or syndrome based.[21] Thus manic symptoms respond to antimanic agents including lithium, psychotic symptoms respond to 'neuroleptics' or first and now second-generation antipsychotic drugs (SGA), and depressive symptoms respond to antidepressants. Other 'mood-stabilizing' agents are also of value especially when combined with antipsychotics. Several SGAs are licensed for bipolar affective disorder and schizoaffective disorder although it is not clear whether they have distinct advantages over older drugs in this regard. Clozapine remains the only antipsychotic medication which is proven to be effective in at least some patients who are otherwise treatment resistant. However, it is possible that with increasing clinical experience and research more specific indications for newer agents will emerge. This will depend on the preservation of skills in history taking and the mental state examination, and a careful attitude towards making a diagnosis rather than use of sloppy catch-all labels such as 'serious mental illness' favoured by healthcare planners.

The prognostic significance of a diagnosis of schizophrenia (versus schizoaffective and affective disorders) has been discussed in Chapters 4.3.7 and 4.3.9. Although predicting outcome in individual patients is notoriously difficult because of the influence

of idiosyncratic factors such as services, relationships within the family, compliance, intelligence, personality, demographics, etc., the more a disorder approaches 'typical' schizophrenia, the poorer the prognosis tends to be.

That said, schizoaffective disorder is the closest disorder, phenomenologically, to schizophrenia but combines schizophrenic symptoms with affective symptoms. The criteria are discussed in Chapter 4.3.9. Schizophreniform (DSM-IV) or acute schizophrenia-like disorders (ICD-10) differ only in terms of duration, as operationally defined (see Chapter 4.3.10). Delusional disorders (Chapter 4.4) differ from schizophrenia in being based around 'non-bizarre' delusions and few or no hallucinations. The onset and course are characteristically later and more benign respectively.

(b) Affective disorders

Typical presentations of either mania or depression usually cause few diagnostic difficulties. Overdiagnosis of schizoaffective disorder is to be resisted although the distinction from schizophrenia proper remains controversial and debatable. The guidelines given in DSM-IV attempt to exclude transient mood disturbances (<2 weeks) in people with psychosis as a basis for a schizoaffective diagnosis.

In practice reaching a diagnosis of schizophrenia in a person with evidence of one or more core symptoms of psychosis (listed under the DSM-IV and ICD-10) may be complicated for the following reasons.

(c) The presence of mood-incongruent delusions (or hallucinations)

'Congruence' is somewhat in the eye of the beholder, especially where mood may be labile or where disturbed mood is suspected but fails to follow clinical stereotypes. The clinician should try to determine if a 'grandiose' delusion is being enjoyed by the patient, and whether the content (e.g. elevated status, magical powers, material riches) is seen as justified by the patient. Similarly a delusion of depressive content (e.g. physical illness, imminent death) must be seen as undeserved or inexplicable to be deemed 'incongruent'. Auditory hallucinations may be comforting, complimentary, or, more commonly, hostile and critical. It is probably their complexity and personification which makes them 'schizophrenic' rather than their mood-incongruent content.

(d) The duration and acuteness of onset criteria

A good history may simply not be available. Symptoms may wax and wane. Partial or successful treatment may modify or curtail a potentially long episode, and onset may be complicated by the use of psychoactive drugs.

(e) Social and occupational disturbance

This is critical to the diagnosis of schizophrenia, especially the DSM-IV criteria. Here the difficulty is in distinguishing 'premorbid deficits', an illness prodrome and the illness itself. Premorbid personality factors will obscure or set in relief discontinuities in an individual's social trajectory. Objective information and informant testimony is crucial as in most of the diagnostic process. Other individual differences such as intelligence will also shape the presentation of schizophrenia. At the extreme, people with intellectual disability (learning disability) may manifest psychosis in less obvious ways (see Chapters 10.5.1 to 10.5.3). The old diagnosis of 'simple schizophrenia', retained in the ICD-10 describes 'insidious and progressive development of oddities of conduct' and the 'inability to meet the demands of society' that is, social disturbance of long duration. The progressive element distinguishes it from personality disorder although problems adjusting to changing social demands through the life cycle may give the appearance of progression in a fixed personality disorder.

Organic conditions

Differentiation of a 'primary' psychotic illness from one secondary to an organic condition may arise in essentially two situations:

- a person with a clear-cut diagnosis of a medical or neurological syndrome in which psychosis is a recognized complication (e.g. epilepsy)
- a person with a presumptive diagnosis of schizophrenia in whom significant abnormalities are detected usually following special investigation (e.g. CT brain scanning).

The list of medical conditions that could potentially give rise to psychosis is enormous. These have been the subject of extensive reviews.[22,23] While it appears that almost any disease that causes a cerebral perturbation can give rise to psychosis, abnormalities affecting the temporal lobes and diencephalon are somewhat more likely to do this.

The time course is obviously important in this context. Chronic inflammatory lesions (e.g. sarcoidosis), degenerative disorders (e.g. presenile dementias), chronic infections (e.g. neurosyphilis, AIDS), space-occupying lesions (e.g. tumour or abscesses), metabolic disorders (e.g. hyper- or hypothyroidism and vitamin deficiencies) may mimic schizophrenia by virtue of a gradual deterioration in social functioning and self-care punctuated perhaps by odd or inexplicable behaviour and rarely hallucinations and delusions. The features of the primary disease are usually evident. Rarer conditions may be misdiagnosed, for example, Wilson's disease (hepatolenticular degeneration). This usually presents with a motor disorder with bulbar features and abnormal liver function, but personality changes and psychotic symptoms are also associated. Diagnosis is made on other associated clinical features (e.g. Kayser–Fleischer rings), copper studies, and liver biopsy. Huntington's disease is characterized by chorea and cognitive decline. Affective disorder and occasionally psychotic symptoms may occur. The main differential diagnosis is with patients with chronic psychosis and tardive dyskinesia and is usually clarified by the family history, inexorable progression, and caudate atrophy on CT or MRI. Neurosyphilis is still encountered from time to time and in the 'general paralysis of the insane' form, may present with chronic delusions (often grandiose) plus dementia. Diagnosis is by appropriate serological testing of blood and cerebrospinal fluid. Finally, metachromatic leukodystrophy, a rare inherited progressive demyelinating condition, has recently been identified as a cause of a schizophrenia-like psychosis, when onset is in childhood or early adult life.[24] Arylsulphatase-A is a diagnostic marker detectable in peripheral white blood cells.

Acute disturbances following head trauma, acute infections (viral encephalitis), cerebrovascular accidents, metabolic abnormalities (e.g. electrolyte disturbances, porphyria), or drug intoxication or withdrawal (including prescribed medication) (see below) may present with a florid psychotic picture, classically dominated by visual distortions or hallucinations and fluctuating levels of

alertness, rather than the stereotyped auditory hallucinations in clear consciousness which are characteristic of schizophrenia.[25]

In practice there are few common conditions that ever give rise to real diagnostic uncertainty. The most important is **epilepsy**. It is well established that epilepsy, particularly focal (complex partial or 'temporal lobe epilepsy') can give rise to psychosis and there are inter-ictal and post-ictal patterns (see Chapter 5.3.3). A survey from a large neurology clinic showed that the incidence of schizophrenia is about nine times that of the rest of the population.[26]

Inter-ictal psychoses include the chronic schizophrenia-like psychoses described by Slater *et al.*[27] and Trimble.[28] These almost always arise in people with many years of well-established temporal lobe seizures, while the post-ictal variety occurs earlier in the life cycle but again in a person with previously diagnosed epilepsy. In post-ictal psychosis the temporal relationship to seizures, sometimes occurring in a cluster, is diagnostic, although a lucid interval is often observed. A clear history and independent description of seizures is the foundation of a diagnosis of epilepsy, with EEG confirmation. Resting EEGs show slight and subtle abnormalities in a substantial minority of patients with schizophrenia which may be accentuated by antipsychotic medication. As such, the EEG may be of limited value in differential diagnosis unless pronounced slowing or frank seizure activity is picked up (see also Chapter 5.3.3.).

(a) Symptoms

Symptoms of schizophrenic psychosis in relative isolation may give rise to diagnostic difficulties.

Auditory hallucinations may occur in alcoholic hallucinosis (see below and Chapter 4.2.2.3). Hallucinations in the context of dissociation (voices representing figures from the patient's past or embodiments of aspects of their personality) must also be distinguished from typical schizophrenic hallucinations. These are often multimodal. Pure auditory hallucinations in organic conditions including epilepsy in the absence of other psychotic features are surprisingly rare.

Certain forms of delusion suggest alternative diagnoses. Transient ill-formed but usually paranoid delusions occur in the context of confusion, memory impairment, or dementia (i.e. things going missing, strange people loitering). Delusions of misidentification are particularly associated with organic illness such as dementia or stroke.

Thought disorder may be confused with a fluent aphasia following stroke or cerebral tumours.

Personality deterioration and inappropriate or disinhibited behaviour can occur in many organic conditions in the absence of overt psychotic features. Isolated frontal lesions may cause diagnostic problems since general cognitive impairments may be absent. The widespread availability of CT and MRI in the more developed world has reduced the likelihood of such patients being misdiagnosed.

A small proportion (approximately 5 per cent) of prevalent and incident cases of schizophrenia, if investigated thoroughly, are found to have a variety of 'organic' conditions which may contribute to the illness.[29] These include metabolic abnormalities, cerebral tumours, multisystem autoimmune disease, cerebrovascular disease, etc. Some of these may be incidental; others may have precipitated the psychosis. The range of diseases counts against any specific aetiological mechanism. Similarly, the phenomenology found in such 'organic' patients is usually indistinguishable from their 'functional' counterparts.[30]

Thanks to increased application of non-invasive neuroimaging techniques to psychiatric patients, particularly those with schizophrenia, another class of organic abnormalities have been noted, namely cerebral anomalies which are often congenital. These include agenesis of the corpus callosum, cavum septum pellucidum, aqueduct stenosis, etc. Again, it is difficult to know how often such findings occur in the normal population and are asymptomatic, although the widespread use of MRI for 'minor' complaints such as mild head injury and headache is uncovering such anomalies. The examples above certainly appear to be associated with psychiatric disorders in general more than would be expected by chance. They tend to be associated with below-average IQ and other neurological problems (epilepsy in the cases of callosal agenesis).

Other factors to be taken into account in the differential diagnosis from organic conditions include the presence of a family history of schizophrenia, and abnormal premorbid personality, both of which weight aetiological judgement in favour of the functional diagnosis. This applies to the psychoses of epilepsy and those related to drug abuse especially. 'Secondary' schizophrenias also tend to have less pervasive effects on the person's personality. Treatment is again based on symptoms with the added complication that antipsychotic drugs lower the epileptic seizure threshold, and will tend to worsen extrapyramidal symptoms in patients with primary movement disorders. Treatment of the primary condition (if this has remained undiagnosed for some time) may be disappointing but should always be attempted especially in the case of chronic infections. Reversal of metabolic abnormalities, even long-standing, can lead to dramatic improvements in the mental state.

(b) Drug-induced psychoses

Many drugs of abuse and prescribed drugs can cause psychotic symptoms. The associations are also considered in Chapters 4.2.3.1 to 4.2.3.9. In the context of a differential diagnosis, drugs of abuse—in adolescents and young adults—must be considered. Chronic amphetamine psychosis may be indistinguishable from schizophrenia. The psychosis is florid and may include visual and auditory hallucinations. Phencyclidine (PCP or angel dust) is a drug of abuse in the United States and causes an acute psychosis with prominent affective symptoms as well as perceptual distortions and depersonalization. Other psychotogenic drugs include cocaine, ecstasy, and Lysergic Acid Diethylamide(LSD).

Cannabis is widely used, especially in large metropolitan areas and by certain ethnic groups (e.g. African-Caribbeans). Cannabis intoxication is more characterized by perceptual distortions and depersonalization than frank psychosis. Clinical experience suggests that cannabis has a propensity to precipitate psychotic relapse in patients with established schizophrenia and a recent meta-analysis of cohort studies concludes that cannabis use is certainly a risk factor for schizophrenia, and other psychiatric disorders.[31]

Delusions and hallucinations may occur rarely during states of alcohol intoxication but are more commonly associated with withdrawal syndromes (Chapter 4.2.2.2). Alcoholic hallucinosis is a chronic hallucinatory state of uncertain nosological status in which the patient with long-standing alcohol dependence often hears 'voices' which may be derogatory and commenting, in clear consciousness, after a lengthy withdrawal period.

(c) Prescribed medication

Again the list of agents that can cause psychotic reactions to be distinguished from schizophrenia is very long, and psychotropic drugs are particularly liable to cause psychotic reactions. Two classes of drug deserve mention because of their widespread use and relatively high incidence of major psychiatric adverse effects:

- steroids can cause a wide range of psychiatric disturbances including psychosis
- dopamine agonists used in the treatment of Parkinson's disease and some pituitary adenomas.

Frank psychosis and affective disorders may be seen. In the treatment of neurological diseases, such as Parkinson's disease, and the use of steroids for diseases of the central nervous system, there is often an interaction between the agent and the underlying condition which increases the likelihood of a drug-induced psychosis.

The diagnostic process

It used to be argued that a diagnosis of schizophrenia in itself caused disability and morbidity due to social 'labelling' and stigmatization. Evidence that this accounts for schizophrenic disability is lacking but the reality of the stigma of mental illness and negative attitudes towards 'schizophrenics' cannot be denied. This is especially delicate in the case of early intervention with people presenting without the full-blown schizophrenic syndrome since arguably, the balance of harms and benefits of diagnosis is tilted slightly away from benefit. Hence, making a diagnosis of schizophrenia should not be taken lightly. In the author's experience, very few psychiatrists spontaneously convey the diagnosis to the patient. If a patient asks whether he or she has schizophrenia, the clinician should first try to understand the motivation behind the question and the patient's knowledge and understanding of the term. Ultimately there is seldom justification in withholding the diagnosis if it is established. A schizophrenia diagnosis can be framed in a relatively positive light—this is a condition which we are now beginning to understand and for which there are effective treatments—and may lessen the burden of responsibility and blame that the patient and his or her family may carry for the disorder.

4.3.5 Epidemiology of schizophrenia

Assen Jablensky

Introduction

Epidemiological research into schizophrenia aims to answer four essential questions.

- What is the 'true' population frequency of the disorder in various populations and how is it distributed across the various groups within populations?
- Do the incidence, manifestations, and course of schizophrenia vary in relation to factors of the physical and social environment?
- Who is at risk and what forces determine or influence the risk of developing schizophrenia?
- Can the answers to the above questions help explain what causes the disorder and how to prevent it?

The hallmark of the epidemiological method (see Chapter 2.7) is the referral of a measure (numerator) of the occurrence of a disorder, or of any associated characteristics, to a population base (denominator), such as **person-years at risk**. The epidemiological study of diseases usually proceeds from a description of its frequency and associations (establishing rates of occurrence) to testing hypotheses about risk factors and causes by analysing ratios between rates.

Schizophrenia has been studied extensively from an epidemiological perspective since Kraepelin[1] introduced the concept of *dementia praecox* in 1896. In the first half of the twentieth century, epidemiological research into schizophrenia took two divergent paths. While European studies tended to focus on population distributions and genetic risks, North American researchers investigated the social ecology of the disorder. A variety of methods were explored and successfully applied by the pioneers of psychiatric epidemiology, and the contours of the epidemiological map of schizophrenia in Europe and North America were effectively laid down between the two World Wars. The early studies were carried out by dedicated researchers who often spent months or years collecting data 'door-to-door' in small communities. Close knowledge of the respondents, access to multigenerational records from the local parish registers, and the cooperation of the community resulted in studies that remain landmarks of psychiatric epidemiology (Table 4.3.5.1).

During the last several decades, the scope of epidemiological studies of schizophrenia has expanded to include populations in Asia, Africa, and South America about which little had been known previously. The World Health Organization (**WHO**) International Pilot Study of Schizophrenia and its successor, the WHO 10-country epidemiological study[9,10] were the first systematic investigations of the comparative incidence, clinical manifestations, and course

Table 4.3.5.1 Historical landmarks in the epidemiology of psychoses

Author	Method	Target population	Case-finding	Assessment
Koller (1895)[2]	The first epidemiological case-control study of psychoses	Probands with psychoses (n = 287) and non-psychiatric controls (n = 370)	Records of psychiatric hospitals and clinics	Genealogical inquiry
Luxenburger (1928)[3]	Twin concordance/discordance analysis; sampling design	Monozygotic and dizygotic twin pairs	Census of inpatients; search of birth registers for twin births	Emphasis on reliability of diagnosis: 'definite' and 'probable'
Brugger (1931)[4]	Census (door-to-door survey)	Area in Thuringia, population 37 561	Records and key informants consulted to detect 'suspected' cases	Personal examination of 'suspected' cases and of a control sample
Klemperer (1933)[5]	Birth cohort study	Random sample (n = 1000) from all births in Munich, 1881–90	Attempted tracing of all cohort members, 44% successfully traced	Personal examination or key informant interview (271 examined)
Ödegaard (1946)[6]	Cumulative national case register	Entire population of Norway	Registration of all first-admissions 1926–35 (n = 14 231)	Statistical analysis of hospital diagnoses and records
Essen-Möller *et al.* (1956);[7] Hagnell (1966)[8]	Census followed by repeated follow-up surveys	Rural community, initial population 2550 (+1013 new residents in the course of follow-up)	Complete census; tracing of migrants	Personal examination (and re-examination) of all residents

of schizophrenia in both developing and developed countries. The WHO programme was an impetus for similar studies in India, China, the Caribbean, and Australia. Two major studies of psychiatric morbidity in the United States, the Epidemiological Catchment Area project,[11] and the National Comorbidity Survey,[12] generated data on the prevalence of DSM-III/IIIR schizophrenia and related disorders in representative population samples. In the 1980s and 1990s, epidemiological studies increasingly utilized existing large databases such as cumulative case registers or birth cohorts to test hypotheses about risk factors, and began to include methods of genetic epidemiology. There is a current tendency towards integrating epidemiological approaches with other types of aetiological research in schizophrenia. This predicts an important role for epidemiology in the era of molecular biology of mental disorders.

Epidemiological methods and instruments in the study of schizophrenia

The measurement of the prevalence, incidence, and disease expectancy of schizophrenia depends critically on the sensitivity of the case-finding method (i.e. its capacity to identify all affected persons in a given population) and the availability of a diagnostic instrument or procedure that selects 'true' cases (i.e. those corresponding to an established clinical concept).

Case-finding

Case-finding designs fall into three broad groups: case detection in clinical populations, door-to-door surveys of population samples or whole communities, and birth cohort studies. Each method has its advantages and limitations.

While case-finding through the mental health services provides a relatively easy access to a substantial proportion of all persons with schizophrenia, the **cases in treatment** may not be fully representative of all individuals with the disorder. Bias related to gender, marital status, socio-economic factors, culture, or ethnicity are known to affect the probability of being in treatment at a given time in a given setting, and generalizations about schizophrenia from hospital or clinic samples are liable to error. Some of the deficiencies of case-finding through service contacts are avoided in cumulative national or regional psychiatric case registers, which cover large well-defined populations and can be linked to other population databases (e.g. birth records). This makes registers efficient research instruments in low-incidence disorders such as schizophrenia.

Surveys involve accounting for every person at risk within a defined community or a population sample in terms of either being or not being a case. Face-to-face interviews (and follow-up) of all residents in defined communities has been a feature of some high-quality research, especially in the Scandinavian countries. However, since the size of the populations surveyed in this way is limited, the number of detected cases of schizophrenia is usually too small to generate stable estimates of epidemiological parameters. Surveys of large populations involve two basic designs: a single-phase survey of a probability sample drawn from the general population, and a two-phase survey where a validated screening test is first applied to the entire population and only those scoring as screen-positive proceed to a full assessment. In the instance of schizophrenia, logistics dictates a choice between assessing large numbers less rigorously and investigating a smaller sample in greater depth. In the absence of a simple and valid screening procedure for schizophrenia, such as a biological or psychological test, the advantages of the two-phase survey may be offset by poor sensitivity or specificity of the screening device which is usually a questionnaire or checklist.

The study of **birth cohorts** at ages when their members have passed through the greater part of the period of risk for onset of schizophrenia is usually done by direct interviewing or by analysing available case register data. Well-characterized birth cohorts are among the best tools for the study of the incidence of schizophrenia and associated risk factors. However, even in settings where the population is stable and mortality and morbidity are adequately monitored, the size of birth cohorts with prospectively collected data may not be sufficient for conclusive epidemiological inferences.

All this suggests that there is no single 'gold standard' of case-finding for schizophrenia that could be applied across all possible settings, and the assets and liabilities of particular case-finding procedures need to be evaluated in the context of each study. This makes the detailed reporting of case-finding methods a mandatory prerequisite for an 'evidence-based' epidemiology of schizophrenia.

Diagnosis

Variation in diagnostic concepts and practices always explains a proportion of the variation in the results of schizophrenia studies, especially if they involve different populations or different periods. Until the 1960s, the diagnostic rules used in epidemiological research were seldom explicitly stated. In the late 1960s, the WHO International Pilot Study of Schizophrenia[10] examined diagnostic variation in schizophrenia across nine countries by comparing the diagnoses made by psychiatrists using a semi-structured clinical interview with diagnostic classification by a computer algorithm[13] utilizing the same interview data. The results demonstrated that in the majority of settings psychiatrists were using comparable diagnostic concepts in the Kraepelin–Bleuler tradition. The introduction of explicit diagnostic criteria and rules with the consecutive editions of **DSM** and the WHO's **ICD-10** improved further the reliability of diagnosis but did not resolve all diagnostic issues with implications for epidemiology. While ICD-10 and DSM-IV tend to agree well on the core cases of schizophrenia, they agree less well on the classification of atypical or milder cases. Such differences may be less important in clinical practice but they present a problem for epidemiological and genetic studies. By providing more restrictive criteria for schizophrenia, both classifications aim to identify clinically similar cases and to minimize false-positive diagnoses. This is not an unequivocal advantage for epidemiology. Applying such criteria at case-finding may result in the rejection of potential cases which fail to meet the full set of criteria at initial assessment. Therefore it is desirable to develop less restrictive screening versions of the DSM and ICD criteria for epidemiological research.

Instruments

The diagnostic instruments used in surveys which involve interviewing fall into two categories: fully structured interviews such as

the Diagnostic Interview Schedule (**DIS**)[12] and the Composite International Diagnostic Interview (**CIDI**)[14] both written to match exactly the diagnostic criteria of DSM-IIIR/IV and ICD-10, and semi-structured interview schedules such as the Present State Examination (**PSE**)[13] and the Schedules for Clinical Assessment in Neuropsychiatry (**SCAN**),[15] which cover a broad range of psychopathology and elicit data that can be processed by alternative diagnostic algorithms.

The DIS/CIDI type of instrument is reliable and capable of generating standard diagnoses of common mental disorders in a single-phase survey design. Its clinical validity in schizophrenia is less certain because symptoms may not be reported accurately or impairment may be underestimated by the respondent. In contrast, the PSE/SCAN allows a greater amount of psychopathological data to be elicited in a flexible clinical interview format, but its use in epidemiological studies presupposes availability of clinically trained interviewers. While SCAN and other similar interviews are suitable as second-stage diagnostic instruments, there is still a need for a relatively simple and effective screening procedure for case-finding of schizophrenia in field surveys.

Persons, place, time: descriptive epidemiology of schizophrenia

The epidemiological description of schizophrenia draws on extensive evidence available today on its frequency, age, and sex distribution in relatively large populations or geographical areas. Less than complete information is available on variations in its epidemiological characteristics that may be found in unusual or isolated populations, or on the temporal trends in its occurrence.

Prevalence, incidence, and disease expectancy

(a) Prevalence

Prevalence provides an estimate of the number of cases per 1000 persons at risk present in a population at a given time or over a defined period. **Point prevalence** refers to the 'active' (i.e. symptomatic) cases on a given date, or within a brief census period. Since asymptomatic cases (e.g. persons in remission) will be missed in a point prevalence survey, it is useful to supplement the assessment of the present mental state with an enquiry about past episodes of the disorder to obtain a **lifetime prevalence** index. In schizophrenia, which tends to a chronic course, estimates of point and lifetime prevalence will be closer to each other than in remitting illnesses.

An overview of selected prevalence studies of schizophrenia spanning nearly seven decades is presented in Table 4.3.5.2. The studies differ in many aspects of methodology but the majority of them feature a high intensity of case-finding. Several studies are repeat surveys in which the original population was reinvestigated following an interval of 10 or more years (the resulting consecutive prevalence figures are indicated by arrows).

The majority of studies have produced point prevalence estimates in the range 2.1 to 7.0 per 1000 population at risk and lifetime prevalence of schizophrenia in the range 15.0 to 19.0 per 1000. The figures are not uniformly standardized, and should be compared with caution because of demographic differences between populations related to factors such as age-specific mortality and migration. A **systematic review** of 188 studies in 46 countries, published between 1965 and 2002,[16] estimated the median value for point prevalence at 4.6 per 1000 persons and for lifetime prevalence at 7.2 per 1000.

Certain populations and groups deviate markedly from the central tendency. Strikingly high prevalence of schizophrenia (two to three times the national or regional average) has been found in geographically and genetically **isolated populations**, including small communities in Northern Sweden and Finland, and several Western Pacific islands (see Table 4.3.5.2). At the other extreme, a virtual absence of schizophrenia and a high rate of depression have been claimed for the Hutterites of South Dakota, a Protestant sect whose members live in close-knit endogamous communities sheltered from the outside world.[33] Negative social selection for schizoid individuals who fail to adjust to the lifestyle of the majority and eventually migrate without leaving progeny has been suggested (but not definitively proven) as an explanation. Results of two surveys in Taiwan,[21] separated by 15 years, point to a falling prevalence of schizophrenia (from 2.1 to 1.4 per 1000) in the context of major socio-economic change and an overall increase in total mental morbidity in the population.

The question about the extent of true variation in the prevalence of schizophrenia across populations has no simple answer. Methodological differences among studies, related to sampling, case-finding, and diagnostic assessment are likely to account for a good deal of the observed variation. As an example, the high mean prevalence rate of DSM-III schizophrenia reported from the Epidemiologic Catchment Area study in the United States[25] is difficult to reconcile with inconsistencies, such as a 13-fold difference in the rates for age group 18–24 years across the various sites of the survey. One possible reason is that the principal diagnostic instrument of the survey (DIS), administered by lay interviewers, may produce both false-positive and false-negative diagnoses of schizophrenia in a number of cases. Similarly, computer-generated diagnoses of 'non-affective psychosis' in the National Comorbidity Survey,[12] based on a version of the CIDI administered by lay interviewers, were found to agree poorly with clinicians' diagnoses when a subsample of the respondents were re-interviewed over the telephone.[34]

Notwithstanding such caveats in the interpretation of survey findings, the prevalence rates are fairly similar in the majority of studies, though certain specific populations clearly deviate from the modal value. Even in those instances, however, the magnitude of the deviation is modest compared with the 10- to 30-fold differences in prevalence observed in other multifactorial diseases (e.g. diabetes, ischaemic heart disease, multiple sclerosis) across populations.

(b) Incidence

The incidence rate (an estimate of the annual number of first-onset cases in a defined population per 1000 persons at risk) is of greater interest for the study of risk factors than prevalence since it represents the so-called force of morbidity (the probability of disease occurrence) in a given population, and is closer in time to the action of antecedent or precipitating factors. The estimation of incidence depends critically on the ability to determine reliably the point of **onset** of the disorder. In the case of schizophrenia, the long prodromal period and the fuzzy boundary between premorbid state and onset of psychosis make this particularly difficult. In the absence of an objective biomarker of the disease, onset is usually defined as

Table 4.3.5.2 Selected prevalence studies of schizophrenia

Author	Country	Population	Method	Prevalence per 1000 population at risk
Brugger (1931)[4]	Germany	Area in Thuringia (*n* =37 561); age 10+	Census; interview of sample	2.4
Strömgren (1938)[17]; Bøjholm and Strömgren (1989)[18]	Denmark	Island population (*n* = 50 000)	Census interviews; repeat census	3.9→3..3
Böök (1953);[19] Böök *et al.* (1978)[20]	Sweden	Genetic isolate (*n* = 9000); age 15–50	Census interviews; repeat census	9.5→17.0
Essen-Möller *et al.* (1956);[7] Hagnell (1966)[8]	Sweden	Community in Southern Sweden	Census interviews; repeat census	6.7→4.5
Lin *et al.* (1989)[21]	Taiwan	Population sample	Census interviews; repeat census	2.1→1.4
Crocetti *et al.* (1971)[22]	Croatia	Sample of 9201 households	Census based on hospital records and interviews	5.9
Dube and Kumar (1972)[23]	India	Four areas in Agra (*n* = 29 468)	Census based on hospital and clinic records	2.6
Rotstein (1977)[24]	Russia	Population sample (*n* = 35 590)	Census based on hospital and clinic records	3.8
Keith *et al.* (1991)[25]	USA	Aggregated data across five ECA sites	Sample survey; interviews	7.0 (point) 15.0 (lifetime)
Jeffreys *et al.* (1997)[26]	UK	London health district (*n* = 112 127)	Census; interview of sample (*n* = 172)	5.1
Kebede *et al.* (1999)[27]	Ethiopia	25 districts of Addis Ababa (*n* = 2 228 490)	Screening by self-report questionnaire, interviews of sample (*n* = 2042)	7.0 (point) 9.0 (lifetime)
Jablensky *et al.* (2000)[28]	Australia	Four urban areas (*n* = 1 084 978)	Census, screen for psychosis; interviews of sample (*n* = 980)	3.1–5.9 (point)[a] 3.9–6.9 (period, one year)[b]
Waldo *et al.* (1999)[29]	Micronesia	Island of Kosrae Genetic isolate	Screen of hospital records, interviews	6.8 (point)
Arajärvi *et al.* (2005)[30]	Finland	Birth cohort (*n* = 14 817) Genetic isolate	Case register data; interviews of 55% of register cases	15.0 (lifetime) 19.0[c] (lifetime)
Wu *et al.* (2006)[31]	USA (California)	Medicaid/Medicare health insurance data	20% random sample of insured subjects	5.1 (period, 1 year)
Perälä *et al.* (2007)[32]	Finland	National sample (*n* = 8028)	Screen for psychosis, interviews of sample; register and case note data also used	10.0 (lifetime) 22.9[d] (lifetime)

the point in time when clinical manifestations become recognizable and diagnosable according to specified criteria. The first hospital admission, which has been used as a proxy for disease onset in many studies, is not a robust indicator because of the variable time lag between the earliest appearance of symptoms and the first-admission across treatment facilities and settings. A better approximation is provided by the first-contact, i.e. the point at which any psychiatric, general medical, or alternative 'helping' agency is accessed by symptomatic individuals for the first time. A limitation common to both first-admission and first-contact studies is that they produce rates of 'treated' incidence and miss symptomatic cases that do not present for assessment or treatment. This limitation can be overcome by periodically repeated door-to-door surveys of the same population or by longitudinal cohort studies (though both are difficult to mount for reasons of cost and logistics).

Table 4.3.5.3 summarizes the essential features of 12 selected incidence studies of schizophrenia. Studies using a 'broad' definition of schizophrenia (ICD-8 or ICD-9) estimate about three-fold difference in the variation of rates, in the range from 0.17 to 0.57 per 1000 population per year, for first-admissions or first contacts. Studies using more stringent criteria, such as the Research Diagnostic Criteria (**RDC**),[121] DSM-IV, ICD-10, or **Catego S+**,[13] have reported incidence rates two to three times lower than those based on 'broad' criteria. A **systematic review** of data from some 160 studies from 33 countries, published between 1965 and 2001,[35] yielded a median value of 0.15 and mean value of 0.24 per 1000, with a five-fold range of the rates and a tendency for more recent studies to report lower rates.

Considering the methodological differences among individual studies, generalizing about the incidence of schizophrenia from pooled data may be problematic. To date, the only investigation

Table 4.3.5.3 Selected incidence studies of schizophrenia

Author	Country	Population	Method	Rate per 1000
Ödegaard (1946)[6]	Norway	Total population	First-admissions 1926–35 (n = 14 231)	0.24 (Hospital diagnoses)
Walsh (1969)[36]	Ireland	City of Dublin (n = 720 000)	First-admissions	0.57 (males, ICD-8); 0.46 (females, ICD-8)
Murphy and Raman (1971)[37]	Mauritius	Total population (n = 257 000)	First-admissions	0.24 (Africans); 0.14 (Indian Hindus); 0.09 (Indian Moslems)
Lieberman (1974)[38]	Russia	Moscow district (n = 248 000)	Follow-back of prevalent cases	0.20 (males) 0.19 (females)
Helgason (1977)[39]	Iceland	Total population	First-admissions (case register)	0.27 (ICD-8)
Lin *et al.* (1989)[21]	Taiwan	Three communities (n = 39 024)	Door-to-door survey	0.17 ('Bleulerian' criteria)
Castle *et al.* (1991)[40]	UK	London (Camberwell)	First-admissions (case register)	0.25 (ICD-9); 0.17 (RDC); 0.08 (DSM-III)
Rajkumar *et al.* (1993)[41]	India	Area in Madras (n = 43 097)	Door-to-door survey and key informants	0.41 (ICD-9)
Wig *et al.* (1993)[42]	India	A rural area (n = 1 036 868) and an urban area (n = 348 609) in Northern India	Case-to-case finding and key informants	0.38 (urban, ICD-9); 0.09 (urban, Catego S+); 0.44 (rural, ICD-9); 0.12 (rural, Catego S+)
Brewin *et al.* (1997)[43]	UK	Nottingham	Two cohorts of first contacts (1978–80 and 1992–94)	0.25→0.29 (All psychoses, ICD-10); 0.14→0.09 (ICD-10 schizophrenia)
Mahy *et al.* (1999)[44]	Barbados	Total population (n = 262 000)	First contacts; PSE interviews; Catego	(0.32 ICD-9); (0.28 Catego S+)
Bresnahan *et al.* (2000)[45]	USA (California)	Birth cohort (n = 12 094)	Case register study; cumulative risk by age 38	0.93 (males, DSM-IV) 0.35 (females, DSM-IV)

that has applied a uniform design and common research tools to generate directly comparable incidence data for different populations is the **WHO 10-country study**.[9] Incidence counts in the WHO study were based on first-in-lifetime contacts with any 'helping agency' within defined areas (including traditional healers in the developing countries) which were monitored over a 2-year period. Potential cases and key informants were interviewed by clinicians using standardized instruments, and the timing of onset was ascertained for the majority of the patients. In 86 per cent of the 1022 patients the onset of diagnostic symptoms of schizophrenia was within the year preceding the first-contact, and therefore the first-contact incidence rate was adopted as a reasonable approximation to the 'true' onset rate. Two definitions of 'caseness', differing in the degree of specificity, were used to determine incidence: a 'broad' clinical definition comprising ICD-9 schizophrenia and paranoid psychoses, and a more restrictive definition of PSE/Catego S+[13] 'nuclear' schizophrenia manifesting with Schneiderian **first-rank symptoms**. The rates for eight of the catchment areas are shown in Table 4.3.5.4.

The differences between the area rates for 'broadly' defined schizophrenia (0.16–0.42 per 1000) were significant ($p < 0.001$) but those for 'nuclear' schizophrenia were not, suggesting that the frequency of this diagnostic subgroup varies less across different populations. No differences were found between cases meeting only 'broad' ICD-9 criteria and the Catego S+ cases with regard to age at onset, or 2-year course and outcome. Therefore it is unlikely that 'nuclear' and 'broad' schizophrenia define two different clinical illnesses.

Replications of the design of the WHO 10-country study, including its research procedures and instruments, have been carried out with very similar results in India, the Caribbean, and the United Kingdom (Table 4.3.5.3).

(c) Disease expectancy (morbid risk)

This is the probability (expressed as a percentage) that an individual born into a particular population will develop the disease if he or she survives the period of risk for that disease. In the instance of schizophrenia the **period of risk** is usually defined as 15 to 54 years. If age- and sex-specific incidence rates are known, disease expectancy can be estimated directly by a summation of the age-specific rates within the period of risk. Alternatively, disease expectancy can be estimated indirectly from prevalence data.

The estimates of disease expectancy produced by a number of studies are fairly consistent across populations and over time. Excluding outliers, such as the northern Swedish isolate,[19,20] they vary about five-fold; in the WHO study, they range from 0.59 per cent (Aarhus) to 1.8 per cent (Chandigarh, rural area) for ICD-9 schizophrenia and from 0.26 per cent (Honolulu) to 0.54 per cent (Nottingham) for Catego S+ 'nuclear' schizophrenia. The frequently cited modal estimate of lifetime disease expectancy for broadly defined schizophrenia at around 1 per cent seems to be consistent with the evidence.

(d) Associations with age and sex

Schizophrenia may have its onset at any age—in childhood as well as past middle age—although the vast majority of onsets fall within the 15 to 54 years of age interval. Onsets in men peak steeply in the

Table 4.3.5.4 Incidence rates per 1000 population, age 15–54, for a 'broad' and a 'narrow' case definition of schizophrenia (WHO 10-country study)

Country	Area	'Broad' definition (ICD-9)			'Narrow' definition (CATEGO S+)		
		Male	Female	All	Male	Female	All
Denmark	Aarhus	0.18	0.13	0.16	0.09	0.05	0.07
India	Chandigarh (rural area)	0.37	0.48	0.42	0.13	0.09	0.11
	Chandigarh (urban area)	0.34	0.35	0.35	0.08	0.11	0.09
Ireland	Dublin	0.23	0.21	0.22	0.10	0.08	0.09
Japan	Nagasaki	0.23	0.18	0.20	0.11	0.09	0.10
Russia	Moscow	0.25	0.31	0.28	0.03	0.03	0.02
United Kingdom	Nottingham	0.28	0.15	0.22	0.17	0.12	0.14
United States of America	Honolulu	0.18	0.14	0.16	0.10	0.08	0.09

(Taken from Report of the international pilot study of schizophrenia, WHO 10-country study, © World Health Organization, www.who.int)

age group 20 to 24 years; thereafter the rate of inception remains more or less constant at a lower level. In women, a less prominent peak in the age group 20 to 24 years is followed by another increase in incidence in age groups older than 35. While the age-specific incidence up to the mid-thirties is significantly higher in men, the male-to-female ratio becomes inverted with age, reaching 1:1.9 for onsets after age 40 and 1:4 or even 1:6 for onsets after age 60. There seems to be no real 'point of rarity' between the symptomatology of late-onset schizophrenia and schizophrenia of an early onset.

The sex differences in mean age at onset are unlikely to be an invariant biological characteristic of schizophrenia. For example, within families carrying high-genetic risk (two or more affected members), no significant differences in age at onset have been found between male and female siblings with schizophrenia. In some populations (e.g. India and China) the male predominance in the frequency of onsets in the younger age groups is attenuated or even inverted.[46,47]

The question of whether the total lifetime risks for men and women are about the same, or different, has not been answered definitively. In the WHO 10-country study, the cumulated risks for males and females up to the of age 54 were found to be approximately equal. Scandinavian studies which followed up population cohorts into very old age (over 80) reported a higher cumulated lifetime risk in women than in men.[48]

Male–female differences have been described in relation to the premorbid history (better premorbid functioning in women), the occurrence of brain abnormalities (more frequent in men), course (a higher percentage of remitting illness episodes and shorter hospital stay in women), and outcome (higher survival rate in the community, less disability in women). However, there is no unequivocal evidence of consistent sex differences in the symptom profiles of schizophrenia, including the frequency of positive and negative symptoms. Generally, the sex differences described in schizophrenia are more likely to result from normal sexual dimorphism in brain development, as well as from gender-related social roles, rather than from sex-specific aetiological factors.

Fertility, mortality, and comorbidity

(a) Fertility

Earlier studies reported low fertility in both men and women diagnosed with schizophrenia. The mean number of children fathered by men with schizophrenia in Sweden was 0.9, and the average number of live births over the entire reproductive period of women treated for schizophrenia in Norway between 1936 and 1975 was 1.8, compared with 2.2 for the general female population.[49] Yet this phenomenon is neither universal nor consistent over time. In the WHO 10-country study,[9] the fertility of women with schizophrenia in India did not differ from that of women in the general population within the same age groups and geographic areas. Although men with schizophrenia continue to be reproductively disadvantaged, the fertility of women with schizophrenia has increased over the last decades and this trend is likely to be sustained as a result of deinstitutionalization and the greater number of people with mental disorders being able to live in the community.

(b) Mortality

Excess mortality associated with schizophrenia has been well documented by epidemiological studies on large cohorts. National case register data for Norway, 1926–1941 and 1950–1974, indicate that, while the total mortality of psychiatric patients was decreasing, the relative mortality of patients with schizophrenia remained unchanged at a level higher than twice that of the general population.[6] Similar findings have been reported from other European countries and North America, with standardized mortality ratios of 2:6 or higher for patients with schizophrenia, which corresponds to about 20 per cent reduction in life expectancy. A **meta-analysis** of 18 studies[50] estimated a crude mortality rate of 189 deaths per 10 000 population per year and a 10-year survival rate of 81 per cent. Mortality among males was significantly higher than among females, and the difference was primarily due to an excess in suicides and accidents. Unnatural causes apart, the leading causes of death among schizophrenia patients are similar to those in the general population, with the exception of a significantly lower than expected cancer morbidity and mortality, especially for tobacco-related malignancies in males with schizophrenia.[51] This puzzling phenomenon has been replicated by several case register and record linkage studies[52,53] and does not appear to be an artifact. Its causes remain unknown, though protective effects of both genes and antipsychotic pharmacological agents have been proposed.

The single most common cause of death among schizophrenia patients at present is **suicide** (aggregated standardized mortality ratios 9.6 for males and 6.8 for females) which accounts for 28 per cent

of the excess mortality in schizophrenia.[54] The suicide rate in schizophrenia patients is at least equal to, or may indeed be higher, than the suicide rate in major depression. In China, the relative risk of suicide in individuals with schizophrenia compared to those without has been estimated at 23.8.[47] Several risk factors, relatively specific to schizophrenia, have been suggested: being young and male, experiencing multiple relapses and remissions, comorbid substance use, awareness of the deteriorating course of the condition, and loss of faith in treatment. Data from successive patient cohorts in Denmark,[55] United Kingdom,[56] and Australia[57] suggest an alarming trend of increasing mortality in first-admission patients with schizophrenia. In the Danish study,[55] the 5-year cumulated standardized mortality ratios increased from 5.30 (males) and 2.27 (females) between 1971 and 1973 to 7.79 (males) and 4.52 (females) between 1980 and 1982. Particularly striking was the standardized mortality ratio of 16.4 for males with schizophrenia in the first year after diagnosis. In the Australian study,[57] suicide risk was highest in the first 7 days after discharge from inpatient care. These trends seem to parallel the significant reductions in the number of psychiatric beds. Whether the increases in suicide mortality are associated with the shift in the management of schizophrenia from hospital to community care remains to be established.

(c) Comorbidity: physical disease

There is significant comorbidity in schizophrenia, comprising: (i) common medical problems and diseases that affect schizophrenia patients more frequently than attributable to chance; and (ii) certain rare conditions or abnormalities which tend to co-occur with the disorder.

Physical disease is common but tends to be seriously undetected and underdiagnosed. Between 46 per cent and 80 per cent of inpatients with schizophrenia, and between 20 per cent and 43 per cent of outpatients, have been found in different surveys to have concurrent medical illnesses.[58] Persons with schizophrenia, and especially those who are homeless or injection drug users, are at increased risk for potentially life-threatening **communicable diseases**, such as HIV/AIDS, hepatitis C, and tuberculosis.[59,60] Among the chronic non-communicable diseases, patients with schizophrenia have significantly higher than expected rates of epilepsy, diabetes, arteriosclerosis, and ischaemic heart disease.[61–63] Obesity and the concomitant **metabolic syndrome** involving insulin resistance are becoming increasingly common problems in schizophrenia patients.[64] Although a high incidence of **diabetes** in schizophrenia patients had been described long before the introduction of neuroleptic treatment, a contributing role for some of the second-generation antipsychotic agents has not been ruled out.

Some rare genetic or idiopathic disorders, such as metachromatic leucodystrophy, acute intermittent porphyria, and coeliac disease, as well as dysmorphic features such as high-steepled palate, malformed ears and other minor physical anomalies have also been reported to co-occur with schizophrenia.[65,66] On the other hand, several studies have found a lower than expected rate of rheumatoid arthritis in schizophrenia patients.[67]

(d) Comorbidity: substance abuse

Substance abuse is at present by far the most common associated health problem among patients with schizophrenia[68] and may involve any drug of abuse or a polydrug combination. It seems, however, that the addictive use of cannabis, stimulants, and nicotine is disproportionately high among schizophrenia patients and may be linked to the underlying neurobiology of the disorder.[69,70] In a nationwide sample of patients with psychotic disorders in Australia,[28] a lifetime diagnosis of comorbid drug abuse, or dependence was made in 36.3 per cent of males and 15.7 per cent of females with schizophrenia (compared to 3.1 per cent and 1.3 per cent respectively in the general population). In addition to poor prognosis of schizophrenia in patients with heavy cannabis use,[71] a **systematic review** of published data on **cannabis** exposure and the onset of schizophrenia[72] concluded that early use increased the risk of psychosis in a dose-related manner, especially in persons at high genetic risk of schizophrenia. Similarly, **stimulants** tend to exacerbate acute psychotic symptoms in over 50 per cent of schizophrenia patients.[73] The prevalence of cigarette **smoking** among schizophrenia patients is, on the average, two to three times higher than in the general population,[74] but the evidence regarding any adverse effects of nicotine use on the onset and course of schizophrenia is equivocal. A population cohort study[75] found that smoking at ages 18–20 was associated with a lower risk of schizophrenia in later life and could have a specific neuroprotective effect independent of its overall harmful impact on health.

Geographical and cultural variation

To date, no population or culture has been identified in which schizophrenic illnesses do not occur. Also, there is no strong evidence that the incidence of schizophrenia is either uniform, or varies widely across populations, provided that the populations being compared are large enough to minimize the effects of small-area variation. The evidence that specific **psychosocial** or cultural factors play an aetiological role in schizophrenia is also inconsistent.[76] However, there are well-replicated findings of variations in the course and outcome of schizophrenia across populations and cultures that involve, above all, a higher rate of symptomatic recovery and a lower rate of social deterioration in traditional rural communities. Data supporting this conclusion were provided by the WHO studies[9] which found a higher proportion of recovering or improving patients in developing countries such as India and Nigeria than in the developed countries. Sampling bias (e.g. a higher percentage of acute-onset schizophreniform illnesses of good prognosis among Third World patients) was not a likely explanation. A better outcome in the developing countries was found in patients with various modes of onset, and the initial symptoms of the disorder did not distinguish good-outcome from poor-outcome cases. What causes such differences in the prognosis of schizophrenia remains largely unknown. The follow-up in the WHO studies demonstrated that the outcome of paranoid psychoses and affective disorders was also better in the developing countries. Such a general effect on the outcome of psychiatric disorders may result from psychosocial factors, such as availability of social support networks, non-stigmatizing beliefs about mental illness, and positive expectations during the early stages of psychotic illness, as well as from unknown genetic or ecological (including nutritional) factors influencing brain development.

The disease and disability burden of schizophrenia

According to WHO estimates[77,78] no less than 25 per cent of the total 'burden of disease' in the established market economies is

at present attributable to neuropsychiatric conditions. Measured as proportion of the disability-adjusted life-years (**DALYs**) lost, schizophrenia, bipolar affective disorder, and major depression together account for 10.8 per cent of the total, i.e. they inflict on most communities losses that are comparable to those due to cancer (15 per cent) and higher than the losses due to ischaemic heart disease (9 per cent).

An epidemiological perspective on risk factors and antecedents

Studies on clinical samples suggest a great variety of putative risk factors in schizophrenia. As clinical samples are rarely representative and often vulnerable to bias, epidemiological evidence helps in evaluating the significance of such conjectures. Genetic and environmental risk factors are considered further in Chapter 4.3.6.1.

Genetic risk: necessary and sufficient?

Family aggregation of schizophrenia is at present the only epidemiologically well-established risk factor for the disorder, with a relative risk for first-degree relatives of persons with schizophrenia in the range from 9 to 18. Allowing for diagnostic variation, the risk estimates generated by different studies are similar and suggest a general pattern of descending risk as the proportions of shared genes between any two individuals decrease.[79,80] Although **heritability** (commonly estimated at about 80 per cent) provides the basis for the search of specific genes and gene networks involved in schizophrenia causation, the extent to which genetic vulnerability alone is necessary and sufficient to produce the disorder remains unclear. While an environmental contribution to the aetiology of schizophrenia is highly plausible, the evidence in support of it is inferential, typically proceeding from the observation that the concordance for schizophrenia in monozygotic twins (sharing 100 per cent of their genes) is only about 50 per cent. The majority of investigators now agree that genes and environments should be studied jointly and three models of conjunction have been proposed[81]:

- The effects of predisposing genes and environmental factors are additive and increase the risk of disease in a linear fashion;
- Genes modulate the sensitivity of the brain to environmental insults;
- By fostering certain personality traits and associated behaviour, genes influence the likelihood of an individual's exposure to stressful environments.

Epidemiological research into possible environmental contributions to the causation of schizophrenia focuses on three main areas: pre- and perinatal brain damage, factors affecting neurodevelopment from infancy to late adolescence, and factors of the social and urban ecology. (See also Chapter 4.3.6.1)

Factors maintaining the incidence of schizophrenia in populations

Since the first epidemiological study on the reproduction patterns of people with psychoses,[82] reduced fertility among individuals with schizophrenia has been documented by numerous investigators. Coupled with the evidence that the lifetime risk of the disorder (about 1 per cent) is similar across populations and remains stable over time, the question about factors that sustain the incidence of schizophrenia despite a reduced **reproductive fitness**. An early hypothesis was proposed in 1964 by Huxley *et al.*[83] who argued that the high frequency of schizophrenia was evidence of 'genetic morphism' (a balanced polymorphism) whereby the low fertility of affected individuals could be compensated for by a higher than average fertility of clinically unaffected 'cryptoschizophrenic carriers' who possessed some selective advantage, e.g. resistance to shock, autoimmune disease, or infection. However, attempts to demonstrate such advantage in terms of disease resistance, adaptability to extreme environments, or ability and creativity, have been unsuccessful. Importantly, the selective advantage hypothesis assumed that schizophrenia was a single-gene disorder with low penetrance, whereas the majority of investigators today agree that schizophrenia is a **complex polygenic disorder** with incomplete or variable expression of the genotype, and widespread locus and allelic heterogeneity. The polygenic model implies that loss of susceptibility alleles resulting from the lower reproductive fitness of affected individuals would have a negligible effect on the overall gene pool in the population. The more recent hypothesis, that *de novo* germ-line mutations inherited from an ageing father[84] may be responsible for a substantial proportion of incident cases of schizophrenia, is difficult to reconcile with current knowledge that mutation rates for most human genes are within the range of 10^{-6} to 10^{-5} per generation, i.e. their contribution to the maintenance of schizophrenia in the population would be insignificant. Considering that both multiple genes and multiple exogenous factors are likely to be involved in the causation of schizophrenia, neither increased fertility in asymptomatic carriers of the risk genes, nor paternal inheritance of germ-line mutations appear to be necessary or sufficient for the persistence of the disorder.

Environmental insults during early development

(a) Season of birth

A 5 per cent to 8 per cent winter–spring excess of schizophrenic births was first described in 1929[85] and since then reported by numerous studies, mostly in the northern hemisphere (southern hemisphere data are less consistent). Though some of these studies did not have the sample size or statistical design needed to definitively prove or rule out a seasonal effect, **winter–spring births** were associated with a mild but significant increase of the relative risk for schizophrenia (RR = 1.11; CI 1.06–1.18) in a large population cohort from Denmark.[86] Thus, birth seasonality appears to be a robust finding in the epidemiology of schizophrenia,[87] though few biologically plausible and testable causal hypotheses have been advanced to explain it. One of them is the seasonally increased risk of intrauterine exposure to viral infection.

(b) Prenatal exposure to infection

In utero exposure to **influenza** has been implicated as a risk factor since a report that a significant proportion of adult schizophrenia in Helsinki was associated with presumed second-trimester *in utero* exposure to the 1957 A2 influenza epidemic.[88] Numerous studies, attempting to replicate the link between maternal influenza and schizophrenia, have since reached conflicting results, with negative findings reported from an increasing number of studies based on large population samples,[89,90] as well as studies including data on schizophrenia risk in the offspring of women with prospectively

recorded influenza infection during pregnancy.[91] However, positive association between schizophrenia in the offspring and maternal infection during pregnancy has been reported for **rubella**[92] and **toxoplasmosis**[93] and the issue of prenatal infection contributing to schizophrenia risk merits further study.

(c) Pregnancy and birth complications

Maternal obstetric complications, ranging from placental abnormalities in the first trimester of pregnancy to diabetes, pre-eclampsia, perinatal hypoxia, and low birth weight, are widely regarded to be risk factors in schizophrenia. This view is supported by a number of studies of small to moderate size, typically using a case-control design and relying on maternal recall of adverse events during pregnancy.[94] Population-based studies[95,96] using prospectively recorded obstetric data tend to report conflicting or inconclusive results, with generally small effect sizes (odds ratio less than two) for any positive findings.[97] However, several birth cohort studies with long-term follow-up have found significantly increased risk of adult schizophrenia in individuals who had survived severe, mainly **hypoxic perinatal brain damage**.[98,99] Birth weight (adjusted for gestation) is another factor that may have a complex relationship with schizophrenia risk. A large cohort study in Sweden[100] found a reverse J-shaped association between **birth weight** and adult schizophrenia, with significant hazard ratios of 7.03 for males of low birth weight (<2500 g) and 3.37 for those of high birth weight (>4000 g). It remains unclear, however, if severe obstetric complications, such as perinatal hypoxia or low birth weight, are capable of raising substantially the risk of schizophrenia in the adult in the absence of increased genetic risk. Maternal schizophrenia is associated with a higher rate of pregnancy complications, including low birth weight,[101] but it is not known if the effects of genetic liability and obstetric complications on schizophrenia risk in the offspring are additive or interactive. It is also possible that genetic predisposition sensitizes the developing brain to lesions resulting from randomly occurring less severe obstetric complications. Such gaps in knowledge or inconsistencies among research findings caution against an unqualified acceptance of obstetric complication as a proven risk factor in schizophrenia. Clarification of their role remains an important priority for epidemiological research.

Further information about studies of obstetric complications and hypoxic-ischaemic damage as risk factors for schizophrenia can be found in Chapter 4.3.6.1.

Developmental antecedents of schizophrenia

(a) Brain development and neurobehavioural markers

Children at high genetic risk for schizophrenia (i.e. having parents or other first-degree relatives with the disorder) tend to show early signs of aberrant neurodevelopment, including ventricular enlargement on computerized tomography[102] and decreased activation in the prefrontal and parietal regions of the heteromodal association cortex on functional magnetic resonance imaging.[103] Such imaging studies are limited by small sample size and their results may not be generalizable. However, population-based or cohort studies, such as the National Child Development Study in the United Kingdom have demonstrated a higher incidence of abnormal **motor and speech development** before 2 years of age, and of soft neurological signs (poor motor control, coordination, and balance), non-right handedness and speech defects between ages 2–15.[104]

(b) Cognitive and neurophysiological markers

Deficits in verbal memory, sustained attention and executive functions, as well as abnormalities in event-related brain potentials and oculomotor control[105–107] are common in patients with schizophrenia and antedate the onset of clinical symptoms. They also occur in a proportion of their clinically normal biological relatives, but are rare in control subjects drawn from the general population (see Chapter 4.3.3). Their specificity to schizophrenia needs to be investigated in larger population samples. Should such **endophenotypes** be validated as biological markers of schizophrenia by epidemiological studies, the power of risk prediction at the level of the individual is likely to increase substantially.

(c) Premorbid intelligence (IQ)

In a cohort study from Sweden,[108] involving a 15-year follow-up of 109 643 men conscripted into the army at age 18 to 20, the individuals who subsequently developed schizophrenia were compared with the rest of the cohort on the performance of IQ-related tests and tasks at the time of conscription. Controlling for potential confounders, the risk of schizophrenia was found to increase linearly with the decrement of IQ. The effect was mainly attributable to poor performance on verbal tasks and tests of reasoning. Similar results have been reported from a study in Israel linking psychometric assessment data of the army draft board with the national psychiatric case register.[109]

Premorbid social impairment

Individuals who develop schizophrenia as adults are more likely to manifest difficulties in social interaction during childhood and adolescence than individuals who do not develop schizophrenia. Among children at increased genetic risk (having a parent with schizophrenia), those who develop schizophrenia as adults have been found to show poorer social competence at age 7 to 12 and more passivity and social isolation in adolescence, as compared to those who do not develop the disorder.[110] The association between early 'schizoid' traits and risk of schizophrenia is not restricted to offsprings of parents with schizophrenia. Population-based evidence of early **socialization difficulties** (school problems, social anxiety, and preference for solitary play) in children who develop schizophrenia as adults is provided by the prospective study of a national birth cohort in the United Kingdom.[104] In the Swedish conscript study,[108] poor social adjustment during childhood and adolescence was significantly more common among those who subsequently developed schizophrenia than among those who did not. It should be noted, however, that the early behavioural traits that tend to be associated with schizophrenia in adult life have low specificity and their predictive value is limited.

Further information about studies of premorbid social impairment can be found in Chapter 4.3.6.1.

The social and family environment

(a) Early rearing environment

Support for an effect of the early rearing family environment on the risk of developing schizophrenia is provided by a study of a Finnish sample of **adopted children** born to mothers with schizophrenia (a high-risk group) and a control sample of adoptees at no increased genetic risk.[111] Though the rates of adult psychosis

or severe personality disorder were significantly higher in the high-risk group compared with the control group, the difference was entirely attributable to a subset of the high-risk children who grew up in dysfunctional or otherwise disturbed adoptive families—a result consistent with a gene-environment model of genetic influence on a person's sensitivity to psychosocial adversity.

(b) The urban environment

Earlier hypotheses that urban environments increase the risk of psychosis, either by contributing to causation (the breeder effect) or by attracting vulnerable individuals (the drift effect), have been revived in the light of recent epidemiological findings suggesting that urban birth is associated with a moderate but statistically significant increase in the incidence of schizophrenia, affective psychoses, and other non-affective psychoses.[112] It remains unclear whether the effect is linked to a factor operating pre- or perinatally, or a factor influencing postnatal development (see also Chapter 4.3.6.1).

(c) Social class

Since the 1930s, numerous studies in North America and Europe have consistently found that the economically disadvantaged social groups contribute disproportionately to the first-admission rate for schizophrenia. Two explanatory hypotheses, of **social causation** ('breeder') and of **social selection** ('drift'), were originally proposed.[113] According to the social causation theory, the greater socio-economic adversity characteristic of lower-class living conditions could precipitate psychosis in genetically vulnerable individuals who have a restricted capacity to cope with complex or stressful situations. In the 1960s, this theory was considered to be refuted by a single study[114] which found that the social class distribution of the fathers of schizophrenic patients did not deviate from that of the general population, and that the excess of low socio-economic status among schizophrenic patients was mainly attributable to individuals who had drifted down the occupational and social scale prior to the onset of psychosis. As a result, aetiological research in schizophrenia in recent decades has tended to ignore such 'macrosocial' variables. However, the possibility remains that social stratification, socio-economic status, and acculturation stress are contributing factors in the causation of schizophrenia.

(d) Migrants and ethnic minorities

An exceptionally high-incidence rate of schizophrenia (about 6.0 per 1000) has been found in the African–Caribbean population in the United Kingdom.[115,116] The excess morbidity is not restricted to recent immigrants and is higher in the British-born second generation of migrants. Similar findings of nearly four-fold excess over the general population rate have been reported for the Dutch Antillean and Surinamese immigrants in Holland.[117]

The causes of the phenomenon remain obscure. Incidence studies in the Caribbean do not indicate any excess morbidity in the indigenous populations from which migrants are recruited. Explanations in terms of biological risk factors have found little support.[118,122] A finding in need of replication is the significant increase of schizophrenia among the siblings of second-generation African–Caribbean schizophrenia patients compared with the incidence of schizophrenia in the siblings of white patients.[119] Such 'horizontal' increase in the morbid risk suggests that an environmental factor may be modifying the penetrance of the genetic predisposition to schizophrenia carried by a proportion of the African–Caribbean population. Psychosocial hypotheses involving acculturation stress, demoralization due to racial discrimination, and blocked opportunities for upward social mobility have been suggested but not yet definitively tested (see also Chapter 4.3.6.1).

Epidemiological issues for the next decade

The unprecedented growth of basic knowledge about the brain and the human genome opens up novel perspectives and opportunities in the study of complex disorders such as schizophrenia, which integrate concepts and tools of genetics, neuroscience, and epidemiology. Several issues with wide implications for future research are already emerging.

Is schizophrenia a single disease or a group of aetiologically distinct disorders?

Schizophrenia is characterized by extensive phenotypic variability and likely genetic heterogeneity. These two factors may be contributing disproportionately to the multitude of research findings that are inconsistent or difficult to replicate and there is increasing concern that the categorical diagnostic concept of schizophrenia may not demarcate a biologically homogeneous entity.[120] The likely existence of different **subtypes** of the disorder (Bleuler's notion of a 'group of schizophrenias') is rarely considered in genetic and other biological research into schizophrenia. Disaggregating a **complex phenotype** by identifying intermediate (endo-) phenotypes and quantitative traits as covariates has been a successful strategy in the genetic study of disorders such as type I diabetes, asthma, and dementia. While the clinical concept of schizophrenia as a broad syndrome with some internal cohesion and a characteristic course over time is well supported by current epidemiological evidence, its dissection into modular endophenotypes with specific neurocognitive and neurophysiological underpinnings is beginning to be perceived as a promising approach in schizophrenia genetics. The study of endophenotypes cutting across the conventional diagnostic boundaries may reveal unexpected patterns of associations with symptoms, personality traits or behaviours, as well as genetic polymorphisms, providing epidemiology with rich material for hypothesis testing at population level.

Molecular epidemiology of schizophrenia

Notwithstanding the difficulties accompanying the genetic dissection of complex disorders, novel methods of genetic analysis will eventually identify genomic regions, genes, and **interacting gene networks** underlying the predisposition to schizophrenia. The majority of genes involved are believed to be of small effect, although one cannot exclude the possibility that genes of moderate effects may also be found, especially in relation to the neurophysiological abnormalities associated with schizophrenia. Clarifying the function of such genes will be a complex task. Part of the solution is likely to be found in the domain of epidemiology, since establishing their population frequency and associations with a variety of phenotypic expressions is a prerequisite for understanding their causal role. Thus the molecular epidemiology of schizophrenia is likely to be the next major chapter in the search for its causes and cures.

Can schizophrenia be prevented?

The increasing investment in early diagnosis and treatment of **first episodes** of schizophrenia has raised questions whether people likely to develop schizophrenia can be reliably recognized prior to the onset of symptoms, and whether early pharmacological, cognitive, or social intervention can prevent the development of the disorder. While early diagnosis and timely treatment of symptomatic cases may improve the short- or medium-term outcome, the detection of people at risk with a view to preventative intervention is problematic. Screening young age groups in the population by using predictors such as family history of psychosis, obstetric complications, or abnormal eye tracking is likely to result in multiple false-positive and false-negative results and a generally low positive predictive value. Other candidate risk factors have not been evaluated at all epidemiologically. Problems of reliability of measurement apart, population-based screening will pose huge practical and ethical problems of having to treat a large number of individuals who do not have the disorder and missing many others who eventually will develop the disorder. From an epidemiological point of view, pre-symptomatic detection and preventative intervention in schizophrenia do not appear to be feasible for the time being.

Summary and conclusions

After nearly a century of epidemiological research, essential questions about the nature and causes of schizophrenia still await answers. Two major conclusions stand out.

- The clinical syndrome of schizophrenia is robust and can be identified in diverse populations, regardless of wide-ranging demographic, ecological, and cultural differences among them. This suggests that a common pathophysiology is likely to underlie the characteristic symptoms of schizophrenia. On balance, the evidence suggests that schizophrenia incidence and disease risk show relatively modest variation at the level of large population aggregates. However, the study of 'atypical' populations or pockets of very high or very low frequency of schizophrenia, such as in genetic isolates or minority groups, may provide **novel clues** to the aetiology and pathogenesis of disorder.
- No single environmental risk factor of major effect on the incidence of schizophrenia has yet been discovered. Further studies using large samples are required to evaluate potential risk factors, antecedents, and predictors for which the present evidence is inconclusive. Assuming that methodological pitfalls will be avoided by risk-factor epidemiology, and that multiple environmental risk factors of small to moderate effect will eventually be identified, the results will complement those of genetic research which also implicate multiple genes and networks. All this suggests that the key to understanding schizophrenia is likely to be in the unraveling of complex **gene-environment interactions**.

4.3.6 Aetiology

Contents

4.3.6.1 Genetic and environmental risk factors for schizophrenia

R. M. Murray and D. J. Castle

One thing that is certain about the aetiology of schizophrenia is that there is no single cause. This might reflect the fact that the schizophrenia construct itself is heterogeneous, such that specific subtypes might in the future be found to have specific causes. But it is more useful at this stage of our knowledge to conclude that, like other disorders such as ischaemic heart disease and diabetes mellitus, schizophrenia results from the cumulative effects of a number of risk factors. These may be crudely divided into the familial-genetic and the environmental, though there are clearly interactions between the two.

Familial–genetic risk

The most powerful risk factor for schizophrenia is having a relative afflicted with the disorder. Numerous studies have shown that the lifetime risk for broadly defined schizophrenia increases from about one per cent in the general population to about 10 per cent cent in first-degree relatives of patients with schizophrenia and to close to 50 per cent in those with two parents with the disorder.[1] However, familial aggregation does not prove that a condition is genetically transmitted; to look at this issue we need to turn to adoptee and twin studies.

Adoption studies

Adoptee studies offer the opportunity of separating the effects of familiality from genetics. In the first such study of schizophrenia, Heston and Denney[2] demonstrated that five out of 47 children of mothers with schizophrenia who were adopted away within a few days of their birth, later developed schizophrenia compared with none out of 50 adoptees with no family history of schizophrenia. Similar findings were reported from the Danish-American Study of Rosenthal *et al*[3] who found that a significantly higher proportion of the adopted-away offspring of parents with schizophrenia were classified as having schizophrenia or 'borderline schizophrenia', than were control adoptees. This study originated the concept of the schizophrenia spectrum disorder, which has come to include not only frank schizophrenia but also schizophreniform disorder, as well as schizotypal and possibly paranoid personality disorder.

In an extension of the Danish-American collaboration, Kety *et al.*[4] took all adoptees in Denmark who had schizophrenia and examined their biological and adoptive relatives; unlike the earlier adoption studies this one also used operational definitions of the

schizophrenia spectrum conditions. Fully 23.5 per cent of the biological first-degree relatives received a schizophrenia spectrum diagnosis compared with only 4.7 per cent of the biological relatives of normal control adoptees; the adoptive relatives of both groups of adoptees had very low rates of spectrum disorders.

Finally, Wender *et al.*[5] studied the grown-up children of normal individuals who, by mischance, had been placed with an adoptive parent who later developed schizophrenia, and found that they were at no increased risk of the disorder. Thus, adoption studies consistently indicate that the familial aggregation of schizophrenia is determined by individuals inheriting genes from someone with the disorder (or a related spectrum condition) rather than any effect of the intrafamilial culture (e.g. being brought up by a parent with schizophrenia).

Twin studies

Twin studies have come to the same conclusion. Gottesman,[1] who reviewed the literature, calculated the average probandwise concordance rate for broadly defined schizophrenia in monozygotic twins to be 46 per cent, compared with 14 per cent in dizygotic twins. This difference reflects that while monozygotic twins share all their genes, dizygotic twins share, on average, only half. Further evidence of the effect of heredity comes from the evidence that the concordance rate in 12 pairs of monozygotic twins who were reared apart was 58 per cent.[1]

The above twin studies preceded the introduction of operational definitions of schizophrenia. When studies with such definitions were carried out, the rates for both monozygotic and dizygotic twins were both lower, but the disparity between the two remained. Cardno *et al.*[6] examined 108 consecutive pairs of twins seen at the Maudsley Hospital in London, and reported probandwise concordance rates for DSM-IIIR schizophrenia of 42.6 per cent in monozygotic twins and 0 per cent in dizygotic twins.

What is the range of the clinical phenotype transmitted?

The fact that an individual can have the same genes as their co-twin with schizophrenia but have a better than evens chance of remaining non-psychotic indicates that it is not schizophrenia *per se* which is inherited but rather a susceptibility to it. Further evidence in support of this comes from a study which showed that the offspring of the identical but well co-twins of individuals with schizophrenia carry a risk of the disorder similar to that of the offspring of the affected twin.[7] Thus, the predisposition is transmitted without being expressed as schizophrenia.

As noted earlier, sometimes the predisposition may be expressed as non-psychotic spectrum disorders. In addition, family studies show that relatives of people with schizophrenia also show an increased risk of other psychotic conditions such as schizoaffective disorder, atypical and schizophreniform psychoses, and affective psychosis with mood-incongruent delusions. Thus, the clinical phenotype transmitted encompasses a range of psychotic conditions, as well as schizotypal personality disorder and paranoid personality. Within schizophrenia, researchers have asked whether different subtypes are differentially inherited. The results have in general been negative which is not surprising since clinicians know that an individual patient can appear predominantly hebephrenic on one admission and schizoaffective on another. However, there has been a consensus that paranoid schizophrenia is less familial than other types and is associated with a lower monozygotic twin concordance. Also, very late onset schizophrenia (late paraphrenia) appears to carry less genetic loading than early-onset types.

It has been repeatedly shown that schizophrenic symptoms can be summarized as three main factors: delusions and hallucinations (reality distortion), negative symptoms (psychomotor poverty), and disorganization or positive thought disorder.[8,9] Is schizotypal personality particularly closely related to one of these three core syndromes? Mata *et al.*[10] showed that schizotypal personality scores in non-psychotic relatives were significantly correlated with the presence of delusions and hallucinations in the probands; indeed, they were also correlated with premorbid schizoptypal traits in the childhood of the probands. Thus, it seems that certain families transmit schizotypal traits which manifest themselves in childhood; some family members remain schizotypal throughout life but in others this predisposition is compounded by other (genetic or environmental) factors so that the individual passes a threshold for the expression of delusions and hallucinations.

Genetic models

From the data reviewed above, we can conclude that schizophrenia cannot be explained by the inheritance of a single major gene. In any case, such simple Mendelian inheritance would be hard to square with the persistence of schizophrenia in the population. Since people with schizophrenia tend to reproduce less frequently than the rest of the population, one would have expected that a single major gene with such damaging consequences would have been selected out of the gene pool.

The evidence is compatible with oligogenic inheritance (a small number of genes involved) but most parsimonious is a polygenic model which postulates that a number of genes of small effect are involved. Support for this model comes from the fact that the risk to an individual increases with the number of affected relatives[1] and also that the monozygotic concordance rate is higher for those twins who had an early rather than late onset of psychosis.[6]

Family studies also show that the relatives of probands with an early onset have a higher morbid risk of psychosis than the relatives of late-onset patients.[11] These findings are compatible with the idea that schizophrenia is in part a developmental disorder and that some of the susceptibility genes may be involved in the control of neurodevelopment.[12]

Molecular genetic studies

Researchers have been using molecular techniques to seek the gene or genes that predispose to schizophrenia. The first technique to be used was that of linkage in which large families with several members affected with schizophrenia are studied to try and find a genetic marker that co-segregates with the disease. Two decades of linkage studies suggest that no gene can exist which increases the overall risk of schizophrenia by more than a factor of around three, and that, therefore, there are likely to be a number of susceptibility genes of small effect. This is the mode of transmission for other chronic disorders such as diabetes and hypertension, and, as with these disorders, the genetic basis of schizophrenia is beginning to be unravelled. In the past few years, findings from linkage studies have led on to detailed mapping studies of certain chromosomal

regions which have in turn implicated specific genes. Those for which there is most evidence currently are neuregulin and dysbindin.

Neuregulin[13]: An association between schizophrenia and a multi marker haplotype (a pattern of DNA within a gene) of Neuregulin 1 (**NRG1**) on chromosome 8p21–22 was found in an Icelandic sample in 2002 and soon replicated in a Scottish population. Subsequently, neuregulin has been implicated in other studies although the exact haplotype has varied in the different studies.

Dysbindin: Also in 2002, Straub *et al.*[14] reported, in Irish families, association between schizophrenia and several SNPs (single nucleotide polymorphisms) and multimarker haplotypes spanning the gene encoding dystrobrevin-binding protein 1 (**DTNBP1**), or dysbindin, located at chromosome 6p22.3. Some but not all other studies have replicated this association.

Another way of identifying susceptibility genes is through the study of chromosomal rearrangements. Thus, Blackwood, *et al.*[15] reported that a large Scottish pedigree showed strong evidence for linkage between a balanced chromosomal translocation (1, 11) (q42;q14.3) (two portions of the different chromosomes swapping positions with each other) and a broad phenotype consisting of schizophrenia, bipolar disorder, and recurrent depression. This translocation caused the disruption of a gene, termed disrupted in schizophrenia 1 (**DISC1**). Subsequent studies have examined DISC1 in Finnish and US samples, and have suggested that it may be a susceptibility gene for both schizophrenia and bipolar disorder.

A third approach, that of association studies, takes a gene that is suspected of involvement in the pathogenesis of the disorder and compares the frequency of its various alleles in a series of individuals with schizophrenia as opposed to a control group without schizophrenia. One such gene is the catecholamine O-methyl transferase (**COMT**) gene which has been extensively investigated because of its role in dopamine metabolism, especially in the prefrontal cortex.[16, 17] A mis-sense mutation (incorrect unit in the genetic code) generates a valine to methionine substitution at codon 158 (Val158Met), producing an unstable enzyme with reduced degradation of dopamine. The evidence that this polymorphism is in itself a susceptibility gene is uncertain but as we shall see later, it may compound other risk factors for schizophrenia.

Neuregulin, dysbindin, and DISC 1 are the most replicated putative susceptibility genes for schizophrenia but other plausible candidate genes identified by linkage and follow-up studies such as **G72** (D–amino acid oxidase activator, DAOA), have been suggested. G72 and several of the other putative risk genes appear to carry not only an increased risk of schizophrenia but also of bipolar disorder, and are thus congruent with the results of a twin study which suggested substantial genetic overlap between the two major psychoses.

Nevertheless, none of the above genes can yet be said to be 100 per cent proven as a cause of schizophrenia since there remain inconsistencies between the specific risk alleles and haplotypes among studies. It is unlikely that there is a simple relationship between carrying one risk allele and developing schizophrenia. Rather, an individual may need to carry a number of risk genes and be exposed to several environmental risk factors. In such a dynamic multifactorial model, several genes of small effect interact with each other and with time-specific exposure to environmental risk factors contribute to both the onset and outcome of schizophrenia.

Biological abnormalities in the relatives of people with schizophrenia

Relatives have been examined for some of the biological abnormalities which are found in their kin with schizophrenia. Thus, in the Maudsley Study of families multiply affected with schizophrenia, both the members with schizophrenia and those unaffected relatives who appeared to be transmitting the liability to the disorder (so-called obligate carriers) showed larger lateral ventricles than controls.[18, 19] McDonald *et al.*[20] went on to show that such families transmit a grey matter pattern that shows deficits in frontal and temporal areas and that the greater the genetic liability, the greater the deficit.

In the same Maudsley Family Study, the non-psychotic relatives exhibited other neurophysiological abnormalities such as an excess of delayed P300 event-related potentials; their prevalence was not as high as in the patients themselves but higher than in unaffected controls.[21] Those patients who showed an excess of saccadic distractability errors tended to have relatives with the same eye-tracking abnormalities.[22] The patients with schizophrenia and their well relatives from these multiply affected families also showed more integrative neurological abnormalities than controls.[23]

These findings suggest that what is being transmitted is not genes for schizophrenia *per se* but rather genes for a variety of characteristics (e.g. schizotypal personality, enlarged lateral ventricles, grey matter deficit, delayed P300, integrative neurological abnormalities) which may increase the risk of schizophrenia or at least be markers thereof. Individuals can inherit these characteristics without being psychotic; perhaps schizophrenia only ensues when an individual inherits a number of such endophenotypic abnormalities and passes a critical threshold of risk.[24]

Advancing paternal age in non-familial schizophrenia

An interesting finding first noted over 30 years ago is that schizophrenia is commoner in those whose fathers were old at the time they were born. One of the largest studies to demonstrate this comes from Sipos *et al.*[25] who studied the risk of schizophrenia in 7 54 330 people born in Sweden. The overall hazard ratio for developing schizophrenia increased with each 10 year increase in paternal age. This association between paternal age and schizophrenia has been repeatedly shown to be present in those with no family history of the disorder, but not in those with a positive family history. This stronger association between paternal age and schizophrenia in people without a family history raises the possibility that accumulation of de novo mutations in paternal sperm with ageing contributes to the risk of schizophrenia.

Environmental factors

It is evident from above that genes exert a probabilistic rather than a deterministic effect on the development of schizophrenia; environmental risk factors appear to be necessary for the disease to become manifest in many, if not all, cases.[26] But what are these environmental risk factors?

Pre- and perinatal complications

More than 20 studies have shown that patients suffering from schizophrenia are more likely to have a history of pre- or perinatal complications (collectively termed obstetric complications) than

are healthy subjects from the general population, patients with other psychiatric disorders, and their own healthy siblings.[27] Some of the studies which reported these findings were based upon interviews with patients' mothers asking them to recall their pregnancies; such interviews are obviously open to distortion by recall bias. However, similar findings have been reported by studies examining data collected in obstetric records at the time of birth of patients and controls.[28] Indeed a meta-analysis of large epidemiologically sophisticated studies which used contemporary records confirmed that there is modest but consistent effect of obstetric complications. [29]

Of course, it is possible that the excess obstetric complications in schizophrenia may be the consequence of some pre-existing abnormality. Since the foetus plays an active role in the normal progress of pregnancy and labour, foetal impairment induced by earlier abnormality may itself result in some perinatal complications. Also, some studies have shown that women with schizophrenia who become pregnant tend to have more obstetric complications, possibly owing to their behaviour during pregnancy, for example smoking and not attending antenatal visits.

The term 'obstetric complications' covers a broad range of obstetric events. An international study on 700 schizophrenic patients and a similar number of controls found that low birth weight, prematurity, and resuscitation at birth were particularly increased in the schizophrenic patients;[27] other complications that have been implicated include retarded foetal growth and rhesus incompatability. Thus, a common characteristic of most of the obstetric complications implicated is that they increase the risk of hypoxia.

Could hypoxic–ischaemic damage be the mechanism that increases the risk of later schizophrenia? Children who were subject to cerebral hypoxia at or before birth show an excess of abnormalities on MRI scan, of minor neurological signs, and of cognitive and behavioural problems, characteristics also found in many preschizophrenic children.[30] As one might predict, studies of monozygotic twins discordant for schizophrenia have shown that the affected twins have larger lateral ventricles and smaller hippocampi than their well co-twins;[31,32] furthermore, those twins who have been subjected to the most severe perinatal difficulties have the largest ventricles and smallest hippocampi.[33]

Similarly, Stefanis *et al.*[34] compared hippocampal volume in three groups, viz, schizophrenia patients with affected relatives but with no personal history of obstetric complications; schizophrenia patients with no affected relatives but who had a history of significant obstetric complications; and normal controls. Hippocampal volume was normal in the first schizophrenia group but reduced in the second group, implying that it is hypoxic-ischaemic damage rather than genetic predisposition alone that determines decreased hippocampal volume in schizophrenia.

Season of birth and maternal exposure to infection

Many studies have shown (in the Northern Hemisphere at least) that people born in late winter and spring are slightly more likely than expected to later develop schizophrenia. Since respiratory viral infections such as influenza tend to occur in autumn and winter, maternal infection might provide the explanation. A number of epidemiological studies have, therefore, addressed the question of whether maternal exposure to influenza during the second trimester of pregnancy is a risk factor for schizophrenia; some but not all studies have suggested that it is.[35] One study[36] reported an association between the presence of antibodies to the influenza virus in first trimester blood, but not during the other trimesters. The possibility that prenatal exposure to rubella may have a similar risk-increasing effect for schizophrenia has been raised, and a significant association has been reported with serologically-documented rubella exposure in gestation[37] Some studies have implicated other infectious agents such as herpes simplex, cytomegalovirus and toxoplasmosis, but there is as yet no consensus as to whether these findings are replicable or not.

Severe prenatal malnutrion appears to have an effect. Thus, children born following the Dutch Hunger Winter when the Nazi occupiers systematically starved the population were shown to have a higher risk of schizophrenia and this finding has recently been replicated in a Chinese population.[38,39]

Childhood risk factors

There is now a wealth of evidence attesting to the fact that a proportion of individuals who later manifest schizophrenia show abnormalities in their early development. The evidence for early developmental abnormalities in schizophrenia come from three main sorts of study:

- high-risk studies in which the offspring of parent(s) with schizophrenia are examined;
- follow-back studies where cases of schizophrenia are ascertained, and their early developmental trajectory plotted with the help of history from the individual and family, sometimes also including such evidence as school reports; and
- cohort studies, where birth cohorts are followed up prospectively, and individuals who later manifest schizophrenia are compared with the rest of the cohort in terms of their early development.

(a) High-risk studies

Studies of the offspring of mothers with schizophrenia, the so-called 'high-risk studies', show that between a quarter to a half show some deviation from normal in terms of their early development (reviewed by Davies *et al.*[40]) In the neonatal period, there is a tendency to hypotonia and decreased cuddliness; in infancy, milestones are delayed; in early childhood, there is poor motor co-ordination; and in later childhood, there are deficits in attention and information processing. Fish *et al.*[41] followed their cohort of 12 high-risk infants into adulthood. One developed schizophrenia and six showed schizotypal or paranoid personality traits; these authors coined the term 'pandysmaturation' to describe the abnormalities which included delayed motor milestones in the first two years of life.

(b) Follow-back studies

High-risk studies have been criticized on the basis that they are unrepresentative because only a minority of people who develop schizophrenia have a mother with the same illness. Therefore, a separate set of studies of representative groups of patients with schizophrenia have used maternal recall to document the early development of adults with schizophrenia. These have shown impairment of cognitive and neuromotor development and interpersonal problems. These findings are more commonly reported in males than females, and tend to be associated with an early onset of illness.[42] The findings are not specific to schizophrenia, being

reported also in the early development of some children who later manifest an affective psychosis.[43]

Of course, one of the major criticisms of follow-back studies is the likelihood of recall bias. Studies that have avoided this problem include those which have accessed IQ scores assessed prior to illness onset; these have shown that premorbid IQ is, on average, lower in those, particularly males, who later manifest schizophrenia.[44, 45]

Another source of material mapping early development has been childhood home videos, which have been reviewed by researchers 'blind' to whether the individual later manifested schizophrenia.[46] In comparison with their healthy siblings, the preschizophrenic children showed higher rates of neuromotor abnormalities (predominantly left-sided) and overall poorer motor skills; the group differences were significant only at two years of age.

(c) Cohort studies

Cohort studies have overcome many of the criticisms of follow-back studies. In an investigation of the 1958 British Perinatal Mortality cohort, comprising 98 per cent of all children ($n = 15\,398$) born in the United Kingdom in a certain week in March 1958, Done *et al.*[47] compared those who later manifested schizophrenia ($n = 40$), affective psychosis ($n = 35$), and neurotic illness ($n = 79$) with each other as well as with 1 914 randomly selected individuals with no history of mental illness. At age seven years, teacher ratings showed the preschizophrenic children to have exhibited more social maladjustment than controls; the effect was most marked in boys. The preaffective children differed little from normal controls, whilst the preneurotic children (expressly girls) showed some maladjustment (over- and under-reaction) at age 11 years.

In a similar study of the 1946 British Birth Cohort, Jones *et al.*[48] determined that 30 out of 4 746 individuals had, in adulthood, developed schizophrenia. This group was more likely than the rest of the cohort to show delayed milestones and speech problems, to have a lower premorbid IQ and lower education test scores at ages 8, 11, and 15 years, and to prefer solitary play at ages 4 and 6 years. Perhaps the most influential of all the cohort studies has been the Dunedin Birth Cohort Study, which followed the development of 1 037 children through the ages of 3 to 15 years, and assessed them again at the ages of 18, 21, and 26 years.[49] This study found that poorer motor development, poorer receptive language, and a lower IQ all increased the risk of subsequently developing schizophreniform disorder by age 26 years. The Dunedin cohort additionally provided evidence that a proportion of children who develop schizophrenia are already experiencing 'quasi-psychotic' phenomena by age 11 years.[50] These phenomena include beliefs that people are reading their minds or following or spying on them, or they are already hearing voices. Children with strong evidence of quasi-psychotic symptomatology were up to 16-times more likely to develop schizophreniform disorders by the age of 26 years; making these phenomena some of the most powerful early predictors of later psychosis.

Together, such studies provide compelling evidence for a tendency of individuals with schizophrenia to show abnormalities in development which antedate the onset of illness. The findings are compatible with the notion that subtle brain abnormalities (which may be genetically or environmentally mediated, or both) underpin schizophrenia. However, it is also possible that some of the childhood risk factors are independent and act in an additive manner to set individuals on an increasingly deviant trajectory towards schizophrenia.

Social and geographic risk factors

Recent dogma about schizophrenia has held that the incidence does not vary by time or place, even though such an occurrence would have made schizophrenia unique among diseases! Now this curious belief has been disproved by a raft of studies. In particular, a systematic review by McGrath *et al.*[50] concluded that the incidence of schizophrenia shows prominent worldwide variation (up to five-fold), and that it is about 40 per cent greater in men than women.

In 1939, Faris and Dunham[52] reported that an excess of individuals with schizophrenia was found in certain deprived inner-city areas. These authors suggested that social isolation in poor deprived parts of the city could precipitate schizophrenia. However, subsequently, their results were interpreted as a consequence of social drift, i.e. the idea that individuals with this illness 'drift' down the social scale.[53] This effect was postulated to result from not only the illness itself but also its prodroma and consequences such as loss of employment and estrangement from family. A related finding is that of lack of upward social mobility in individuals with schizophrenia. For example, Hollingshead and Redlich[54] reported that individuals with schizophrenia to be less likely than expected to attain the socio-economic status of their fathers.

More recently, research has focused on the apparent excess of individuals who later manifest schizophrenia, who actually start life in a setting which appears to increase the subsequent risk of schizophrenia. Kohn[55] stated that '... in all probability, lower class families produce a disproportionate number of schizophrenics' but the evidence concerning such 'social causation' is contradictory. Thus, Turner and Wagenfeld[56] reported fathers of schizophrenia patients to be themselves over-represented in lower socio-economic groups. However, Jones *et al.*[48] did not find this.

It may be that it is not so much poverty as being born or brought up in a city which increases the risk of the disorder. For example, Lewis *et al.*[57] found that Swedish conscripts who later manifested schizophrenia were 1.65 times more likely to have been born in urban than rural areas. Similarly, Marcelis *et al.*[58] reported that birth in an urban area of Holland carried twice the risk of later schizophrenia of birth in a rural area. Similar findings have come from Denmark where those individuals born in Copenhagen appear to have twice the risk of schizophrenia of those born in rural areas.[59] It is now generally accepted that the incidence is higher amongst those brought up in urban areas, and that the larger the town, and the longer the individual has lived in the city, the greater the risk. The exact mechanisms underlying this effect remain unclear.

Immigration

Since the classic study of Odegaard in 1932,[60] many studies have reported that migrants are at increased risk of schizophrenia. A recent meta-analysis of 18 studies of migrants from different backgrounds confirmed a weighted mean relative risk for first-generation migrants of 2.7 (95 per cent CI 2.3–3.2) and for second generation migrants, 4.5 (95 per cent CI 1.5–13.1). Risk was higher for migrants from lower socio-economic countries, and for black people moving into predominantly white societies.[61]

A notable example has come from a series of studies of African-Caribbeans resident in the United Kingdom, who show a markedly higher rate of schizophrenia than do their white

British-born counterparts.[62]This is in the absence of any increased risk to Caribbeans who remain in the West Indies.[63] The increase is striking. The large and sophisticated AESOP study of three English cities demonstrated a ninefold increase in the incidence of schizophrenia among African Caribbeans, and a six-fold increase among those of African origin.[64] Boydell *et al.*[65] further demonstrated that migrants were especially vulnerable if relatively isolated in localities where their own ethnic group were in a small minority. Of particular interest is that this increased risk also pertains to British-born offspring of Caribbean migrants, discounting an explanation in terms of migration stress alone. Furthermore, there is a marked increased risk in the siblings but not the parents of this second generation;[63] this suggests an environmental effect operating particularly upon this second generation.

Initial studies sought to ascertain any evidence of developmental disadvantage such as poor maternal nutrition, poor obstetric care, and possible maternal susceptibility to novel viruses. However, these studies have shown that, if anything, African-Caribbean schizophrenic patients in England show less evidence of neurodevelopmental insult than their white counterpart patients. Other research focuses on the possibility that a paranoid reaction to social disadvantage and discrimination may be one factor. The findings relating to skin colour potentially support the notion of perceived or real discrimination being an important variable. Other work suggests that people in certain migrant communities are particularly likely to be exposed to risk-increasing factors such as childhood adversity (e.g. parental separation) and adult social exclusion.

Life events

Brown and Birley[66] reported an excess of life events in the 3 weeks preceding schizophrenic relapse. Further studies were conflicting in their findings, possibly due to methodological problems. The study of Bebbington *et al.*[67] avoided many of the methodological pitfalls, assessing life events in 97 psychotic patients (52 with schizophrenia) and general population controls. There was a significant relationship between life events and onset or relapse of schizophrenia, although it was not as strong as for depressive psychosis. One possibility is that certain types of schizophrenic patients are particularly vulnerable to relapse following adverse life events. For example, Bebbington *et al.*[67] found females to be particularly prone, whilst van Os *et al.*[9] found life events to be associated with a less severe good-outcome illness.

There is also evidence that families who exhibit high 'expressed emotion' (comprising critical comments, hostility, and/or over-involvement) can provide an environment which enhances the risk of relapse in a family member with schizophrenia. Again, cause and effect are difficult to tease apart. Thus, it is possible that patients with more severe and intractable illnesses may induce more expressed emotion in their relatives. It is clear, though, that family interventions aimed at reducing levels of expressed emotion can be effective in reducing relapse rates in the individual.

Drug abuse

Numerous studies attest to the fact that illicit substance use is more prevalent in patients with schizophrenia than in the general population; estimates of the prevalence of such comorbidity in individuals with schizophrenia range from 20 to 60 per cent, and are consistently higher than in well controls.[68]

Whether illicit substances actually cause schizophrenia has been very contentious. The most robust methodology to consider this issue is a cohort design, and a number of such studies have now investigated whether premorbid exposure to cannabis is associated with an increased later risk of schizophrenia. Arseneault *et al.*[69] reviewed these studies and concluded that cannabis could be considered a cumulative casual factor in some cases of schizophrenia, operating in consort with other predisposing factors to 'tip the scales' in some individuals who might not otherwise have manifested the disorder. This literature needs to be seen in the light of the fact that the vast majority of people who use cannabis do not develop schizophrenia, and the majority of cases of schizophrenia are not caused by cannabis; it has been estimated that the population attributable fraction for cannabis and schizophrenia is of the order of 5 per cent to 8 per cent.

Similarly, although clinical wisdom suggests that illicit substance use has a negative impact on the longitudinal course of schizophrenia, there are few methodologically sound studies in this area.[70, 71] Indeed, even the finding of an excess of use, and the association of such use with a poor longitudinal course, is potentially explicable by confounding factors such as substance abuse by the patients who are more ill. On balance, though, it seems reasonable to conclude that illicit substances make the longitudinal course of illness worse, and that patients with schizophrenia should be strongly advised to seek help to cease such behaviours.

Risk factors, age of onset, and outcome

Individuals who have been exposed to certain risk factors for schizophrenia tend have an earlier onset of psychosis than those who have not. Thus, age of onset is earlier in those whose relatives show a high morbid risk of schizophrenia;[11] similarly, those twin pairs in which the schizophrenia has an early onset show the highest monozygotic concordance.[6]

Schizophrenia patients with an early age at onset of psychosis are also more likely than those with later onset to have had a history of exposure to obstetric complications,[72] while those who showed childhood deficits such as low IQ also tend to have an early onset.[45] Schizophrenia patients who abuse cannabis have also recently been shown to have an earlier onset than those who do not.

If a factor operates to increase the risk of schizophrenia and to bring on its onset, then it is logical to think that if it is still present then it will be associated with a poor outcome. Thus, a family history of schizophrenia, a history of obstetric complication, childhood low IQ, and continued drug abuse are all associated with a poor outcome. On the other hand, those patients who develop psychosis following stressful life-events tend to have a better outcome than those with no such precipitant.[9]

The risk factor model: Gene–environment interaction

Thus, one way of construing the aetiology of schizophrenia is to see individuals on a stress-vulnerability continuum in which genetic and environmental factors act in an additive manner until a threshold of liability for expression of psychosis is passed. An individual might, for instance, inherit a schizotypal personality but not develop frank psychosis unless exposed to some cerebral insult which

causes cognitive impairment; the sum of the two factors could produce the psychotic illness.

Assuming such a model in which a number of genes and environmental factors of small effect act additively, then the heritability of schizophrenia can be calculated to be between 66 and 85 per cent (i.e. a high proportion of liability to the disorder is under genetic influence). However, this assumes that the various factors operate additively, and much evidence is against this assumption. Rather, it seems that there is often an interaction between genetic susceptibility and environmental effects. As van Os and Marcelis[26] point out, it seems that certain individuals exposed to an environmental risk factor have a high risk of developing schizophrenia while others with a different genotype are at low risk.

Thus, the quality of upbringing can interact with genetic predisposition. For example, the Finnish Adoption Study has shown that when the offspring of women with schizophrenia are placed in a well-adjusted family, they have a lower risk of developing a schizophrenia spectrum disorder than if they are placed in a dysfunctional family, i.e the genotype renders the individual susceptible to the adverse effect of an adverse family environment.[73] Obstetric complications also appear to interact with, and compound, a genetic liability; the offspring of parents with schizophrenia are more likely to develop increased ventricular size following obstetric complications.

Similarly, there is evidence that individuals with a family loading for schizophrenia may be more susceptible to psychosis following abuse of cannabis.[74] The latter situation may be complicated by the possibility that individuals who inherit certain personality characteristics may be more likely to take drugs such as cannabis, i.e. their genotype renders them more liable to expose themselves to a factor to which they are genetically susceptible. Caspi *et al.*[75] investigating the Dunedin birth cohort study, presented evidence of a gene by environment (G x E) interaction between a functional polymorphism in the catechol-O-methyltransferase gene (COMT) and exposure to cannabis. The enzyme COMT has an essential role in the breakdown of dopamine in the prefrontal cortex. Caspi and colleagues showed that COMT moderates the influence of adolescent cannabis use, with at least a five-fold increased risk of developing schizophreniform disorder in cannabis users homozygous for the high activity Val allele (COMT); the Met/Met status offered relative protection (OR=1.1) while risk for heterozygotes was intermediate (OR=2.5). Furthermore, there was no correlation between the COMT genotype and cannabis use, indicating that COMT genotype does not influence cannabis consumption. This appears to be a the first clear example of a specific gene x environmental interaction predisposing for schizophrenia, but it remains to be replicated.

The implications

Having identified various risk factors for schizophrenia, we can proceed to consider the theoretical possibility of reducing the prevalence of certain risk factors and thus reducing the incidence of the disorder. From the point of view of public health, rare risk factors which have a big effect are much less important than common risk factors of even small effect. Thus, although familial risk has by far the biggest effect, it makes a smaller contribution to the total incidence of the disorder than environmental effects. Therefore, if all cases with an affected first-degree relative could be prevented, we would eliminate only about 10 per cent of the total cases. However, because being born in an urban area is so common, this small effect accounts for a much greater proportion of the population attributable fraction (33 per cent), i.e. if we could bring down the incidence of schizophrenia in cities to that in the countryside, we could theoretically eliminate one-third of all cases of the disorder. Of course, we could only do this if we knew what the critical urban factors were!

The importance of the evidence that early developmental factors are involved in the aetiology of schizophrenia lies in the fact that at least some of these are preventable. For example, advances in antenatal and perinatal care have reduced the frequency, and toxicity, of some obstetric complications. Similarly, vaccination programmes have reduced exposure to some viral infections in pregnancy and childhood. There could be a link between these developments and the decreased incidence of schizophrenia which has been observed in some western countries over recent decades.[76]

Nevertheless, most babies who are exposed to even severe obstetric complications will not later suffer from schizophrenia. Thus, there is at present no sense in attempting to improve antenatal care with the aim of reducing the occurrence of schizophrenia. There is one important exception. It is indisputable that the children of schizophrenic mothers have a higher risk of the disease if they are also exposed to obstetric complications. Therefore those women with schizophrenia who conceive must have the best possible antenatal care during their pregnancy, and steps should be taken to avoid any event (e.g. prolonged labour) which might lead to hypoxic damage to the baby.

The fact that preschizophrenic children show a number of impairments raises the possibility that predisposed individuals could be identified and 'rescued' by some intervention. Unfortunately, the childhood characteristics of such children are non-specific, and their predictive value for the later manifestation of the illness is too low to be of value for any preventative intervention, i.e. many children who show such deviation from normal in terms of early development do not later manifest schizophrenia, whilst other children who later develop schizophrenia have perfectly 'normal' early development. Furthermore, any such abnormalities must be seen in the total context of development, and it should be remembered that many such abnormalities are not static, but may be evident at some stages of development and not at others.

One might think that there is as yet little that can be done systematically to reduce the incidence of schizophrenia. However, one area where prevention is possible concerns drug abuse. The evidence concerning the abuse of cannabis is clear. If the population could be persuaded to avoid heavy use of cannabis, particularly the more potent varieties, then it is likely that a small but nevertheless significant proportion of cases of schizophrenia could be avoided.

4.3.6.2 The neurobiology of schizophrenia

Paul J. Harrison

The neurobiology of schizophrenia remains the subject of intense research activity. Here, the key issues and findings are described, divided into functional and structural aspects, and followed by a summary of the major neurobiological theories. Where possible, meta-analyses and systematic reviews are cited in preference to individual studies.

Functional neurobiology of schizophrenia

Dopamine

The dopamine hypothesis of schizophrenia has been neurochemically pre-eminent since the 1960s.(1) It proposes that the symptoms of schizophrenia result from dopaminergic overactivity, whether due to excess dopamine, or to an elevated sensitivity to it, for example because of an increased number of dopamine receptors. The hypothesis originated with two complementary observations: that effective antipsychotics were dopamine (D_2) receptor antagonists, and that dopamine-releasing agents such as amphetamine produce a paranoid psychosis.(2) It received support from various

findings of increased dopamine content and higher densities of D_2 receptors in post-mortem brain studies of schizophrenia, but proved difficult to refine or refute, for two main reasons. First, predictably, antipsychotics have marked effects on the dopamine system, confounding all studies of drug-treated subjects. Second, molecular biology revealed an unexpected complexity and diversity of dopaminergic genes, increasing the number of potential sites of dysfunction and mechanisms by which it might occur. For example, soon after the D_4 subtype of dopamine receptor was cloned, there were high profile reports that the receptor was up-regulated several-fold in schizophrenia, and might also be relevant for the actions of clozapine. However, neither suggestion was confirmed by further studies, and interest in this topic has subsided.

Despite these difficulties, substantial support for the dopamine hypothesis has now emerged, attributable largely to the availability of imaging-based methods to assess the dopamine system in the brain in vivo, free of medication, and post-mortem confounds. Notably, there is now strong evidence for a pre-synaptic dopamine abnormality, with several studies showing elevated dopamine synthesis, release, and higher dopamine receptor occupancy in the striatum.[3] The findings indicate a dysregulation and hyper-responsiveness of dopaminergic neurones in schizophrenia, sometimes referred to as 'hyperdopaminergia'. These abnormalities are present in patients with acute psychosis but not in patients in remission; recent data suggest that they may also occur in subjects in the prodrome of schizophrenia, and that they are localized to the associative parts of the striatum. It is not known whether the findings are specific to schizophrenia or common to other acute psychoses, whether they also affect dopamine pathways in the cerebral cortex, and whether they apply in all subjects with schizophrenia.[4] Neither is the cause of the hyperdopaminergia understood; one hypothesis is that it is downstream of a developmental deficit in the glutamatergic projections that regulate dopamine transmission,[5] another that it involves an imbalance between phasic and tonic modes of dopamine release.[6]

In addition to the excessive dopamine function associated with acute psychosis, there is also increasing evidence that deficiencies in dopamine transmission, especially in the dorsolateral prefrontal cortex, and genetically influenced, may underlie the working memory and allied cognitive deficits that occur in the disorder.[7] The relationship between these two facets of dopaminergic involvement in schizophrenia is not understood.

Glutamate

Phencyclidine and other non-competitive antagonists of the *N*-methyl-D-aspartate (NMDA) subtype of glutamate receptor produce a psychosis closely resembling schizophrenia.[8] This has driven the hypothesis of glutamatergic dysfunction in the disorder, particularly a disturbance of NMDA receptor-mediated glutamate transmission.[9] In support, drugs that enhance NMDA receptor function (via a variety of indirect mechanisms, since direct agonists are toxic) have some beneficial effects on positive, negative, and cognitive symptoms.[10] Also, impairment of NMDA receptor function in animal models, induced by either genetic or pharmacological manipulation, produces behavioural, structural, and neurochemical findings consistent with a 'schizophrenia-like phenotype'.[11,12] There is also a range of alterations in parameters of glutamate transmission in subjects with schizophrenia, including levels of glutamate receptors and of endogenous glutamate receptor modulators such as D-serine.[9,13] Interest in the glutamate system has been heightened with the realization that many of the putative susceptibility genes for schizophrenia have effects on NMDA receptors and their pathways[14] (see below).

Other neurotransmitters

A 5-hydroxytryptamine (5-HT, serotonin) involvement in schizophrenia was suggested because the hallucinogen lysergic acid diethylamide (LSD) is a 5-HT agonist. Recently, interest has focused on the 5-HT_{2A} receptor, for several reasons.[15] There is lowered 5-HT_{2A} receptor expression in the frontal cortex in schizophrenia, and a blunted neuroendocrine response to 5-HT_2 agonists; a high affinity for the receptor may contribute to the profile of atypical compared to typical antipsychotics, and variants in the gene are weakly associated with response to clozapine, and perhaps with schizophrenia. Elevated cortical 5-HT_{1A} receptors are also a replicated finding. Explanations for 5-HT involvement in schizophrenia include the trophic role of the 5-HT system in neurodevelopment, interactions between 5-HT and dopaminergic neurones, and impaired 5-HT_{2A} receptor-mediated activation of the prefrontal cortex.

GABA, the major inhibitory transmitter in the brain, has been implicated in schizophrenia, on the basis of findings of alterations in specific markers of GABAergic neurones and their connections as well as changes in GABA receptors.[16,17] The position of these alterations in the pathogenesis of schizophrenia is not known, as is also the case for the many other neurochemical differences that have been reported, e.g. in neuropeptides, endocannabinoids, muscarinic receptors, etc.[18]

Functional neuroimaging and cerebral activity

Cerebral activity in schizophrenia has been investigated by several methods, initially using positron emission tomography to measure regional cerebral blood flow and glucose utilization, and more recently using functional magnetic resonance imaging. The studies have addressed several questions: are there differences between cases and controls at rest, or correlations between patterns of activity and clinically defined groups of subjects, or does brain activation during the performance of cognitive tasks differ in those with and without the illness?

Hypofrontality—decreased activity in the frontal lobes—has been widely studied in schizophrenia since the first report in 1974. Results have broadly supported the notion, but with several important qualifications. The current view is that, whilst hypofrontality does occur in unmedicated subjects,[19] it is not an invariable finding, and may be related to clinical state.[20] Similarly, there are few other robust baseline differences in cerebral activity or perfusion between cases and controls. Instead, the focus has shifted towards the link between regional patterns of activation with specific symptoms, or with performance during cognitive tasks. Among the former category, a well-known example is that of Liddle *et al.*[21] who found that each of the three subsyndromes of chronic schizophrenia they had identified by factor analysis was associated with a different regional profile of cerebral blood flow. A relationship between superior temporal gyrus metabolic activity and auditory hallucinations has often been reported, sometimes lateralized to the left hemisphere.[22] Many other correlations between regional patterns of (de)activation and individual symptoms have also been reported.

A number of studies have investigated regional brain activation during the performance of various neuropsychological tests. For example, the hypofrontality of schizophrenia can be seen most clearly during working memory tasks, such as the Wisconsin Card Sort Test, which require activation of the frontal lobes, and at which patients are impaired. Conversely, when groups are matched for performance, subjects with schizophrenia show increased activation of these areas compared to controls, suggesting that they are less 'efficient' in how the information is processed, and requir greater 'effort' to achieve the same result. These issues illustrate that the situation is more complex than simply hypo- (or hyper-) frontality, but rather that there is a dynamic disturbance of frontal cortex function and regulation.[23] Beyond working memory and hypofrontality, a range of other specific correlations of this kind have been reported, but the key conclusion of this research is that cerebral dysfunction in schizophrenia is better conceptualized not as reflecting a static or single focal disorder, but as arising from abnormalities in distributed circuits linking specific cortical areas and subcortical nuclei. A prominent model is that of Andreasen,[24] who proposed the concept of 'cognitive dysmetria', in which deficits in activity in a circuit involving the cerebral cortex, thalamus, and cerebellum are key, and underlie the memory difficulties of schizophrenia. The view of the disorder as one of disturbed neural connectivity affecting multiple brain regions and their integration is supported by structural imaging and neuropathological data (see below). The model also highlights two other recent research themes: first, that brain areas beyond the 'traditional' ones (e.g. prefrontal cortex, hippocampus) and their interconnections are involved in the pathophysiology of the disorder; the most notable region of this kind is the cerebellum, formerly overlooked because of the erroneous view that it is entirely involved in motor control.[25] Second, the model places the cognitive deficits of schizophrenia centre stage in its pathophysiology, a view that was neglected for many years, but has regained prominence and is now widely cepted (Refs[26–28]; see Chapter 4.3.3).

Electrophysiology

A number of electrophysiological indices are altered in schizophrenia, and are relevant to the understanding of its neurobiology.[29] First, evoked potentials (electrical activity in the brain measured after a brief sensory stimulus); in particular, the P300 component is reduced and delayed in response to auditory and visual stimuli, indicative of impaired sensory processing.[30] Second, there is a high rate of eye movement abnormalities in schizophrenia, especially affecting smooth pursuit tracking, suggestive of impairment in the neural pathways subserving oculomotor control.[29] There are also differences in the cortical signal to noise ratio in the electroencephalogram, suggestive of an impairment of cortical information processing,[31] and consistent with the hypothesized abnormalities in cortical neural circuitry.

Structural neurobiology of schizophrenia

Finding the neuropathology of schizophrenia has been one of the major quests of biological psychiatry for over 100 years. Indeed, Alzheimer wrote a paper on the subject in 1897, 10 years before he described the disease that bears his name. However, whilst fundamental neuropathological discoveries were made in the dementias, there was no such progress for schizophrenia. In the past 20 years or so, the situation has changed. There is now compelling evidence that there is a neuropathology of schizophrenia, in the sense that there are statistically robust structural differences in the brains of patients with the disorder compared to normal subjects, both on structural imaging and at post-mortem (Table 4.3.6.2.1). On the other hand, the details and meaning of these changes are still elusive, and they are of limited clinical utility—they are not diagnostically specific, and they are only demonstrable when groups of cases and controls are compared.

Table 4.3.6.2.1 Morphological findings in schizophrenia

Replicated positive findings
Enlarged lateral and third ventricles
Decreased brain size and weight
Decreased cortical volume, especially temporal lobes
Fewer neurones in pulvinar thalamic nucleus
Decreased synaptic markers
Replicated negative findings
No increased incidence of Alzheimer's disease
No gliosis
Selected controversial findings
Increased density of cortical neurones
Smaller neurones
Reduced density of parvalbumin-positive interneurones
Aberrant distribution of white matter neurones
Fewer glia (oligodendrocytes)
Smaller mediodorsal thalamus with fewer neurones
Hemispheric asymmetry of pathology
Decreased dendritic markers
Effects of antipsychotic drugs on brain structure

Structural neuroimaging and macroscopic findings

The landmark study of Johnstone and colleagues showed, using computerized tomography, enlargement of the lateral ventricles in schizophrenia.[32] Although similar findings had been reported by pneumoencephalography, it was this paper which stimulated the field. It has been followed by many imaging studies, mostly in the last 20 years using magnetic resonance imaging,[33] and several meta-analyses. The latter show clearly that ventricular enlargement (with an average volume increase of ~40 per cent) is a feature of schizophrenia.[34–36] Accompanying this change there are decreases in cortical and whole brain volume of ~3 per cent,[36, 37] paralleled by a similar reduction of brain weight.[38] The regional localization of volume deficits is less clear, with different studies and meta-analyses implicating the hippocampus,[39] left superior temporal gyrus and medial temporal lobe (including hippocampus),[40] other regions of cerebral cortex, and thalamus.[41] For a narrative review of structural MRI studies, see Shenton *et al.*[42]

Structural brain changes are present in first episode patients.[43] Some differences are also present in subjects before they develop psychosis,[44,45] as well as in unaffected relatives,[46] indicating that part of the structural pathology is related to risk for schizophrenia (whether genetic or otherwise). Equally, other volumetric changes develop in high-risk subjects when they develop psychosis (e.g. hippocampal volume loss), suggesting that these changes are state-related rather than trait-related.[45, 47]

Two issues regarding structural imaging in schizophrenia remain controversial. First, the extent to which changes are progressive

after the onset of established illness.[48] The meta-analyses of the cross-sectional studies show no clear evidence of progression (in keeping with the stability of cognitive impairments, and the nature of the neuropathology to be described). On the other hand, several longitudinal studies do report greater shrinkage of various brain regions with time compared to control subjects, leading to pathophysiological theories related to aberrant plasticity and neurotoxicity.[49,50] The second controversy, which may be related to the first, concerns medication effects. Again, there is little consensus: there are positive and negative reports concerning effects of antipsychotics on whole or regional brain volumes, and some suggesting differential effects of typical versus atypical antipsychotics.[51]

Recent studies are using novel imaging methods to assess the status of white matter tracts in schizophrenia, to investigate hypotheses of aberrant anatomical connectivity.[52] A number of abnormalities have been demonstrated, broadly consistent with these notions,[53] although their interpretation (i.e. what is different functionally and/or anatomically) is not wholly clear.

The neuropathology is not degenerative

Despite the continuing uncertainties, the appreciation that there are structural brain changes in schizophrenia in terms of magnetic resonance imaging findings helped stimulate a new generation of morphometric and molecular post-mortem studies designed to determine the histological and cellular basis of the observations.

The most robust and important histological findings in schizophrenia are both negative.[54] Firstly, the neuropathology is not degenerative[55–57]: there are no lesions such as neurofibrillary tangles, amyloid plaques, or Lewy bodies, which would indicate the presence of any known neurodegenerative process.[56,57] Importantly, this conclusion even applies to the significant subgroup of elderly patients who develop dementia; the neuropathological basis for the dementia of schizophrenia is entirely unexplained.[56] Secondly, there is no excess of gliosis in the brains of patients with schizophrenia.[58] Gliosis, the proliferation and hypertrophy of astrocytes, is a sign of inflammation, injury, or other ongoing pathological processes. Hence the lack of gliosis is taken to denote that the disorder is likely to be neurodevelopmental in origin, affecting mechanisms involved in the normal maturation of the brain. Indeed, some recent studies suggest there is actually a decrease in the number or activity of some glial cells, an issue returned to later.

Morphometric and cytoarchitectural changes

Having ruled out these important possibilities, it has been difficult to pin down just what the histological changes are, and therefore the cellular basis for decreases in regional brain volumes. Nevertheless, the positive findings can be grouped together and viewed as broadly cytoarchitectural in nature—i.e. affecting the morphology and spatial organization of neurones and their processes (Ref.[54]; Table 4.3.6.2.1).

As a rule, the more dramatic (and well publicized) the initial finding, the less robust it has proved to be. For example, dysplasia (disorganized, misplaced, and misshapen neurones) in the entorhinal cortex was reported in 1986. Such a finding would be strongly suggestive of a prenatal developmental anomaly. However, subsequent studies have, at best, only partially replicated this observation. Similarly, a report that pyramidal neurones in the hippocampus are not aligned in their usual regular orientation, also indicative of a developmental disturbance, has not been consistently observed.

A decreased size of neurones, particularly in the hippocampus and prefrontal cortex, has been found in several studies. The size of a neurone is related to the volume of axon and dendrites, which it has to support, and also to its metabolic activity. Thus, the finding of smaller neurones in schizophrenia suggests the neurones may be receiving and making fewer, abnormal, or less-active connections. Support for this interpretation comes from studies of synaptic and dendritic markers, which have been reasonably consistent in showing decreases in the same brain areas.[59] It is unclear as to which specific populations of neurones and synapses are most affected in schizophrenia, and it may vary from one region to another; in both hippocampus and prefrontal cortex, there is evidence for involvement of excitatory (glutamatergic) pathways[60,61] as well subtypes of inhibitory (GABAergic) ones,[16,17] especially the class of parvalbumin-positive interneurones.[17] In addition to the neuronal pathology, several recent studies show reductions in markers of oligodendrocytes and their activity.[62] This type of glial cell is intimately involved in myelination, and contributes to synaptic homeostasis, and therefore their involvement in schizophrenia is in keeping with the occurrence of synaptic as well as white matter pathology.

A further area of interest is the thalamus, specifically the pulvinar and mediodorsal nuclei. Both have been found to be smaller and to contain fewer neurones in several studies of schizophrenia; in the case of the pulvinar nucleus, the evidence is amongst the most compelling of any brain region, coming from four methodologically rigorous studies (as well as complementary findings in the imaging literature, noted above), and with no corresponding negative studies.[63] These thalamic nuclei have extensive reciprocal connections with the prefrontal and temporal association cortices, and it is assumed that there is some causal link between the changes in each thalamic nucleus and its cortical partner.

Neuropathology and medication effects

Most patients studied neuropathologically were treated in life with antipsychotic drugs, and so the findings in schizophrenia are open to the criticism that they may have been caused by antipsychotic medication.[64] However, as noted above, many imaging studies show that the pathology, at least in terms of the gross alterations summarized in Table 4.3.6.2.1, is present in first episode and medication-naïve subjects. Also, in post-mortem studies, the reported neuropathological findings rarely if ever correlate with the extent of antipsychotic exposure. In some instances it may also be that medication ameliorates the disease effects. Nevertheless, the possibility that antipsychotic drugs have neuropathological effects should not be overlooked. Firstly, typical antipsychotics produce enlargement of, and synaptic structural alterations in, the basal ganglia (caudate, putamen, globus pallidus).[64] Secondly, a recent monkey study found that chronic administration of haloperidol or olanzapine at therapeutic levels led to decreased brain volume[65] along with increased neuronal density and decreased glial density,[66] thus reproducing several of the changes reported in schizophrenia.

Neurobiological theories of schizophrenia

Schizophrenia as a neurodevelopmental disorder

The neurodevelopmental model of schizophrenia is the prevailing pathogenic hypothesis.[5,67–69] Neurobiological data form an

important component of the evidence, along with epidemiological and other observations (Table 4.3.6.2.2). A specific version of the theory is that the pathology of schizophrenia originates in the second trimester *in utero*. An earlier timing is excluded since overt brain abnormalities would be seen if neurogenesis were affected, whilst the lack of gliosis has been taken to mean that the changes must have occurred prior to the third trimester when the gliotic response begins.[57] Other forms of the neurodevelopmental theory advocate abnormalities in processes such as myelination, synaptic pruning, and apoptosis, all of which continue long into post-natal life. Overall, a parsimonious view is that the neuropathological data are indicative merely of a basically developmental, as opposed to degenerative, disease process, but do not, in isolation, point to a particular mechanism or timing.

Schizophrenia as a disorder of connectivity

The functional imaging and histological data summarized above have together contributed to the emerging consensus that the pathophysiological basis of schizophrenia is one of connectivity.[24, 54, 70–72] The nature of the 'dysconnectivity' is not a simple lack, or gross mis-routing, of connections, but likely a subtle change in a more fine-grained aspect, such as the precise molecular composition, location, or activity of subpopulations of synapses.[71] Both intrinsic (local) and extrinsic (long-range) connections may be affected. The extent to which there is a structural basis to the aberrant connectivity remains uncertain,[73] but in so far as it exists, the histological basis of the syndrome is a difference in the circuitry, or 'wiring' of the brain, manifested by the cytoarchitectural differences in the morphology and organization of neurones and their synapses. If there is indeed a structural basis to the pathophysiology of the syndrome, it would help explain why many of the cardinal features are trait rather than just state abnormalities, and perhaps why individuals are vulnerable to relapse, in that a 'miswired' brain may be less able to respond rapidly, appropriately, or fully to environmental stressors.

Table 4.3.6.2.2 Evidence adduced for a neurodevelopmental basis to schizophrenia

- Usual age of onset in late adolescence and early adulthood
- Most environmental risk factors operate prenatally or in early childhood
- Neuromotor, intellectual, and behavioural differences in children many years prior to onset
- Structural brain changes and cognitive impairments present at, and prior to, onset of illness
- Nature of the neuropathological findings—lack of gliosis or neurodegeneration, plus cytoarchitectural disturbances
- Changes in expression of neurodevelopmental genes (e.g. reelin)
- Minor physical anomalies—for example, craniofacial dysmorphology and dermatoglyphics.
- Animal models—early lesions or pharmacological interventions lead to delayed 'schizophrenia-like' phenotypes

Cerebral asymmetry and schizophrenia

Many neuropathological, neurochemical, neuropsychological, and electrophysiological studies of schizophrenia report lateralized abnormalities. Although there are also important negative findings, reductions in normal brain asymmetries, and a left hemisphere preference of the pathology, do seem more common than one would expect by chance.[74,75] Crow's influential theory sees a fundamental connection between schizophrenia, asymmetry, handedness, and language, causally linked to each other and to the same gene.[76] Alternatively, altered asymmetry in schizophrenia is viewed as an epiphenomenon of its developmental origins, a process which interferes with normal brain lateralization.

Susceptibility genes and neurobiology

Given its high heritability,[77] it can be assumed that genes are the major influence on the neurobiological features of schizophrenia, likely modified by the various environmental risk factors (see Chapter 4.3.6.1). The recent discovery of several probable susceptibility genes[14,78] now allows this question to be addressed more specifically, in terms of the normal functions of the genes, and how this is altered in those carrying the risk variants of the genes.

Neuregulin 1 (NRG1) is the best established susceptibility gene.[79] It encodes a family of proteins that have multiple roles in the nervous system, ranging from cell fate determination, to neuronal migration, neuronal-glial signalling, and NMDA receptor functioning.[80] As such, it is a good candidate gene for schizophrenia given the existing theories outlined above regarding aberrations in neurodevelopment, connectivity, and glutamate synaptic transmission. Equally, at present it is not clear which of these functions is actually affected in schizophrenia or explains the contribution that NRG1 plays in the disease process,[81] and determining this will not be simple. Initial data suggest an impairment of NRG1 signalling via its receptors,[82] and an alteration in the expression of one specific subtype of NRG1.[83,84]

An interaction with synaptic neurotransmission is also seen for most of the other leading susceptibility genes (Table 4.3.6.2.3), leading to the notion that this effect is a point of pathophysiological convergence of the genes.[14] Such a convergence is an attractive concept for several reasons, not least parsimony, but whilst there is some evidence to support it, it remains highly speculative. Indeed,

Table 4.3.6.2.3 Susceptibility genes and their neurobiological functions

Gene symbol	Functions include
NRG1	Multiple roles in brain development, synaptic plasticity, and glutamate signalling
DTNBP1	Glutamate release
DISC-1	Multiple roles in development, cell functioning, and synaptic signalling
PPP3CC	Critical molecule for integration of dopamine and glutamate signalling
DAOA	Affects metabolism of the NMDA receptor modulator D-serine
COMT	Regulation of dopamine function in frontal cortex

NRG1, neuregulin 1; DTNBP1, dysbindin; DISC-1, disrupted in schizophrenia-1; PPP3CC, calcineurin Aγ subunit; DAOA, D-amino acid oxidase activator COMT, catechol-*O*-methyltransferase.

Table 4.3.6.2.4 Key recent findings in the neurobiology of schizophrenia

- Elevated dopamine release and receptor occupancy during acute psychosis
- Confirmation (by meta-analysis) of structural brain changes, including in first-episode patients, and in unaffected relatives
- Exclusion of a neurodegenerative disease process
- Discovery of neuregulin and several other putative susceptibility genes, and of molecular mechanisms by which they may increase schizophrenia susceptibility

Table 4.3.6.2.5 Current key questions to be addressed in the neurobiology of schizophrenia

- Which, if any, of the neurobiological findings are clinically useful (i.e. will influence diagnosis, treatment, or prognosis)?
- What is the relationship between the dopaminergic changes, and those affecting other neurochemical systems and brain structure?
- Are there differing neurobiological substrates for the psychotic, cognitive, and negative components of schizophrenia?
- How do the genes interact with each other, and with the environmental risk factors, to produce their effects?

it will probably remain difficult to determine in detail the genetic contribution to the neurobiology of schizophrenia, given that there are many genes, each of small and complex effects.[85]

Summary

Significant progress has been made in understanding the neurobiology of schizophrenia over the past decade (Table 4.3.6.2.4). In particular, there is now good evidence for a dopaminergic dysfunction, and for structural brain changes that are present at, and in part before, the onset of illness. There is also emerging evidence for several susceptibility genes, accompanied by data suggesting mechanisms by which these genes contribute to the neurodevelopmental and other pathogenic processes that are thought to lead to schizophrenia. Whilst highlighting the progress, one must also acknowledge that much remains unknown (Table 4.3.6.2.5), and it is a moot point how and when the research advances will impact on the diagnosis, treatment, or prognosis of schizophrenia.

4.3.7 Course and outcome of schizophrenia and their prediction

Assen Jablensky

Introduction

The course of schizophrenia is as variable as its symptoms. Systematic investigations of course of the psychoses were initiated by Kraepelin who believed that, in the absence of demonstrable brain pathology and aetiology, a common outcome into 'psychic weakness' of the clinical syndromes he grouped together as **dementia praecox** would provide a validity test for the disease entity. Later, Kraepelin revised his claim that the prognosis of dementia praecox was invariably poor and noted that 'permanent cures' had occurred in about 15 per cent of his cases.[1] Subsequent longitudinal studies have confirmed the striking variability of course as one of the salient characteristic of the 'natural history' of schizophrenia.

Methodological issues

The large number of studies on the course and outcome of schizophrenia published since the beginning of the twentieth century might suggest that the longitudinal aspects of the disorder are well established and exhaustively documented. Unfortunately, this is not the case since the methodological difficulties that accompany this type of research are complex and few studies have adequately dealt with all the major sources of error and confounding, including sample selection, definition of outcome, and diagnostic criteria used.[2,3]

The studies of the course and outcome of schizophrenia comprise statistical reports on admissions and discharges, long-term **follow-back studies** (in which the initial features of the cases and the course of the disorder are reconstructed retrospectively from admission records), and prospective investigations (in which patients are enlisted at an early stage of the disorder and followed up for a varying length of time). Each design is vulnerable to bias: admission and discharge statistics usually comprise patients at different stages of disease progression; follow-back studies rely on prevalence samples in which chronic cases tend to be over-represented; and **prospective studies**, though superior to other designs, tend to exclude patients who initially have diagnoses other than schizophrenia but are subsequently re-diagnosed as schizophrenic. The methodological issues that need to be considered in interpreting the results from longitudinal research into schizophrenia include the following.

Diagnosis

The use of either 'broad' or 'restrictive' definitions of schizophrenia may result in vastly different samples on which follow-up data are reported. Systems with an inbuilt illness duration criterion, such as **DSM-III**, **DSM-IIIR**, and **DSM-IV** which require at least 6 months of unremitting symptoms and a decline in functioning, are likely to overselect patients already developing a chronic course. The result would be a greater homogeneity of outcome at the cost of a compromised representativeness of the sample as regards the range of

possible outcomes of schizophrenia. Diagnostic systems which emphasize the cross-sectional features of the disorder, such as **ICD-10** (which requires 1 month's duration of clinically characteristic symptoms) avoid this limitation, possibly at the expense of including some cases of good prognosis that may be aetiologically or pathogenetically different from poor prognosis schizophrenia. However, until aetiology is elucidated, or validating biomarkers are established, the decision as to what constitutes 'true' schizophrenia will remain arbitrary. With regard to prognostic studies, less restrictive diagnostic systems have the advantage that a broad spectrum of outcomes would be available at the end point of prospective observation, allowing for subgroups to be identified and their characteristics related to the initial manifestations of the disorder and various risk factors.

Definitions and assessment of course and outcome variables

There is no single measure of course and outcome of a complex disorder such as schizophrenia. Blanket terms such as 'recovery', 'improvement', or 'deterioration' tend to conflate substantially different aspects of the evolution of the disorder over time. Most investigators today agree that course (comprising the pathways or trajectories of the disorder) and outcome (the net balance of the clinical and functional descriptors at the end point of observation) are multivariate composites. As a minimum, three domains that need not co-vary over time should be independently assessed: symptom severity; functional impairments including cognitive deficits, and disablement in social and occupational role performance. Each one of these can be further articulated into a number of areas or dimensions. In addition, one must consider extrinsic variables such as measures of environmental and treatment-related influences on course and outcome, as well as subjective experiences commonly described as 'quality of life'. Standardized, reliable instruments (interviews, inventories, rating scales) are required for the assessment of most variables. **Operational definitions** and criteria of relapse and remission have been proposed.[4,5] It should not be forgotten, however, that some of the richest sources of information are the perceptive, in-depth clinical case studies based on personal patient contact over many years. Collectively, such single case observations can generate hypotheses for testing in epidemiologically designed studies.

Length of follow-up

The evidence from previous research suggests that very different impressions of the course and outcome of schizophrenia would be gained depending on the duration of prospective observation and the degree of control over the inclusion of patients that are comparable in terms age and length of previous illness.

Cohort attrition

In any follow-up study, a proportion of cases will be lost to observation because of death, migration, refusal of contact, or other reasons for untraceability. Since such loss of subjects is likely to correlate with particular patterns of course and outcome, it is essential to estimate its possible effect (e.g. by statistical modelling) on the interpretation of the final results, especially if cohort attrition is greater than 15–20 per cent of the original sample.

Other aspects of study design

Variation in the sources of recruitment of cases (e.g. any admission to a treatment facility or catchment area sampling), and of information regarding course and outcome variables (e.g. face-to-face interviews or collateral data from case notes or informants), can obviously influence the results of any follow-up study. In addition, subtle variations in study design, such as whether investigators assessing patients' symptoms and functioning at any point in time are 'blind' to data from previous assessments, can bias the final results. Inclusion of a comparison group (e.g. patients with other psychotic disorders) would help evaluate the extent to which any observed patterns of course and outcome are specific to schizophrenia, whereas appropriate controls drawn from the general population can provide reference points for assessing social variables, such as occupational functioning, stressful life events, or habit-related behaviour such as substance use.

Statistical analysis

Longitudinal research poses a number of specific requirements with regard to data analysis. Thus, the problem of **multiple comparisons** is likely to arise when examining the data for significant associations; time series, survival, or path analysis may be required when observations are made and recorded at successive time points in the evolution of the disorder; and methods of unconfounding are called for at each step of the analysis of longitudinal data. While no single study up to date has met all the rigorous methodological requirements, a number of studies have succeeded in controlling at least some of the sources of bias and confounding. The results from previous research are, therefore, not strictly comparable in specific detail, but are informative as regards general trends and patterns.

The 'natural history' of schizophrenia before the neuroleptic era

Since the great majority of schizophrenic patients are today receiving pharmacological treatment, current and recent studies may not reflect the 'natural' course and outcome of the disorder. Studies in urban communities in Scotland[6] and India,[7] and a study in a rural community in China[8] estimated the proportions of never hospitalized schizophrenic patients at 6.7 per cent, 28.7 per cent, and 30.6 per cent, respectively. About half of the Scottish patients had been prescribed neuroleptics by their general practitioners while the Indian and Chinese patients had been virtually untreated. In all three settings the outcomes of these interesting samples (which presumably approximate the 'natural' history of the disorder) were heterogeneous but, except for a larger proportion of Chinese patients having marked psychotic symptoms, they did not differ much from the outcomes in the treated groups. In a historical study of 70 Swedish patients with first admissions in 1925, lifetime records were retrieved and re-diagnosed in accordance with DSM-III.[9] None of these patients had received neuroleptics. The final outcome was rated as good in 33 per cent (but no patient was considered as completely recovered), as 'profoundly deteriorated' in 43 per cent, and as intermediate in 24 per cent.

A long-term perspective on the course of schizophrenia ove successive generations is provided by a meta-analysis of 320 outcome studies on schizophrenia or dementia praecox published between 1895 and 1992 and including a total of 51 800 subjects.[10]

Overall, about 40 per cent of the patients were reported as improved after an average length of follow-up 5.6 years. There was a significant increase in the rate of improvement during the period 1956–1985 compared to 1895–1955, clearly related to the introduction of neuroleptic treatment, but a secular trend towards better outcomes with every successive decade had been present for much longer. Coupled with the virtual disappearance of the most malignant or 'catastrophic' forms of schizophrenia resulting in a profound defect state after a first psychotic episode, or death ('lethal catatonia'), these observations suggest that a transition to a less deteriorating course of the disorder had occurred prior to modern pharmacological treatment. Among the factors explaining this shift one should consider improvements in general care, progressive changes in attitudes and hospital regime which occurred in a number of institutions on both sides of the Atlantic in the 1930s and 1940s, as well as heightened expectations that psychosocial measures such as psychotherapy or rehabilitation could result in a cure in some cases.

Long-term prognosis

Results of course and outcome studies published over the last six decades are shown in Table 4.3.7.1. The studies have been selected on the basis of the length of follow-up (>5 years), effective sample size (>50), and intensity of follow-up and assessment to provide a global overview of the long-term course of schizophrenia.

Although the studies differ in their design (prospective, follow-back, or retrospective), their results have much in common.

Manfred Bleuler's monograph[11] is the account of an intensive study of 208 patients first admitted in 1942–1943 and personally followed up by the author for 22 years or until death. A recent re-interpretation of Bleuler's diagnoses in terms of DSM-IIIR, DSM-IV, and ICD-10 diagnostic criteria concluded that although some 30 per cent of the original cases would today meet criteria for schizoaffective disorder, the distribution of the types of long-term course did not change significantly.[12] Another 23-year follow-up of 504 patients admitted in 1945–1959 has been completed by Ciompi,[14] and Huber *et al.*[15] interviewed 289 surviving patients in Switzerland first admitted between 1900 and 1962 (median follow-up length 36.9 years).

Notwithstanding methodological constraints which apply to these studies, their findings are a unique record of what probably represents the closest approximation to the 'natural history' of schizophrenia. In summary, they indicate the following.

- Lasting recovery ('complete cure') occurred in 15 per cent to 26 per cent of the cases; 43 per cent had either remitted or exhibited mild residual abnormalities which did not interfere with their living in the community.
- Forty-four per cent were still in hospital and severe chronic states had developed in 14 to 24 per cent.

Table 4.3.7.1 Results of selected course and outcome studies in schizophrenia, 1972–2005

Author	Country	Sample size	Length of follow-up (years)	Proportion good outcome*
Bleuler (1972)[11]	Switzerland	208	23	20% Complete remission; 33% mild defect
Tsuang *et al.* (1979)[13]	USA	186	35	46% Recovered or improved significantly
Ciompi (1980)[14]	Switzerland	289	37	20% Recovered; 43% definitely improved
Huber *et al.* (1980)[15]	Germany	502	22	26% Recovered; 31% remission with mild defect
Harding *et al.* (1987)[16]	USA	118	32	62% Recovered or improved significantly
Ogawa *et al.* (1987)[17]	Japan	140	21–27	31% Recovered; 46% improved
Shepherd *et al.* (1989)[18]	UK	107	5	22% Recovered, no relapse
Johnstone *et al.* (1990)[19]	UK	530	3–13	14% Excellent; 18.5% very good social adjustment
Carone *et al.* (1991)[20]	USA	79	5	17% Complete remission
Marneros *et al.* (1992)[21]	Germany	249	25	Full remission in 24% ('broad') or 7% ('pure') schizophrenia
Thara *et al.* (1994)[22]	India	90 (first-onset cases)	10	12% Complete recovery; 62% remission
Mason *et al.* (1995)[23]	UK	67	13	17% Complete recovery; 52% remission
Wieselgren and Lindström (1996)[24]	Sweden	120	5	30% Good outcome
Wiersma *et al.* (1998)[25]	Holland	82	15	27% Complete; 50% partial remission
Ganev *et al.* (1998)[26]	Bulgaria	60	16	32% Complete; 5% partial remission
Gureje and Bamidele (1999)[27]	Nigeria	120	13	22% Unimpaired (social outcome); 19% some impairment
Finnerty *et al.* (2002)[28]	Ireland	67 (first-onset cases)	15	35% Complete remission; 46% partial remission
Thara (2004)[29]	India	90 (first-onset cases)	20	6% Complete recovery; 15% clinically stable
Lauronen *et al.* (2005)[30]	Finland	91 (birth cohort members)	To age 31 years	4% Complete recovery; 3% partial remission

*Descriptive categories used by the authors.

- In 50 per cent to 75 per cent of the patients, a clinically stable state set in after the fifth year since onset, with no significant further deterioration.
- Remitting course with multiple episodes and full remissions characterized 22 per cent of the patients; catastrophic course (rapid onset of chronic deterioration) was observed in 1 per cent to 4 per cent.
- The 20-year suicide rate was 14 per cent to 22 per cent.

Two American studies largely concur with these findings. In the Vermont study,[16] no less than 62 per cent of the cohort had achieved significant improvement or recovery after an average length of follow-up 32 years; the corresponding proportion in the Iowa 500 study[13] was 46 per cent.

The most striking finding from the long-term follow-up studies is the high proportion of patients who recover, either completely or with mild residual abnormalities, after decades of severe illness[31] This contrasts with the ingrained image of schizophrenia as an intractable, deteriorating illness that many clinicians tend to adopt on the basis of a limited follow-up horizon and patient samples selected for unfavourable course and treatment response. It is unlikely that the high percentage of recoveries in the long-term studies could be explained by cases of affective illness or brief transient psychoses misdiagnosed as schizophrenia (the retrospective re-diagnosis of cases according to DSM-III criteria in the American studies did not alter significantly the results). Similarly unlikely would be the attribution of all the good outcomes to the antipsychotic treatment many of these patients received in the later stages of their illnesses, since comparable proportions of improvement of recovery had been reported for patients who never received neuroleptics.[32] A tentative conclusion from such follow-up research would be that schizophrenia is not an invariably chronic deteriorating disorder, and that the progression of the disease can be arrested or even reversed at any stage. The causes of such reversibility remain poorly understood, but research focusing specifically on the recovering cases will undoubtedly provide essential clues for understanding the nature of schizophrenia.

The results of longitudinal studies published in the last decade generally tend to corroborate the pattern of outcomes outlined by the earlier studies. However, several recent studies suggest a trend of worsening clinical and social outcomes in patients with schizophrenia in both developed countries[28,30] and developing countries.[27,29] A 13-year follow-up of 120 Nigerian patients[27] reported much higher rates of severe impairment in social and occupational functioning than those found in the same region of the country by follow-up studies in the 1970–1980s.

Patterns and stages of the course of schizophrenia

The marked heterogeneity of the course of schizophrenia can be reduced to a limited number of patterns into which cases tend to cluster over time. In earlier long-term follow-up studies, eight different categories of course have been described by Bleuler[11] and by Ciompi,[14] and 12 by Huber *et al.*[15] These classifications were derived from empirical observation, rather than statistical modelling, and conflated into single categories the mode of onset, longitudinal aspects such as frequency and duration of psychotic episodes, remissions, and end states. Treating these various aspects of the longitudinal profile of the illness as independent dimensions has been recommended.[19] However, the complexity of statistical modelling of the course of schizophrenia is such that the development of a classification of course that would be both useful in clinical practice and rigorous in a statistical sense may not be easy to achieve. Therefore, a heuristic compromise between these two requirements should, as a minimum, define operationally and assess separately: (i) the number and duration of discrete episodes of illness; (ii) the predominant clinical features of each episode (e.g. psychotic or affective); (iii) the number and length of remissions and their quality (presence/absence of residual negative or deficit symptoms and signs). By combining these variables, several patterns of course have been derived that have found good empirical support in international follow-up studies:

1 single psychotic episode followed by complete remission;

2 single psychotic episode followed by incomplete remission;

3 two or more psychotic episodes, with complete remissions between episodes;

4 two or more psychotic episodes, with incomplete remissions between episodes;

5 continuous (unremitting) psychotic illness.

With some modifications, these longitudinal patterns have been incorporated into ICD-10 and DSM-IV as additional descriptors.

Although the components of the course patterns, such as episode, remission, residual symptomatology, etc. may not represent 'pure' dimensions, it is desirable to restrict the definition of **pattern of course** to clinical variables only, in order to be able to examine its correlations with risk factors and predictors, such as premorbid impairments, mode of onset, or social outcomes. Assessing social functioning independently of the clinical pattern of course is critical to the study of illness-environment interactions and the causes of disablement in schizophrenia.

At present it does not seem possible to define with any precision **discrete stages** in the progression of schizophrenic illnesses by using combined clinical and pathological criteria, as in cancer or cardiovascular disease. Nevertheless, a 'softer' form of staging is feasible since there is on the whole a good agreement between the results of different studies on the general pattern of course in schizophrenia. On the basis of long-term follow-up studies, the lifetime course of schizophrenia can be articulated into a premorbid phase (from birth to the onset of psychosis), a phase of acute or positive schizophrenic symptomatology, and a residual phase.[21] Various sub-stages have been proposed to describe in finer detail the pre-onset and early psychosis period.[33,34] For most practical and research purposes, a three-stage classification of **post-onset course** has been proposed:[24]

1 an early deteriorating phase (the first 5–10 years);

2 a middle (stabilization) phase;

3 a gradual improvement phase.

This model agrees well with the empirical evidence and could be useful in the collection and summarizing of data on individual risks and prognosis.

Geographical and cultural variation

Three prospective investigations initiated by the World Health Organization (WHO): the **International Pilot Study on**

Table 4.3.7.2 Two-year course and outcome features of 1070 patients with schizophrenia in the WHO 10-country study[37]

Course and outcome descriptor	% Patients in developing countries[1] (*n* = 467)	% Patients in developed countries[2] (*n* = 603)
Remitting, complete remissions	62.7	36.8
Continuous or episodic, no complete remission	35.7	60.9
Psychotic <5% of the follow-up	18.4	18.7
Psychotic >75% of the follow-up	15.1	20.2
No complete remission during follow-up	24.1	57.2
Complete remission for >75% of the follow-up	38.3	22.3
On antipsychotic medication >75% of the follow-up	15.9	60.8
No antipsychotic medication during follow-up	5.9	2.5
Hospitalized for >75% of follow-up	0.3	2.3
Never hospitalized during follow-up	55.5	8.1
Impaired social functioning throughout follow-up	15.7	41.6
Unimpaired social functioning >75% of follow-up	42.9	31.6

Schizophrenia (IPSS);[35,36] the 10-country study on **Determinants of Outcome of Severe Mental Disorders**;[37] and the study on **Assessment and Reduction of Psychiatric Disability**[38,39] laid the ground for a broad-based, cross-cultural evaluation of the course and outcome of schizophrenia. These studies comprise extensive initial and follow-up information on a total of 2736 patients in 16 countries, diagnosed with schizophrenia according to strict and comparable criteria. Identical or closely similar, standardized assessment procedures and instruments were employed, ensuring a high level of comparability across the multiple sites. Results of the WHO 10-country study (pooled data on 1070 patients in all the research sites) are presented in Table 4.3.7.2.

A more recent, transcultural investigation coordinated by WHO, the **International Study of Schizophrenia** (ISoS) involving 18 research centres in 14 countries,[40,41] achieved tracing 75 per cent of cases assessed in the earlier WHO studies referred to above, as well as additional cohorts from mainland China, Hong Kong, and India. Follow-up data were collected on a total of 1633 cases (surviving or dead), and 890 patients were re-interviewed at either 15- or 25-year follow-up since their first assessment. Key findings from this landmark study are presented in Table 4.3.7.3.

The following general conclusions can be drawn from the WHO studies.

1 There is a striking heterogeneity and variability of the course and outcome of schizophrenia, both across and within populations. Patients with similar clinical and diagnostic characteristics at baseline assessment develop a spectrum of outcomes ranging from stable clinical and social recovery after a single psychotic episode to chronic unremitting psychosis and severe impairment. Long-term follow-up studies lend credibility to the conclusion that a high proportion (over 30 per cent) of patients meeting the diagnostic criteria for schizophrenia have relatively favourable outcomes.

2 The frequencies of both relapses and remissions tend to increase over time: while at 2-year follow-up of the International Pilot Study of Schizophrenia (IPSS)[35] 11 per cent of the patients had experienced two or more psychotic episodes followed by complete remission, and another 18 per cent had two or more episodes followed by residual symptoms and impairments, the corresponding proportions at 5-year follow-up were 15 per cent and 33 per cent.[36] These trends are now bolstered by the findings of the International Study of Schizophrenia (ISoS)[40] which found a 48 per cent recovery rate at the 15-year follow-up and 54 per cent at the 25-year follow-up.

3 Regardless of the increasing relapse rate, the cumulative proportion of follow-up time during which patients have psychotic symptoms (as a percentage of the total follow-up time), tends to remain stable or decrease. At the end of the 5-year follow-up, 57 per cent of the patients had experienced a total of less than 9 months of active psychosis; only 22 per cent had been psychotic for 45–60 months. At 15-year and 25-year follow-up, 43 per cent and 41 per cent, respectively, have been free of active psychotic symptoms for the past 2 years.

4 The levels of social impairment assessed at 2 years changed very little during the subsequent years of follow-up. Overall, most of the observed change in the clinical state and social functioning of patients between the 2-year follow-up and the 5-year follow-up

was towards improvement rather than deterioration. This also is congruent with the findings at 15-year and 25-year follow-up.

5 While the percentage of patients with continuous, deteriorating illness was similar across the sites of the WHO studies, there were significant differences in the proportions of patients who achieved symptomatic and social recovery. In this respect, outcome was generally better in the developing countries. This unexpected finding of the first follow-up of the International Pilot Study of Schizophrenia patients,[35] who had been recruited from consecutive hospital admissions with the attendant possibilities of a selective bias, was subsequently replicated by the 10-country study which had an epidemiological design and recruited only first-contact patients from delimited populations.[37] The better course and outcome in the developing country areas could not be attributed to any particular subtype of the disorder, e.g. cases of acute onset, since it applied equally to the cases of slow, insidious onset. The main outcome difference across the study areas was in the occurrence and average length of symptom-free remissions. Remissions tended to be more frequent and to last longer in the developing countries. No single factor accounting for this difference could be identified and it is likely that complex interactions between illness and environment are involved that may include both population differences in **predisposing genes**,[42] and environmental or cultural factors, such as relative absence of an institutionalized role of 'the schizophrenic',[43] less intrafamilial **expressed emotion** towards the affected family member,[44] or better integration of the mentally ill person in the domestic economy in traditional rural communities. It should be noted, however, that the long-term WHO follow-up studies include patients whose onset of psychotic illness occurred decades ago, and that increasing social and economic stresses experienced by both rural and urban communities in many developing countries may have eroded the traditional support systems, resulting in worse outcomes, as suggested by several recent studies.

Whether the better outcome of schizophrenia in the developing countries is 'transportable' following migration to other settings, remains unclear. Data on immigrants treated for first episodes of schizophrenia in the United Kingdom suggest that while Asian patients have a lower relapse and readmission rate than British-born Whites, Afro-Caribbean's show a higher rate.[45] The marked social and family structure differences between the Asian and the Afro-Caribbean immigrant communities suggest that the likelihood of a more benign course in the new setting may depend on the degree to which the immigrant group has retained its traditional values and intra-group cohesion.

First episode psychosis

The recent focus on early detection and treatment of first episodes of psychosis, driven by theoretical considerations and clinical concerns, is supported by evidence suggesting that the course and outcome of the earliest stages of a schizophrenic illness may have a **pathoplastic effect** on its subsequent course. Specifically, the period between the first onset of psychotic symptoms and the initiation of treatment (**duration of untreated psychosis, DUP**) has been shown to correlate with increased time to remission and poor response to treatment.[46,47] Plausible clinical considerations have been proposed in support of the view that the first episode of psychosis represents a critical developmental transition that may impact the subsequent course of schizophrenia, possibly by inducing neurotoxic alterations in neural networks, thus preparing the ground for chronic illness.[48] An extension of this mode of thinking is the suggestion that a behavioural or pharmacological intervention prior to the onset of psychotic symptoms could delay or prevent the onset of schizophrenia.[49]

None of these hypotheses has been conclusively tested. However, a number of studies focusing on the **prodrome** and the earliest manifestations of psychosis have highlighted features such as a presymptomatic drop in cognitive performance and social functioning;[50] early co-occurrence of 'positive' and 'negative' symptoms;[37] as well as a general malleability of such dysfunction in response to appropriate behavioural interventions and low-dose, time-limited pharmacological treatment.[51–53] This suggests that clinical research bridging the gap between statistical investigations of risk factors or antecedents of disease and individual pathways to psychotic illness may have an important role to play in understanding and, ultimately, influencing the development and course of schizophrenia.

Prognosis of specific clinical symptoms and syndromes

Longitudinal studies suggest that the characteristic symptoms of schizophrenia tend to 'breed true', i.e. only a minority of patients are eventually reclassified into other disease categories because of a significant and lasting change in the predominant symptoms. However, the proportion of cases warranting a re-diagnosis seems to increase with the length of follow-up.

Depression in schizophrenia

In the WHO International Pilot Study of Schizophrenia,[35, 36] the proportion of patients with initial schizophrenic symptomatology who developed non-schizophrenic (mostly affective) episodes in the course of time increased from 3 per cent in the first 2 years to 17 per cent at the end of the 5-year follow-up. In contrast, subsequent episodes with schizophrenic features occurred in less than 10 per cent of the patients with an initial diagnosis of major depression. Depression is the most common non-schizophrenic syndrome co-ocurring with schizophrenia also in those patients who retain the essentially schizophrenic character of their illnesses. The proportion of patients who develop clear-cut episodes of major depression ranges from 15 per cent during a 5-year follow-up[54] to 24 per cent during a 12-year follow-up.[55] This is a much higher period prevalence than depression in the general population, which suggests that mood disorder may be an intrinsic part of the clinical spectrum of schizophrenia. Based on such data, a diagnostic rubric of **post-schizophrenic depression** has been added to the classification of schizophrenia in ICD-10.

First-rank (schneiderian) symptoms

Subjective thought disorder phenomena, such as thought broadcast or insertion, passivity ('replacement of will') experiences, and particular type of auditory hallucinations (third-person or commenting 'voices') were attributed 'first-rank' significance in the differential diagnosis between schizophrenic and affective psychoses by Kurt Schneider.[56] These symptoms are accorded special diagnostic weight in the current diagnostic criteria of both ICD-10

and DSM-IV. Although Schneider explicitly disclaimed any particular prognostic value for the first-rank symptoms, they have a strong tendency to recur in the course of schizophrenia. In the WHO 10-country study, patients with one or more first-rank symptoms on the initial examination had a three-fold increased risk of recurrence of such symptoms in subsequent episodes compared to patients with no first-rank symptoms at initial examination.[37]

Prognosis of schizophrenia subtypes

The evidence that each of the 'classic' subtypes of schizophrenia is associated with a characteristic pattern of course is generally weak but surprisingly good for some of the subtypes. Consistent differences have been reported between **paranoid**, **hebephrenic**, and **undifferentiated** schizophrenia (diagnosed according to DSM-III) on a long-term follow-up of 19 years.[57] Paranoid schizophrenia tended to have a remittent course, and to be associated with less disability, in contrast to hebephrenia which had an insidious onset and poor long-term prognosis. Undifferentiated schizophrenia occupied an intermediate position. In the WHO International Pilot Study of Schizophrenia,[35] four alternative groupings of the ICD-9 subtypes were tested by a discriminant function for differences with regard to six course and outcome measures. Clear discrimination was achieved between simple and hebephrenic schizophrenia grouped together, on the one hand, and the schizoaffective subtype on the other. However, the comparison of simple and hebephrenic schizophrenia with paranoid schizophrenia resulted in a considerable degree of overlap.

Better discrimination has been claimed for groups of patients diagnosed according to the criteria of Leonhard.[58] A 5–13 years follow-up study of 178 patients admitted with a diagnosis of schizophrenia and re-diagnosed according to the Leonhard's criteria as **systematic schizophrenia**, atypical (unsystematic) schizophrenia, **cycloid psychosis**, or **reactive psychosis**[59] resulted in marked outcome differences on blind assessment. While only 10 per cent of the cases in the two schizophrenia groups were judged to have 'recovered', the corresponding proportion in the cycloid and reactive psychoses group was 38 per cent. Conversely, the proportions of 'unimproved' cases were 49 per cent and 3 per cent.

The question whether good prognosis, remitting schizophrenia with an acute onset is a separate subtype that could be distinguished symptomatologically was addressed in the WHO 10-country study[37] by comparing 274 patients with an initial ICD-9 diagnosis of acute schizophrenic episode and 752 patients with other schizophrenia subtypes. The group of acute cases tended to be younger and had a lower male/female ratio, but was no different from the rest of the schizophrenic patients with regard to initial symptomatology. This argues against acute **schizophreniform** illness being a discrete syndrome, outside the clinical spectrum of schizophrenia.

The course and outcome data on **schizoaffective** disorders seem to support their placement within the broad category of schizophrenia. A retrospective and prospective study of 150 schizoaffective patients and 95 bipolar affective patients[60] established general similarities between the two groups but the schizoaffective cases were less likely to achieve a full remission and more likely to develop a residual state (in 57 per cent compared to 24 per cent in the bipolar group). An intermediate outcome between that of schizophrenia and bipolar affective disorder is a common finding in schizoaffective disorders.

Predictors of course and outcome

A wide range of variables have been explored as possible predictors of course and outcome in schizophrenia: (i) socio-demographic characteristics; (ii) features of the premorbid personality and premorbid functioning; (iii) family history of psychiatric disorder; (iv) history of past psychotic episodes and treatments; (v) substance use; (vi) characteristics of the onset; (vii) features of the initial clinical state and treatment response; and (viii) variables related to brain morphology and neurocognitive functioning. Many predictors have been independently replicated by different investigators and there is reasonable agreement on the general direction of their effects. However, definitions of both the independent (predictor) and the dependent (outcome) variable tend to vary across studies, and the statistical methods employed range from basic descriptive statistics (e.g. *x* per cent of the patients with characteristic *y* developed outcome *z*) to complex statistical models with capacity to quantify the independent contribution of individual variables to a specified outcome.

Table 4.3.7.4 lists the best predictors of the 2-year outcome in the WHO 10-country study[37] and Table 4.3.7.5 summarizes the findings about predictors of 15-year outcome for the subset of participants in the WHO 10-country study who were re-examined as part of the International Study of Schizophrenia.[40] Apart from the variable 'setting' (i.e. research centre), which is a proxy for an unspecified number of local area features ranging from population genetic background to the multiple facets of 'culture', the mode of onset of symptoms (acute versus insidious), drug abuse, and premorbid psychosocial functioning were the best predictors of the duration of psychotic episodes, achievement of remission, and social outcome at 2-year follow-up. Importantly, the total time with psychotic symptoms during the first 2 years post-onset emerged as the best predictor of 15-year outcome, highlighting the potential importance of interventions aiming to contain and minimize active psychosis during this critical stage.

Limitations of clinical prediction

The explanatory power of any predictor in schizophrenia (in terms of accounting for a proportion of the outcome variance) varies depending on sample size, setting, homogeneity of patient groups, and measurement error, but generally tends to be limited (rarely exceeding 30 per cent of the outcome variance). This suggests that no single background or premorbid characteristic of the person, and no clinical symptom or sign among the initial manifestations of the disorder, is strongly associated with its prognosis in the longer-term. Similarly to the genetic epidemiology of schizophrenia, where non-shared environmental influences account for a greater amount of variance than the shared environment, person-specific, emergent life events or changes in the mental state may have a similar or even greater impact on the outcome as the initial or premorbid predictors. Indeed, variables such as negative symptoms have been shown to gain in predictive power if they are assessed two or more years after the onset, or after the patients have received adequate treatment. The predictive capacity of other variables, for example, mode of onset, or a high index of expressed emotion, tends to become attenuated in the course of time. Thus, there is

– Not significant or not applicable.

no fixed set of predictors of the course and outcome of schizophrenia, but rather a number of prognostic indicators which allow a judgement to be made about the probability of one or another type of course over a limited time period (usually not exceeding 5 years).

Short-term predictors

There is good agreement between different studies on the factors that help predict a relapse of psychotic symptoms after a period of stabilization or remission. By and large, the best predictor of relapse in the short-term remains the withdrawal of antipsychotic medication, usually due to non-compliance.[61] Heavy cannabis use has been shown to be associated with an increased risk of relapse in a dose-response relationship.[62] Other factors, such as stressful **life events**[63] and **expressed emotion** (EE) within the family,[44] have attracted considerable interest, both as independent predictors and as modifiers of the effects of pharmacological treatment. A high expressed emotion index, assessing a key family member's emotional over-involvement with, and concomitant criticism of the patient, has been found to be a reliable short-term predictor of psychotic relapse. However a limitation of the method is that it is only applicable to situations of intensive daily interaction between a patient and a carer (typically a family member) which may not be the case for many people with schizophrenia living in hostels or marginal accommodation. Moreover, the cross-cultural validity of the expressed emotion index still remains to be established.[64]

Medium- and long-range predictors

In first-episode cases, male sex, single marital status, premorbid social withdrawal and insidious onset have been shown to be relatively robust predictors of a poor outcome in the short- to medium-term (2–5 years), while female sex, being married, having social contacts outside the home, and acute onset predict a relatively good outcome. No consistent findings have been reported for age at onset as a predictor, and the long-term follow-up studies do not lend support to the view that an early onset is always associated with a poor prognosis. Similarly, a history of psychotic illness (including schizophrenia) in a first-degree relative does not necessarily predict a worse prognosis. On the contrary, in some studies[65] patients with a high familial load were found on follow-up to have a better outcome than 'sporadic' cases with no psychotic illness among their first-degree relatives.

A consistent finding of many studies is that the clinical symptoms in either the early, or the advanced stages of schizophrenia, have limited capacity to predict future course and outcome. An exception is the modest predictive power of clear-cut negative symptoms appearing early in the course of the disorder, or when assessed under the conditions referred to above.

The **socio-cultural setting**, i.e. a developing country or a developed country, was found to be among the best predictors of 2-year and 5-year outcome in the WHO studies.[35,36] It remained a

significant predictor of 15-year outcome in the International Study of Schizophrenia.[40] Exactly what factors may be underlying these marked cultural differences in the prognosis of schizophrenia remains an unresolved issue.

There is a growing interest in the predictive power of **neurocognitive functions**, such as verbal memory, working memory, processing speed, and sustained attention. Though positive results have been reported from a number of studies, the proportion of variance in outcome measures that could be explained by such factors varies from low 14 per cent[66] to as high as 60 per cent,[67] depending on sample selection, patients' age, and length of follow-up. Overall, there is increasing evidence that neurocognitive functioning at the early stages of a schizophrenic illness predicts significantly global psychosocial and occupational functioning in the medium-term. Neurocognition is therefore likely to be an increasingly important target for novel pharmacological and cognitive behavioural interventions in schizophrenia.

Recovery from schizophrenia

There is consistent evidence from longitudinal studies reviewed in this chapter that, notwithstanding the high risk of chronic disability, loss of developmental potential, and diminished quality of life associated with schizophrenia, there is a non-negligible proportion of people who meet the current diagnostic criteria for the disease but ultimately attain nearly complete recovery and a stable level of psychosocial functioning. The existence of a good outcome subgroup within schizophrenia has been known for a long time and the prevailing view is that it is not an artefact of misdiagnosis. Yet little focused research has been conducted to bring to light the characteristics and predictors of this clinical subpopulation. A retrospective study of 436 people diagnosed with schizophrenia in the United Kingdom[68] found that over a follow-up period of 6 years, 15.6 per cent had a single psychotic episode with complete remission. A 15-year prospective study of 145 patients in the United States[69] revealed that up to 25 per cent of DSM-III diagnosed schizophrenia patients had ceased on their own accord antipsychotic medication since the first 5 years of follow-up and the majority of them had remained symptom-free for the rest of follow-up. Common findings in these two studies were that the non-relapsing, high-functioning patients were characterized by a higher level of premorbid occupational achievement and social competence, were less likely to use street drugs,[68] had better insight and an internal 'locus of control'.[69] Further study of the implications of such indicators of better prognostic potential and internal resources should advance efforts to design management and treatment strategies reducing the disabling impact of the disorder.

Summary and conclusions

Studies conducted over many decades consistently demonstrate that schizophrenia presents a broad spectrum of possible outcomes and course patterns, ranging from complete or nearly complete recovery after acute episodes of psychosis to continuous, unremitting illness leading to progressive deterioration of cognitive performance and social functioning. Between these extremes, a substantial proportion of patients show an episodic course with relapses of psychotic symptoms and partial remissions during which affective and cognitive impairments become increasingly conspicuous and may progress to gross deficits. Although no less than one-third of all patients with schizophrenia have relatively benign outcomes, in the majority the illness still has a profound, lifelong impact on personal growth and development. The initial symptoms of the disorder are not strongly predictive of the pattern of course but the mode of onset (acute or insidious), the duration of illness prior to diagnosis and treatment, the presence or absence of comorbid substance use, as well as background variables such as premorbid adjustment (especially during adolescence), educational and occupational achievement, marital status, and availability of a supportive social network allow a reasonable accuracy of prediction in the short- to medium-term (2–5 years).

One of the most striking aspects of the longitudinal course of schizophrenia is the so-called 'terminal improvement'. A relatively high proportion of patients tend to improve substantially with ageing. What determines this long-term outcome is far from clear but the stereotype view of schizophrenia as an invariably progressive, deteriorating disorder does not accord well with the evidence. Similarly, a model of schizophrenia as a static **neurodevelopmental encephalopathy** decompensating post-adolescence under the influence of a variety of stressors fits only part of the spectrum of course patterns. In a significant proportion of cases, the disorder exhibits the unmistakable features of a shift-like process with acute exacerbations and remissions which may progress to severe deterioration or come to a standstill at any stage. Whether a single underlying pathophysiology can explain the variety of clinical outcomes, or several different pathological processes are at work, remains obscure. It has been suggested that the longitudinal course of schizophrenia should be seen as an open-ended, dynamic life process with multiple, interacting biological and psychosocial determinants. Obviously, such issues cannot be resolved by clinical follow-up studies alone, and require a strong involvement of neurobiological research in prospective investigations of representative samples of cases spanning the entire spectrum of course and outcomes. No such studies have been possible until recently, both because of the technical complexity of such an undertaking and because of the tendency to selectively recruit for biological investigations patients from the severe, deteriorating part of the spectrum. Overcoming such limitations will be essential to the uncovering of the mechanisms driving the 'natural history' of schizophrenia.

4.3.8 Treatment and management of schizophrenia

D. G. Cunningham Owens and E. C. Johnstone

Introduction

Historically, there was no shortage of interventions to 'treat' insanity, and later, schizophrenia. Most were palliative, barely effective and often barbaric. It was only with the development of antipsychotic drugs and evolution of trial methodology in the 1950s that a new era of care arrived.

With chronic or recurrent psychiatric disorders, 'treatment' and 'management' are not strictly synonymous. The former has a narrow, patient-specific and largely *symptom* focus, comprising traditional medical tools, especially medications, while the latter can be defined as encompassing a broader range of targets with techniques less specifically part of traditional 'medical' repertoires, including psychological, social, and behavioural interventions. In both its 'treatment' and 'management' aspects, schizophrenia has undergone a concerted therapeutic assault in the past few years but rather than introducing clarity into care, the recent literature might indicate that certainties which seemed so recently within our grasp, remain elusive.

Evidence-based medicine (EBM) has had a major impact on care recommendations for those suffering from schizophrenia. A number of national and international 'guidelines' have been published[1–3] and the Cochrane database provides reviews on a range of relevant issues. This move has been important in smoothing out variability in patient care but although influential and increasingly endorsed, the trend is not beyond criticism. Guidelines are largely derived from *efficacy* data, which may translate awkwardly to real-life *effectiveness*, while considering solely the 'bottom lines' of trials masks the qualitative problems inherent to design, execution, and analysis. Furthermore, over-adherence to guidelines diminishes the impact that *individual variability* within the patient pool makes to optimizing treatment choices while deskilling those charged with care of a complex condition where 'quality' requires greater skill than is usually credited to those who do it well.

Thus, while evidence-based guidelines can offer a *framework* for good care practices, they are *not* a substitute for a broad range of expertise in *individualized* care planning.

Evidence for efficacy

Drug treatment

Schizophrenia comprises a number of domains of disability that form useful targets for drug treatment. These include:

- 'positive' features
- 'negative' features
- cognitive ability
- affective symptomatology
- general behaviour

In addition, comprehensive treatment planning requires awareness of efficacy in:

- maintenance and
- treatment resistance

(a) 'Positive' features

In providing a scientific basis for the use of antipsychotic drugs in 'acute' schizophrenia, the NIMH/VA Collaborative Study comparing the efficacy of three phenothiazines of differing chemical type (chlorpromazine, thioridazine, trifluoperazine) cannot be bettered.[4] Although its conclusions referred specifically to *phenothiazines*, subsequent research justifies the generalization of its findings to 'antipsychotics', making this elegant study relevant still.

Five main points emerged:

1 *Antipsychotics produce a significantly greater improvement in patients with acute schizophrenic symptomatology than placebo.* This action on the positive (or 'acute') symptomatology is the *primary class action* and is beyond doubt. Reviewing the first two decades of antipsychotic use, Davis and Garver[5] found that in 86 per cent of controlled studies chlorpromazine was superior to placebo and that *all* 26 trials utilizing more than 500 mg/day reported definitely greater benefit than placebo. In this dose range *no* trials found only marginal benefits. A similar view can be drawn regarding the efficacy of licensed second-generation antipsychotics.

LEARNING POINT: The antipsychotic effect of antipsychotic drugs (or the magnitude of that effect) is *not* shared by other types of psychotropic agent such as sedatives, is not in need of further replication, and forms a valid basis for classification.

2 *Antipsychotics of (three) different chemical types do not differ in efficacy*. The conclusion that all antipsychotics have comparable 'acute' efficacy is *not* to say that clinically there is nothing to choose between them. Although sharing a primary class action, antipsychotics encompass diverse pharmacologies that in practice can overshadow the action they share in common. There are therefore many ways of viewing class members apart from the traditional subgrouping by chemical structure—e.g. clinical adverse effect profile, subdivided into *general* or *extrapyramidal* tolerability; pharmacodynamically in terms of potency, receptor-binding profile or binding characteristics ('loose' or 'tight'), etc. This is a large 'extended' family!

Table 4.3.8.1 Antipsychotic and placebo response rates in schizophrenia

	Antipsychotic	Placebo	%
Very much improved	16	1	15
Much improved	29	11	18
Improved	16	10	6
Slightly improved	31	31	0
Not improved	6	15	
Worse	2	33	

Data from NIMH Collaborative Study.[4]

LEARNING POINT: In choosing an antipsychotic drug for 'acute' treatment, tolerability not efficacy, is the key consideration.

3 *A substantial proportion of patients show limited or no response to antipsychotic drugs*. Overall, 61 per cent of those on active drug were considered 'improved' to 'very much improved'.[4] It has usually been agreed that standard drugs produce a satisfactory response in approximately 60–70 per cent of patients with 'acute' schizophrenia, while approximately 6–8 per cent do not respond at all.[6] However, if one includes placebo response rates a less favourable picture emerges, suggesting that significant benefits could be more realistically expected in approximately 40 per cent of patients (Table 4.3.8.1).

Not all those non-responders could be classified as 'treatment resistant' (this concept, now operationally defined, long post-dated the Collaborative Study), but it does mean that in the mixture of first episode and relapsed patients presenting in routine practice, expectations for 'acute' (i.e. 'positive') symptom resolution must be *realistic* and cannot necessarily be improved by increasingly aggressive drug treatments alone.

LEARNING POINT: While providing a necessary foundation for clinical improvement to *acute* psychotic symptomatology, expectations of antipsychotic drugs on this single domain must be realistic. Treatment objectives should be correspondingly broad-based.

4 *A rapid phase (over the first week) of improvement is followed by a slower, more protracted pattern of improvement (over several weeks).* This finding has recently been replicated but with a somewhat different interpretation to that traditionally adopted. In a review of placebo-controlled studies, Agid *et al.*[7] also found that standardized ratings of positive symptomatology began to decline in the first week and improvement was significantly greater in the first 2 weeks of treatment than in the subsequent two. This was interpreted as rejecting the conventional view that antipsychotic onset is delayed. In an early clinical test of the dopamine hypothesis, Johnstone *et al.*[8] compared the two isomers of flupenthixol (flupentixol), one a dopamine blocker, the other not. They found that antipsychotic efficacy between the two groups, although evident in the first week, only became *significant* in the third week, often taken as supportive of the delayed onset hypothesis. A compromise between these two viewpoints comes from other data from this study, which showed that the first week of treatment

was also a time of significant improvement in non-specific symptomatology, especially anxiety, in those exposed to the antidopaminergic isomer.[9]

LEARNING POINT: While early improvement on antipsychotics may comprise a component of primary efficacy, such early benefits should be interpreted circumspectly in treatment planning, especially dose modifications, as they may reflect *mainly* non-specific changes.

5 *Patients in placebo arms of antipsychotic drugs trials can—and do—show improvements in positive symptomatology*. This is a standard finding in clinical trials often overlooked in routine practice. Non-specific benefits that can accrue from the environment where treatment is undertaken can contribute to maximizing outcomes.

LEARNING POINT: Drug effects have a context!

Despite their limitations, antipsychotics are unquestionably *the* key element in acute treatment. In a unique study, May *et al.* compared response rates and outcomes in a large group of schizophrenic patients randomly assigned to one of five regimes: individual psychotherapy, antipsychotics, individual psychotherapy plus antipsychotics, ECT, and 'milieu' therapy (ward environment). Patients who received physical treatments did better with increased rates of discharge, reduced lengths of stay, and decreased need for additional treatments.[10] Two years after discharge, twice as many of those treated with antipsychotics as with psychotherapy were in employment, while in the 3 years post-discharge, drug-treated patients spent less time back in hospital.[11]

(b) 'Negative' features

The issue of whether antipsychotics exert *efficacy* on negative schizophrenic features rose to prominence in the 1980s as a result of the implications of Crow's Type 1/Type 2 hypothesis.[12] The inference of this is that efficacy is 'unlikely' owing to different pathophysiological substrates proposed for 'positive' and 'negative' states. Controversy has persisted, with claims that whatever the case may be for first-generation drugs, new generation antipsychotics do possess this action. Recent reviews, however, have been increasingly circumspect.[13]

One consequences of testing Crow's proposal was that 'negative' schizophrenic symptomatology came to be viewed as something ratable *cross-sectionally*. This was a radical shift for traditionally the 'defect state' was conceptualized as a set of phenomena evident mainly from *longitudinal* appraisal, relating to complex behavioural *signs* such as psychosocial and occupational functioning. This switch assumed that the varied states that can underlie 'negative' presentations can be distinguished using cross-sectional clinical means alone. This assumption has never been validated and seems to push at the limits of clinical examination.

A major confound in assessing trial data in this field is the bradykinesia of drug-related parkinsonism, a common, pervasive feature in those exposed to antipsychotics yet one whose boundaries remain poorly defined, especially for its *subjective* components.[14] Changing to drugs or doses with lower extrapyramidal liability, or improving psychotic phenomena that may underlie social withdrawal is a therapeutic action of sorts, but hardly addresses the question. Likewise, utilizing elaborate statistics (e.g. path analysis) to support efficacy for second-generation antipsychotics ignores the fact that the problem is clinical attribution, not analysis.

Table 4.3.8.2 The classification of 'negative' states in schizophrenia

Primary	Authentic schizophrenic state
Secondary	Positive symptomatology Depressed mood Extrapyramidal disorder Early dysphoria Bradykinesia Psychosocial isolation

After Carpenter et al.[29]

Carpenter and colleagues[15] raised awareness of this issue by emphasizing the varied clinical states that can present 'negatively', thereby introducing a differential diagnosis (Table 4.3.8.2). Furthermore, by emphasizing 'durability' in their definition of 'deficit' syndrome,[16] they reintroduced a longitudinal component, aligning this more with the historical concept of schizophrenic negativity. Interestingly, this group found clozapine's benefits on negative features to be confined to patients who did *not* conform to criteria for 'deficit' state.[17]

One cannot help wondering whether the quest for antipsychotic 'therapy' of negative states has been a wild goose chase, predicated on assessment that was reliable—but lacking validity. This view will be controversial, as will our conclusion that Crow's hypothesis has *not* yet been disproven—that it remains to be shown that antipsychotics as a class exert any therapeutic benefits on primary negative schizophrenic symptomatology.

(c) Cognitive ability

The importance of cognitive deficits underlying the overt symptomatology of schizophrenia is being increasingly highlighted. They comprise a valid endophenotype in predisposed individuals, general cognition suffers a decline in the shift to florid illness and specific cognitive impairments, especially in executive function and memory, may relate to structural changes in specific brain areas.[18] The pharmacological question is whether drug treatments can enhance cognitive performance and thereby promote benefits in other domains.

Evaluation of cognitive actions of antipsychotics faces major methodological problems and findings remain contradictory. Standard antipsychotics initially impair aspects of attention and motor behaviour which improve following continued exposure, though working memory and long-term recall do not appear to be fundamentally affected.[19] Paced performance tests tend to be affected while those that are untimed tend to be insensitive, perhaps reflecting subtle motor effects.[20]

While new generation drugs may be associated with marginally less cognitive impairment than standard drugs, data are inadequate for firm conclusions.[21] In the absence of consistent evidence of differential effects on a range of neuropsychological tests, it has been suggested that measurements of 'social competence' may represent a more appropriate target for study.[22]

Furthermore, in studies evaluating cognitive-enhancing agents as 'add on' therapy no consistent evidence of utility has emerged.[21,23]

(d) Non-specific symptomatology

Affective symptomatology is prominent in schizophrenia but the efficacy of antipsychotics on such features has received little attention.

Their utility in the treatment of *anxiety* and other manifestations of 'arousal' in acute episodes of illness has not been systematically addressed and rests largely on clinical wisdom.

There is however, a tradition in Continental Europe of attributing *antidepressant* actions to low-dose antipsychotics[24,25] (e.g. flupentixol, sulpiride L-enantiomer, amisulpride) when they may exert preferential actions at presynaptic (autoreceptor) dopaminergic sites. Data remain inconclusive but it is unlikely that such an action would be clinically useful, as presynaptic selectivity is lost at doses usually required for antipsychotic efficacy.

Depression is a common feature of untreated schizophrenia and resolves as positive psychotic phenomena diminish.[26] This probably does not reflect an antidepressant action but symptom covariation. Of greater concern is what was formerly referred to as the 'depressogenic' action of antipsychotics.[27] This again raises the difficulty of distinguishing between similar presentations of pathophysiologically different states. Van Putten and May described a dysphoric mood state in antipsychotic-treated patients ('akinetic depression'),[28] which resolved following administration of anticholinergic. This was most likely a subjective manifestation of bradykinesia.

(e) Behaviour

Behaviour can be variously disturbed in schizophrenia, though is seldom considered other than as part of a global assessment. While certain confrontational behaviours such as hostility, belligerence, and resistiveness do improve with antipsychotics,[29] this is usually attributed to improvement in positive symptoms. There is, however, evidence that certain types of behavioural disorder correlate with negative, not positive, features and may represent a distinct domain of disorder.[30] It seems likely that certain manifestations of behavioural disorganization represent independent dimensions of pathology with their own, predominantly negative, prognostic implications.[31]

(f) Maintenance

With mood disorders, 'relapse' (exacerbation of an ongoing episode) and 'recurrence' (emergence of a new episode) are well-defined. In schizophrenia, where full remission of acute symptomatology may not be a realistic treatment goal, the distinction is less clear. As the long-term aim is usually minimizing the likelihood of florid exacerbation in a disorder characterized by persisting symptomatology, the term 'maintenance' is preferable to 'prophylaxis'.

The efficacy of antipsychotic drugs in long-term maintenance of schizophrenic illness is beyond doubt.[32] This applies to first-episode patients and to those who have suffered multiple episodes. Nonetheless, it remains difficult to quantify the effect as published figures vary widely. Reviewing relevant trials (covering variable follow-up intervals), Janicak *et al.* concluded that on average 55 per cent of those on placebo relapsed compared to 21 per cent on active medication, providing overwhelming statistical support for the maintenance effect.[32] In qualification, maintenance studies tend to be biased towards patients who have already shown a degree of response and it is likely that the magnitude of this effect, at least over 12–24 months, is less than trial-based analyses suggest.

A crucial question for clinicians is how long maintenance medication should be continued. The evidence is clear. Relapse rates have been shown to be similar following cessation in groups maintained well for differing lengths of time, from months to years.[33] Furthermore, no difference in relapse has been found in those who responded well compared to those whose response was less good.[34] The implication is that, no matter the *duration* or the *quality* of well-being on antipsychotic maintenance, relapse is *inevitable* following discontinuation in those with an established relapsing-remitting illness pattern (i.e. two or more episodes), which comprise the majority.

Not only is relapse a characteristic inherent to these illnesses, it seems so too is *time* to relapse. Davis *et al.* showed that placebo relapses plotted over a 2-year period occurred along an exponential line, indicating a constant *rate* of relapse, calculated from pooled data at a steady 11.5 per cent per month.[35]

Thus, the clinician's position is clear—for maintenance of well-being following second or subsequent acute episodes, 'long-term' antipsychotic maintenance means 'lifelong'. Should patients decide to discontinue, past experience can offer an invaluable tool in predicting when relapse is likely.

Some patients see long-term maintenance as 'well-being' only of sorts, in which quality-of-life is unacceptably impaired. In such individuals, *targeted intervention*, where treatment is focused on prodromal relapse symptomatology, has intuitive appeal. Alas, the trial evidence does not support this as a general strategy. No controlled studies so far have found advantage in targeted intervention and in a meta-analysis, Davis *et al.* calculated 25 per cent relapse rates in those continuously treated, rising to 50 per cent in the targeted group.[36] While carefully selected individuals, who can work with family and psychiatrists, may prefer this approach, a further potential concern is that intermittent exposure to antipsychotics may increase liability to tardive dyskinesia.[14]

Intermittent treatment is, of course, a feature of poor compliance (also known as 'adherence' or 'concordance'), itself perhaps *the* major contributor to relapse. In terms of major medical events, antipsychotics have a highly favourable risk:benefit ratio but in terms of medically trivial but unpleasant, intrusive adverse effects, the risk:benefit ratio is *unfavourable*, something often overlooked. Ensuring a maximally effective *and* tolerable maintenance regime is a joint exercise, from which the doctor cannot be excused.

The evidence that depot formulations enhance compliance is strong, if largely indirect. Support comes from 'mirror image' studies, where time in hospital is compared prior to and after starting depot. Six such studies were unanimous in showing substantial reductions in time spent in the hospital after switching to depot (average reduction: 77.8 per cent).[36] There is nothing to suggest that this reflects additional *therapeutic* advantage inherent to depots, whose benefit lies simply in facilitating regular administration and objective monitoring of compliance. Long-acting injectable risperidone (not a 'depot' in the traditional sense) has so far received favourable assessment[37] but it is too early to provide head-to-head comparative data with conventionally formulated depots. Dosages are also an important consideration in maintenance, as those compatible with maximizing long-term tolerability and well-being are likely to be considerably *lower* than those necessary for acute symptom control. However, the data are insufficiently clear to provide specific guidance. Kane *et al.* showed that relapse rates were significantly higher in patients receiving fluphenazine decanoate in a dose of 1.25 to 5 mg two weekly compared to those receiving 25 mg,[38] yet Baldessarini *et al.* have calculated that in long-term treatment, half-maximal effective doses (ED50) may be as low as one-fifth to one-tenth those normally employed.[39] In the absence of

specifics, general principles must suffice. Kane and colleagues also showed that while relapse was more likely on low-dose regimes, neurological tolerability and psychosocial/quality-of-life parameters were superior.[38] Gradual pursuit of the minimal effective dose is all that can be recommended. Bearing in mind the exponential pattern of relapses, with a modal point at 3–5 months,[40] 'gradual' should equate to decrements at intervals of *months*, not weeks.

(g) Treatment resistance

The limitations of antipsychotic treatment in schizophrenia have been known since the 1960s but the concept of 'treatment resistance' only sprang to prominence with publication of the US multicentre clozapine study.[41] Within an operationally defined framework of 'resistance' (failure to respond to at least two antipsychotics of different chemical type administered in adequate dose for a minimum of 8 weeks), Kane *et al*. showed that 30 per cent of those on clozapine improved, while only 4 per cent on chlorpromazine/benztropine did likewise ($P < 0.001$).[41]

This has been interpreted as proving that clozapine possesses superior *efficacy* over standard agents. While this is one interpretation, it is not the only one. In this study, a chlorpromazine: clozapine dose equivalence of 2:1 was assumed, which might have disadvantaged chlorpromazine, allowing the interpretation that clozapine's advantage lies in its unique neurological *tolerability*. However, many other studies have confirmed clozapine's edge in patients who fail to respond satisfactorily to other antipsychotics and whatever the explanation, this is *real* added benefit. It does not mean however, that clozapine is a 'miracle' drug. While 30 per cent of such patients improving is welcome, the criteria for 'improvement' here were modest and subsequent review has failed to show substantial long-term benefits in higher level functioning, such as occupational ability.[42] Overall expectations of clozapine, a potentially difficult drug to administer, and for patients to tolerate, must be realistic.

Similar benefit has been claimed for other second-generation antipsychotics. However, there is *no* conclusive evidence that such advantages can be attributed to *any* other antipsychotic agent.

Management: psychological and psychosocial interventions

While nowadays, there is no suggestion that *the* core intervention in schizophrenia should be anything but medication, the limitations of medication alone in symptomatic, relapse prevention, and satisfaction/quality-of-life terms have long prompted interest in wider forms of management. Randomized-controlled studies of psychological and psychosocial interventions are complex and expensive to undertake and hold many potential problems—sample representativeness, high drop-outs, appropriateness of controls, fidelity to the intervention, blindness, etc. As a result, there have been many fewer such studies than of drugs, though in recent years new work, evaluating especially psychological interventions, has been published.

The major types of intervention include:

- Cognitive behaviour therapy
- Psychodynamic psychotherapy
- Social skills training
- Psychoeducation
- Family interventions

It is also convenient to consider aspects of service organization here.

(a) Cognitive behaviour therapy

As striking as the decline in dynamic psychotherapies over the past two decades has been the rise of *cognitive behaviour therapy* (CBT) as a clinical and research focus across psychiatry. Especially in the UK, this has extended to advocacy in schizophrenia. With over 20 randomized-controlled trials and five meta-analysis seeming to support its use, a place in management should be beyond doubt.[43]

The fact is, however, that doubt *does* remain. A recent Cochrane review[44] found that CBT did *not* reduce relapse and readmission compared to standard care (though it did decrease the risk of staying in hospital) and while it improved mental state over the medium term, after a year these slight benefits had disappeared. Continuous measures on mental state did not demonstrate consistent effects. Compared to supportive psychotherapy, CBT had no effect on relapse and when combined with a psychoeducational approach, no significant reduction in readmission rates relative to standard care alone could be demonstrated.

While some individual studies have shown impressive results, the powerful advocacy CBT has attracted as adjunctive management in schizophrenia seems, at this stage, disproportionate to the evidence base. Studies have been built around fundamental design flaws, most notably in relation to control conditions, allowing some to conclude that CBT can be shown to work only in poorly controlled trials and not in well controlled ones.[45] Even between studies showing benefit, it is difficult to discern what the most appropriate target(s) should be and what components ought to comprise an/the ideal CBT package. A further problem, specific to assessing CBT in group contexts, is inappropriate data analysis where independence of observations is universally assumed, something group interactions violate, with a resultant increase in Type 1 errors.[46] While CBT *may* hold promise, widespread endorsement of a resource intensive management would seem premature until more and better designed work reports.

A further application of CBT techniques in psychosis has been in enhancing compliance. While *compliance therapy*,[47] combining cognitive behaviour and motivational interviewing techniques, has shown promise, it has been insufficiently evaluated to support robust recommendations. A recent Cochrane review[48] identified only one study comparing this with non-specific counselling. No significant differences were found in overall 'non-compliance' rates or in mental state measures, attitudes to treatment, global functioning, or quality of life. Although at 1 and 2 year follow-ups, average number of days in hospital was reduced, this was not statistically significant. This study did not show any effect on insight, but other work has claimed that improvements can be achieved by short, insight-focused CBT interventions, but at the expense of increasing depression,[49] an observation also reported with non-CBT approaches targeting insight.[50]

Cognitive remediation (or rehabilitation), in which the desired end-point is not symptom reduction per se but improved *global* functioning via amelioration of cognitive deficits such as impaired vigilance, attention, and planning/decision-making, has also been applied in adjunctive management. Once again, while some individual findings are encouraging, data remain inconclusive.[51]

LEARNING POINT: While present evidence does support the use of CBT led interventions in adjunctive management of schizophrenia, the research is flawed and further, *well controlled* studies are necessary to determine a precise role.

(b) Psychodynamic psychotherapy

Unlike Freud, many analysts of the early-mid twentieth century were undaunted in pursuit of psychodynamic understanding of, and management for, schizophrenia but theories were universally unsupported by evidence. When assessed against supportive psychotherapy, no advantages could be demonstrated.[3] While some modest revival of interest may be detected, especially amongst advocates of 'early intervention', a recent review provided no support for such revisionism.[52] Furthermore, May's study[10,11] offers a cautionary warning of the potential for harm.

LEARNING POINT: Insight-orientated dynamic psychotherapy has no current place in the management of schizophrenia.

(c) Social skills training

As a result of the early age of onset, relapsing nature, and persistence of many clinical features, schizophrenia can potently disrupt smooth acquisition and evolution of skills essential for developing mature interpersonal relationships, occupational competence, and independent living. *Social* (or life) *skills training* evolved in the context of resettlement programmes aimed at discharging long-stay, institutionalized patients but in various forms remain widely practised. It is based on a structured learning-orientated approach to the acquisition of skills relevant to the individual and the demands of his/her environment.

Unfortunately, social skills training is difficult to evaluate, as this has become a 'blanket term' covering a wide range of applications and targets. While some studies have focused on rehearsal of activities of daily living, others concentrate on communication and conversational skills, and although some view improvement in symptoms as the underlying goal, for others the benefit lies with cognitive ability. Blindness of assessments is a major problem, though can be easily achieved using blinded video techniques. Thus, while individual studies have found improvements in assertiveness, general social competence, and even speed of discharge, with benefits extending to a widened social network and that generalize, a recent Cochrane review failed to find conclusive evidence of benefit.[53]

Illness self-management is part of several social skills training programmes but has been singled out as the focus of specialized techniques, comprising video modelling, role-play, and specific problem-solving combined with homework. While promising results have been reported,[54,55] this intensive approach requires further evaluation.

Vocational training (or rehabilitation) is not directly dependent on social skills training but is related to it. Although the majority of schizophrenic patients end up unemployed (up to 85 per cent in the US; 73 per cent in the UK),[56] specialist vocational training remains a scarce component of long-term illness management in most services. A review[56] concluded that *supported employment* models were significantly more effective than *pre-vocational training* in facilitating competitive employment, the latter being no better than standard community care. Supported employment was also associated with higher earnings and more hours working per month. It is sobering that even in trial contexts an average of only 34 per cent of individuals in supported employment were actually employed at 18 months, the comparable figure for those who received pre-vocational training being 12 per cent.[56]

LEARNING POINT: Although intuitively sound and generally appreciated by patients and families, 'social skills training' can only be given a firm evidence base with further well controlled studies in which individual components of therapy are 'teased out' for separate evaluation and specific end-points are genuinely blindly assessed.

(d) Psychoeducation

Much of the above comprises an element of 'education' in the widest sense but programmes have been advocated in which information exchange is *the* key intention. *Psychoeducation* can be targeted on the patient to improve outcomes, enhance compliance, and increase knowledge, including on early relapse recognition, thereby contributing to a better sense of well-being. Imparting factual material is also a fundamental component of many family interventions (see below).

In general, patients appreciate sessions in which their illness is explained, reinforcing the idea that some understanding is possible in situations which may seem incomprehensible. Furthermore, explaining bizarre experiences and beliefs in *illness* terms can help de-stigmatize preconceptions they themselves may hold.

Like most psychological and social interventions advocated as adjunctive strategies for schizophrenia, 'psychoeducation' is not a single procedure with standardized delivery, something that inherently limits systematic reviewing. Nonetheless, it has a favourable review in the Cochrane Library,[57] which found that relapse and readmission rates were significantly reduced (NNT = 9) at 9 to 18 months. Beyond this however, no effect was found on insight, medication-related attitudes or overall satisfaction with services by patients or families. Thus, while data to date are consistent with some *overall* benefits from psychoeducation, those that are proven remain few.

LEARNING POINT: Psychoeducation, as a blanket concept, is attractive to patients and carers and, because it is brief and inexpensive, to service providers, but its *therapeutic* impact may be limited. Future studies must define component elements and address complexities, such as the distinction between knowledge and understanding, and the vulnerability of learned material to degeneration.

(e) Family interventions

The therapeutics of schizophrenia broadened from sufferers to families and carers with the observation that criticism and hostility from a close relative ('expressed emotion': EE) was an important determinant of relapse. As families remain the key element of support for most patients, development of positive, constructive ways of helping them provide this has rightly formed a considerable research focus over the past 30 years. With regard to EE, the consensus is that reduction reduces relapse risk when combined with maintenance medication.[58] However, this appraisal is *not* unanimous and the importance of EE reduction is in need of modern systematic review.

Family interventions have broadened to include not only educational input about the illness, its consequences and service availability, but also psychosocial interventions aimed at developing an alliance (especially important during first presentations), reducing emotional distress, boundary setting, and instillation of realistic expectations of both patient and services. This component

heterogeneity again makes straight literature comparisons difficult. A recently updated Cochrane review[59] reported somewhat more equivocal findings than previously, suggesting that while family intervention *may* decrease relapse frequency, the number needed to be treated to prevent an episode of relapse (NNT) had risen from six in a previous review to eight. The authors emphasized that some negative studies may have been missed by their search, rendering even this figure tentative. There was clearer evidence of an effect in reducing hospital admission (NNT = 8) and a *likely* beneficial effect on compliance (NNT = 7). There was no effect on the tendency of individuals to drop out of care but a *likely* improvement in general social impairment and in levels of EE. The effect on suicide seemed neutral. While this may be taken as an endorsement of family interventions, the reviewers offer a salutary caution, suggesting that interested parties—clinicians, patients, policy makers—'cannot be confident on the effects of family intervention from the findings of this review'.

LEARNING POINT: Families generally welcome professional input dedicated to *them* and *their* needs at distressing times such as first diagnosis and subsequently, with realization of the implications. As a quality-of-care issue, such involvement is beyond the benefits trial evaluation can provide. However, in proposing what *works* therapeutically—and works *best*—further research is necessary to define specific elements of interventions that are not only appreciated but that contribute unequivocally to well-being of sufferers and family members.

So—using the *evidence*—what can be concluded from the above? In reviewing psychosocial management strategies advocated for those with schizophrenia and their relatives, two observations emerge. First, is a certain 'regression to the mean'—the more interventions are studied, the harder it becomes to replicate benefits enthusiastically identified early on. The second might be viewed as cynical but is worth stating nonetheless—namely, that in our quest to maximize the care of those with this fell disorder, it has been conclusively established that *drugs plus* 'something' produces better outcomes than *drugs alone*. What remains unclear is whether 'something' amounts to more than projecting high levels of professionalism and/or a common humanity or whether there is indeed a *specific* therapeutic component (or components) to any or all of these 'somethings'.

It is disappointing that after decades of research such a conclusion is still possible and future studies not only need to address the standardization of component element(s) of psychosocial management but must establish a supremacy for it/them before psychiatrists in routine practice and policy makers alike are able to invest not simply in services that others 'like' but that doctors can confidently endorse as having firm *evidence* of therapeutic benefit.

(f) Service organization

The rationale of 'community care' in promoting independence and choice is noble but its implementation has frequently been found wanting. A major thrust in community care management has been the introduction of *community mental health teams* (CMHTs), comprising a comprehensive range of disciplines that bring both collectivism to decision-making and varied expertise to service delivery. Compared to non-team care, CMHT management does promote a greater acceptance of treatment options but further advantages are hard to identify, though reductions in admission and suicides are *possible* benefits.[60]

It has long been clinical experience that not all patients with acute psychoses, including schizophrenia, require hospitalization and, although the research base (specifically in relation to schizophrenia) is slender, *home treatment* programmes have vocal advocates, partly because of the promise they hold for reduction in costly bed numbers. While patient satisfaction is usually high, early quality-of-life benefits may not be sustained and, owing to ongoing need for inpatient facilities, cost benefits may be limited long-term.[61,62] These are difficult services to organize, require intensive staffing and sophisticated multiagency working, and even then, staff morale can be hard to sustain.[63] They are highly selective in who they accept[64] and may work most effectively for those whose family units remain well-integrated and supportive,[65] such as adolescents, but doubts spanning all the potential benefits are sufficient to suggest caution in making empirically based leaps to such radical service reorganization in the absence of further data.

The policy of institutional closures that began in most developed countries in the 1960s/1970s did not result in reduced patterns of acute bed usage. In fact, *rising* admission rates caused concern that day and outpatient care alone were inadequate because of failure to maintain engagement or to meet complex needs. Case management and a variant, assertive community treatment (ACT), arose as ways of optimizing ongoing service involvement and ensuring coordination and delivery of care appropriate to individual clinical and social needs. Both aim to: maintain patients in contact with services; reduce frequency and durations of admissions; improve outcomes, especially social functioning and quality of life. Case management is essentially based on 'brokerage', where an *individual* member of the multi-disciplinary team is responsible for assessing needs, developing a care plan, arranging implementation and monitoring quality and engagement, and is also involved in an element of delivery. This is now seen as the least robust model and more complex variants have arisen. With ACT, the emphasis lies in *team* working.

Systematically reviewed, *case management* ensures that more people remain in contact with services but with the consequence of *increased* admission rates.[66] Furthermore, rather than shortening admissions, it may actually increase their duration. There is no evidence that it improves outcomes on any clinical or social variables. Compared to standard community care, patients receiving ACT are more likely to remain in contact with services, less likely to be admitted, and spend less time in hospital with other benefits in terms of accommodation, employment, and satisfaction.[67] However, mental state and social functioning are *not* improved and with overall costs accounted for, ACT is *not* less expensive. In comparison to case management, ACT has advantages in terms of reduced time in hospital but overall there are no cost benefits.[67] Few other comparisons are possible due to inadequate data.

The impression that case management should be dropped and ACT flourish[67] is somewhat oversimplified. The negative appraisal of case management as of 'questionable value' has been criticized[68] while the 'effectiveness' of ACT seems to rest on the recurrent problems of content and fidelity of delivery noted in relation to all the psychosocial interventions discussed here.

LEARNING POINT: Like drugs, organizational structures operate in a social and service development context and what applies to one patient group in one national or local environment might not reap similar benefits in another. Community-based

or otherwise, *the* weakness in the care of those with chronic, relapsing-remitting disorders like schizophrenia, characterized by autistic withdrawal and social dislocation, is failure to maintain engagement with specialist services. Any structure that fosters a proactive approach to engagement while maintaining staff morale is likely to be better appreciated and to provide better outcomes.

Treatment and management principles

The following is based on UK experience and may not translate completely across international borders where local traditions and organizational constraints may modify practice. It is only presented as an *outline* of issues to be considered and cannot provide a universal blueprint for care. As will become apparent, the authors would argue that such 'blueprints' do not best serve the interests of patients or the expertise of those implementing care.

Doctors confronted with a patient believed to be acutely psychotic must address three preliminary questions:

1 *Does the patient require admission or can they be managed as an outpatient?*

Some of the issues were aired above but from the *medical* point of view, there are a number of scenarios in which admission remains a priority (Table 4.3.8.3).

2 *Can the clinical situation be dealt with informally or are compulsory legal powers required?*

Table 4.3.8.3 Considerations in relation to admission policies in patients with acute schizophrenia

Supporting admission	Supporting non-admission
Unstable mental state Rapidly extending content Variable affect	Mental state disorder stable/slowly evolving
Imperative auditory hallucinations To harm self To harm others	Absent/no will to act
Marked affective change Suspiciousness, anger Depression	Affective change mild/amenable to reassurance
Behavioural disturbance Disorganization Dangerousness Commission Omission	Minimal behavioural disturbance/risk of harm
Cognitive disturbance Lack of insight Impaired attention/distractability Inability to comprehend advice Hopelessness/suicidal ideation	No barrier to engagement
Inadequate social support Living alone Vagrancy/neglect	Good social supports
Any (other) reason for non-compliance	Likelihood of compliance
Medical state Intercurrent physical illness Substance misuse/dependency	Physically fit
'Asylum'	Aversion to inpatient care

This will depend on the thorough *risk assessment* that must be a part of every examination. This must, of course, include the *health* risks, not solely those involving threat. The details of implementing compulsory detention for assessment and/or treatment will differ in different jurisdictions.

3 *What is the best first step in treatment?*

There is *no* single first–line drug for the treatment of acute schizophrenic episodes—nor, the authors would suggest, any first-line *type* of antipsychotic. Guidelines are fairly unanimous in recommending 'atypical' antipsychotics, especially in first episodes, and any recommendation qualifying this requires justification.

Despite its persistence, the term 'atypical' has never attained *pharmacological* credibility. It rests on a single *clinical* parameter—a perceived reduction in liability to promote extrapyramidal side-effects (EPS)—*quite specifically*, drug-induced parkinsonism. The problems surrounding a subclassification based on such a vague parameter are multiple (e.g. the boundaries of parkinsonism; inadequacies of rating schedules; discrepancies in dose equivalences between trial and comparator agents) making 'atypicality' of dubious scientific validity.[14] Carefully conducted trials, not sponsored by industry, have recently raised questions about putative advantages in EPS tolerability, even with high potency comparators such as haloperidol, when appropriate equivalence is used.[69] With quality-of-life parameters no different after up to 1 year, and no detectable patient preference,[70,71] objectively it is hard to see 'atypicality' as having any merits beyond product marketing. There is certainly little to support any *inherent* value for clinical decision-making beyond the fact that new generation drugs extend the options.

However, there is now strong *evidence* to challenge the blinkered 'algorithmic' prescribing guidelines can foster, especially in relation to 'atypical' antipsychotics. Results of the Clinical Antipsychotic Trials of Clinical Effectiveness (CATIE) study raise important issues about the tolerability profiles of different new generation compounds in relation to first-generation drugs[72] and challenge cost-effectiveness benefits.[73] These data form part of an emerging trend that, we contend, opens up once again the *full range* of antipsychotics—new and old—to consideration as treatment options.

An alternative to 'algorithmic' practice is to view guidelines as providing a *framework* only, within which *all* clinical information can be brought to bear in prescribing decisions. This approach takes its cue from drug regulation, where the appropriateness of granting a license is based on an *individual risk*: *benefit appraisal*. This is a *clinical* judgement, the outcome of which is dependent on *context* (e.g. not simply adverse effect burden but availability of alternatives). Patients, psychotic illnesses and drugs to treat them are each diverse, harbouring far greater differences than the few similarities they share. These diversities should be entered into the individual risk:benefit appraisal in making prescribing choices. So too should the *phase* of illness one is planning for—acute through to maintenance—as the risk:benefit appraisal may shift between these in particular individuals.

Some examples of issues for consideration in individual risk: benefit appraisals are shown in Table 4.3.8.4, but the professionalism psychiatry claims can only come from expertise in recognizing and accounting for the many varied possibilities.

Table 4.3.8.4 Individual risk:benefit appraisal in the use of antipsychotics : examples of some considerations

Presentation	Possible Strategies	Schedule
Behavioural disturbance 'positive' or 'negative' = arousal	Low potency standard (solo treatment)	'diminuendo' or 'crescendo'
Prominent non-specific affective symptomatology	Low potency standard Or New generation + benzodiazepine (potentiation)	Rapid 'crescendo' to tolerance
Marked insomnia	New generation + benzodiazepine Or low potency standard	'crescendo' to 6–8 hours nocturnal sleep + maximum of two hours in the day
High risk of psychiatric emergency	Low potency standard (+/- additional medication)	Slow 'diminuendo'
Tenuous engagement Poor past medication experiences (tolerability) Overfamiliarity with common regimes	New generation (solo treatment)	Slow 'crescendo'
Poor physical health Overweight Family history of CV disease	High potency standard	'crescendo'
Middle aged High CVS risk factors	High potency standard	Low dose regime assessed without change over protracted period
Prior or present EPS symptomatology	'loose binding' new generation (quetiapine)	Slow 'crescendo'
Established history of poor long-term engagement/ compliance	Long-acting injectable	Ultra-slow 'crescendo'

'diminuendo' = starting with higher doses and tailing down to tolerability

'crescendo' = starting with lower doses and building up to tolerability

Identifying goals and defining structure

The key to avoiding confusion and 'decision paralysis' in dealing with the complex clinical situations schizophrenia presents is to delineate the *structure* within which it is hoped to achieve a series of treatment/management *goals*. Although arbitrary, three 'phases' can be identified:

- Acute
- Post-acute
- Maintenance

The acute phase

This encompasses treatment during the maximally florid symptomatic period, corresponding to first presentation or subsequent acute exacerbations (Fig. 4.3.8.1). It is characterized by a significant shift to *illness*, though surprisingly, it remains unclear exactly what changes define this shift.

The goals include:

i) control of intrusive, non-specific symptomatology (e.g. anxiety, agitation, and especially insomnia);

ii) maximizing safety and well-being of the patient and others by containing chaotic, socially damaging behaviours;

iii) engaging the patient in therapeutic recommendations and (mental state permitting) gaining consent for treatment plans;

iv) implementing an appropriate foundation drug regime;

v) stabilizing positive symptomatology;

vi) preventing, or if unavoidable, treating psychiatric emergencies.

The risk:benefit appraisal at this early stage is driven by the first four of these, for the ultimate goal of acute phase treatment—stabilization of positive symptomatology—is, as noted, likely to be delayed. It is important not to overlook other goals that can be achieved quickly, especially those that can be held up as evidence of progress, such as improved sleep.

These goals may be achieved using a single antipsychotic, which is the *ideal*. In this regard, low potency first-generation drugs, such as chlorpromazine, have appeal because of low cost, extensive usage, wide dose flexibility and potent, if rapidly habituating, sedative properties. Flexible dose studies suggest the majority of responses will be achieved in the range of 500–600 mg/day[5] with some suggestion that first-episode patients may respond at lower doses. While low potency drugs have a justifiably admirable reputation in the treatment of presenting, acute phase symptomatology, they are not generally ideal as sole long-term treatment in view of the often intrusive effects of lingering sedation. As patients who have experienced benefit on a particular regime tend not to like changes, and such switches can be clinically problematic because of poor dose equivalence data, chlorpromazine alone is usually best reserved as an initial, short-term strategy.

High potency first-generation drugs, especially haloperidol, have also been widely used, especially in the United States, and while effective, contain a potential problem. High potency drugs are *safe* and tend to be used in higher doses than low potency ones (in one study, 4–6 times the low potency equivalent[74]). This undoubtedly follows from the fact that low potency compounds are inherently dose-limited by anti-autonomic and sedative actions. Unsurprisingly, liberal early use of high potency drugs is associated with higher rates of EPS (dystonias, akathisia, and parkinsonism).[14] Two points should be borne in mind in using high potency first-generation antipsychotics. Firstly, it has been shown in both clinical and functional imaging (PET) studies using D2 occupancy levels that usual minimum effective daily doses of haloperidol lie somewhere between 2 and 5 mg.[75,76] Secondly, even utilizing slightly higher doses, EPS need present no greater problems with haloperidol than they do with placebo or olanzapine.[69,75]

Nowadays, most clinicians tend to pursue a new generation drug as their first choice and this does have some practical advantages, not least single dosing and orodispersable formulations. However, while most new generation drugs have some sedative properties, these are clinically less prominent than with low potency first-generation compounds, so achieving early acute phase goals can be protracted. Furthermore, these drugs usually now come with defined protocols relating to starting doses and rate of increments which do not apply to older drugs. A number of guidelines address

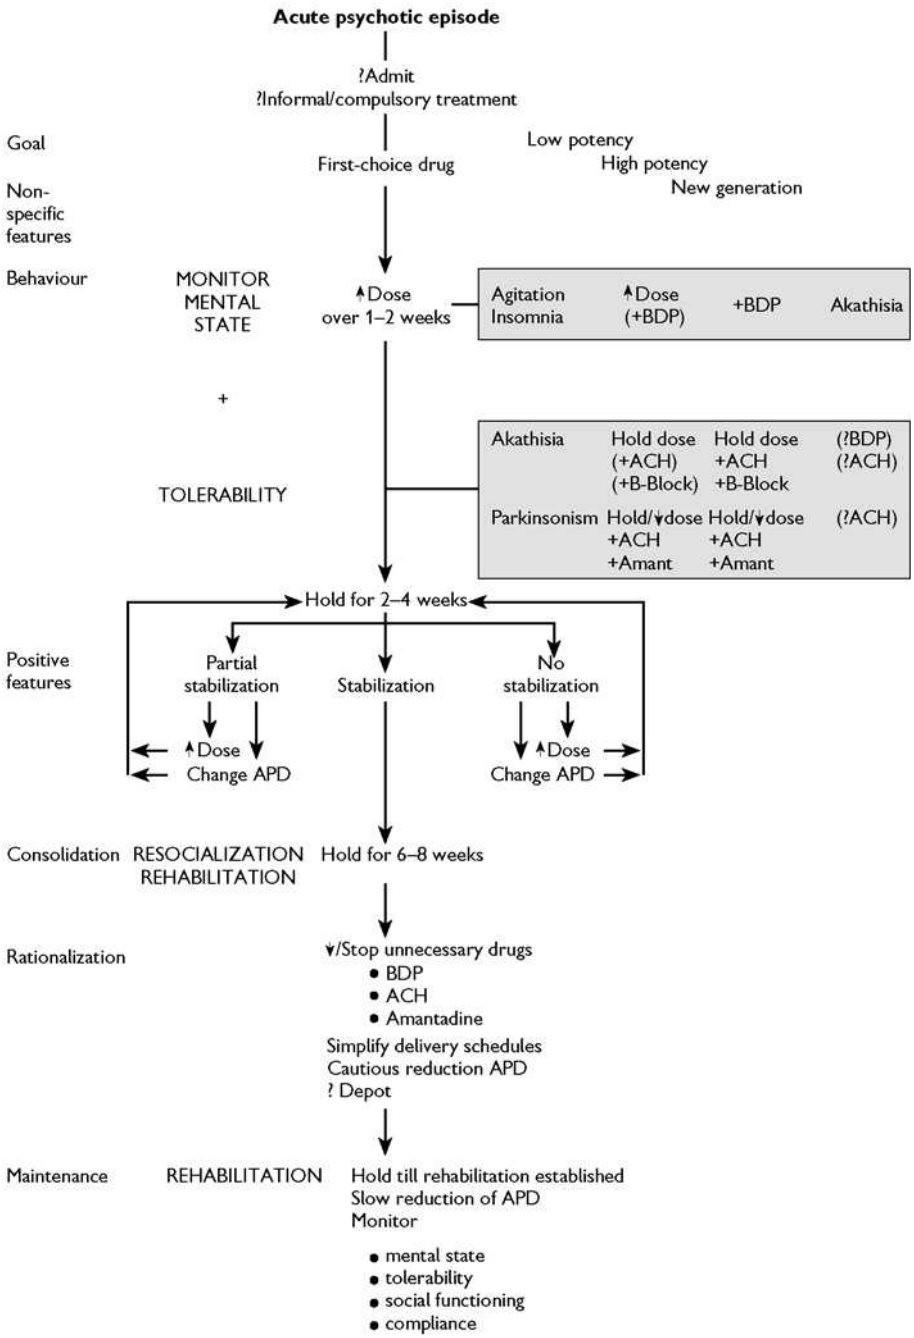

Fig. 4.3.8.1 Outline plan for treatment/ management of schizophrenia: APD, antipsychotic drug; BDP, benzodiazepine; ACH, anticholinergic; B-Block, ß-blocker; Amant, amantadine.

the potential impediment this introduces into achieving acute phase goals by recommending the adjunctive use of a sedative drug, especially benzodiazepines, to gain early control of intrusive non-specific symptomatology.[77] While this is sound, there is another, more traditional, approach—namely, the addition of a second, sedative antipsychotic.

This introduces the issue of polypharmacy, against which the literature has long (and rightly) railed. However, notwithstanding these many cautions, it might seem more logical to treat non-specific symptomatology that is *psychotically mediated* with an antipsychotic, even if one's goals are largely short-term and symptomatic, rather than to introduce a further class of medication whose benefits will not contribute to the fundamental treatment issue (see below) and may cause their own, unrelated problems, including behavioural 'dyscontrol'. Antipsychotic polypharmacy *must* be reviewed regularly, justified constantly and rationalized when possible. The real 'sin' of polypharmacy is its persistence in the treatment plan 'by default'. However, it must be acknowledged that behavioural disturbance and non-specific symptomatology may be so overwhelming that benzodiazepines may be useful in order to avoid over-rapid, excessive escalations of antipsychotic doses.

Even if not introduced as a fixed part of early treatment recommendations, prescription of additional antipsychotic on an 'as required' (or 'PRN') basis is virtually standard practice, allowing nursing staff to intervene at their discretion in the face of escalating symptomatology. This has no trial basis[78] and although a pragmatic solution to inherently unstable situations, must be utilized with discretion. Indications, maximum doses, frequencies, and modes of administration must all be written up separately and unambiguously. Such regimes should *not* be viewed merely as a means of 'keeping the peace' but should be used to inform judgements about how far short of practical requirements initial treatment recommendation fall, invaluable information to incorporate into each treatment review.

Antiparkinsonian medication should be automatically used with higher doses of high potency standard antipsychotics (=/> 10 mgms haloperiod daily or equivalent)[69]but not with lower doses or other acute phase choices.[14] While anticholinergics reduce the risk of acute EPS, only a minority will develop these to a clinically significant degree and antiparkinsonian drugs will interact with antipsychotics to interfere with their actions. These drugs have their own profile of antimuscarinic effects which can be minimized by choosing the most M1-selective compounds (e.g. biperiden, procyclidine) should be used.[14]

A further point relates to goal (iii) above. Patients are often more experienced psychopharmacologists than their doctors! In deciding treatment regimes in those with past histories, be advised by the patient. Medications in which they have confidence should always be one's first-line in treating acute relapses.

Prior to the emergence of goal (v) above, monitoring of acutely psychotic patients should be *frequent*, and preferably daily, each assessment resulting in a review and, if necessary, modification of the treatment plan. At this stage it is rarely useful to commence formal psychosocial, including educational, programmes with patients, whose cognitive difficulties will make it hard to engage meaningfully, though as part of one's ongoing dialogue, monitoring progress and addressing tolerability and compliance serves an elementary educational purpose. Likewise, one's interactions with families are best restrained to exchange of such basic information as the patient will permit (e.g. diagnosis and treatment) and to general support.

The boundary of acute phase of treatment is not rigidly defined, nor is it necessarily set by major symptomatic reversals. The ultimate aim is 'stabilization', as evidenced by the psychotic process becoming less 'active', delusions are recalled as yesterday's events, hallucinations become less preoccupying, behaviour more amenable. It may also be that sedation, previously an ally, becomes intrusive and a source of complaint.

The post-acute phase

This is characterized by the re-emergence of stability in both mental state and behaviour. The following goals should be considered:

i) consolidation of clinical improvements;

ii) rationalization of treatment regimes;

iii) resocialization.

The different domains of schizophrenic symptomatology do not all improve at the same rate and the first signs of amelioration should not be taken as evidence that the tide has turned. Global improvements need to mature into *specific* improvements in particular domains of symptomatology before this can be assumed. Practically, caution is important as over-rapid reductions in antipsychotic dosages before fundamental therapeutic changes have bedded down increases the risk of symptom exacerbation and although there is little evidence on the matter, clinical experience suggests that such very early setbacks are not only demoralizing but more difficult to stabilize, requiring higher doses for longer periods to recapture previous gains.

Nonetheless, the transition from acute to post-acute phase usually marks a pivotal point when the balance of appraisal shifts towards the increasing contribution of 'risk' to the risk:benefit assessment. Taking account of this shift is important in maximizing compliance, both short and long term. So an important step of post-acute treatment is about *gradual* change towards simplifying regimes and maximizing tolerability. The emphasis on 'gradual' is still important, as over-rapid reductions may be implemented ahead of relapse set in train by previous reductions.

In monitoring progress, two issues should be borne in mind. First, is a clear impression of the *criteria* on which 'improvement' are to be based. The traditional medical emphasis is on symptomatology, especially positive symptoms, but elimination of *all* psychotic phenomena, or development of *full* insight, may be unrealistic goals, particularly in those with established illness. Such attempts usually come at the expense of dose regimes significantly higher—and with correspondingly greater long-term risks—than are necessary for a good quality of life and maximum compliance.

Secondly, patients and families—and those who pay for care—often have unrealistic expectations of the timescale over which outcomes can be assessed in acute schizophrenic episodes. Considering both psychopathology and 'degree' of remission, Lieberman *et al.* found that the median time to 'remission' was 11 weeks, with a *mean* time of almost 37 weeks—and that, in a first-episode sample![79] Other studies have produced similar findings. Even if full 'remission' is not the goal of acute and post-acute treatment, the relatively protracted timescales over which 'benefit' is to be considered must be taken into account. There is *no* evidence that this process can be speeded up by escalating doses, which on the contrary, may prolong the situation by introducing unnecessary and intrusive adverse effects.

In this regard, it is worth introducing another concept from past studies. In the 1960s a number of authors described a phenomenon of so-called 'neuroleptic toxicity', an apparently paradoxical worsening of mental state with escalating antipsychotic doses.[80] In reviewing the dose–response literature, Baldessarini and colleagues suggested that the curvilinear relationships usually found may be explained by increasing extrapyramidal symptomatology.[39] Thus, with antipsychotic drugs, while 'less' may not necessarily be 'more', 'more is usually less'!

The post-acute phase is the time to introduce appropriate elements of wider 'management'. With the patient, this might include 'education' in a more formal sense than hitherto, tackling the nature of the condition and, most importantly, the key role of medication in its treatment, including addressing potential long-term recommendations. Regardless of one's interpretation of the literature on its specific benefits, CBT *principles* can be helpful in structuring goals and realistic pathways to attaining them and in re-instilling a sense of control and optimism. Families, too, can now more productively be brought into formal educational programmes, either singly or in groups.

The maintenance phase

The boundary between post-acute and maintenance phases is the least defined but is reached when remission—maximal improvements in all major domains of disorder—can reasonably be considered to have occurred. The major goals now are:

i) maximum well-being with minimum adverse effects;

ii) monitoring efficacy/effectiveness and tolerability;

iii) continuing or extending rehabilitation and social integration.

Attempts to reduce medication should still be cautious but, over the longer term more determined, as one seeks the *minimal effective dose*. As noted, evidence suggests that maintenance regimes can be considerably lower than those utilized for acute treatment but this aspect of long-term care is often omitted, perhaps on the basis that no one wishes to 'rock the boat'. The result is that maintenance may be facilitated by unnecessarily high doses that, in turn, may impede compliance and increase the liability to long-term adverse effects. These need not be simply neurological but may extend to wider domains of functioning. In the Northwick Park First Episodes study significantly more patients in the placebo group were found to have some clear achievement at 2-year follow-up compared to those on active antipsychotic.[81]

This finding referred to small numbers but raises the important question of what are the most satisfactory criteria by which to gauge long-term treatment response-domain-specific criteria or global outcomes. Whichever is selected, a second important shift occurs in the risk:benefit appraisal in this phase, the goal being the active elimination of as many components of 'risk' (i.e. side-effects) as possible.

Monitoring neurological tolerability should involve both enquiry into *subjective* adverse effects as well as examination for signs,[14] the most efficient being simply an assessment of the patient walking.

The most ambitious aim of maintenance comprises engagement in management geared to attaining the highest possible level of psychosocial and, where possible, occupational functioning for the patient, with carers able to exert the greatest degree of understanding and coping skills.

Depression, affecting up to 70 per cent of patients in the acute phase, tends to remit with the psychosis[26,82] but as many as one-third will develop depression in the maintenance phase. This *post-psychotic* (or post-schizophrenic) *depression* is likely to be as aetiologically heterogeneous as depression in other contexts but has been poorly studied including from a therapeutic perspective. Despite initial pessimism, there is evidence that such mood states respond to tricyclic antidepressants[83] though response is impeded in those experiencing residual or recurring psychotic symptoms on low maintenance antipsychotic regimes.[84]

Negative symptoms are present throughout the course of schizophrenia but are most likely to raise specific therapeutic issues during maintenance. An outline of care options is shown in Table 4.3.8.5.

Table 4.3.8.5 Outline management of 'negative' states in schizophrenia

Question	Intervention
1 Is the patient actively psychotic?	Start/increase antipsychotics Reduce levels of stimulation
If not: 2 Is there evidence of extrapyramidal side-effects?	Anticholinergics Amantadine Reduce antipsychotic doses Switch antipsychotic New generation Low ptency
If not: 3 Is there evidence of dysphoric mood?	Antidepressants Anxiolytics Reduce antipsychotics Supportive management Switch to new-generation antipsychotic
If not: 4 Has psychosis recently resolved?	Supportive management
If not: 5 Is the environment impoverished?	Resocialization Rehabilitation
If not: 6 Is the patient receiving long-term medication?	Reduce to reasonable maintenance dose Switch to new-generation antipsychotic Clozapine
Then: 7 Is the problem a 'deficit' state?	Adapt expectations to the patient's capabilities

After Carpenter *et al.* (29)

Prodromes

Some would say the above is far from comprehensive, missing *the* key element in the care of schizophrenia nowadays—prevention. In fact, they would argue, by concentrating on recommendations that only apply once the possibility of prevention has passed, we are submitting to traditional therapeutic pessimism, which is out-of-step with the optimism of the times.

Prodrome refers to features that, for any illness, characterize the difference between well-being and the state of illness evolution. The patient is not unwell as such but the journey to illness has commenced.

In schizophrenia research, 'prodrome' applies to two scenarios. The first, and perhaps most therapeutically relevant, relates to second and subsequent episodes where the clinical team may have a basis for prevention—not of the illness but of the episode (i.e. *relapses*). The universally negative trial evidence in relation to targeted intervention on early relapse symptomatology has been mentioned but this may be one of those situations in which trial *efficacy* does not translate well to *real-life* situations. Maybe the patients selected for such approaches must be 'targeted' as much as the symptomatology!

Early symptom recognition should certainly be a key part of the education of both patients and their families, a task helped by the fact that as a rule, psychotic episodes run 'true to form'. Non-specific and positive features recognized from an earlier episode can be recruited to help identify emergence of subsequent episodes. Especially sensitive, is a change in sleep pattern. As was noted,

if patients have stopped maintenance medication, knowledge of the *time* to relapse following previous cessations can be useful in high lighting the 'critical period' for subsequent relapse. Such knowledge can be empowering, especially for families and carers and even though trial support is lacking, clinical experience suggests it can sometimes be useful in facilitating swift reintroduction of medication or increasing dosages from maintenance to treatment levels.

Relapse prevention through early symptom recognition is *not*, however, from where optimism currently springs. This comes from the second application of 'prodrome'—to the early phase of *illness*, not episode, development.

The '*early intervention*' movement has swelled to an influential grouping within both the research and policy arms of psychiatry. Its origins lie in a very real concern—the delay that many schizophrenic patients experience between the first signs of illness and entry into specialist care. This so-called 'duration of untreated psychosis' (DUP) is on average 1–2 years but can be longer[85] and has been linked to adversity of outcome, initially on the theoretical basis of some factor mediating neurotoxicity,[86] though this remains unsupported.

While a degree of consensus is possible on what the key elements *might* comprise, it is as yet impossible to construct a valid model of what 'early intervention' *should* comprise and thereafter to measure fidelity.[87] Nonetheless, its principles have been enthusiastically adopted and development of services is government policy in many countries, including the UK. This does however, remain controversial—not at the *quality-of-care* level, where the aims of improving awareness and service access are inherently sound, but at the *scientific* level, where evidence supporting improved outcomes remains weak.

Recent systematic reviews do point to modest benefits in terms of a lower symptom burden and delayed readmission in the short-intermediate term.[88,89] However, assessment of DUP is invariably retrospective and although it may be done with reliability, validity remains suspect. Also, the link may be confounded by, for example, some illness characteristic that mediates both delay in entering services and poor outcome, making interpretation difficult. The authors' own work with those at high risk of developing schizophrenia has pointed to the problems of attributing a 'prodromal' psychotic state solely to the emergence of what are traditionally considered 'psychotic' symptoms and to the non-specific nature of those symptoms that do seem to point to a later formal diagnosis.[90]

The precise delineation of pathway(s) to illness remains to be refined to a degree that provides meaningful positive predictive values, thereby avoiding the awkward issue of unnecessary and potentially risky interventions in those whose 'operationally defined normality' is merely different, not necessarily prepsychotic. Continued investment in 'early intervention' services must for the present be driven more by quality-of-care considerations than an evidential base.

Psychiatric emergencies

In dealing with acutely ill psychotic patients, one must always bear in mind the 'unpredictability factor' and the *potential* for aggressive or violent outbursts during acute symptomatic 'shifts'. Risk assessment of dangerousness is an imprecise science but should be incorporated into all routine clinical assessments during acute phase treatment—and conclusions *documented*. Caution should be exercised with patients who are profoundly suspicious, verbally aggressive, resistant to engagement, whose presentation does not allow for comprehensive mental state examination, whose clinical condition is complicated by substance misuse and especially, those who have a past history of assaultive or threatening behaviour.

Principles of wider management are crucial in *avoiding* emergency situations including the quality of the (ward) environment, staff:patient ratios, etc., but even with high levels of vigilance, pre-emptive plans and good quality management, emergency situations may still occur and must be dealt with decisively.

An outline plan relating to emergency situations is shown in Fig. 4.3.8.2.

Poor response and treatment resistance

Where a patient has not responded satisfactorily to an adequate dose (600–800 mg/day chlorpromazine or its equivalent) of antipsychotic for an adequate period of time (at least 6–8 weeks) they might be considered a 'poor responder' but not yet 'treatment resistant'. Several strategies have been suggested in this situation.

Antipsychotics

Conventionally, the first approach is to modify the antipsychotic regime by:

1 increasing first-choice drug to a high-dose schedule (up to 1000 mg chlorpromazine or its equivalent) for 6–8 weeks;

2 changing to a drug of different chemical type in standard dose ranges for 6–8 weeks. (Current research would suggest this should include changes between not just old and new drugs, but in the other direction too);

3 increasing the dose of the second-choice drug to a high-dose schedule for 6–8 weeks.

As far as the literature is concerned, it is only when at least one, and preferably two, of these steps have failed that the illness should be considered 'treatment resistant'.[41]

Despite adoption in routine practice, there is little evidence that such manoeuvrings are of themselves effective. More *time* may still be the crucial factor. There is some evidence that in those switching from a new generation drug, slightly better results may be achieved with risperidone and olanzapine than quetiapine or ziprazidone,[91] though this might be saying simply that, when tolerated, relatively high potency compounds do better than relatively low potency ones.

In clinical practice, especially when external pressures and a sense of therapeutic confusion have clouded therapeutic goals, antipsychotic doses can escalate 'by default'. The issue of 'neuroleptic toxicity' has been mentioned and where high-dose regimes cannot be specifically *justified*, it is worth *reducing* to average or low doses and assessing response. Furthermore, patients showing poor response may benefit from addition of a *depot*, even when compliance is not in doubt, possible advantages perhaps relating to adverse pharmacokinetic parameters, such as poor absorption or enhanced metabolism with complex or high-dose oral regimes.

IMPENDING EMERGENCY

Non-drug intervention	Drug intervention
• Talking down • Distraction • Seclusion	Antipsychotic (with sedative properties) orally e.g. chlorpromazine 50 – 100mgs (liquid/tabs) haloperidol 5 – 10mgms Low-distribution benzodiazepine e.g. lorazepam 1 – 2mgms

Review 30 –60 minutes
If no response – repeat
Or
If no response or no initial co-operation

• Talking down • Distraction • Seclusion • Monitor physically	(Sedative) antipsychotic IM e.g. haloperidol 5-10mgs olanzapine 10mgms chlorpromazine 50-100mgms (with care in frail elderly or drug naïve) Low-distribution benzodiazepine e.g. lorazepam 1-2mgms

Revise treatment plan – start/increase baseline antipsychotic
Review 30 –60 minutes
If no response – repeat (with higher dose ranges, vital signs permitting)
Revise treatment plan

ESTABLISHED EMERGENCY

Non-drug intervention	Drug intervention
• Seclusion • Talking down • Monitor vital signs	sedative antipsychotic IM (as above) in adequate dose ± Low distribution benzodiazepine as above, administered separately (depending on severity of incident) Or zuclopentixol acetate (Acuphase) IM * High potency antipsychotic IV e.g. haloperidol 5 – 10mgms

Review 30 – 60 minutes
Revise treatment plan
Repeat if necessary (vital signs permitting)

* should be used with care in the frail or drug naïve

Fig. 4.3.8.2 Outline plan for treatment/management of psychiatric emergencies.

Adjunctive medications

Simplifying any complexities that may have entered into treatment is a useful strategy when response is poor, such as reducing or stopping anticholinergics or other drugs, such as antidepressants, where possible. For kinetic (and possibly dynamic) reasons, such drugs may be acting against the primary therapeutic aim.

While a number of other drugs have been recommended for adjunctive treatment of suboptimally responding schizophrenia, there is inadequate evidence to support any of them.

Lithium, independent of its actions on mood, is not 'antipsychotic'[92] but has been recommended for patients with schizoaffective disorders. The evidence is inconclusive and its use is best considered empirical in those with prominent affective symptoms.[93] There is some evidence of a more rapid improvement in symptoms with *valproate* augmentation but any benefits seem to be transient.[94] This is more than can be said for *carbamazepine*, whose widespread adjunctive use comes with no supporting evidence, though such studies that have been done have been small.[95] A recent Cochrane review of the role of *lamotrigine* did provide tentative support from small, poor quality studies, suggesting that PANSS total and positive and negative subscale scores significantly decline on lamotrigine compared to placebo.[96] Further work is required before clear recommendations can be made.

At one time, *benzodiazepines* were advocated in both the sole and adjunctive treatment of schizophrenia, usually in high doses

(~100 mg/day diazepam). Benefits beyond simple sedation have been hard to find and systematic reviews highlight a small number of small, supporting studies.[97] While, as noted, benzodiazepines are widely used for treating psychotically mediated acute behavioural disturbance, such evidence as there is suggests little difference between them and antipsychotics.[97]

Finally, it is worth remembering that the theory behind the introduction of ECT, however flawed, related to *schizophrenia* and there is some evidence to support its use in this condition, especially when rapid global improvement is required and when antipsychotic response has been limited.[98] However, as in depression, its benefits are usually short-lived and do not substitute for an effective long-term medication strategy.

When the patient satisfies criteria for 'treatment resistance', the evidence is, as noted, overwhelming that *clozapine* is better than any other drug regime.[41] There is *no* evidence that any other antipsychotic, old or new, shares its edge and in this regard, clozapine remains a *unique* compound.

Of the psychosocial interventions, only CBT has been suggested as possibly helpful in modifying symptoms and improving outcomes in those with 'treatment resistance'[99] though further work is required to confirm these tentative findings.

Concluding remarks

The above might be interpreted as inferring that nothing much has changed in the treatment and management of schizophrenia, which remains a somewhat pessimistic, even unrewarding, area of therapeutic endeavour: one that is regressing far less moving on. This is far from our experience and the opposite of the impression we wish to create.

Certainly, as far as drug treatments are concerned, no single agent or type of agent now seems more satisfactory across the board than any other, but the challenge to 'atypicality' as a valid subgrouping of antipsychotics does not limit options—rather it *broadens* them, restoring to the treatment repertoire the wide range of choices that is the key to individualized care planning. With psychosocial interventions, there does remain more work to be done in *proving* absolute efficacy and/or effectiveness and the relative place of each, but in service development and care planning, risk:benefit appraisal is sophisticated enough to encompass what has qualitative *value* as well as what is quantitatively *proven*.

As in all branches of medicine where chronic and relapsing disease is encountered, restoring order on chaos, fostering engagement and lighting a way forward when none may be obvious are for the highest levels of skill, in which evidence-based practice can provide the direction but not yet the specific path. We are fortunate in now having available to us the greatest *ever* range of interventions to bring to the care of those who suffer from this most complex and fell disorder. None is comprehensive, all have limitations, but if we wish to provide quality care, care that accounts for the multifarious manifestations patients present, it is our duty to apply not only the experience of others but of ourselves too.

There is no 'quick fix' in gaining competence in the treatment and management of schizophrenia—and, as yet, no curative 'holy grail' either. But there is, more than ever, the opportunity for clinicians to demonstrate *real* expertise in moulding the range of therapeutics now at our disposal. If that is not reason for medical optimism, what is!

Further information

There is at present a sense of 'flux' in care recommendations for those who suffer from schizophrenia and the authors would recommend that some of the articles below should be *read* as opposed to just 'referred to'. Both the American[2] and the Australian[3] guidelines are good examples of present trends in this approach, though illustrate the slight differences of emphasis that even 'evidence' permits. The CATIE study[72] is seminal and mandatory reading for all those involved in treatment planning (the background to this is presented in *Schizophrenia Bulletin* (2003, vol. 29(1))—the CUtLASS study likewise.[71] Both mark a change from simply efficacy-based studies to pragmatic, 'everyday' designs that is likely to intensify. For a background to the importance of absolute doses of standard comparator drugs in efficacy trials and dose equivalence issues, the studies of Rosenheck *et al.*[69] and Strakowski *et al.*[70] are informative, as is that of Baldessarini *et al.*[74] from an earlier period. Crow's original paper on the Type 1/Type 2 dichotomy[12] is historically important (in the 1980s/1990s, the most cited source of research-testable hypotheses in psychiatry) and helpful in understanding what was being proposed and the limitations of subsequent efforts to disprove it.

The authors would contend that behind much of the confusion in the clinical psychopharmacology of the antipsychotic drugs in recent years lurks the long shadow of parkinsonism. This, rather than tardive dyskinesia, has always been the extrapyramidal side-effects issue, partly because of its pervasive presence but also because of its wide and ill-defined boundaries. Those wishing to familiarize themselves with more than just the basics are referred to the book by Owens,[14] one of the few texts to specifically present drug-induced parkinsonism in both its subjective and objective components for primarily a psychiatric audience.

Finally, all practicing psychiatrists nowadays should be familiar with the address of the Cochrane Library (www.thecochranelibrary.com) and its Database of Systematic Reviews and should feel comfortable referring to it themselves, not just second-hand. It presents quality syntheses of complex material of relevance to many key areas of psychiatric practice.

4.3.9 Schizoaffective and schizotypal disorders

Ming T. Tsuang, William S. Stone, and Stephen V. Faraone

Introduction

This chapter focuses on two disorders in the schizophrenia 'spectrum': schizoaffective disorder and schizotypal personality disorder. The emphasis includes the clinical features, classification, diagnosis, epidemiology, aetiology, course, prognosis, and possibilities for prevention for each disorder. Some aspects will be underscored to reflect controversial issues, such as the heterogeneity apparent in each condition. Such issues relate to the accurate classification of the disorders, which is important for at least two reasons. First, it is essential to develop reliable and valid diagnostic criteria in order to study the aetiology of the disorders and then utilize that knowledge to develop rational and testable intervention strategies. Heterogeneity adds variance to the process that reduces both the reliability of diagnosis and also the statistical power of experimental designs to detect intervention/treatment effects. Second, the development of newer generations of psychopharmacological treatments holds the promise of matching more appropriate and efficacious medications with specific syndromes or types of symptoms. This trend underscores the importance of differential diagnosis in determining what treatment a patient will receive. Heterogeneity within a diagnostic category complicates achievement of this goal. Another area to be emphasized involves the goal of early interventions, in addition to palliative treatments for these disorders. In contrast, other areas such as the genetic aetiology of schizoaffective disorder and schizotypal personality disorder, and treatments for schizoaffective disorder, will receive less emphasis here, to avoid redundancies with other chapters in this volume. Each disorder will be considered separately, starting with a review of schizoaffective disorder, the more severe of the two spectrum conditions.

Schizoaffective disorder

Clinical features

Schizoaffective disorder afflicts patients having schizophrenic and affective symptoms. Either they have affective symptoms of sufficient severity and chronicity to exclude an uncomplicated diagnosis of schizophrenia, or they show features of schizophrenia that are sufficient to exclude an uncomplicated diagnosis of an affective disorder.[1] These types of symptoms may or may not occur simultaneously, which underscores the importance of viewing the course of the illness longitudinally in addition to its cross-sectional presentation. Symptom clusters that are primarily affective or primarily schizophrenic predominate at different times.

Compared to patients with schizophrenia, patients with schizoaffective disorder often (though not always) demonstrate relatively high levels of premorbid function,[2,3] but nevertheless show significant premorbid weaknesses in multiple cognitive and clinical functions.[4] Patients with schizoaffective disorder also tend to show more identifiable precipitating events. The nature of the precipitating stressor may vary widely; for example it may be physical (e.g. recently giving birth or experiencing a head injury) or interpersonal (e.g. change in an important relationship). The clinical course of the disorder is often characterized by a periodic, rapid onset of symptoms that shows a relatively high degree of remission after several weeks or months. As Vaillant pointed out in the 1960s, many of these patients 'recover' completely after an episode, and resume their lives at premorbid levels of function.[5] As will be noted further below, the clinical features of some cases of schizoaffective disorder mainly resemble those of schizophrenia, while the features of other cases are more similar to those of bipolar disorder. Regardless of the subtype or variant of the disorder, however, the mortality rate is of special concern. Rates of death due mainly to suicide or accident show elevations in this disorder that are similar to those observed in schizophrenia and in major affective disorders.[6]

In general, schizoaffective disorder is more common in females than in males.[3] The age of onset varies, but tends to be younger than that of unipolar or bipolar disorder. Tsuang *et al.* found the median age of onset for schizoaffective disorder was 29 years, which was significantly lower than groups with bipolar or unipolar affective disorder, but similar to a group with schizophrenia.

Marneros *et al.*[2] also reported that a median age of onset of 29 years for schizoaffective disorder was lower than the median age for groups with affective disorders (35 years), but reported that it was higher than a group with schizophrenia (24 years). In contrast, Reichenberg *et al.*[4] reported no differences in the age of first hospitalization between patients with schizophrenia, schizoaffective disorder, or non-psychotic bipolar disorder. These differences between studies reflect differences in both the diagnostic criteria employed, and the heterogeneity of the disorder.

Classification

The classification of schizoaffective disorder has always been controversial. Kraepelin reported in 1919 that patients with both affective and schizophrenic symptoms complicated the differential diagnosis due to the 'mingling of morbid symptoms of both psychoses'. Kasanin first employed the term 'acute schizophrenic psychoses' in 1933 to describe a group of patients who experienced a rapid onset of emotional turmoil and psychotic symptoms, but who recovered after several weeks or months.[3] In other words, the symptoms appeared similar to schizophrenia during periods of exacerbation, but unlike schizophrenia, they showed a greater tendency to remit between episodes. These features sparked an ongoing debate by the 1960s about the proper classification of schizoaffective disorder. Much of this discussion involved the following proposals:

1 It was a type of schizophrenia (e.g. 'remitting schizophrenia');
2 It was a type of affective disorder;
3 It was a unique disorder that was separate from both schizophrenia and bipolar disorder;
4 It reflected an arbitrary categorization of clinical symptoms that masked a continuum of pathology between schizophrenia and affective illness;
5 It contained a heterogeneous collection of 'interforms' between schizophrenia and affective disorder (i.e. symptoms of both disorders).

The last possibility is not mutually exclusive of the first four; for example, one or more variants of schizoaffective disorder may be related closely to schizophrenia, while another may be related more closely to an affective disorder.

The puzzle has yet to be solved. Family and outcome studies provide useful ways of assessing the relative merits of each of the possibilities outlined above. These approaches are informative and will be reviewed below, although interpretations of such studies are complicated at times by the use of different diagnostic criteria across investigations.

(a) Family studies

Family studies provide an important tool for assessing the relationship between disorders. They are a type of genetic study that assumes that related disorders will co-aggregate more frequently among biologically related individuals than they would in the general population. Thus, a disorder is more likely to be in the schizophrenia spectrum if it occurs more frequently among the relatives of schizophrenic patients, compared with suitable controls. Similarly, a disorder is more likely to be in the affective spectrum if it occurs more frequently among the relatives of patients with affective disorders. Evidence for the inclusion of schizoaffective disorder in the schizophrenia spectrum is discussed in greater detail elsewhere (see Chapter 4.3.6.1). Only representative findings pertinent to the present discussion about the classification of schizoaffective disorder will be summarized here.

Bertelsen and Gottesman[7] summarized a series of seven family studies published between 1979 and 1993, using structured diagnostic criteria. Analyses of risk to the development of schizophrenia, schizoaffective disorder, and affective disorder in the first-degree relatives of patients with schizoaffective disorder, were included. In all seven studies, the relatives showed a higher risk of developing an affective disorder than of developing schizoaffective disorder. In five of the seven studies the risks of developing schizophrenia was equal to or greater than the risk of developing schizoaffective disorder. Thus, the relatives of schizoaffective patients showed generally higher risks of developing disorders other than the one with which they were diagnosed. These findings were consistent with a heterogeneous view of schizoaffective disorder, in which individual cases represented subtypes of either schizophrenia or of affective disorder. The findings were also consistent with the possibility that schizoaffective disorder represents a chance collection of 'interforms' between schizophrenia and affective disorder.

These findings were not consistent with the view that schizoaffective disorder represented a continuum between the other two disorders, because in that case, the rate of schizoaffective disorder in first-degree relatives would have been higher, compared with the rates at which these relatives developed schizophrenia or affective disorder. The findings were also inconsistent with the possibility that schizoaffective disorder represented a unique disorder that was independent of either schizophrenia or an affective disorder. In that case, the first-degree relatives of patients with schizoaffective disorder should show relatively high rates of schizoaffective disorder itself, but relatively low rates of the other disorders. In the series of studies reviewed by Bertelsen and Gottesman,[7] the morbid risk for schizoaffective disorder itself ranged from 1.8 to 6.1 per cent in first-degree relatives of patients with schizoaffective disorder, which was still higher than the rate observed in the general population (see the section on epidemiology below). These results, taken together with the higher risks for both schizophrenia and affective disorder, suggest that schizoaffective disorder is a heterogeneous condition. Recent reviews of family studies, including those that considered depressed (i.e. unipolar) and bipolar subtypes, have also underscored both the heterogeneity of schizoaffective disorder, and the controversial nature of its classification.[8,9]

(b) Outcome studies

A majority of outcome studies show that schizoaffective disorder has a better course than schizophrenia, but a poorer course than affective disorder.[10–12] For example, Tsuang and colleagues reviewed 10 outcome studies reported between 1963 and 1987 that assessed patients with either schizoaffective disorder or schizophrenia.[10] Global, marital, social, occupational, hospital course, and symptom dimensions of outcome were measured. In each category, patients with schizophrenia showed poorer outcomes. In contrast, their review of 11 outcome studies comparing schizoaffective disorder with affective disorder showed that affective disorder was associated with equal or better outcomes on almost all dimensions. Thus, despite differences in methodology and diagnostic criteria,

schizoaffective disorder was frequently associated with clinical outcomes that were intermediate between those associated with schizophrenia and those related to affective disorder.

Other researchers reported similar findings. Kendler *et al.*, for example, showed intermediate levels of clinical impairment for schizoaffective disorder in an epidemiological family study.[13] Marneros *et al.* reported on outcomes as part of the Cologne Longitudinal study, using modified DSM-III-R diagnoses.[14] The outcomes were measured by symptoms in five dimensions (psychotic symptoms, reduction of energetic potential, qualitative and quantitative disturbances of affect, and other disturbances of behaviour) that persisted for at least 3 years. Consistent with the pattern described thus far, poor outcomes in the schizoaffective group occurred at a rate (49.5 per cent of the sample) that was intermediate between those observed in the schizophrenic (93.2 per cent) and affective groups (35.8 per cent), and differed significantly from both of them. In a more recent study, Jäger *et al.* studied 241 patients at the time of their first hospitalization, and then again 15 years later.[15] Similar to these other examples, schizoaffective subjects presented a clinical picture that was less impaired than the one shown by schizophrenic subjects, but more impaired than the one shown by affective subjects.

While these studies show schizoaffective disorder to have intermediate outcomes generally, there are categories in which it resembles schizophrenia or affective disorder more closely. For example, Samson *et al.*[10] and Reinares *et al.*[12] noted that outcomes for schizoaffective disorder were equivalent to those for affective disorder in several dimensions. Marneros *et al.*, showed that 70 per cent of a schizoaffective group was rated as good or excellent on a measure of social adjustment, which did not differ significantly from 84 per cent of an affective group who received the same rating.[12] Both groups differed significantly from a schizophrenic group, however, in which only 44 per cent of the group demonstrated good or excellent outcomes. Moreover, the schizoaffective and affective disorder groups did not differ on a rating scale of psychological impairments (e.g. body language, affect display, conversation skills, and cooperation), although both were rated as significantly less impaired than the schizophrenic group.

Other studies, however, such as Kendler *et al.*[13] reported similarities between some types of psychotic symptoms in schizoaffective disorder and schizophrenia, including the severity of delusions and positive thought disorder, and the frequency of hallucinations. Each of these groups showed higher levels of these symptoms than an affective disorders group. Hizdon *et al.* showed recently that individuals with schizoaffective disorder did not differ from individuals with schizophrenia on basic cognitive measures of executive function, memory, and processing speed, although the schizoaffective group did perform better on measures of social cognition.[16] Reichenberg *et al.* showed that individuals with schizophrenia and schizoaffective disorder who were assessed premorbidly performed similar to each other but lower than individuals who later developed non-psychotic bipolar disorder, on tests of non-verbal and verbal intellectual function, and on tests of basic reading and reading comprehension.[4]

These overall differences in outcome serve to validate the classification of schizoaffective disorder as a separate syndrome further. Its heterogeneity, however, raises the issue of whether such intermediate outcomes might reflect the mean of a combination of mainly good and mainly poor outcomes. This in turn leads to the question of whether schizoaffective disorder can be subtyped in a useful and valid manner. If so, are better and worse outcomes associated with different variants of the syndrome?

Vaillant suggested in the 1960s that prognostic indicators, including a good premorbid level of adjustment, the presence of precipitating factors, an acute onset, confusion, the presence of affective symptoms, and a familial history of affective disorder (or the absence of a schizophrenic history), could predict remission in approximately 80 per cent of cases of 'remitting schizophrenia'.[17] The inclusion of affective symptoms and a positive family history for affective illness on the list contributed (later) to hypotheses that variants of schizoaffective disorder were related to affective illness and to better outcomes. In contrast, variants associated more with schizophrenic symptoms or family history were associated more with schizophrenia and with relatively poor outcomes.[18]

There have been a variety of attempts to subtype schizoaffective disorders, based on whether affective or schizophrenic symptoms predominate. The validity of many of these attempts, however, is inconclusive. Bertelsen and Gottesman noted, for example, that at best, relatives of individuals with affective type schizoaffective disorder, or schizophrenic type schizoaffective disorder, showed only trends towards higher rates of affective disorder or schizophrenia, respectively.[7] Similarly, Kendler *et al.* did not detect different rates of schizophrenia or affective illness in first-degree relatives of patients with schizoaffective disorder when the patients were subtyped into bipolar and depressive subgroups.[13] Moreover, the subtypes did not predict differences in outcomes.

Conversely, a latent class analysis of psychotic patients from the Roscommon study showed that most cases of DSM-III-R schizoaffective disorder were categorized in either a bipolar schizomania class ($n = 19$), or in a schizodepression class ($n = 13$), rather than in schizophrenia ($n = 1$), major depression ($n = 0$), schizophreniform ($n = 3$), or hebephrenia ($n = 3$) classes.[19] Moreover, Reinares *et al.* reviewed evidence showing that bipolar and depressive subtypes differed from each other in ways consistent with differences between bipolar and unipolar affective disorders.[12] For example, the bipolar schizoaffective subtype was associated with more total episodes, more episodes with shorter periods and cycles, and higher frequency of cycles. Higher numbers of cycles were associated with poorer long-term outcomes. Taken together, these studies show at least some recent support for the subtyping of schizoaffective disorder into mainly affective and mainly schizophrenic variants.

Other factors associated with poor outcomes include poor inter-episode recoveries,[13] persistent psychotic symptoms in the absence of affective features, poor premorbid social adjustment, chronicity, a higher number of schizophrenia-like symptoms,[20] and the presence of schizoaffective mixed states.[12]

Diagnosis and differential diagnosis

The DSM-IV diagnosis of schizoaffective disorder[1] is listed in the category of 'schizophrenia and other psychotic disorders'. The major feature of the disorder is that, in addition to meeting the clinical criteria for schizophrenia (criterion A), an individual must also experience a major depressive, manic, or mixed episode concurrently. In addition, in the same period of illness, a patient must experience symptoms of psychosis (hallucinations and/or

delusions) for a period of at least 2 weeks, in the absence of mood-related symptoms (criterion B). Nevertheless, affective symptoms must comprise a substantial portion of total duration of the illness (criterion C), and symptoms may not be attributable to either substance use or to a major medical condition (criterion D). Two subtypes of the disorder, including bipolar type and depressive type, may be diagnosed.

The criteria for schizoaffective disorder in ICD-10 are similar to those in DSM-IV. The essential requirement is that prominent symptoms of affective disorder and prominent symptoms of schizophrenia are present together for at least 2 weeks. Depressive, manic, and mixed subtypes are recognized.

The differential diagnosis includes, most prominently, either schizophrenia or affective disorder, which may be differentiated in part by consideration of the longitudinal criteria (criteria B and C), in addition to the cross-sectional criteria (criterion A). The presence of conditions relating to general medication and substance use should also be considered in the differential diagnosis.

Epidemiology

The epidemiological status of schizoaffective disorder is somewhat uncertain compared with schizophrenia, largely because of dilemmas related to the diagnosis and classification of the disorder. To help in the standardization of data from different studies, representative incidence and prevalence estimates will be emphasized from recent investigations that utilized research diagnostic, DSM-III-R or DSM-IV criteria.

(a) Incidence

Earlier studies showed that new cases of 'schizomanic' patients (i.e. manic patients who also demonstrated schizophrenic or paranoid symptoms) numbered approximately 1.7 per 100 000 per year.[20] This was less than the 4 per 100 000 per year shown by 'schizodepressive' patients. The number of schizoaffective cases in this study exceeded the number of manic patients, and made up half of the number of schizophrenic cases. Since then, Tien and Eaton analysed data from the Epidemiologic Catchment Area study for three non-overlapping groups with psychotic symptoms.[21] One of these groups comprised individuals with 'psychotic affective syndrome', which was similar to schizoaffective disorder except that most members of the group (59 per cent) demonstrated psychotic symptoms only in conjunction with a mood disturbance (essentially DSM-III-R mood disturbance with psychotic symptoms). The incidence of this disorder was 1.7 per 1000 per year, which was approximately equal to the rate for schizophrenia (2.0 per 1000 per year). Even if the 59 per cent of the group who met the criteria for a mood disorder with psychotic features was excluded, the remaining 41 per cent would still comprise a higher incidence rate than that detected by earlier studies. Differences in sampling procedures (treated versus non-treated samples) may have contributed to the differences observed in the rates. More importantly, however, these studies showed that schizoaffective disorder occurred at 50 to 85 per cent of the rate of schizophrenia, thus confirming that patients with this disorder comprise a clinically significant population. One current but long-standing issue involves questions about the temporal stability of incidence rates in schizophrenia-related disorders, as reflected by reports of both increases and decreases.

(b) Prevalence

Until recently, prevalence estimates for schizoaffective disorder relied mainly on samples that were treated in clinics or other psychiatric settings. Because a variety of factors influence the decision to enter and remain in treatment, the estimates varied substantially. For example, Okasha reviewed studies that reported rates varying between 2 and 29 per cent.[8] A recent epidemiological study in Finland using 8028 people who were at least 30 years old showed a lifetime prevalence rate of 0.32 per cent for schizoaffective disorder (compared to 0.87 per cent for schizophrenia), which accounted for 10.5 per cent of all psychotic disorders.[22] This is a lower estimate than many earlier studies reported, and likely results from a combination of factors (including a narrowing of diagnostic criteria, and increased utilization of multiple sources of information such as case notes and registers, in addition to interview data) that together have improved diagnostic accuracy. Prevalence estimates of putative schizoaffective subtypes remain subject to the same inconsistencies of diagnosis and selection factors that affect schizoaffective disorder itself. Not surprisingly, there is little consensus about whether manic or schizophrenic subtypes predominate (see also Tsuang *et al.*[20]).

(c) Review of evidence

Treatments for schizoaffective disorder are the same as those for schizophrenia and affective disorders alone. As the nature and efficacy of those treatments are discussed elsewhere, they will not be considered here. Rather, this section will focus on management issues related to the need to treat symptoms of both disorders simultaneously, or sequentially.

Management

The authors have found it useful to consider psychopharmacological treatment in terms of putative subtypes, including affective type schizoaffective disorder and schizophrenic type schizoaffective disorder.

Treatment of schizoaffective disorder, affective subtype, will include antipsychotic medication (e.g. clozapine, risperidone quetiapine, ziprasidone, or olanzepine), particularly if psychotic symptoms are present. In addition, antidepressants, mood stabilizers (e.g. lithium), or anticonvulsants (e.g. valproate or carbamazepine) may be useful with this group. It will be necessary in such cases to weigh the potential risks of such medications, such as elevated toxicity, against the potential benefits.

In schizoaffective disorder, schizophrenic subtype, combination treatments may also be more effective than a single treatment. We find, however, that antipsychotic treatments alone may be more efficient in many cases. This is particularly true if affective symptoms (i.e. depression) are largely secondary to the experience of having a psychotic condition, and its attendant interpersonal, social, and financial difficulties. In these cases, remediation of the psychotic symptoms may also have the effect of easing the affective problems. For other cases, which include more of a treatment-refractory depression, antipsychotic medication may be augmented with lithium (or another mood stabilizer) or antidepressant medication. Moreover, electroconvulsive therapy may reduce mortality rates in schizoaffective patients.

The authors note that it may be difficult at times to distinguish the affective subtype from the schizophrenic subtype, especially in the presence of florid psychotic symptoms. In these cases,

treatment decisions may rest on the presenting symptoms of the patient. Treatment during intermorbid periods is in part dependent on the presence or absence of psychotic symptoms. As noted above, psychotic episodes in this period are associated with relatively poorer outcomes, and are likely to require chronic antipsychotic therapy.

Schizotypal personality disorder

Clinical features

Like schizoaffective disorder, schizotypal personality disorder is a complex and chronic condition that includes some, but not all, of the features of schizoaffective disorder and schizophrenia. Most notably, persistent psychosis is not part of the syndrome, although mild forms of thought disorder may occur, such as magical thinking or ideas of reference (as opposed to delusions of reference, which indicate psychosis). Moreover, brief episodes of psychosis may occur in times of stress, but will not persist.

Schizotypal patients show pervasive deficits in social and interpersonal traits. They often demonstrate aloofness, poor eye contact, affective constriction, and suspiciousness. Consequently, close interpersonal relationships are either avoided, or cause discomfort and anxiety. These individuals usually have few friends. Not surprisingly, schizotypal patients are often deficient in accurately sensing social cues or affective signals from others. Although they can interact with people when necessary, they often prefer not to, and do not become more comfortable in social situations with time.

Schizotypal patients may also show magical thinking, ideas of reference, unusual perceptions (e.g. sensing the presence of another person, or that people are talking about them), and/or perceptual illusions (e.g. often perceiving a dimly lit lamp-post as a person). Both their social deficits and these cognitive–perceptual problems contribute to an overall impression of oddness. However, this feature may occur independently of other clinical symptoms,[23] and manifest itself in odd speech or unusual appearance. The oddness or eccentricities evident in these patients are often ego syntonic (i.e. they are not experienced as problems). Moreover, schizotypal patients show deficits in attention, long-term verbal memory, and executive functions. These deficits are qualitatively similar to those seen in schizophrenia (and schizoaffective disorder), but like many other clinical manifestations of this disorder, they are quantitatively milder.

Like schizophrenia, schizotypal personality disorder is often evident by early adulthood, but schizotypal traits may be evident in late childhood or adolescence. Once it appears, the disorder tends to show a chronic course, but one that includes periodic exacerbations and attenuations of symptoms. A recent study that followed individuals with schizotypal personality disorder for 2 years showed that paranoid thoughts and unusual perceptual experiences were among the most stable and least malleable DSM-IV symptoms, while the most changeable were odd behaviours and restricted affect.[24] The former symptoms were thus more trait-like, and the latter were more intermittent. Consistent with these findings, the same group also showed that in the course of 2 years (with treatment), 61 per cent of schizotypal patients no longer met DSM-IV diagnostic criteria for the disorder.[25] With a more stringent definition of improvement (12 months with two or less symptoms meeting criteria), the rate of remission dropped to 23 per cent. These studies show that both the severity and the expression of the disorder vary over time and probably, as a function of treatment.

Classification

In contrast to the controversy surrounding the classification of schizoaffective disorder, family, twin, and adoption studies clearly support the view that schizotypal personality disorder is best classified in the schizophrenia spectrum.[26] Nevertheless, it is a complex and chronic disorder that in all likelihood, is also heterogeneous. Kendler pointed out that this heterogeneity was at least partly related to the two primary methods used to study the disorder.[27] One of these involves the 'clinical method', which identifies patients with mild forms of schizophrenic or psychotic-like symptoms. This type of patient, for example, is often characterized by relatively high levels of positive psychiatric symptoms (e.g. magical thinking and perceptual distortions).

In contrast, the 'family research method' identifies relatives of patients with schizophrenia who have subtle, schizophrenia-like symptoms. Features associated more with familial than with clinical schizotypal personality disorder include a predominance of negative symptoms (e.g. social withdrawal and impairment, and higher levels of anxiety and poor rapport), cognitive impairments (e.g. impaired language comprehension, eye-tracking, and attentional dysfunctions), and elevated rates of schizophrenia and related disorders in family members.[26] Thaker *et al*. reported that familial and clinical schizotypal personality disorders were similar on measures of physical or social anhedonia,[28] and that some neuropsychological deficits were also associated with both groups.[26]

The concept of familial schizotypal disorder is particularly important because it may share a common genetic basis with schizophrenia. Paul Meehl first proposed the term 'schizotaxia' to describe the genetic vulnerability to schizophrenia, and suggested that individuals with schizotaxia would eventually develop either schizotypal personality disorder or schizophrenia, depending on the protection or liability afforded by environmental circumstances. As the concept evolved, Meehl reformulated it to allow for the possibility that some people with schizotaxia would develop neither schizophrenia nor schizotypal personality disorder. In fact, evidence now shows that the clinical symptoms observed in many non-psychotic, first-degree relatives of people with schizophrenia are similar to those observed in familial schizotypal personality disorder.[26] Psychiatric features in such relatives frequently include an aggregation of negative symptoms that are qualitatively similar to, but milder than, those often cited in schizophrenia.[29] Positive symptoms, however, are usually less evident in these relatives than they are in schizophrenia or in schizotypal personality disorder. Neuropsychological impairments in biological relatives of people with schizophrenia are also qualitatively similar to, but milder than, those seen in people with schizophrenia.[26] In particular, these neuropsychological deficits frequently include problems in working memory/attention, long-term verbal memory, and concept formation/abstraction.

Faraone *et al*. recently suggested a reformulation of Meehl's concept of schizotaxia that focuses on these features of negative symptoms and neuropsychological deficits.[26] Unlike schizotypal personality disorder, which occurs in less than 10 per cent of the adult relatives of patients diagnosed with schizophrenia, the basic

symptoms of schizotaxia occur in 20 to 50 per cent of adult relatives, suggesting further that the genetic liability to schizophrenia does not lead inevitably to schizophrenia, schizotypal personality disorder, or schizoid personality disorder.

Diagnosis and differential diagnosis

The DSM-IV criteria for schizotypal personality disorder include a 'pervasive pattern of social deficits' and 'cognitive or perceptual distortions' and behavioural 'eccentricities' (criterion A).[1] At least five of nine specific symptoms (e.g. ideas of reference, constricted affect, odd behaviour, or appearance) must be present to satisfy this criterion. These symptoms must occur by early adulthood. They must not occur exclusively during the course of four other conditions, including schizophrenia, a mood disorder with psychotic features, any other psychotic disorder, or a pervasive developmental disorder (criterion B).

The differential diagnosis includes a variety of other disorders. A key difference between schizotypal personality disorder and schizophrenia, a psychotic mood disorder, or another psychotic condition involves the transient nature of psychotic symptoms in schizotypal personality disorder. It may be distinguished from developmental communication disorders by a lack of compensatory means (e.g. gestures) of communicating, and it may be distinguished from autistic or Asperger's disorders by the relatively greater deficits in social awareness and frequent presence of stereotyped behaviours in those syndromes. Schizotypal personality disorder may be confused with several other personality disorders, but can be distinguished from them. In particular, it differs from schizoid personality disorder by its pattern of cognitive–perceptual distortions, and by the odd appearance or behaviour shown frequently by schizotypal patients. The pattern of schizotypal symptoms also differs from that manifested in borderline personality disorder, although there are similarities between these conditions. Schizotypal personality disorder differs from borderline personality disorder, however, in that psychotic-like symptoms and social isolation are more likely to persist in the absence of affective turmoil, and schizotypal individuals are less likely to display the impulsive and manipulative traits that are often associated with borderline personality disorder.

Epidemiology

(a) Incidence

To the authors' knowledge, there continue to be no published incidence studies for schizotypal personality disorder.

(b) Prevalence

A review by Lyons showed that prevalence rates for schizotypal personality disorder in non-clinical samples ranged from 0.7 to 5.1 per cent, with a median near 3.0 per cent.[30] Higher rates occurred in clinical samples—2.0 to 64.0 per cent, with a median of 17.5 per cent. More recently, Torgersen *et al.* reported a rate of 0.6 per cent for DSM-III-R in a community sample, which is lower than the rates in studies reviewed by Lyons.[31] Similar to recent prevalence rates reported for schizoaffective disorder (described above), more recent studies have tended to show lower rates than earlier studies. In contrast to non-clinical samples, the prevalence of schizotypal personality disorder among the relatives of schizophrenic individuals is as high as 10 per cent.[32]

Treatment

(a) Review of evidence

There is, unfortunately, a dearth of outcome studies involving psychotherapy, psychosocial, or psychopharmacological treatments for schizotypal personality disorder. Older published studies often show methodological limitations (e.g. small samples, subjects with mixed diagnoses, inadequate controls, and problems with internal validity), or provide outcome data on only limited aspects of the disorder. Despite these caveats, it is clear that few treatment gains are evident in earlier studies. This is particularly true of studies that utilized psychodynamically oriented psychotherapy, either alone or in combination with other treatments (e.g. group therapy or art therapy) as the primary treatment modality.[33] Recent evidence for the efficacy of psychotherapy for personality disorders is more promising, but is limited mainly to other personality disorders.[34]

Several earlier studies investigated the usefulness of medications in treating schizotypal personality disorder, although they typically employed small numbers of subjects, combined samples of schizotypal and borderline personality disorders, and showed little clinical improvement.[33] Typical antipsychotic drugs, in particular, were proposed to reduce positive symptoms or depressed mood in times of acute stress, but the high incidence of adverse side effects discouraged their widespread use at other times, including the more chronic stable (i.e. non-crisis) phases of the disorder. Other types of medication, including fluoxetine, have shown generally non-specific effects of treatment.

Hymowitz *et al.* administered a low dose of haloperidol, a first-generation antipsychotic medication, to 17 outpatients with DSM-III diagnoses of schizotypal personality disorder, for 6 weeks.[35] The initial dose of 2.0 mg was intended to rise to 12.0 mg, but side effects prevented increases beyond a mean dose of 3.6 mg. Even with lower doses, 50 per cent of the sample withdrew from the study because of side effects. The 17 subjects who completed 2 weeks of the protocol improved somewhat in ratings of ideas of reference, odd communications, social isolation, and overall functioning.

More recently, Koenigsberg *et al.* employed a double-blind protocol to administer low doses of risperidone (0.25 mg/day—2.0 mg/day), a second-generation antipsychotic medication, to 25 patients with DSM-IV schizotypal personality disorder, for 9 weeks.[36] Compared to a placebo control group, patients who received risperidone demonstrated significant reductions in positive and negative symptoms, with no difference in dropout rates between groups. These findings are encouraging and consistent with evidence described above that schizotypal symptoms are amenable to change.[24,25] Hopefully, findings like this will stimulate additional research into pharmacological treatments for this disorder.

Management

Patients with schizotypal personality disorder often view their worlds as odd and threatening places and may require extended courses of treatment. Although trust and rapport with the therapist are often difficult to establish in schizotypal personality disorder, the therapeutic relationship may be used to mitigate the marked deficits in interpersonal relationships that characterize this syndrome.[37] The frequent occurrence of paranoia and suspiciousness, together with social aloofness and constricted affect, may

make exploratory psychotherapeutic approaches less effective than supportive cognitive behavioural therapies. In fact, these patients may only seek treatment to alleviate circumscribed problems, like anxiety or somatic complaints. Approaches that emphasize concrete, interim goals, and stipulate explicit means of attaining them, thus have the best chances of success. Because individuals with this disorder are vulnerable to decompensation during times of stress and may experience transient episodes of psychosis, they may also benefit from techniques to facilitate stress reduction (e.g. relaxation techniques, exercise, yoga, and meditation). Fortunately, some people with schizotypal features are likely to seek treatment in times of stress.[38] In the short-term, brief courses of antipsychotic treatment may be useful if symptoms of psychosis appear.

Cognitive problems are also frequently amenable to concrete goal-oriented approaches to treatment. Patients benefit from understanding their cognitive strengths and weaknesses because it helps them confront and cope with long-standing difficulties in their lives. For example, problems in attention, verbal memory, or organizational skills contribute to failures in educational, occupational, and social endeavours, while reinforcing negative self-images and increasing performance anxiety. Knowledge of circumscribed cognitive problems allows patients to reframe their difficulties in a more positive manner, and facilitate selection of realistic personal, educational, and occupational goals. Moreover, specific cognitive deficits are often subject to partial remediation. For example, standard procedures will attenuate deficits in the acquisition, organization, and retrieval of new information (e.g. writing information down in a 'memory notebook', using appointment books or planners, and rehearsing new information, among others). In some instances, the documentation of specific cognitive deficits (e.g. attention) can lead to academic accommodations in school (e.g. more time to take exams), which will help individuals function closer to their intellectual potentials.

Possibilities for prevention

At present, most early intervention programmes involve secondary prevention, which includes the early identification and treatment of clinical (usually psychotic or psychotic-like) symptoms. While intervention is necessary to alleviate clinical symptoms at any point during the disorder, it is particularly important early on because it might alter the course of the illness. Patients treated with antipsychotic medication during their first or second hospital admission, for example, show better outcomes than those who are not treated until later in the course of their disorders.

Primary prevention, which involves treatment before the disorder manifests itself clinically, is not yet available for schizoaffective disorder, schizotypal personality disorder, or other disorders in the schizophrenia spectrum. To develop such treatments, it will be necessary to predict who is most likely to develop a disorder. There are a few encouraging approaches, including ongoing 'high-risk' studies that follow the offspring of schizophrenic parents longitudinally.[39] Such studies help to identify traits early in life that predict which individuals are most likely to experience emergent clinical symptoms in adulthood. This type of study is particularly important because it can facilitate the formation of homogeneous high-risk groups, which in turn can facilitate the development of focused prevention strategies.

With our current knowledge, it is difficult to justify preventive treatments—especially medication—for people without symptoms. The authors have argued elsewhere, however, that if people in high-risk groups (like first-degree biological relatives of patients with schizophrenia) show clinically meaningful symptoms that can be organized into valid liability syndromes, then intervention attempts may become appropriate.[26] The authors proposed this course of action for people with 'schizotaxia', and suggested preliminary research guidelines.[40]

Eventually, prevention will be a primary therapeutic approach for the treatment of disorders in the schizophrenia spectrum. While primary prevention has yet to occur, the authors are optimistic that high-risk studies, progress in secondary prevention, and progress in discovering the genetic aetiology of the schizophrenia spectrum, will facilitate primary prevention strategies eventually.

4.3.10 Acute and transient psychotic disorders

J. Garrabé and F.-R. Cousin

Historic introduction

Acute and transient psychotic episodes have been described since the end of the nineteenth century. Descriptions have varied from one country to another, so that the exact nosology has not yet been established. The links between acute psychoses (generally defined as having brief obvious psychotic symptomatology) and chronic psychoses (schizophrenic psychoses and psychoses with persistent delusions) are still under discussion.

For instance, Sections F20 and F21 in ICD-10[(1)] are devoted to 'Schizophrenia, schizotypal and delusional disorders'. A specific diagnostic category named 'Acute and transient psychotic disorders' is included, distinct from Schizophrenia (F20), Schizotypal disorder (F21), Persistent delusional disorder (F22), Induced delusional disorder (also called *folie à deux*) (F24), and Schizoaffective disorder (F25).

In this textbook, the acute and transient psychotic disorders (Chapter 4.3.10) appear in the section dedicated to schizophrenia,

which also includes schizotypal disorders and schizoaffective disorders (Chapter 4.3.9). However, this section is clearly distinguished from the chapter in which the persistent delusional disorders are discussed (Chapter 4.4). These taxonomic divergences are justified more by the history of acute psychoses than by scientific findings.

In the nineteenth century, German psychiatrists had already described *akute primäre Verruckheit*,[2] termed *paranoia acuta* by Karl Westphal. In 1876 (published in 1878), Westphal used this term to describe an acute form of paranoia with an outburst of perceptual hallucinations, consisting mostly of hallucinatory voices and delusions, with clouding of consciousness. In 1890, Meynert repeated the clinical description but named the condition amentia.[3] Sigmund Freud chose this type of acute delusion with hallucinations for his psychoanalytic conception of psychosis.[4]

In the sixth edition of his textbook, published in 1899, Kraepelin[5] included all the paranoias under dementia praecox, and in the eighth edition (1908–1915) he combined manic and melancholic periodic disorders in a single group, leaving acute psychosis with no place between these two diagnostic categories.

In 1911, Bleuler[6] replaced the single disease dementia praecox by the concept of a group of schizophrenias of various clinical forms. He noticed that schizophrenia often began with an acute excitatory episode lasting from a few hours to a few years. He described a wide variation of outcome of acute forms of psychosis, but he separated acute schizophrenias from simple schizophrenia as he believed that acute forms do not necessarily end in deterioration.

In 1916, based on Karl Jaspers' psychopathology, the Danish psychiatrist Wimmer[7] described psychogenic psychosis as a reactive psychosis arising after psychosocial trauma. Mayer-Gross,[8] who proposed an organic aetiology for schizophrenia, described 'oneiroid states' consisting of acute psychotic symptomatology with no other specific organic features.

In 1961, Leonhard[9] used Kleist's concept of marginal psychosis (*Randpsychosen*) to develop his description of 'cycloid psychoses' as endogenous psychoses separate from schizophrenic psychoses and from manic and melancholic psychoses. These cycloid psychoses tend to have a benign and periodic course.

Earlier (1933), Kasanin[10] had described 'acute schizoaffective psychoses', raising questions about the links between schizophrenic and affective diseases.

Langfeldt[11] suggested that observation for 5 years was required to be able to distinguish schizophrenia and what he called schizophreniform psychosis. This long-term observation is a reminder of the Bleulerian concept of acute schizophrenias which could last for several years. Epidemiological studies have led to the presence in modern classifications of a group of acute schizophreniform psychoses under the rubric 'Schizophreniform disorder' (DSM-IV Section 295.40) or 'Acute psychotic disorder schizophrenic-like' (ICD-10 Section F23.2).

In France, the concept of *bouffée délirante* led naturally to a specific class of acute psychoses. In 1895, Magnan[12] and his disciple Legrain[13] described *bouffée délirante* or *délire d'emblée* (immediate delusion) within the polymorphic delusions of the chronic insane. This concept is based on Morel's theory of degeneration, commonly accepted in the nineteenth century. The question of whether there is a susceptibility or a predisposition to the occurrence of an acute psychosis remains unanswered.[14]

In 1954, Ey[15,16] described the development of the concept of *bouffées délirantes* and of acute psychoses with hallucinations from the time of Magnan to a symposium devoted to the clinical subdivision of schizophrenic psychoses held at the First World Congress of Psychiatry in 1950, where the various ideas were discussed by Langfeldt, Karl Leonhard, and Aubrey Lewis (Table 4.3.10.1).

Table 4.3.10.1 Historical development of the terminology of acute and transient psychotic disorders

Historic term	Current terminology
1876 Westphal *Akute primäre Verruckheit* *Paranoia acuta*	F23.3 Other acute predominantly delusional psychotic disorder
1890 Meynert Amentia	
1895 Magnan and Legrain *Bouffées délirantes*	F23.0 Acute polymorphic psychotic disorder without symptoms of schizophrenia
1899 Kraepelin Dementia praecox	F20.0 Schizophrenia
1909–1913 Kraepelin Paranoia	F22.0 Persistent delusional disorder
1911 Bleuler Acute-onset forms of schizophrenia	F23.1 Acute polymorphic psychotic disorder with symptoms of schizophrenia F23.2 Acute schizophrenia-like psychotic disorder
1916 Wimmer Psychogenic psychosis	F23.3 Other acute predominantly psychotic disorder
1924 Mayer-Gross *Oneroide Erlebnisform*	F23.3 Acute schizophrenia-like psychotic disorder
1933 Kasanin Acute schizoaffective psychoses	F25 Schizoaffective disorders
1939 Langfeldt Schizophreniform states	F23.2 Acute schizophrenia-like psychotic disorder
1954 Ey *Bouffées délirantes et psychoses hallucinatoires aigues*	F23.0 Acute polymorphic psychotic disorder without symptoms of schizophrenia
1961 Leonhard Cycloid psychoses	F23.0 Acute polymorphic psychotic disorder without symptoms of schizophrenia

Clinical description: psychopathology

The heterogeneous group of acute and transient psychotic disorders are characterized by three typical features, listed below in descending order of priority:

- suddenness of onset (within 2 weeks or less);
- presence of typical syndromes with polymorphic (changing and variable) or schizophrenic symptoms;
- presence of associated acute stress (stressful events such as bereavement, job loss, psychological trauma, etc.).

The onset of the disorder is manifested by an obvious change to an abnormal psychotic state. This is considered to be abrupt when it occurs within 48 h or less. Abrupt onset often indicates a better outcome. Full recovery occurs within 3 months and often in a shorter time (a few days or weeks). However, a small number of patients develop persistent and disabling states.

The general (G) criteria for these acute disorders in DCR-10 (Diagnostic Criteria Research of ICD) are as follows.

G1 There is acute onset of delusions, hallucinations, incomprehensible or incoherent speech, or any combination of these. The time interval between the first appearance of any psychotic symptoms and the presentation of the fully developed disorder should not exceed 2 weeks.

G2 If transient states of perplexity, misidentification, or impairment of attention and concentration are present, they do not fulfil the criteria for organically caused clouding of consciousness as specified for F05, criterion A.

G3 The disorder does not satisfy the symptomatic criteria for manic episode (F30), depressive episode (F32), or recurrent depressive disorder (F33).

G4 There is insufficient evidence of recent psychoactive substance use to satisfy the criteria for intoxication (F1x.0), harmful use (F1x.1), dependence (F1x.2), or withdrawal states (F1x.3 and F1x.4). The continued moderate and largely unchanged use of alcohol or drugs in the amounts or with the frequency to which the individual is accustomed does not necessarily exclude the use of F23; this must be decided by clinical judgement and the requirements of the research project in question.

G5 There must be no organic mental disorder (F00–F09) or serious metabolic disturbances affecting the central nervous system (this does not include childbirth). (This is the most commonly used exclusion clause.)

A fifth character should be used to specify whether the acute onset of the disorder is associated with acute stress (occurring 2 weeks or less before evidence of first psychotic symptoms):

- F23.x0 without associated acute stress and
- F23.x1 with associated acute stress.

For research purposes it is recommended that change of the disorder from a non-psychotic to a clearly psychotic state is further specified as either abrupt (onset within 48 h) or acute (onset in more than 48 h but less than 2 weeks).

Six categories of acute psychoses are presented in ICD-10, and we shall discuss them in order.

F23.0 acute polymorphic psychotic disorder without symptoms of schizophrenia

The diagnostic criteria are based on the classical symptoms of the true *bouffée délirante* described by Magnan and Legrain.

(a) Suddenness of onset

Bouffée délirante occurs over a period of a few hours or days, usually to young adults and often women in their 30s. The onset of the delirious episode is 'like a thunderbolt in a serene sky'. This aphorism from Legrain has the same meaning as the French classical expression *délire d'emblée* (immediate delusion).

Although premonitory symptoms, such as increasing perplexity and anxiety, may occur, the delusions start suddenly and are always accompanied by a break-up in the individual psychic life. If the onset is preceded by a stressful or traumatic event, such as resettlement or acculturation, this may take place some months previously and the outburst of the delirious episode is delayed. The fifth code character of category F23 is used to specify whether acute stress is associated with the onset of the disorder (e.g. F23.00 has no associated acute stress).

(b) Polymorphic psychotic symptoms

The delusional themes are varied and include grandeur, persecution, influence, possession, body transformation (depersonalization), derealization, or world alteration; these themes change with time and may combine. Other symptoms are also varied, including hallucinations, illusions, interpretations, and intuitions.

(c) The emotional state

As a consequence of the delusions the patient experiences mood change and emotional turmoil (happiness, ecstasy, anxiety, irritability). However, the criteria for manic episode, depressive episode, schizoaffective disorder, and schizophrenia are not satisfied.

Consciousness fluctuates with the delirious convictions and changes of emotion. There is a specific disorientation with respect to time and place—the passage of time (*temps vécu* according to Eugène Minkowski) and 'temporality' (*Sein und Zeit* according to Ludwig Binswanger) are disturbed. This disorientation, described by Karl Jaspers as a 'first delirious experience' (*Erlebnisse*), has to be understood as a dream-like state.

Ey[15,16] differentiated the acute psychoses in terms of the specific alteration in the perception of time rather than their transient course. According to Jacksonian ideas, the acute psychoses are the expression of a destructuring of consciousness to levels related to each acute psychosis.

(d) The duration of the delirious experience

In ICD-10, the criterion of a duration of less than a month distinguishes other categories from schizophrenia (F20) and manic or depressive episodes (F30 and F32).

(e) Short recovery time

In most cases recovery from the acute psychotic disorder occurs within a few weeks or months. However, long-term prognosis is difficult because of the risk of relapse into either a repeated episode or a more chronic disease. If resolution of the symptoms has not occurred after 3 months, the diagnosis should be changed to persistent delusional disorder (F22) or non-organic psychotic disorder (F28).

(f) Suggested criteria

Pull *et al.*[17] have suggested the following empirical criteria for *bouffée délirante*.

- Abrupt or acute onset, with no previous psychiatric disorder except other similar episodes.
- Absence of chronicity: the active stages disappear completely in a few weeks or months. Relapses can occur, but there is no psychiatric disorder between consecutive episodes.
- Specific symptoms: delusions and/or any type of hallucination, depersonalization and/or derealization with or without confusion, and affective disturbance manifesting as depression or euphoria. The symptoms change from day to day and even from hour to hour.
- There is insufficient evidence for organic mental disorder, alcoholism, or drug addiction. The exclusion clauses are less restrictive in ICD-10, since a moderate, continued, and unchanged use of alcohol or drugs in habituated individuals does not exclude the diagnosis.

- The true acute psychotic disorder occurs without any associated psychosocial stress factor. When psychosocial stress factors are found, there is only a temporal link with the so-called 'reactive' acute psychosis.

(g) Long-term evolution

Bleuler[6] described one-third of cases of acute schizophrenic psychoses as single episode, one-third as recurrent episodes with repetition of the same acute and transient psychoses (either manic or depressive), and one-third following a course which developed as schizophrenia.

Between 1976 and 1989, Metzger and Weiber[18] studied 885 cases of acute psychoses. Using the criteria of Pull *et al.*[17] they found group 303 cases of genuine *bouffée délirante* (two-thirds female, one-third male, average age of 32 years). They followed the course of 191 cases (over an average period of 6.2 years): 34 per cent did not relapse, 24 per cent had recurrent and transient episodes, 34 per cent developed schizophrenia, and over 7 per cent developed a periodic affective disorder (manic and depressive states). The relapse or chronic course rate was higher in the group without triggering factors ($n = 92$) than in the group with triggering factors ($n = 99$). The difference between true *bouffée délirante* (no triggering factors) and other acute and transient psychotic disorders raises questions about their pathogenesis.

In the first 2 years, it is essential to distinguish *bouffée délirante* from schizophrenia[19] and other acute psychoses.[20] Follow-up during this period must be very careful.

F23.1 acute polymorphic disorder with symptoms of schizophrenia (*bouffée délirante* or cycloid psychosis with symptoms of schizophrenia)

This diagnostic category combines the symptoms of acute polymorphic psychotic disorder with some typical symptoms of schizophrenia (F20) present for most of the time. However, the schizophrenic symptoms are not precisely listed. F23.1 can be a provisional diagnosis, which is changed to schizophrenia if the criteria of F20 persist more than a month.

Acute polymorphic disorder with symptoms of schizophrenia satisfies the general criteria for acute and transient psychotic disorders:

- acute onset of less than 2 weeks
- polymorphic delusions and hallucinations or perceptual disturbances leading to incomprehensible or incoherent speech
- clouding of consciousness with impairment of attention or concentration, disorientation, perplexity, etc.
- emotional turmoil and affective symptoms (depressed mood, euphoria, anxiety, irritability) without the symptomatic criteria for manic–depressive or recurrent depressive disorders
- rapid changes of the type and intensity of symptoms
- no evidence of causation by organic or psychoactive substances.

It is also associated with some schizophrenic symptoms which are present most of the time:

- mental automatism (thought echo, insertion, withdrawal, or broadcasting)
- control, influence, passivity referred to body movements, thoughts, actions, or sensations
- hallucinations with commentary
- catatonic behaviour
- negative symptoms.

The ICD-10 clinical criteria give no information about psychotic or schizophrenic symptoms or about the action of antipsychotic drugs on these symptoms.

Leonhard[9] described cycloid psychosis as an episode with clouding of consciousness and a marked alteration of thinking. Many authors have reported follow-up studies of cycloid psychoses,[21–23] which confirm the better prognosis of cycloid psychoses than of schizophrenias and schizoaffective disorders.

F23.2 acute schizophrenia-like psychotic disorder (schizophreniform psychosis)

This acute psychotic disorder lasts for less than a month and is mostly schizophrenic. The polymorphic psychotic symptoms are stable (no rapid changes, no emotional turmoil or confusion), sometimes with emotional instability.

The duration criterion is the most important. This category is a provisional diagnosis and appears to include such disparate descriptions as oneirophrenia (oneiroid states or *Erlebnisform*[8]), schizophrenic reaction (DSM.IV 298.8, Brief reactive psychoses), and schizophreniform psychosis.[11] In ICD-10, if the first episode lasts for more than a month, it has to be considered as an acute onset of schizophrenia.

The Scandinavian psychiatric school[24] justify the retention of this category because of the very good and rapid recovery, and have tried to determine factors in the personal and family history predicting the onset of schizophrenia.

Schizophreniform disorder remains in DSM-IV (295.40) because the evidence linking it to typical schizophrenia remains unclear, but the duration criterion is less restrictive (up to 6 months). Features suggesting a good prognosis are onset within 4 weeks, confusion at the height of the psychotic episode, previously good social and occupational functioning, and absence of blunted or flat affect.

F23.3 other acute predominantly delusional psychotic disorders

The main clinical features of this category are delusions and hallucinations. The foreground delusions are mostly persecutory (delusions that the person or close relatives are being malevolently treated or are under external influence, with thought disturbances); auditory hallucinations are present in the background. Despite their stability, these psychotic features do not meet the criteria for schizophrenia (F20).

As for F23.0, the duration of this acute predominantly delusional psychotic episode must be less than 3 months. If the persecutory delusions persist for more than 3 months, the diagnosis changes to persistent delusional disorders (F22). This development from F23.3 to F22 is reminiscent of the classical *paranoia acuta*. Thus, both paranoid reaction and psychogenic paranoid psychosis are included in F23.3. Paranoid reaction must be distinguished from induced delusional disorder or *folie à deux* (F24), in which the delusions of the 'dominated' patient disappear when the two people are separated (see Chapter 4.4).

If the background auditory hallucinations persist for more than 3 months, the diagnosis is changed to other non-organic psychotic

disorders (F28). This diagnostic category is defined by exclusion: the persistent hallucinatory disorder does not meet the criteria for schizophrenia (F20), persistent delusional disorders (F22), acute and transient psychotic disorders (F23), psychotic types of manic episode (F30.2), or severe depressive episode (F32.3). F28 also corresponds to chronic hallucinatory psychosis, as explicitly noted in ICD-10.

F23.8 other acute and transient psychotic disorders

This category includes any other acute and transient psychotic disorders with no evidence of organic cause that are not classifiable under previous F23 categories, such as ephemeral delusions or hallucinations and undifferentiated excitement.

F23.9 acute and transient psychotic disorder unspecified

Brief psychotic disorder (298.8) is defined in DSM-IV as an episode of acute and transient psychotic disorders (delusions and hallucinations with disorganized speech and behaviour) which lasts at least a day but less than a month with eventual full return to previous level of functioning. If the symptoms occur after stressful events in the person's life, brief psychotic disorder with marked stressor(s) has to be specified. If the symptoms occur within 4 weeks post-partum, brief psychotic disorder with post-partum onset has to be specified.

Cultural variants

Other forms of acute psychoses have been observed in both traditional and developing countries, with high prevalence in Asia, Africa, and Latin America. These brief psychotic episodes are culture-bound syndromes, often with immediate precipitating stress or life events.[25] There is disorganized behaviour, delusions, thought disorders, confusion, and mood disorders, usually with full recovery and no relapse in a 1-year follow-up.

The culture-specific disorders[26] and their potentially related syndromes are often acute and transient. The status of these culture-reactive disorders is controversial and needs more clinical and epidemiological research. The mode of assignment to categories in ICD-10 does not suggest category F23.

Appendix I of DSM-IV (Outline for cultural formulation and glossary of culture-bound syndromes) lists 25 syndromes, with a glossary mostly using the local terms (seven in Hispanic languages, five in English, and one in French). *Bouffée délirante*, described only in West Africa and Haiti, is defined as episodes resembling brief psychotic disorder and classified in F23.0. Messich and Lin[25] have suggested that the whole group of culture-bound syndromes should be classified as acute and transient psychotic disorders, although this is justified only for a very few such as *amok* (dissociative episode with persecutory ideas and aggressive behaviour from Malaysia), *shin-byung* (Korean dissociation and possession), and spell (trance state in southern United States).

ICD-10 includes the two Malaysian syndromes *koro* and *latah* as well as *dhat* (India) in F48.8, Other specified neurotic disorders.

International follow-up studies have shown that cultural factors can influence the course and prognosis of acute psychotic disorders. In 1979, the World Health Organization compared the course of schizophrenia (295), psychotic depression, mania, and other psychoses in different cultures, using the ICD-9 criteria for the diagnoses. The outcome for the schizophrenic group was better in emerging countries than in the industrialized world. These results probably explain the individualization of category F23 in ICD-10.

Some authors[27] have suggested that short-lived psychotic episodes are expressions of overcharged mechanisms of defence, or of individual psychological fragility. The brief psychosis is an understandable development of the psychic life of the subject and has a cathartic effect.

Culturally related syndromes are discussed further in Chapter 4.16.

Treatment

Short-term treatment

Acute psychotic syndromes require early hospitalization in either an inpatient psychiatric unit or a crisis centre. These syndromes are to be considered as psychiatric emergencies. The decision to admit to hospital is taken in order to make a careful physical and mental examination clinical evaluation, to separate the patient from his or her environment, to provide a reassuring setting, and to prevent any suicidal or aggressive tendencies.[28]

The goals are to prevent auto or heteroagressivity (suicidal potential, affective symptoms, agitation, aggressive behaviour, command hallucinations, etc.), to reduce the acute psychotic symptoms, to suppress the causal factors and to establish an early therapeutic alliance with the patient and his family. Antipsychotic drugs medications are prescribed.[29] Some clinicians wait for a day or two before starting neuroleptic therapy in order to eliminate an organic cause (a general medical condition or substance abuse disorder can be present with acute and transient psychoticsymptoms) and prescribe benzodiazepines rather than neuroleptics. More often, however, antipsychotic treatment starts immediately after physical, electrophysical, radiological assessments, and laboratory tests (CBC, blood electrolytes, cholesterol, triglycerides, toxicology screen, etc.) to evaluate health status.

The choice of antipsychotic medication depends on the clinician's experience and the clinical features. Second-generation antipsychotic medications (amisulpride, aripiprazole, olanzapine, quetiapine, risperidone, ziprasidone) are commonly prescribed as first-line treatment; clozapine is reserved to schizophrenia with high suicidal potential or to resistant schizophrenia. First-generation antipsychotic medications (chlorpromazine, haloperidol, etc.) are second choice or adjunctive medications.

In cases of major anxiety or agitated behaviour, short-acting sedative drugs neuroleptics such as first-generation antipsychotics chlorpromazine (100–500 mg/day), (loxapine: 50–300 mg/day), with or without benzodiazepines (lorazepam) can be prescribed or levomepromazine (25–300 mg/day) are chosen, or zuclopenthixol acetate (100–300 mg every 3 days by intramuscular injection) is used as a short-acting depot antipsychotic. Parenteral administration (standard intramuscular administration) may be required if the patient refuses oral medication, or if a rapid effect is required because the patient is seriously uncooperative or is too dangerously disturbed.

Predominance of delusions and hallucinations indicates a high-potency antipsychotic agent as haloperidol (5–15 mg/day) or flupenthixol (80–200 mg/day).

Benzodiazepines may be given to potentiate the action of the neuroleptics. Alprazolam (0.5–4 mg/day), clorazepate (50–200 mg/day), and lorazepam (2–5 mg/day) produce rapid sedation in acutely psychotic patients if they are used with a neuroleptic. Some clinicians prefer the combination of two neuroleptics (haloperidol–levomepromazine, haloperidol–cyamemazine).

New compounds with fewer adverse effects can be used (amisulpride, 800–1200 mg/day; olanzapine, 5–20 mg/day; quetiapine, 75–500 mg/day; risperidone, 2–10 mg/day).

In culture-bound syndromes the prescription of antidepressants is often recommended as primary treatment.

The dosage may be adjusted from low doses and gradually increased, or adjusted to the standard dose after a first loading dose. Frequent monitoring to assess drug response and adverse effects (extrapyramidal side-effects, orthostatic hypotension, anticholinergic effects, and temperature dysregulation) is essential, and corrections and prophylactic prescriptions (e.g. antiparkinsonian medications) may be necessary.

Sociotherapy (occupational or intensive) and psychotherapy (reality–adaptive–supportive) are indicated depending on the state of the patient and his environment, with individual, family, or rehabilitation care.

Continuation treatment

The effectiveness of psychopharmacotherapy is usually manifested in the first 6 weeks, with improved sleep, regression of agitation, recovery from anxiety and delusion, and finally disappearance of the psychotic features. When there is no recovery or improvement either another antipsychotic drug should be used or the dosage of the first increased. Worsening of the symptoms, serious side-effects, or a poor response to pharmacotherapy may lead to the main indications for electroconvulsive therapy.

If mood disorders or cyclic episodes occur, treatment with antidepressants, mood stabilizers (lithium or valproate), or an anticonvulsant drug (carbamazepine) may be indicated. Care must be taken to distinguish between a post-neuroleptic depression and the development of a (schizo)affective disorder.

Prevention of recurrence

The possibility that psychotic symptoms may re-emerge has to be borne in mind during the first 2 years of follow-up. Low-dosage pharmacotherapy must be maintained for 1 or 2 years after recovery. During this long-term follow-up, periodic assessment and effective clinical care with social and psychological therapy are essential.

Advice about management

Patients are often hospitalized under constraint because they do not acknowledge the disorder. The initial non-compliance leads to the frequent use of first-generation antipsychotic medications classic intramuscular neuroleptics. After remission recovery, a switch to a second-generation antipsychotic medication newer antipsychotic drug, which is better tolerated, helps to ensure the acceptance of long-term treatment when the psychotic symptoms have disappeared.

In general, psychotherapy and psychosocial care are more effective in an outpatient setting after symptomatic remission recovery has started. A good relationship between patient and psychiatrist together with collaboration with the family practitioner and social workers improve the long-term prognosis. If resources allow, psychotherapy by a trained practitioner, behavioural therapy, or family therapy may be combined with a low-dose pharmacotherapy.[30]

Further information

There are no substantial sources of information in the English language. The following will be of use to those who read French or Spanish. Others should seek further information using an information retrieval system such as Medline.

4.4

Persistent delusional symptoms and disorders

Alistair Munro

Introduction

Delusional disorder (DSM-IV 297.1 and ICD-10 F22)[1,2] is a psychotic illness with some superficial resemblances to schizophrenia from which, however, it is quite distinct. It presents with a stable and well-defined delusional system, which is typically 'encapsulated' within a personality, which retains many normal aspects, unlike the situation in schizophrenia in which there is widespread personality disorganization in addition to the psychotic features. Nevertheless, although many normal aspects of the personality are preserved, the individual's way of life becomes progressively distorted by the intensity and intrusiveness of the delusional beliefs. Hallucinations may be present but are not usually prominent. This is a chronic disorder, probably lifelong in most instances, which retains an unjustified reputation for being untreatable. Because of the nature of their delusions, many patients are unwilling to accept that they have a mental disorder or that they require psychiatric treatment but, if they can be persuaded to cooperate and accept appropriate medication, the condition can be shown to respond to treatment in a remarkably high proportion of cases.

Delusional disorder used to be known as 'paranoia', and the terms are virtually synonymous. Paranoia and its related disorders were regarded as an important group of psychiatric illnesses until the early part of the twentieth century. Then, because of changing diagnostic and classificatory approaches, especially a tendency to overdiagnose schizophrenia, the diagnosis of paranoia all but disappeared from standard classificatory systems. In 1987, paranoia was again officially recognized by DSM-IIIR but was renamed delusional (paranoid) disorder—since simplified to delusional disorder. It is the only officially acknowledged member of the old group of paranoid illnesses appearing in DSM-IV and ICD-10.

Although the diagnosis of paranoia all but ceased for many years, the illness and its sufferers did not disappear. When the phenomena of the disorder came to attention the patient was either labelled as schizophrenic or else a specific feature of the delusional phenomenology was seized upon and spurious diagnoses were described. Thus we have a multiplicity of apparently disparate diagnoses such as de Clérambault's syndrome (delusional erotomania), the Othello syndrome (delusional jealousy), querulant paranoia (a form of persecutory delusional disorder), monosymptomatic hypochondriacal psychosis (delusional disorder with somatic preoccupations), and many others. The result has been an extraordinarily scattered literature with cases recorded in a variety of medical and non-medical sources, but very few in psychiatric journals until recently. Since DSM-IIIR there has been a serious attempt to resolve the confusion and to diagnose paranoia/delusional disorder by its own intrinsic features, but many problems still bedevil the nomenclature.

Jaspers, in discussing paranoia, said: 'Why are the paranoics as defined by Kraepelin so rare, yet when they do occur they are so typical?' This remains true because there are striking similarities from case to case and the illness' features clearly distinguish it from other psychoses, yet many psychiatrists continue to label it erroneously.

DSM-IV and ICD-10 provide criteria to differentiate delusional disorder as an illness *sui generis* and these are now widely accepted. This section adopts that official approach but with two caveats. The first is that the descriptions are bald and not very helpful to the clinician who has not actually seen cases of the disorder. The second is that the category of delusional disorder (persistent delusional disorders in ICD-10) may well be overrestrictive as it stands. However, some well-respected authorities take a somewhat different approach, regarding 'delusional disorders' as all psychiatric illnesses with delusions and then subcategorizing according to the underlying syndrome, which might be severe mood disorder, schizophrenia, actual delusional disorder, etc. Therefore the reader of any text must be aware of a particular author's criteria for diagnosis in this area.

Emil Kraepelin (1856–1926) clearly described paranoia and included it in a continuum of illnesses with delusional features, especially paraphrenia and paranoid schizophrenia. This so-called 'paranoid spectrum' will be briefly alluded to later. Paranoid schizophrenia continues to be a widely used diagnosis but usually in the context of schizophrenia. Paraphrenia is not officially acknowledged in DSM-IV or ICD-10 but cases fitting its traditional description are quite commonly seen in practice. The present author regards it as a significant entity and the reader is encouraged to become familiar with descriptions to be found elsewhere.

At present, 'delusional disorder' is both an illness category and essentially the only syndrome contained within that category. In recent years, another diagnosis—delusional misidentification syndrome (**DMIS**)—has come into increasing prominence. Originally described in 1923 by Capgras and Reboul-Lachaux[3] as

an illness in which the individual is delusionally convinced that someone familiar in the environment has been replaced by an almost exact double, this 'Capgras syndrome' led a rather marginal existence in the literature for many years. Lately, however, there have been considerably more case-reports of better quality and clinical subtypes have been established. Most importantly, sound psychological and neuropathological work has increasingly shown significant cerebral pathologies in a high proportion of sufferers.

DMIS is not currently recognized by DSM or ICD but in many respects it resembles delusional disorder and should certainly be included in an expanded category of that disorder.

Finally, there is an important phenomenon which is found in association with all illnesses with delusions, especially delusional disorder. This is named 'shared psychotic disorder' in DSM-IV and 'induced delusional disorder' in ICD-10, but is often still referred to by its long-established name *folie à deux*. Here, the primary patient has a bona fide delusional illness and a secondary patient has come to accept the delusional beliefs as true. The secondary patient is usually a highly impressionable individual living in prolonged close contact with the other; he or she is not truly deluded, but retains the beliefs tenaciously as long as the intimate relationship is maintained. A less common variety is when two people each have genuine delusional disorders and, through close proximity, come to share identical abnormal beliefs. *Folie à deux* is not uncommon and, as will be explained later, there are very practical reasons why the clinician should be aware of its possible presence and the ways in which it may influence management of the case.

The paranoid spectrum[4]

Since Kraepelin's time there has been a tacit acceptance by many psychiatrists of a spectrum simplified as:

delusional disorder—paraphrenia—paranoid schizophrenia.

Somewhat anecdotally, the literature suggests that approximately 10 per cent of cases of delusional disorder or paraphrenia will deteriorate to schizophrenia though, in general, most cases of delusional disorder remain diagnostically stable in the long term. Several reports have indicated that, as one moves to the delusional disorder end, a family history of schizophrenia becomes progressively less common. The risk for schizophrenia in the close family of a case of delusional disorder appears to be much the same as in the general public. In paranoid schizophrenia the family history of schizophrenia is approximately half as common as in other schizophrenias and profound disintegration of personality is less frequent.

When dealing with cases in this general area the clinician should bear in mind the concept of a paranoid spectrum. This, plus knowledge of constituent illnesses, will make it easier to distinguish delusional disorder from superficially similar conditions, a matter of considerable importance when considering treatment and prognosis.

Problems of nomenclature

Although English-speaking psychiatrists (and most members of the public) use the word 'paranoid' to mean 'persecutory', strictly speaking it just means 'delusional'. In many writings on 'paranoia' and 'paranoid' disorders, authors do not make it clear whether delusions are present or not in their cases.

Unfortunately, with the passage of time, the term 'paranoid' has come to be used so loosely that it has lost any meaningful clinical connotation. Paranoia should now be regarded as an historical usage, pretty well synonymous with delusional disorder.

The word 'paranoid' is still used in the official diagnoses of paranoid schizophrenia and paranoid personality disorder. The former is acceptable because the illness has delusions as a prominent feature, but it is quite illogical in describing a personality disorder, which cannot have delusions. Since it is unlikely that the personality disorder will be renamed soon, the reader should be aware of such pitfalls in our psychiatric terminology and consequently the need for ultra-careful case-descriptions.

Although the **form** of delusional disorder is remarkably characteristic, the delusional **contents** and the ways in which cases come to attention are extremely varied, and this has led to an extraordinarily complex history. The core description, that of paranoia, gradually crystallized in the latter half of the nineteenth century and was definitively delineated by Kraepelin, who recognized subtypes with delusional contents of grandiosity, persecution, erotomania, and jealousy, and also allowed for the possibility of a hypochondriacal content. He clearly differentiated paranoia from *dementia praecox* (i.e. schizophrenia). Kraepelin later doubted whether hallucinations could be present: in fact, non-prominent hallucinations are now acceptable and in every other respect Kraepelin's century-old definition of paranoia still largely serves to describe present-day delusional disorder.[5]

Subsequently, Kraepelin[5] introduced the concept of paraphrenia, an illness similar to paranoid schizophrenia but with significantly better preservation of affect and of personality. As already mentioned, he regarded paranoia, paraphrenia, and paranoid schizophrenia as a relatively discrete group of illnesses, later referred to as the paranoid spectrum.

It was later found that a minority of cases of paranoia and paraphrenia eventually deteriorated to schizophrenia and this somewhat illogically led to these diagnoses being progressively ignored. Despite this, speculation on the nature of delusions continued, most notably by Jaspers (1883–1969),[6] Kretschmer (1888–1964),[7] and Freud (1856–1939) and his followers. These speculations contributed a good deal to the descriptive phenomenology of delusions but whereas we know a good deal about delusional contents, we understand little about the origin of delusions or of delusional illnesses, or the reasons for their unique features.[8] Unfortunately, as much of the writing on delusions appeared when most psychoses, and certainly paranoia, had no effective treatments, writers usually dwelt on the untreatability of paranoia, a pessimistic view that persists but is no longer warranted.

From the 1970s onwards, interest in paranoia reappeared and a more optimistic view of treatment emerged. Since its renaissance as delusional disorder in DSM-IIIR in 1987, paranoia has again become a respectable diagnosis. Not only that, it has subsumed several quasi-disorders which were undoubtedly delusional but which had been described superficially on the strength of their delusional content alone. Several of these have already been noted (see p. 281).

Nowadays the clinical description of delusional disorder is well established, but adequate case series are rare and scientific investigations are in their infancy, except in the case of the diagnosis which still remains officially unrecognized, delusional misidentification syndrome, in which underlying brain abnormalities are

commonly demonstrable. The separateness of delusional disorder from schizophrenia is beyond doubt, but its relationship to the other constituents of the paranoid spectrum still has to be determined. Delusional disorder is no longer regarded as rare, but many years of neglect have left many psychiatrists sadly unaware of its characteristic features.

Delusions: clinical aspects

A delusion may be defined very loosely as a mistaken idea which is held unshakably by the patient and which cannot be corrected. As will be seen, this is not a satisfactory definition, although it may be a useful starting point for clinical recognition of a delusional process. This brief exposition is concerned to facilitate clinical recognition and not to dwell on psychopathological theories, which are dealt with in detail elsewhere in this book.

It is a widely held opinion that delusions are qualitatively different from normal ideas or beliefs and have an all-or-nothing aspect. The DSM-IV definition initially seems to accept this viewpoint, stating that a delusion is 'A false belief based on an incorrect inference about external reality that is firmly sustained despite what almost everyone else believes and despite what constitutes incontrovertible and obvious proof or evidence to the contrary. The belief is not one ordinarily accepted by other members of the person's culture or subculture'. But the definition goes on to say that it is often difficult to distinguish between a delusion and an overvalued idea (in which there is an unreasonable belief or idea but not held with such pathological certitude as in a delusion), and that 'Delusional conviction occurs on a continuum' from normal to abnormal. These two statements markedly lessen the initial description of the absolute nature of the delusional wrongness.

The definition of delusion by Mullen[9] based on the earlier description by Jaspers is widely quoted and its implications are largely accepted by DSM-IV and ICD-10. He characterizes delusions as follows:

1 They are held with absolute conviction.

2 The individual experiences the delusional belief as self-evident and regards it as of great personal significance.

3 The delusion cannot be changed by an appeal to reason or by contrary experience.

4 The content of delusions is unlikely and often fantastic.

5 The false belief is not shared by others from a similar socio-economic group.

Clinicians widely employ the terminology on delusions introduced by Jaspers, for example when they use terms such as 'primary' and 'secondary' delusions, 'delusional mood' (*Wahnstimmung*), and 'delusional memory'. These concepts are of some descriptive and possibly heuristic value, but they do not prove particularly helpful in distinguishing delusions from overvalued ideas in individual cases, nor in deciding whether a particular delusional phenomenon is specific to a given mental disorder.

In a sense, all delusions are secondary in that they are the product of a pathological process in the brain which, in most cases, we can only guess at. It is sometimes useful to differentiate clinically between the 'primary' or 'autochthonous' delusion, which appears fully fledged and relatively suddenly, and the 'secondary' delusion, which is a further development within the delusional system and may sometimes seem to be the individual's way of rationalizing his delusional beliefs although, of course, the rationalization must necessarily be filtered through a mind already thought-disordered and affected by delusions. For example, the initial belief may be that the police are watching him night and day; the secondary delusion 'explains' that this is because he has secret information about aliens which the authorities do not wish divulged. The better organized the delusions, the more convincing are the 'explanations', even to outsiders.

Not all primary delusions arise suddenly and, in fact, it must be presumed that in most cases the suddenness is more apparent than real. Almost certainly, unless the delusion is the result of an acute brain dysfunction such as may follow a head injury or delirium, there is a lead-up process, which may be accompanied by the aforementioned *Wahnstimmung*, a mood state compounded of anxiety, perplexity, and a sense of impending crisis. When the delusion crystallizes, the delusional mood often disperses and is replaced by a sense of revelation and of certainty. It seems likely that this phenomenon occurs in a proportion of delusional disorder patients and it often happens that, at the moment of revelation, some coincidental but irrelevant circumstance is picked upon to explain the appearance of the new belief. For example, a media event, a thunderstorm, a chance telephone call, etc., may thereafter be, in the patient's mind, the 'cause'.

While we regard delusions as one of the most characteristic elements of all the psychotic illnesses and a sine qua non in the diagnosis of delusional disorder, clear-cut description, and delineation have proved elusive despite many years of study and experiment.[10] In fact, it would seem that none of the characteristics of delusion which we traditionally accept stand up completely to scientific scrutiny. In particular, nowadays the so-called bizarreness of a delusion has been shown to have little or no distinguishing value.[11]

Much of the classical work on delusions was done in pretreatment times when the chronic condition was readily available for study in institutions. In the present era our aim is to diagnose psychotic disorders as early as possible, sometimes even before frank delusions are evident, and to begin treatment at once. Neuroleptics rapidly interfere with many psychopathological processes; they certainly suppress delusions, although not necessarily permanently. Of course this makes ongoing experimental observations of delusions, especially of the acute variety, all but impossible in clinical circumstances. Psychiatrists find themselves in the paradoxical situation of diagnosing illness because of the presence of delusions whose scientific validity is largely unsubstantiated, and then causing these to disappear before they can be verified properly. Nevertheless, until we have more objective means of making diagnoses it remains essential that, as far as we can, we recognize delusions when they occur and separate them from other abnormal psychopathological appearances.

How can a clinician deal with this? Firstly it seems inescapable that he or she be both experienced and insightful. Given these qualities, it often does seem possible to have an informed sense of whether a belief is true or false and, if the latter, whether it is being held with delusional intensity. A key element in the decision is a comparison between the patient's current beliefs and those he

habitually held, and here a corroborative account from an informed outside source is usually necessary.

The observer's educated suspicion that a delusion is present is the starting point, but it is evident that that suspicion has to be aroused by the context of the apparently delusional idea because, no matter how isolated it appears to be, it nearly always occurs in the setting of a mental disorder whose other features may indicate a specific psychiatric diagnosis. Illogically, instead of recognizing the delusion and using it to make a definite diagnosis, we develop the conviction that we are dealing with a probable psychosis and thereafter judge all the patient's utterances in light of that. While he may indeed be experiencing delusions, it is essential that we do not automatically assume that anything the psychotic individual says has of necessity to be of a delusional nature.

We must accept that we cannot be absolute in our recognition of a delusion. In addition to the illness context we base our estimate on a series of nuances, no one of which is pathognomonic but an accumulation of which becomes increasingly convincing. The abnormalities to be sought are as follows:

1 An idea or belief is expressed with unusual persistence or force.

2 As far as we can tell, the idea is not typical of the individual's previously prevailing thinking and is not shared by his or her social community.

3 The idea appears to exert an undue influence on the person's life and consequently the way of life is altered to an extraordinary degree.

4 Despite the significance to the patient of the belief, he or she often displays secretiveness or resentment when questioned about it.

5 The individual tends to be humourless and oversensitive about the belief.

6 There is a quality of 'centrality'; no matter how strange the belief or its consequences, the patient rarely questions that incredible things are happening to him or her. For example, why should a perfectly ordinary harmless person be singled out for constant surveillance by the security agencies? But this is simply accepted.

7 Attempts to contradict the belief are likely to arouse an inappropriately strong emotional reaction, often with irritability and hostility and with a superciliousness that may be a form of grandiosity.

8 On reflection the belief appears unlikely to the observer, but at the time of history-taking the vehemence of its expression may temporarily disguise its improbability.

9 The patient is so emotionally overinvested in the idea that it swamps other elements in the psyche, and many everyday activities are neglected.

10 If the delusion is acted out, uncharacteristic behaviours, sometimes involving violence, will occur which may be partly understood in terms of the abnormal belief.

11 Others who know the patient well will usually observe that his or her thinking and behaviour are alien, unless *folie à deux* is present when, paradoxically, the other person's denials of abnormality are themselves possible confirmation of the presence of delusion.

12 An odd feature of delusions is that, no matter how strongly they are held, when the patient is given the opportunity to obtain real proof he or she persistently evades accepting the opportunity.

13 One must always look for the features which frequently accompany delusions, especially suspiciousness, hauteur, grandiosity, evasiveness, and eccentric or threatening behaviour, as well as evidence of thought disorder, mood change, and hallucinations.

Particular features of delusions in delusional disorder

In addition to any of the above, in delusional disorder we find several other elements, which are of importance in leading to the diagnosis:

1 The delusional system is stable and is expressed or defended with intense affect and with highly rehearsed arguments. The form of logic used by the patient is very consistent but the propositions are based on false premises. Since the individual is so focused on his beliefs and is so self-assured, he often succeeds in making the enquirer feel inept.

2 The delusional system is markedly 'encapsulated', so that the beliefs therein and their accompanying symptoms are to a considerable extent separated from the rest of the personality which retains a good deal of normal function. However, the compelling force of the delusions often overshadows these normal aspects and this is increasingly so with advancing chronicity of the illness, when the tendency to express and act out the delusions may well increase.

3 When the individual is preoccupied with the delusional system there is strong emotional and physiological arousal, but when he or she is engaged on neutral topics, the arousal abates and an ordinary conversation can take place. Switching between normal and abnormal 'modes', sometimes very rapidly, is virtually pathognomonic of delusional disorder.

4 Because of the encapsulation of the delusions and the normal–abnormal switch just described, the patient may have phases of relative normality interspersed with psychotic periods. The switch can occur spontaneously or as a result of external provocation; the two are difficult to disentangle because the hypervigilant individual may perceive provocation in almost anything. Since it is a chronic illness the symptoms never remit, but if they are temporarily in the background the patient may converse and function almost normally and may have sufficient quasi-insight to keep the delusions concealed for the moment. Total denial of mental abnormality and resistance to psychiatric referral are almost universal in cases of delusional disorder and lead to severe underestimation of the illness's frequency.

5 As a result of the features just described, many delusional disorder patients can continue to exist in society, sometimes with very abnormal but harmless beliefs but in other instances with highly malignant delusions, which they may or may not act out.

6 As will be repeatedly emphasized, delusional disorder must be diagnosed on the **form** of the illness and the content of the delusion is not used to make the primary diagnosis. On the other hand, the particular content is employed to categorize into subgroups, as will shortly be described.

Delusional disorders: clinical features

Official diagnostic criteria

The DSM-IV and ICD-10 criteria are shown in Tables 4.4.1 and 4.4.2, respectively.

As will be seen, the DSM-IV and ICD-10 descriptions are very similar in overall outline but with a number of rather striking minor differences. The following specific items should be noted:

1 DSM-IV uses the term 'non-bizarre' delusions; this criterion has been shown to have little or no validity.[11]

2 DSM-IV allows the presence of tactile and olfactory hallucinations, while ICD-10 mentions only auditory hallucinations; in practice most modalities may be represented but the important point is that they are relatively non-prominent and usually parallel to the content of the delusion(s).

3 DSM-IV says that delusions should have been present for 1 month and ICD-10 insists on 3 months. Both are guesses, but ICD-10 is probably right to err on the side of caution and it provides category F22.8 as a temporary niche until the definitive diagnosis emerges.

4 Both classifications exclude delusional illnesses due to organic brain disorder, medical illnesses, medication effects, or psychoactive substance abuse. In essence this is correct, especially in an illness of acute onset. However, as will be noted later, an apparently typical delusional disorder may arise as a long-term complication of any of these factors.

5 DSM-IV and ICD-10 agree emphatically that delusional disorder is not schizophrenia and DSM-IV notes that general functioning is not impaired. Both say that mood disturbance may accompany the delusional illness but is not a cause of it.

6 The list of subtypes according to delusional content is similar in both classifications, although ICD-10 adds self-referential and litigious themes.

Table 4.4.1 DSM-IV delusional disorder (297.1)

Principal features
(a) Non-bizarre delusions of at least 1 month's duration
(b) Criterion A for schizophrenia has never been met, although tactile and olfactory hallucinations may be acceptable if they are related to the delusional theme
(c) Apart from the impact of the delusion(s) or its consequences, functioning is not markedly impaired and behaviour is not obviously odd or bizarre
(d) Concurrent mood episodes, if present, are brief relative to the duration of the delusional disorder
(e) The disturbance is not the direct outcome of a drug or medication or of a medical disorder
Subtypes
Erotomanic
Grandiose
Jealous
Persecutory
Somatic
Mixed (allowing for the presence of more than one of the foregoing)
Unspecified or other

Table 4.4.2 ICD-10 persistent delusional disorders

Delusional disorder (F22.0)
Principal features
(a) A delusion or set of related delusions, other than those described as typically schizophrenic, must be present; the most common are persecutory, grandiose, hypochondriacal, jealous, or erotic
(b) The delusion(s) must be present for at least 3 months
(c) The general criteria for schizophrenia are not fulfilled
(d) There are no persistent hallucinations, but there may be transitory or occasional auditory hallucinations that are not speaking in the third person or making a running commentary
(e) Depressive symptoms or episodes may be intermittently present, but the delusional symptoms must persist at times when there is no disturbance of mood
(f) There must be no evidence of primary or secondary organic mental disorder or of a psychotic disorder due to psychoactive substance use
Subtypes
Persecutory
Litigious
Self-referential
Grandiose
Hypochondriacal
Jealous
Erotomanic
Other persistent delusional disorders (F22.8)
This is a residual category for persistent disorders with delusions that do not fully meet the criteria for delusional disorder or schizophrenia. Illnesses with prominent delusions accompanied by persistent hallucinatory voices or by psychotic symptoms insufficient to satisfy the criteria for schizophrenia are included here. A delusional disorder of less than 3 months' duration is coded under Acute and Transient Psychotic Disorders (F23) until proven otherwise.

7 Neither classification specifies that the essence of delusional disorder is a highly organized delusional system, largely encapsulated from normal aspects of the personality, although DSM-IV hints at this when it comments that functioning is not markedly impaired and behaviour is not obviously odd or bizarre. Neither comments that the patient can demonstrate alternating 'normal' and 'delusional' modes.

8 The ICD-10 category of 'other persistent delusional disorders' is vaguely described and is largely a catch-all heading or, as mentioned above, a temporary holding station. However, it could conceivably be used for the time being to subsume the unofficial delusional disorder diagnoses of paraphrenia and delusional misidentification syndrome.

9 Overall, DSM-IV and ICD-10 give rather laconic descriptions of delusional disorder and it will be necessary to flesh them out with relevant clinical details. This will be done after the next section on aetiological considerations.

General aetiological considerations in delusional disorders

It must be stressed that knowledge of aetiology in delusional disorder is scanty and highly speculative, largely because so little modern research has been conducted. What follows is an outline,

and certain other factors will be noted when we come to consider some of the illness.

(a) Genetic factors

Changes in definitions of paranoia/delusional disorder over the years and the frequent confusion with schizophrenia make most studies all but impossible to interpret. Conclusions are inferential rather than evidence based. However, it seems well established[12] that delusional disorder and paranoid schizophrenia are less directly inherited than other forms of schizophrenia, and that there is little or no evidence of a genetic link between delusional disorder and schizophrenia.

There may be genetic links with certain severe personality disorders, especially of the paranoid and schizoid varieties, but these are difficult to substantiate. There does seem to be an excess of such disorders in relatives and premorbidly in delusional disorder patients themselves. It is suggested that paranoid and schizoid traits are particularly liable to lead to social isolation and aggravation of delusional tendencies.[13,14]

(b) Organic brain factors

Recent evidence from the study of delusional misidentification syndrome (see later) indicates that delusions of a very specific type may arise in association with certain well-defined brain insults. There are strong hints, but much less supportive evidence, to suggest that organic brain factors may also be important in cases of delusional disorder. For example, head injury may lead to the development of marked paranoid symptoms, and there is a long-established association between chronic alcoholism and pathological jealousy.[15] Old age itself may be linked to the onset of symptoms typical of delusional disorder, and early evidence of brain changes, especially in subcortical areas, is starting to appear in studies of various kinds of senile 'paranoid' illness.[16–18] Amphetamine and cocaine abuse[19] can induce delusional illness, as can therapeutic drugs, including L-dopa and methyldopa,[20] at times. Delusional illness induced by the brain effects of AIDS infection has been documented.[21]

Gorman and Cummings[22] have proposed that delusional illnesses of organic origin have underlying features in common, particularly temporal lobe or limbic involvement and an excess of dopamine activity in certain areas of the brain.

If organic factors predominate in a particular case, delusions must be seen as a secondary feature of an organic brain disorder. However, if the organic factors are subtle and of long duration, the clinical appearances may be those of a quite typical delusional disorder which, interestingly, may well respond to neuroleptic treatment as effectively as idiopathic cases. (In fact, 'idiopathic' may simply denote organicity at a more subtle level.) It is very possible that organic brain factors are much more common than we suspect in delusional disorder, especially in young males who have previously abused alcohol or drugs or have suffered a head injury in the past, and in older patients (more commonly female) who suffer from effects of an ageing brain.[23,24]

(c) Interplay with mood factors

We have already seen that DSM-IV and ICD-10 agree that mood symptoms may accompany delusional disorder but not cause it. Delusional and mood disorders are separate illnesses with their own natural histories and responses to treatment, yet there is a complex relationship between them, as is also the case with mood disorder and schizophrenia. For example, it is well documented that some cases of apparently typical mood illness, unipolar or bipolar, can progress to delusional disorder or schizophrenia over time. Conversely, cases which appear to be delusional disorder but with an episodic course may prove to be bipolar illness. There are a number of anecdotal reports of delusional disorder responding to antidepressant treatment, and it is more than likely that these represent a failure to recognize the true nature of a mood disorder associated with delusions.

Both depressive disorder and mania may be complicated by delusions. On the other hand, mood symptoms, especially dysphoria with anxiety, are a common complication of delusional disorder, while individuals with the grandiose subtype may show elation, which mimics mania but is far more sustained. In recovering delusional disorder, one may see postpsychotic depression of varying degrees of severity and this is described later. Suicide is not unknown in delusional disorder but its frequency is undetermined.

In many delusional disorder patients the illness is profoundly isolating and sets them at odds with the rest of the society, which often generates suspiciousness, dejection, anxiety, and agitation in the individual. It seems that a vicious circle results whereby the delusion induces distress and physiological overarousal which, in turn, reinforces the strength of the delusion and progressively diminishes reality input.

(d) Psychodynamic theories of causation

The psychodynamic literature continues to discuss aspects of 'paranoia' but often fails to differentiate clearly between trait, symptom, personality disorder, and psychotic illness. Most of the emphasis is on the persecutory aspect of paranoia, with only occasional references to other types of delusional content. Since psychotherapists rarely treat psychotic patients, their experience of delusional phenomena must actually be rare and their knowledge of the features correspondingly scanty. Their theoretical bias is to interpret the origins of paranoia in terms of psychological maldevelopment, ignoring the increasing weight of evidence that faulty brain mechanisms are involved. One must read the psychoanalytic literature on this particular topic with an ultracritical attitude, since it usually fails to provide adequate illness definitions or clear case reports and generates explanatory theories which are unjustifiably presented as proven facts.

(e) Conclusions regarding aetiology

No systematic research on paranoia took place for more than half a century and modern investigations into delusional disorder are only beginning to appear. Therefore it is premature to propose specific aetiological theories. However, a gathering weight of evidence does suggest a localized and relatively circumscribed brain disorder associated with the possible influence of abnormal neurotransmitter activity, probably involving dopamine overactivity. Whatever the original basis of delusional disorder, it certainly seems that provocative influences such as head injury, alcohol abuse, and ill effects of drugs may play a part, whereas speculation about psychological causations suggest that this is at most a secondary influence. There is an urgent need for the study of extended case series utilizing modern neurophysiological and neuropsychological investigative methods.

Delusional disorder: general features and introduction to the subtypes

We have already outlined the diagnostic criteria for delusional disorder in DSM-IV and ICD-10 and have amplified these with descriptions of many of the clinical phenomena associated with the illness. It has been emphasized that this is a stable and readily recognizable disorder, provided that the clinician is informed of the essential criteria and has dealt with at least several cases to familiarize him- or herself with its very characteristic 'feel'. With this experience it becomes much more possible to delve under the prominent symptoms related to delusional content and to discern the underlying form of the illness. However, it is the predominant delusional content in an individual case, and the symptoms and behaviours related to this, which decide how a patient will present for assessment. Therefore we shall consider the main subtypes in some detail. It cannot be stressed enough that these are not separate types of illness, but variants on a single psychopathological theme.

All cases of delusional disorder occur in clear consciousness and have a stable and persistent delusional system which is relatively encapsulated. Since much of the personality remains remarkably intact, a considerable degree of social functioning is retained in many cases. The patient experiences a heightened sense of self-reference within the delusional context and ordinary events take on unusual significance. He or she clings to the delusion with fervid intensity and spurns any suggestion that a mental illness is present. Outside the delusional system the patient shows quite normal thinking, affect, and behaviour, but there is a marked tendency for gradual pushing to one side of these normal aspects. The retention of such a degree of normality makes the illness totally different from schizophrenia.

Earlier it has been indicated that the DSM-IV criterion of non-bizarreness is unhelpful, although in all cases of delusional disorder the delusions are relatively well structured, coherent, and consistent, and the logic would often be acceptable if it weren't that its basic premises are irrational. Many affected individuals can maintain overtly normal activities, at least in public, but increasing pressure of the delusion tends to cause corresponding responses in behaviour; these may be channelled socially, as in hypochondriacally deluded patients who utilize medical resources, albeit excessively, or antisocially, as in the aggression of the jealously deluded individual. Mood abnormalities are common as a response to the effects of the illness.

Hallucinations do occur in some cases and may affect any modality, but they are often difficult to assess and to differentiate from delusional misinterpretations and illusions. Widespread persistent hallucinations in more than one sensory sphere should make one cautious about the diagnosis of delusional disorder.

The illness appears to affect men and women approximately equally, but it is not clear if this is true of all subtypes. Despite older assertions that the illness is restricted to the middle-aged and elderly, the age of onset can actually be from late adolescence to extreme old age, with male patients appearing on average to experience earlier initiation. Some patients behave in an eccentric or fanatical fashion and, as a group, delusional disorder sufferers are excessively likely to be unmarried, divorced, or widowed, probably reflecting restriction of affective responses and some isolative tendencies. Despite this, the condition can be compatible with marriage and continued employment. The premorbid personality is usually described as asocial and there may indeed be an excess of long-standing schizoid and paranoid personality disorders. However, when a patient makes a good recovery there may be little evidence of this, and it is possible that in some cases a 'personality disorder' is actually the prolonged and insidious prodrome of the illness.

Onset may be gradual or acute. In the latter the patient often identifies a precipitating stressor, which is difficult to confirm (e.g. the person who has a delusion of skin infestation may attribute it to a single insect bite many years previously). While most individuals are secretive about their abnormal beliefs or express them by such means as physical complaints or legal processes, a certain number actually utilize them, perhaps within the context of an extreme religious sect or by becoming an excessively insistent agitator on some social issue. Disinhibited and overtly aggressive behaviour seems more likely to occur in males, at times leading to clashes with the authorities.

In all cases of delusional disorder, no matter what the nature of the delusional theme, the investigator should look for the relatively unique feature of the illness—the patient's ability to move between normal and delusional modes of thinking. In the former there is relatively calm mood, reasonable rapport, and appropriate emotional responses, whereas in the latter there is overalerting, suspiciousness, and the sense that the person is being remorselessly driven by the delusional beliefs. This situation is difficult for the inexperienced observer to comprehend, since it is inconceivable to most people that someone who can appear perfectly rational at one moment can almost instantaneously change to a possessed irrational being—and then back again just as quickly. In a sense the same patient is both sane and insane, and when in the latter mode may be ultrapersuasive about the acceptability of his or her beliefs. One may imagine the plight of a lawyer faced with a client who has committed some uncharacteristically outrageous act as a result of a delusion, who can then discuss his case with apparent insight and logic, and even genuine remorse, but who nevertheless remains totally self-justifying. As a corollary, the client will usually deny the possibility of mental illness and often refuses to cooperate with psychiatric assessment. He may also refuse to cooperate with the legal process, to his knowing detriment.

Delusional disorder, when it was known as paranoia, often had a bad reputation because patients were regarded as angry, suspicious, accusatory, and potentially violent. Some undoubtedly are, but as we consider the various subtypes nowadays we realize that many sufferers, perhaps the majority, lead lives of internalized despair in progressively isolated circumstances. Anger and suspiciousness are often secondary, at least in part, to the perceived neglect of their overwhelming concerns. The illness is chronic and self-reinforcing, and it is likely that only a minority of cases are recognized or helped. Psychiatry does not have an impressive record of helpfulness towards this group of patients.

The subtypes of delusional disorder

As previously noted, DSM-IV recognizes five main subtypes based on the predominant delusional themes: the erotomanic, grandiose, jealous, persecutory and somatic, plus mixed and unspecified types. ICD-10 also recognizes these subtypes, and adds litigious and self-referential categories. Here, the litigious variety is included within the persecutory group and self-referential cases are not given separate status since self-reference is, in reality, a feature of the illness as a whole and prominent in all cases.

When delusional disorder was resurrected in DSM-IIIR, single delusional themes were emphasized, but the mixed category in DSM-IV accepts the reality that, for example, a hypochondriacal individual can also feel persecuted and an erotomanic patient can be extremely grandiose. Also, we shall find that there are considerable individual variations within the overall themes, so that in the somatic subtype there are cases involving different body systems. Yet the range of major themes does not appear to be all that wide and we have no explanation for this relative restriction in their number. The 'unspecified' category in DSM-IV allows us to accommodate any case whose delusional theme is unusual and leaves a door open to the discovery of other themes in the future.

In presenting the subtypes, relatively more attention will be given to the somatic form. This should not be taken as an indication that this is the most common variant; rather, it happens to be the one which has been best documented in the recent psychiatric literature. Other types of delusional presentation are much more often described in non-psychiatric and non-medical sources, where the fundamental nature of the illness may be overlooked, and so we are only beginning to correlate such descriptions with modern findings on delusional disorder.

Delusional disorder: persecutory and litigious subtypes

In most people's minds the persecutory type of delusional disorder is the archetype of 'paranoia' and it is usually assumed that it is the most common variety. Therefore it is surprising to find that the literature, while full of speculation, is very lacking in good descriptions of the phenomenology of the illness and, apart from unreliable psychoanalytic theory, says relatively little about persecutory delusions themselves.

Clinical features

By definition the illness is a chronic psychotic disorder with a well-systematized delusional system and with relative sparing of the surrounding personality. The persecutory threats may be perceived simply as coming from 'them', but can elaborate to descriptions of the most labyrinthine plots involving a variety of known and unknown adversaries. The beliefs are extremely stable and usually increase in complexity with the passage of time. There is heightened awareness and misinterpretation of neutral environmental cues and, not unnaturally suspiciousness, extreme anxiety, and irritability are present. Elements of grandiosity are not uncommon, with the individual accepting that he or she is the centre of focused and malignant attention that would be inexplicable to the normal person. As the illness progresses there is a tendency to involve an increasing number of people in the persecutory system, not uncommonly relatives, physicians, law-enforcement agencies, aspects of government, and others.

As with other subtypes of delusional disorder, many individuals are able to conceal their increasingly insistent delusions for some time, but because of fear of harm they are likely to isolate themselves more and more. If they live alone they may come to be regarded as eccentrics, but if they remain in contact with society the suspicion and anger must eventually become evident, so that interactions with family, social agencies, or the authorities become increasingly confrontational.[24] Despite the reputation of 'paranoia' for violence, only a small proportion of these individuals resort to threat or assault, but with those who do the danger may be profound as the individual is without reservation in his beliefs and will act as though genuinely under severe provocation. Disinhibition may at times be engendered by alcohol or drug use, which makes such situations even more volatile.

Even in a long-standing illness, islands of normal functioning remain; despite this there is little or no insight and the patient resists any psychological explanation for his beliefs. He usually refuses to see a psychiatrist voluntarily; many patients of this kind are encountered in a forensic setting only after an outburst of unacceptable behaviour and are minimally cooperative.[25]

Litigious variety of the persecutory subtype (querulous paranoia)[26,27]

In some individuals with delusional disorder there is a profound and persistent sense of having been wronged in some way, and these people endlessly and repetitively seek redress, sometimes personally but often through the legal system. In a proportion of cases there may initially have been a genuine grievance and there may also have been unsatisfactory recompense, but the subsequent pursuit of 'justice' becomes never-ending and also becomes self-reinforcing because no satisfactory resolution is possible.

This group may not be large but it generates considerable media publicity. Reports of cases naturally tend to be in the literature of the legal profession, the law-enforcement agencies, and, to some extent, forensic psychiatry, but rarely from general psychiatry. Because the individual appears relatively high functioning apart from his delusional beliefs, the complaintive behaviour may be regarded as mere eccentricity for a long time. As in many cases of delusional disorder, the immediate complaint and behaviour may seem coherent and not unreasonable but over time their ongoing, never-ending, and extraordinarily demanding quality begin to raise the suspicion of severe underlying psychopathology. Even then, unless the person begins to be perceived as a threat, little may be done and prolonged harassment of officialdom and the legal system may be tolerated for surprisingly long periods. In some national communities (e.g. Germany and the Scandinavian countries) there are legal provisions to stop 'barratry' or unreasonable use of the law by declaring an individual a querulous litigant.

Goldstein[28] has described three typical ways in which 'litigious paranoia' presents. The first is the 'hypercompetent defendant' who knows and uses the letter of the law up to and beyond its limits but pays no heed to its spirit. The second is the 'paranoid party in a divorce proceeding' who is often consumed with jealousy and pursues vendettas against the ex-spouse, the lawyers on both sides, and even the judge. The third is the 'paranoid complaining witness' who endlessly initiates litigation despite repeated adverse judgements. All such individuals pursue their grievances in a driven manner, see conspiracy in every corner, and are often quite unscrupulous in their single-mindedness, blatantly bending facts to fit with their beliefs. Since they hold the delusional belief with total conviction, they can accept no counterargument or contrary facts. In the past, persistent litigation was virtually a preserve of the rich, but many modern societies provide a variety of avenues for complaintiveness and will even support complaint procedures, and so abnormally litigious behaviour appears to be on the increase.[29]

Diagnosis of the persecutory subtype

All the features of a delusional disorder as previously described are present. In this subtype, wariness, irritability, suspiciousness, and threatening behaviour are especially prominent, and both impulsive and planned violence may occur. Gaining confidence is extremely difficult, but if this succeeds, the more normal aspects of the individual's personality may become apparent and one may also perceive how chronically anxious and overalerted he or she is.

Differential diagnosis

The illness must be distinguished especially from the following:

- paranoid schizophrenia
- paranoid and antisocial personality disorders
- substance-related disorders
- organic brain disorders, including early dementia and some epileptic disorders
- obsessive-compulsive disorder.

Epidemiology

Virtually nothing is known of the frequency and distribution of persecutory delusional disorder. As with other subtypes it occurs in both sexes, but male cases are probably overreported because of a readier tendency to violence and antisocial acts. The literature is biased by the reporting of the most overt cases, often in the news media or through the courts. It is open to speculation how many cases avoid diagnosis; as noted, relatively few come to the clinical attention of psychiatrists other than in forensic work.

Course and prognosis

Delusional disorder is very chronic, and it is presumed that cases of the persecutory subtype are as likely as others to be lifelong and to show increasing psychopathology with the passage of time. In a proportion of cases there is always a risk of violence and illegal behaviour. Since cooperation with assessment and treatment is usually minimal, the overall figures for prognosis must be bad, but we have no reliable data to confirm this.

Forensic complications[30,31]

If someone with a generalized psychotic disorder like schizophrenia becomes sufficiently disorganized, functioning in the community becomes impossible. In contrast, many delusional disorder patients retain a sufficient grasp of reality to continue existing in society, sometimes indefinitely. However, this does not imply that their illness is quiescent. Intellectual ability, capacity for reasoning, and the form of thought remain relatively intact, but the delusional process worsens. They retain the ability to brood on their beliefs so that normal thought processes and delusions interweave, as do normal and abnormal behaviours. Anger may express itself explosively, but some individuals carry out violent actions in a very calculated way, believing that a just vengeance is being exacted. Afterwards there may be real regret and a clear awareness of a wrong having been committed against society, but the actions are seen as justifiable and necessary. The patient is usually aware that by societal standards his deed is legally and morally wrong, but that awareness resides within the normal non-delusional aspect of his mental functioning. Within the confines of the delusional system, the person unswervingly believes that it was obligatory for him to behave as he did.

In such cases, the judge and jury are placed in a quandary, made worse by the individual's frequent arrogance (related to grandiosity), self-justification, and ambivalent expression of regret. The ability to acknowledge the wrongness of one's action in general terms and even to show remorse for it, while also asserting that it was necessary to carry it out, may well be regarded as indicating wilfulness or hypocrisy. Then, paradoxically, culpability may be determined by the content of the delusion, although this has minor relevance to the disinhibition of behaviour. Thus, as Goldstein has pointed out, if the person felt threatened because of a delusional belief and reacted, as he genuinely perceived, in self-defence, his degree of blame may be adjudged to be low. But if he were equally deluded and carefully plotted revenge, this might be seen as highly culpable. Such a distinction cannot be defended logically either in the clinical situation or at law.

Delusional disorder defies any definition of insanity in black or white terms; it is both black and white. Because few psychiatrists, even in the forensic field, are familiar with its detailed characteristics, psychiatry has had limited success in educating the legal profession about the subtleties of the illness or the conundrum that delusions can induce such abnormal behaviour in an individual who superficially appears rational and for significant periods of time is effectively sane even though the illness is always lurking there.

Treatment of the persecutory subtype

Treatment is discussed later in this chapter in the section on overall treatment aspects.

Delusional disorder: somatic subtype (monosymptomatic hypochondriacal psychosis)

Modern society, especially in developed countries, is preoccupied with health concerns. While much of this is positive, there is no doubt that many people worry excessively about health matters and a proportion of these show pathological self-concern. This can shade into hypochondriasis, in which there is a persistent conviction of illness in the absence of objective evidence, with misinterpretation of bodily sensations as disease and with inability to accept reassurances. In many cases the individual shows some degree of body image disturbance, sometimes of extreme degree.[32] Usually we think of hypochondriasis as referring to physical complaints, but nowadays it seems that an increasing number of people are also liable to complain of psychological disorder.

Hypochondriasis is common and may be a personality trait, but it can also be an accompaniment to many psychiatric illnesses, both delusional and non-delusional. It is the presenting feature of the somatic subtype of delusional disorder and in different patients we see many varieties of alteration of body image expressed in delusional terms. Certain themes of delusional content tend to predominate and this has meant an unfortunate proliferation of descriptive names scattered across a fragmented literature, leading to many difficulties in conceptualizing the subtype and in separating it from other psychiatric disorders with prominent hypochondriasis. As with all subtypes of delusional disorder, the clinician

must bear in mind the advice already given that, for the diagnosis of delusional disorder, it is the characteristic form of the illness, which is of prime importance, not the content of the delusional beliefs. The hypochondriasis in delusional disorder may superficially resemble that of somatoform disorder, psychotic depression, or obsessive-compulsive disorder, but careful investigation will reveal an illness very different from these.

Clinical features

We shall consider the manifestations of the somatic subtype under four major theme areas:

1 delusions involving the skin;

2 delusions of ugliness or misshapenness (dysmorphic delusions);

3 delusions of body odour or halitosis;

4 miscellaneous.

(a) Delusions involving the skin[33]

In the delusion of skin infestation, the patient insists that he has organisms, usually insects, crawling over the surface of the skin and sometimes burrowing into the skin or under the nails. In most instances he cannot see the creatures, but sometimes there may be graphic descriptions. This may represent a visual hallucination but more usually seems to be a vivid ideational projection.

The delusion of parasites burrowing deeply under the skin is often attributed to worm-like parasites, and internal body sensations or the rippling of small superficial muscles are misinterpreted as evidence of their activities. Sometimes the patient believes that the worms have spread throughout the body or intermittently migrate from place to place.

In the delusion of discrete foreign bodies under the skin or nails, these bodies are occasionally described as inanimate, but generally the patient says they are seed-like or believes that they are parasite eggs. In some individuals this is associated with an irresistible urge to pick, and multiple deep excoriations may result. Such people are sometimes labelled as having 'neurotic excoriations' or factitious disorder, but in fact the picking behaviour is delusionally motivated and is an irresistible urge to stem the invasion of the parasites.

Chronic cutaneous dysaesthesia[34] is an unremitting burning sensation of the skin or mucosae, sometimes generalized but at other times largely confined to complaints of glossodynia or vulvodynia. A minority of these patients appear to have a delusional disorder.

A subgroup of patients with trichotillomania and onychotillomania[35] have delusional illnesses, and the hair-pulling or nail-picking may be part of the attempt to rid themselves of parasites.

In all the above presentations, the delusion and its associated behaviours typically occur in the setting of many well-retained personality features and the patient can often make very clear-cut and apparently rational complaints, convincing the many physicians they attend, at least for a time, that actual physical disease is present. However, no somatic treatment works and the complaining becomes increasingly shrill and unreasonable. The sufferer cannot be persuaded that infestation is not present and often becomes very angry at the perceived incompetence of the dermatologists he has visited.

Usually the story of the infestation is presented in great detail, perhaps involving an original event such as an insect bite. 'Proof' is presented by displaying skin lesions, deformed nails, bald patches, etc. The 'matchbox' or 'pill-bottle' sign, in which the patient produces a small container in which 'insect corpses' or 'eggs' are kept, is typical; the contents nearly always turn out to be dried mucus, skin scrapings, or pieces of lint. Often, there is incessant cleaning of self and surroundings, and repeated demands may be made to local authorities or pest-control agencies for disinfestation of the home. At times bizarre and even dangerous self-treatment is resorted to, such as applying boiling water or corrosive substances to the skin. The more normal part of the psyche is dominated by shame or fear of passing on the infestation, so that progressive social isolation tends to occur, with attendance on doctors as virtually the only outside activity.

(b) Dysmorphic delusions

'Dysmorphophobia', an old term which implies a morbid fear of being deformed, is still sometimes employed to describe cases in this category but should be abandoned since it has been so loosely used to denote both delusional and non-delusional complaints as well as a variety of very different illnesses.[36] In the present context we are considering only cases typical of delusional disorder, which present with a false belief of ugliness or deformity. In some instances there may indeed be some minor deformity, but the complaining and demand for alleviation are out of all proportion and expressed with delusional intensity.

A specific feature is often singled out by the complainer, such as an overlong nose, prominent ears, over-large or undersized breasts, dissatisfaction with the appearance of the genitalia, a skin blemish, or some other. However, in other cases the total body is perceived as abnormal, and there is evidence that a small group of apparent cases of anorexia nervosa and bulimia nervosa may have an underlying delusional disorder.

Many of the patients with dysmorphic delusions go from surgeon to surgeon demanding cosmetic procedures and usually being refused, but if the surgeon does not perceive the illogicality of the complaint an operation may take place. While some successes have been reported, the general consensus is that most cases need psychiatric rather than surgical intervention and unnecessary operations may seriously worsen the mental disorder in the long term.

It is sometimes very difficult to distinguish cases of delusional disorder of somatic subtype from severe somatization disorder, and claims have been made that there is a continuum between these illnesses.[37] The evidence for this is minimal and a diagnostic distinction is essential since treatments of the two disorders are very different.

(c) Delusion of smell or of halitosis[38]

In this category it is often very difficult to distinguish between delusions and hallucinations of smell or taste. The term 'olfactory reference syndrome' is often used to describe olfactory delusions, but in fact it should properly only refer to hallucinatory experiences. Sometimes the deluded patient will say that he or she has not actually experienced the odour, which is usually unpleasant, but 'knows' that it is present because of remarks made by others or their avoidant behaviour. In other cases the stench is described graphically and consistently (like 'burning rubber' or 'faeces') and here a hallucination may be present. There may be no explanation, or else the smell may be attributed to escaping flatus, abnormal sweat secretion, or sinus or dental problems leading to halitosis

etc. As is typical, an unending and escalating search for a physical cure occurs.

(d) Miscellaneous delusional contents

Presumably there is an almost infinite possibility of different themes, but in practice their numbers are somewhat limited. The following have been described.

(i) Dental

Although his dentition is satisfactory, the patient insists that his dental bite is abnormal and obtains repeated corrective treatments from successive dentists, none of which works. This has been termed the 'phantom bite syndrome', and may sometimes be associated with complaints of facial pain for which no physical basis is apparent. There may also be delusional complaints of deformity of the jaw or abnormality of the temporomandibular joint.

(ii) Delusion of transmitting non-sexual diseases

Some patients may be convinced that they are causing illnesses in others (e.g. tuberculosis), and they will cite as evidence, for example, that everyone starts coughing when they enter a room.

(iii) Delusion of sexually transmitted disease[39]

Hypochondriasis is, of course, rampant around the topic of sexually transmitted disease. A subgroup of delusional disorder patients develop the conviction that they have venereal disease, often when there is no evidence of risk-taking behaviour having occurred. In the past syphilis was probably the greatest fear, but nowadays it is usually AIDS. Repeated tests showing negative serology have no reassuring effect. Interestingly, a few cases of actual AIDS have been described in which a delusional illness with hypochondriasis has emerged, usually due to direct effects of the virus on the brain.

Differential diagnosis of delusional disorder: somatic subtype

First, the presence of a significant physical disorder must be excluded (although it is possible for a physical illness and delusional disorder to coexist). The illness must be distinguished from the following:

- paranoid schizophrenia
- substance-related disorders (e.g. itching related to alcohol-related liver failure, cocaine abuse, etc.)
- organic brain disorders
- severe depressive disorder with hypochondriacal delusions
- somatoform disorders, especially body dysmorphic disorder
- obsessive-compulsive disorder
- factitious disorder

Epidemiology

Cases usually present in medical and surgical practices and much less often in a psychiatric context. We have no idea of the frequency because non-psychiatrists make a variety of diagnoses, often untranslatable in psychiatric terms. However, the somatic subtype of delusional disorder is certainly not uncommon, and this is increasingly being revealed as consultation–liaison psychiatry develops.

These cases make a strong impression on physicians and surgeons because of their insistence and unreasonable demands. To date, dermatologists have been most aware of the nature of the delusional complaining and, in some cases, have learned to treat the deluded patients satisfactorily with appropriate medication. Infectious and tropical disease specialists also have an awareness, as do gastroenterologists and some dentists, and they are gradually referring more cases for psychiatric help. Plastic and cosmetic surgeons see a considerable number of cases with dysmorphic delusions, but it is still rather uncommon for them to seek psychiatric consultations. Since the patient with delusional disorder generally refuses to visit a psychiatrist willingly, it is often necessary for us to consult on the other specialists' territory in order to offer practical help and to obtain a better idea of the illness's frequency.

From what we know, the somatic subtype affects both sexes approximately equally and the age of onset may be from late adolescence to extreme old age. The illness is more common in the unmarried, divorced, and widowed.

Course and prognosis

Typically the illness is long term with a tendency to worsen with time. Some patients eventually lapse into a rather apathetic state, and some attempt or commit suicide in chronic despair, but the majority continue to move from doctor to doctor demanding treatment on their own deluded terms.

Treatment of the somatic subtype

Treatment is discussed later in this chapter in the section on overall treatment approaches.

Delusional disorder: jealousy subtype[40]

This is sometimes known as the Othello syndrome, but the term is not recommended as it lacks specificity.

The phenomenon of jealousy

Jealousy can arise in various contexts, but here we shall deal with sexual jealousy. This is a virtually universal human emotion, especially when a rival is attempting to lure away someone's sexual partner. Males and females are equally prone to jealousy but may express it differently; Mullen and Martin[41]suggest that men are mainly concerned with losing the partner whereas women worry about the effect of infidelity on the ongoing relationship.

Broadly there are three levels of jealousy. Normal jealousy is understandable in terms of the situation and the individual's perception of it, and its expression can range from pique to severe rage. How it is expressed is largely related to temperament; some people habitually vent anger with slight provocation and others usually bottle up their feelings. On the whole, men tend to act out their jealous anger more physically.

Neurotic jealousy occurs where the mood and its mode of expression are relatively normal but owing to non-psychotic psychiatric illness, including personality disorder, the reaction is impulsive and excessive. Although the individual is reacting to an overvalued idea rather than a delusion, this type of jealousy can be irrational and quite persistent, and may be expressed dangerously.

Psychotic jealousy, as in delusional disorder, is characterized by a fixed delusional belief which cannot be swayed by reasoned argument or presentation of contrary evidence. This is the most

alarming type since there is no dissuasion and there is an inexorability about the way that the individual accuses, controls, and even stalks the victim. Since the accusations are usually untrue, the latter is bewildered by them, but occasions do arise when a partner actually has been unfaithful and it is then very difficult for the observer to know at first how much of the jealousy is justified and how much is delusional. Eventually the savageness and unreasonableness of the accusations reveal themselves as undoubtedly abnormal, but meanwhile a frightened partner will have suffered enormous abuse and possibly repeated assault.

When does jealousy become pathological?

Jealousy, which appears justifiable is regarded as normal, although perhaps not laudable, and it will usually be accepted by society if its manifestations are not antisocial. Nowadays we increasingly disapprove of jealous violence, whether provoked or not, but in some communities there is still acknowledgement of the *crime passionel*, the crime committed out of jealous love. However, this is an excuse extended only to males, and the jealous woman who commits assault or murder is usually treated more harshly.

Cobb[42] proposed the following as clinical features of pathological jealousy, whether it be neurotic or psychotic.

1 The jealous thinking and behaviour are unreasonable in expression and intensity.

2 The jealous individual is convinced of the partner's guilt but the evidence is dubious to others.

3 A recognizable psychiatric illness is present which could plausibly be associated with abnormal jealousy.

4 In a proportion of cases, the jealous person has habitual personality characteristics of jealousy, suspiciousness, and overpossessiveness.

5 The jealousy persists unduly and reinforces itself.

6 Pathological jealousy is usually focused on one specific person.

In neurotic jealousy, which in some ways resembles obsessive-compulsive disorder, there is high self-awareness of the emotion and sometimes of its irrationality. In delusional jealousy the person is totally at one with the belief, which has come to occupy much of his or her time. Counterargument or contrary evidence is rejected, yet in delusional disorder the individual may be so high functioning that he or she is totally convincing to outsiders and may even be able to brainwash the innocent victim into admission of guilt, a form of *folie à deux*.

The impact of pathological jealousy

Delusional jealousy is anguishing to the sufferer and even more so to the sexual partner who is accused of infidelity. The latter is subjected to escalating emotional abuse, and indignation, protest, and proof of innocence are unavailing. Physical violence, especially by males, is common[43] and in a proportion of cases finally ends in homicide, sometimes followed by the suicide of the perpetrator.[44] Subjected to prolonged threat, many victims are too terrified to speak up, and some become housebound in a vain attempt to prevent accusations of philandering. From time to time the situation reveals itself when the desperate partner attempts suicide and talks to a helping professional when recovering.

Clinical features

The person's belief in the other's infidelity is absolute and brooks no contradiction. There is much associated irritability, despondency, and, in some cases, aggressiveness. An ever-increasing proportion of time is spent searching for spurious 'proofs', and 'clues' are pounced upon and misinterpreted; for example, an innocent stain is declared to be semen. The victim is put through endless interrogations and is kept under constant surveillance.

Paradoxically, when the jealous individual is questioned closely about his or her specific charges, details prove vague, there is dismissiveness, and there are self-justifying repetitive assertions. Evidence is always about to be produced but rarely materializes. Strangely too, the jealous person often avoids taking the action, which might provide definite proof of guilt or innocence, and this passivity in the midst of intensiveness may be evidence of some volitional defect.

As noted, delusional jealousy is more commonly reported in men, but this is probably an artefact due to their greater likelihood of violence. Also, there is a link between chronic alcohol abuse, as well as amphetamine and cocaine abuse, and delusions of jealousy, and it is known that these substance abuses are more common in males.

Epidemiology

The overall prevalence of abnormal jealousy and the specific prevalence of the delusional disorder subtype are unknown and, because of fear on the part of the victim, both are invariably underreported. Both heterosexual and homosexual cases occur, and family patterns of jealous behaviour have been described, but there is little evidence of direct inheritance.

Course and prognosis

The condition may appear gradually or suddenly, but even when the onset seems rapid there may have been a previous period of rumination and perplexity of varying duration. When the delusion crystallizes the perplexity vanishes and the patient is then totally sure of his belief.

Delusional jealousy is typical in being chronic and often lifelong. Without treatment the prognosis is poor and the danger to the victim is ever present. Most patients refuse psychiatric help and unfortunately may only receive it after incarceration for a violent crime.

Differential diagnosis

The illness must be distinguished from the following:

- actual marital or sexual problems, including spousal infidelity
- mental handicap, where a simple-minded person may develop a 'crush' and be unable to understand that the other person does not reciprocate, or else enters into a sexual relationship and cannot cope with the partner's motives and behaviours
- schizophrenia, especially of the paranoid type
- major mood disorder with delusions, either depressive or manic
- personality disorder, especially of the paranoid, antisocial, borderline, histrionic, and narcissistic types
- obsessive-compulsive disorder

- substance abuse (which may complicate any of the other differential diagnoses)
- organic brain disorders, including dementias and some epileptic disorders
- sexual dysfunction may lead to fears that a normal partner is seeking satisfaction elsewhere

It should be noted that an important part of the diagnostic process, an accurate collateral history, may be impossible to obtain in cases of delusional jealousy because of the victim's fears.

Forensic complications

In cases of identified physical abuse in a relationship one possibility that must always be considered is delusional disorder of jealous type. Severe assault and even murder are not uncommon, and the physician has a duty to warn and protect the partner if these dangers seem real, perhaps divulging confidential information if necessary. Of course the patient denies that his beliefs are unjustified and may present his case more convincingly than the terrified victim can. If involuntary committal is necessary it may be very difficult to sustain, partly because of the individual's ability to maintain a pseudonormal facade and often because he or she threatens litigation.

Occasionally, cases of stalking, usually of females by deluded males, are jealousy related and the victim is nearly always well aware of the stalker's identity in these instances.

Treatment

This will be discussed when considering the overall treatment approach to delusional disorder. If successful treatment can be achieved, the couple may require considerable psychotherapy and counselling to re-establish a trusting and fear-free relationship.

Delusional disorder: erotomanic subtype[45–48]

In erotomania the individual has strong erotic feelings towards another person and has the persistent, unfounded belief that this other person is deeply in love with him or her. The belief is usually delusional, though a small number of non-delusional cases have been reported. Occasionally the imagined lover does not actually exist, but more often he or she is a real person who is unaware of the situation. The phenomenon is often referred to as de Clérambault's syndrome, but this usage is obsolete and can be misleading since it is used to describe erotomanic manifestations in a number of different mental illnesses.

In the older literature it was claimed that erotomanic delusions were largely confined to women, especially isolated and frustrated elderly spinsters, but more and more cases of male erotomania are being reported nowadays.[49] In both sexes the majority of cases described involve heterosexual emotions, but homosexual erotomania is now well documented in both males and females.

Clinical features

The patient yearns for another person and has the unshakeable belief that these feelings are reciprocated. The person is often socially unattainable, may be of higher social status, and can be a celebrity. There has rarely been close contact and the love object will usually be unaware of the situation, but despite this the patient believes that the other initiated the imagined relationship, often with covert signals or utterances. Many patients experience strong erotic, even orgasmic, feelings, but some insist that the 'relationship' is platonic and that the other person is maintaining a non-sexual attitude of watchful protectiveness.

In many instances the patient makes no attempt to get in touch with the love object, perhaps writing letters or buying gifts but not sending them. When given a chance to make actual contact he or she will frequently avoid doing so and will make spurious excuses such as not wanting to offend the other person's spouse. In those cases where the patient does attempt contact, false reasons are presented to explain the almost inevitable rejection that results.

Since this is erotomania in the setting of delusional disorder, the illness will have the typical form of a tightly knit delusional system with preservation of relatively normal personality features and with greater or lesser ability to continue functioning in society. There is often enough insight or inhibition present for the patient to keep the delusional beliefs concealed. However, at times he or she may be profoundly angered by being 'inexplicably' rejected and may act this out, occasionally dangerously. This is more likely to occur in males.

The onset of erotomania can be gradual or apparently sudden. Hallucinations are sometimes present but are not prominent, although the patient may be encouraged by 'hearing' the other person express passionate feelings. Occasionally, the presence of tactile hallucinations leads the patient to believe that a lover has paid a visit during the night (sometimes picturesquely referred to as the 'incubus syndrome').

Diagnosis and differential diagnosis

Many covert examples necessarily go unrecognized and so there is a bias towards diagnosis of cases with some sort of acting out behaviour. Otherwise the most common situation is one where the patient, after years of silent suffering, becomes unhappy enough to be treated for depression and then, during sympathetic history-taking, lets the delusional belief slip out. There is often much accompanying anguish and perhaps anger, and of course the beliefs are regarded as indisputable. Obviously, if the patient has been very secretive, a confirmatory history may be impossible to obtain. In married patients the spouse may be totally unaware of delusions which have lasted for years.

The following disorders may be associated with secondary erotomanic features:

- Schizophrenia, especially paranoid, in which the erotomania coexists with other delusions, florid hallucinations, and more widespread thought disorder.
- Major mood disorder, in depressive or manic phases.
- Organic brain disorders, including epilepsy, post-head-injury states, following long-term substance abuse, senile dementia, and possibly as a side effect of steroid treatment.
- Mental handicap, in which misunderstanding occurs regarding another's feelings or intentions. However, we must remember that the mentally handicapped are liable to sexual abuse and we must not unthinkingly dismiss sexually laden remarks that they may make about other individuals. Conversely, we must also remember that mental handicap can coexist with psychotic disorders and delusional expressions.

- Delusional misidentification syndrome has occasionally been described with erotomanic features.
- Non-delusional erotomanic beliefs may emerge in unstable individuals, sometimes complicating transference in the course of psychotherapy. If associated with histrionic traits there may be florid acting out, but the beliefs do not have the qualities of a delusion.

Epidemiology

Nothing is known of the frequency of erotomania in general, or of the erotomanic subtype of delusional disorder. As will be noted below, the more dangerous aspects of the illness are proving to be not uncommon.

Course and prognosis

Without treatment this is a chronic illness, which is likely to worsen gradually over time.

Forensic complications[50]

Males who irrationally act out their erotomanic delusions are usually diagnosed as schizophrenic but some prove to have delusional disorder. Often the overt behaviour is in the nature of harassment, but even without violence the individual's persistent intrusiveness and incorrigibility can be thoroughly alarming to the victim, who is bewildered by the situation and by the other's accusations of duplicity.[51]

Severely aggressive behaviour can lead to assault, kidnapping, and even murder, sometimes of the love object but at other times of an acquaintance who is viewed as a rival. A manifestation, which has gained much recent publicity is that of victim stalking, and in a considerable number of cases the victim has no idea who is carrying out the stalking.

While women are generally less prone to aggressive acting out of their delusions, they may sometimes demonstrate their false beliefs in devastating ways. For example, a deluded woman may claim publicly that a physician, counsellor, or teacher has demonstrated strong erotic feelings towards her. This belief may be the result of a delusional memory. If she has an undeteriorated personality, is coherent, totally believes her own story, and presents it with typical vehemence and persistence, it may be virtually impossible to persuade the public and the authorities that the accusations are totally false. Any professional person dealing with deluded patients must be aware of abnormal transference emotions that may arise in the patient during treatment, usually of a heterosexual nature but sometimes homosexual. Great circumspection is then required and the therapist must immediately seek collegial (and possibly legal) help.

Treatment

Treatment is discussed later in the section on overall treatment of delusional disorder.

Delusional disorder: grandiose subtype[23]

This is the least well-described variant of delusional disorder, not surprisingly in view of its nature. An individual who is habitually elated, even exalted, and who may believe himself or herself rich or powerful is unlikely to seek help, especially psychiatric help. If he or she remains sufficiently high functioning to remain in the community, the delusions may be undetected; indeed some people capitalize on their beliefs by belonging to fringe organizations, apocalyptic religious groups, or doomsday sects. Sometimes these groups develop malignant qualities, especially under a deluded but charismatic leader, and one cannot minimize the dangerous qualities of the forceful megalomaniac whose grandiosity is alloyed with persecutory anger. Like-minded and impressionable people are readily drawn in and a kind of mass shared psychotic disorder may result; comparisons with Nazi Germany are not inapt.

Clinical features

This disorder often only becomes apparent over time and with observation. The few cases that we identify tend to fall into two categories. The first are those whose state of bliss is so profound that they totally neglect self-care. The rest are usually seen in custody after they have committed an offence under delusional influence. The characteristic underlying features of a delusional disorder have already been well described.

Differential diagnosis

The illness must be distinguished from the following.

- Mania, in which grandiosity is associated with euphoria, overactivity, and, at times, irritability and suspiciousness. As the mood is often volatile and/or phasic, so the grandiose features are unstable.
- Schizophrenia in which there is marked incongruity between ecstatic affect and relative thought poverty.
- Organic brain disorders, especially affecting the prefrontal cerebral lobes, which cause labile mood, disinhibited behaviour, and some degree of cognitive deficit. Cerebral syphilis (general paralysis of the insane) used to be the best-known exemplar.
- Antisocial personality disorder in which the individual feels above the law and may express grandiose ideas and behaviours. In these cases one finds evidence of lifelong impulsivity, lack of remorsefulness, and usually a long history of delinquency.

Epidemiology

We have virtually no information. The illness can occur in either sex and apparently at any age from adolescence onwards. It may appear gradually or suddenly.

Course and prognosis

As far as we know, the grandiose subtype is as chronic and unremitting as the other subtypes of delusional disorder. For many years the presence of grandiosity in any psychiatric disorder has been regarded as a bad prognostic factor. In delusional disorder this may be so, because a grandiose delusional system is particularly likely to be associated with spurning of treatment. Even if treatment begins to be effective, the abandoning of highly pleasurable beliefs may not be welcomed by some patients.

There may be forensic complications if grandiose delusions are acted out.

Treatment

This is discussed later when considering the overall treatment of delusional disorder.

Delusional disorder: mixed and unspecified subtypes

There is little to be added regarding these categories. In DSM-IV it is accepted that more than one delusional theme can exist side by side so that, provided that the form of the illness is that of delusional disorder, it is acceptable to have combined themes of, for example, hypochondriasis and persecution, persecution and grandiosity, erotomania and jealousy, etc.

The unspecified type is a residual category and again the illness must have the form of a delusional disorder, but the delusional content is one other than those specifically listed. No reliable data exist on either the mixed or the unspecified subtypes.

Other disorders with persistent delusions

As mentioned previously, ICD-10 has a category for 'other persistent delusional disorders' (F22.8), but this is too loosely worded to delineate any coherent clinical entity. Paraphrenia, as has been noted before (p. 283) is regarded by some, including the present author, to be a candidate for inclusion in an expanded category of delusional disorders but currently is not receiving official notice. Therefore, the only condition we shall consider here is delusional misidentification syndrome.

Delusional misidentification syndromes (DMIS)[52]

The abilities to recognize individual faces and to discriminate between different faces are fundamental human processes and normally we are extraordinarily adept at them. Changes in a familiar facial appearance can be unsettling and even frightening, in both children and adults. A great deal of sophisticated neurophysiological and neuropsychological investigation has been carried out on normal and abnormal face-recognition processes.

A number of clearly defined neurological disorders are associated with very specific abnormalities of face recognition.[53] Here we shall emphasize those cases in which a delusion of misidentification is the principal symptom of the disorder and in which the form or structure of the illness is in many ways similar to that of delusional disorder. These are the delusional misidentification syndromes. However, it is important to note that superficially similar presentations may occur as secondary features in cases of schizophrenia, severe mood disorder, or dementia, and in these we refer to a misidentification phenomenon rather than syndrome.

(a) Clinical features

There are four main variants of DMIS:

1 the Capgras syndrome, in which the individual falsely perceives that someone in his environment, usually a close relative or friend, has been replaced by an almost exact double

2 the Frégoli syndrome, where the patient believes that one or more individuals have altered their appearances to resemble familiar people, usually to persecute or defraud him or her

3 intermetamorphosis, in which the patient believes that people around have exchanged identities so that A becomes B, B becomes C, and so on

4 the syndrome of subjective doubles, where the patient is convinced that exact doubles of him- or herself exist, a kind of *Doppelgänger* phenomenon

Additional alternative forms have been described and sometimes features of more than one variant occur in an individual case, especially in the subjective doubles phenomenon.

Although the patient is convinced of the deception, he is often aware that something is wrong and that the replacements are subtly incorrect. Many sufferers are extremely distressed and frightened and fear impending harm. In some cases, they may become enraged and attack the 'impostor' with considerable violence. Their belief is of delusional intensity and they usually cannot be dissuaded by argument or by demonstration of contrary proof.

It is of particular interest that the misidentification is not indiscriminate but involves a limited number of usually familiar people. In some cases, substitution also involves places and objects. An admixture of depersonalization and derealization is not unusual, especially in the earlier stages.

(b) Classification

Delusional misidentification syndromes have not been included in DSM-IV or ICD-10, though if misidentification occurs in the setting of a psychotic illness like schizophrenia it is regarded as a feature of that illness. However, if it is the principal aspect of a psychosis it should be regarded as a disorder *sui generis*. In those cases where there is a discrete delusional system occurring in clear consciousness and within a relatively intact personality, it would seem logical to assign it as a new subcategory within Delusional Disorder (DSM-IV) or Persistent Delusional Disorders (ICD-10). In cases where organic brain disease is prominent, the proper assignment would be to Mental Disorders due to a General Medical Condition (DSM-IV) or Organic, Including Symptomatic, Mental Disorders (ICD-10).

(c) Diagnosis and differential diagnosis

The diagnosis is based on recognition of the delusional nature of the belief, the accompanying agitation, and uncharacteristic behaviours, possibly including violent attacks on others. A full neurological investigation is mandatory.

Differential diagnosis includes:

- Schizophrenia
- delusional disorder, persecutory subtype
- major mood disorder with delusions
- organic brain disorder
- substance abuse disorders.

(d) Epidemiology

The frequency of DMIS is unknown but an increasing number of cases are being reported. The disorder occurs in both sexes and across a wide age range, but particularly in the middle-aged and elderly.

(e) Aetiology

When DMIS was first recognized, attempts were made to explain its symptoms on psychodynamic grounds. Such theories have been almost totally undermined of late by the increasing recognition of significant brain pathology in a high proportion of cases.

Nowadays we have many reports on brain dysfunction in DMIS[18,54,55] but large case series are lacking. There is some consensus that abnormalities of the right cerebral hemisphere, especially temporoparietal, are especially likely to be present but are not

inevitable, and lesions in other cerebral locations have been found. The lesions can be regarded as causal of specific abnormalities of face recognition, a function mediated especially in the right hemisphere. Also, there appears to be dissociation of sensory information from its normal affective accompaniment and failure of suppression of inappropriately repetitive behaviours (also a right-sided function). These last two features are very typical of delusional disorders in general.

We know little of the biological substrate of delusional symptoms, but one proposal is that there may be a dysfunction of the limbic–basal ganglia mechanisms, with particular emphasis on dopamine overactivity. In DMIS there seems to be a breakdown in integration of information between the right parietotemporal cortex, the limbic system, and certain basal ganglia, resulting in the specific misidentification, associated with inappropriate emotion and inability to suppress abnormal thoughts and behaviours. Very tentatively it is possible to postulate a complex brain mechanism which normally integrates sensory and affective impulses and downregulates repetitive behaviour, and whose malfunction results in delusional beliefs, altered judgement, overintense mood, and inability to change or develop insight. The particular delusional content might be determined by the specific site within the mechanism at which the brain dysfunction occurred.[56]

Although the above is simply an attempt at a paradigm, it is also a model with potential for the study of delusional and concomitant phenomena by modern neurobiological investigative methods. It also allows us to conjecture about the general similarities and specific differences between DMIS and delusional disorder.

(f) Course and prognosis

Although DMIS may appear insidiously, it not infrequently appears relatively suddenly in a previously normal individual, presumably related to the underlying cerebral pathology. Where brain damage is substantial, the prognosis is that of the brain disease. If the brain dysfunction is more subtle and does not remit, the delusional symptoms may become chronic. Forensic complications may occur if the patient becomes violent,[47] and a small number of murders by patients have been reported in DMIS.

(g) Treatment

Acute treatment may involve sedation and antipsychotic medication. Ongoing treatment is by maintenance doses of an antipsychotic with possible addition of an anticonvulsant. Psychological counselling may be beneficial as the patient improves.

Folie à deux: a phenomenon which may accompany illnesses with delusions[57,58]

This phenomenon is listed as a psychiatric disorder in DSM-IV (Shared Psychotic Disorder, 297.3) and in ICD-10 (Induced Delusional Disorder, F24) but there is a conceptual difficulty in regarding it as a psychotic illness in its own right, as will be discussed shortly.

Folie à deux is a venerable term used to describe a situation in which mental symptoms, usually but not invariably delusions, are communicated from a psychiatrically ill individual (the 'primary patient') to another individual (the 'secondary patient') who accepts them as truth. As noted, DSM-IV and ICD-10 refer to this by different names and there have been several confusing changes of official terminology over the years. The older name, which is used as an alternative by DSM-IV, is well known to most psychiatrists and is used here by preference. However, *à deux* may sometimes be a misnomer since several people can be involved, and then we read of *folie à trois*, *folie à plusieurs*, *folie à ménage*, etc.

Taking the dyad as the classical situation, the two people are usually closely associated, especially husband–wife, siblings, or parent–child, and often live in social isolation. The content of the shared belief depends on the predominant delusion(s) of the primary patient and can include convictions of persecution, delusional parasitosis, belief in having a child who does not exist, misidentification delusions, and many others. There have been descriptions of shared persecutory and apocalyptic beliefs in quasi-religions and cults led by a charismatic leader with gullible followers. In many shared delusional examples there is a sense of antagonism from 'them' who may be defined or who may be what Cameron[59] referred to as the 'paranoid pseudocommunity', the hovering 'they' who carry out oppression which is evident to the sufferers but not to normal others.

Once thought rare, *folie à deux* has been increasingly described in the literature. Milder cases may not be recognized and, also, many delusional people strive to avoid psychiatric referral; collusion between primary and secondary patient in this has been noted. The physician should be aware of *folie à deux* and never overlook it.

'Shared psychotic' and 'induced delusional' both imply that two members of the dyad are psychotic. In delusional disorder the primary patient is psychotic but the recipient of the beliefs usually is not. Most often, the latter is highly impressionable and dependent and adopts the false beliefs because of their intense and unceasing transmission by the primary patient. Social isolation, accentuated by induced mistrust of 'them', discourages adequate reality testing. Thus one can say that the content of the secondary patient's false belief derives from psychotic thinking, but he or she is not usually psychotic.

Nearly all cases of *folie à deux* are reported in association with schizophrenia, delusional disorder, severe depressive disorder with delusions, or early dementia, but it is probable that the condition also sometimes coexists with non-psychotic illnesses such as obsessive-compulsive disorder, somatoform disorder, and histrionic–dissociative personality disorder, in which the beliefs are intensely held and communicated but are not delusional. This makes the DSM-IV and ICD-10 terms even less appropriate.

Subtypes

In practice, the great majority of cases are of the type described, sometimes known as *folie imposée* because the belief is impressed on the secondary patient.

However, one occasionally sees an alternative presentation, the so-called *folie simultanée*, in which two predisposed people develop illnesses with delusions and through long and over-close association come to share identical false beliefs. This is said to be likelier when there is a genetic link (for example two unmarried siblings) or when older people have lived together in considerable isolation for many years.

Classification

Folie à deux is included with schizophrenia and other psychotic disorders in DSM-IV and with schizophrenia, schizotypal, and delusional disorders in ICD-10, and is regarded as a separate psychotic illness. It would be better to treat it as an important clinical phenomenon, which may be associated with other identifiable mental disorders. However, rather than encourage pedantic argument, it is best to alert the clinician to its existence, its frequency, and, as will be seen, its importance.

Diagnosis

The phenomenon is recognized by the identical nature of the two individuals' false beliefs, their gross affective investment in these, and their refusal to accept alternatives even when overwhelming proof is presented. Careful history-taking will usually readily distinguish the primary from the secondary patient, but this can sometimes prove difficult. In the much less common *folie simultanée*, the distinction is largely irrelevant.

Epidemiology

This is unknown except that, by definition, it will occur most in association with an illness characterized by delusional beliefs or severely overvalued ideas, especially under isolated conditions, and it is by no means rare. It is extremely important for the clinician to be on the lookout for it. He or she may be convinced that a patient is expressing delusional ideas but be thoroughly perplexed when an apparently rational relative unswervingly supports these. This can lead to serious mismanagement of the case. Conversely, recognition of *folie à deux* may solve a baffling diagnostic problem and result in appropriate care for both individuals.

Aetiology

Folie à deux appears to arise from a combination of the following:

1 innate impressionability and marked dependence on the primary patient
2 personality traits such as suggestibility, low initiative, poor reality testing, etc. in the secondary patient
3 in some cases, low intelligence in the secondary patient
4 the intensity of the abnormal beliefs expressed by the primary patient
5 the length of time over which the abnormal beliefs have been imposed
6 the degree of social isolation

Treatment

In *folie imposée* the logical approach is to identify the primary patient and treat his or her mental disorder adequately. It may also be helpful to separate the two individuals for a time, for example by hospitalizing the primary patient. With both people, every attempt must be made to reduce social isolation and to reintroduce them to reality. If the primary patient's delusions improve with treatment, the secondary patient's beliefs usually also improve. It is rarely appropriate to treat the secondary patient with antipsychotic medication, although this is sometimes mistakenly done.

In *folie simultanée*, both patients require neuroleptic treatment.

Theoretically, treatment is straightforward but in practice it can be problematic. For example, the primary patient with delusional disorder often resists psychiatric help, and subterfuge and resistance by both individuals is common. In group situations, for example a cult, this resistance is likely to be widespread and intense, and will be justified by the participants in terms of religious, social and legal rights, which they claim are being suppressed. The propagators should be separated from the recipients as much as possible, and the treatment team has to expend much time and diplomacy in gaining some confidence and a degree of cooperation. Direct challenge of the beliefs in any shared delusional situation is usually totally counterproductive.

Mass suicide is a reported outcome of shared delusions in some cult situations and any danger of this must be countered with great urgency.[60]

Treatment of delusional disorder

There are special aspects to the treatment of delusional disorder, which need emphasis, especially since many clinicians are unfamiliar with them. The first is that we must realize that delusional disorder is indeed treatable, despite frequent pessimistic statements to the contrary. In fact, the greatest difficulty is not treatment responsiveness, but persuading the patient that he needs psychiatric help because his delusions militate against this. With careful diagnosis and an approach that encourages the patient to cooperate, delusional disorder can respond to treatment, which in all cases will primarily be by neuroleptics.

General aspects of the treatment of delusions[61]

We usually aim to treat the illness of which the delusion is a part, but there is good evidence that delusions themselves, as well as hallucinations, can be considerably modified by a psychological approach. In severe psychotic illnesses the initiation of psychological treatment usually has to follow the initial controlling of serious symptoms with medications or, on occasion, electroconvulsive therapy. Thereafter, a cognitive behavioural approach or, to a much lesser extent, conventional psychotherapy can help the individual to reduce preoccupation with false beliefs, become less isolated, and reorientate towards reality.[62,63] But there is no good evidence that psychological methods by themselves can completely eliminate established delusions.

Since many illnesses are associated with delusions we have to tailor the psychopharmacological approach to suit each particular condition. In delusional disorder, the schizophrenias, and schizoaffective disorder, neuroleptics are the mainstay, with antidepressants, mood stabilizers, and electroconvulsive therapy sometimes playing subsidiary roles.

The rate of symptom response to treatment in a psychotic disorder is not uniform. For example, hallucinations often resolve quite quickly, but delusions can be much more persistent. Despite vigorous treatment they can last for many months and, in some patients, never fully remit. If the patient continues to be deluded, non-compliance with treatment is likely to be present, especially in delusional disorder where the individual is often expert at concealing his or her lack of cooperation. At present it appears that all the subtypes of delusional disorder are potentially responsive to treatment. If treatment fails, always consider non-compliance before abandoning the current approach.

Treatment approaches

Since so many delusional disorder patients actively resist seeing a psychiatrist, it is best to see them in a non-psychiatric setting if possible, for example in the office of the referring specialist or family physician. The psychiatrist who treats cases of delusional disorder needs much patience and tact, and it is common to spend one or more sessions first gaining the individual's confidence and finally persuading him to give a psychotropic medication a trial. Many of them argue vehemently and with well-organized pseudologic against the premise that they are mentally ill and use all kinds of sophistry to deny the need for a neuroleptic, but a calm and persistent approach will gain cooperation in a good proportion of cases.

Whatever neuroleptic is prescribed it is essential to begin with the lowest effective dose. This dose is only raised if required and then very gradually to avoid side effects which are guaranteed to prompt withdrawal from treatment. The patient should be seen at least once a week as an outpatient in the initial stages. Inpatient treatment is not often indicated, although forensic cases will nearly always be seen in an institutional setting.

With a positive treatment response it is not unusual to see minor improvements in a few days, such as reduced agitation, a slight increase in well-being, improved sleep, and a little less preoccupation with the delusion. On average it is about 2 weeks before the delusional system is significantly ameliorated, but in some patients this may take 6 weeks or more.

Quite often if this degree of improvement occurs the patient decides that there is no further need of treatment and stops it. Within days or weeks there is an inevitable return of the delusion with its accompanying agitation and preoccupation. It is then that the psychiatrist must be available to encourage resumption of medication. Although at this stage the patient still believes in his delusions, the experience of improvement followed by relapse makes a deep impression and, given trust in the therapist, often leads to long-term cooperation.

It is striking that good recovery is often relatively rapid and can be surprisingly complete, even when the illness has been present for many years. Some patients return to a considerable degree of intrapsychic, interpersonal, and occupational functioning, with little evidence of the personality disorder that is supposed to be so prevalent in delusional disorder. Also, many patients require surprisingly little counselling or psychotherapy in resuming a reasonable life, although these should always be available if required. Such results suggest that this profound illness may be due to a relatively circumscribed brain abnormality and also that, in some cases at least, a very insidious onset may cause initial symptoms, which mimic personality disorder.

In most cases, treatment has to be continued for an indefinite period since delusional disorder is potentially a lifelong illness. Naturally the drug dosage should be the lowest, which keeps symptoms under control and this maintenance dose is often very low indeed. Perhaps up to one-third of patients can eventually be weaned successfully from medication, but we have no means of predicting who these will be, so that any reduction in effective treatment must be carried out with extreme caution. Sadly, a proportion of relapses are due to injudicious withdrawal of treatment by a physician and we must assume the need for treatment to be permanent unless proved otherwise. It is interesting that successfully treated patients, whether on maintenance drugs or not, keep a lookout for subsequent recurrences themselves and may report that tension-inducing circumstances provoke some reappearance of symptoms. Such patients may then request to have their medication resumed or increased.

There is no necessary correlation between acquired insight into the desirability of taking one's medication and true insight into the illness itself. Many patients never fully accept the psychotic nature of their experience, but as long as they are benefiting from treatment and are functioning reasonably there is nothing to be gained from challenging them on this. If, despite treatment, the delusions remain intrusive, cognitive behavioural therapy and counselling should be available,[62,63] but intrusive psychotherapy must be avoided.

Overall, the best-attested treatment results refer to the somatic subtype, with smaller literatures on the erotomanic, jealousy, and persecutory subtypes, and virtually nothing on the grandiose form. A wide variety of neuroleptics have been reported, but for a considerable time pimozide, a diphenylbutylpiperidine, was the drug of first choice.[64] Recently a study by Manschrek and colleagues[65] has apparently shown that some of the newer atypical antipsychotics can produce comparable results. Antidepressants and benzodiazepines are ineffective as first-line treatments and monoamine oxidase inhibitor antidepressants are absolutely contraindicated.

Currently, the best estimate of treatment outcomes is that, if the diagnosis is correct, the patient compliant, and the treatment adequate, recovery (defined as 'return to full function with total or near-remission of symptoms') occurs in approximately 50 per cent of all patients, and a further 30 per cent will show significant but less complete improvement. An unknown, but considerable, proportion of those who show no improvement can be assumed to have been non-compliant. Although mostly based on non-blind trials, these figures are culled from a worldwide literature, which does show considerable consistency.

Recognition and treatment of postpsychotic depression

Ten per cent or more of delusional disorder patients whose illness responds to neuroleptics experience significant degrees of mood disorder during recovery, sometimes very severe depression with suicidal risks.[66] This has also been noted in recovering schizophrenics. Various explanations have been proposed such as a medication side effect or perhaps the achievement of painful insight. The most likely reason is neurochemical, due to rapid changes in neurotransmitter balance.

If the neuroleptic is withdrawn, the depression tends to improve but the delusions return. Therefore the proper approach is to continue with the minimum effective dose of neuroleptic and to add an antidepressant drug in an effective dose. Occasionally, in extremely severe cases, electroconvulsive therapy is required. Subsequently the neuroleptic is continued but, in most instances, the antidepressant can be gradually reduced.

All cases of delusional disorder should be monitored for the possible emergence of mood symptoms during recovery and treatment immediately instituted if necessary. If suicidal symptoms appear, inpatient admission is highly recommended.

Conclusions

Paranoia/delusional disorder is unique in psychiatry in that it is virtually a newly discovered illness, yet much of the fundamental descriptive work was done a century or more ago. This long hiatus means that most practitioners have little knowledge or experience of the disorder, and the few who are aware of it usually only see a small part of the fabric. The dermatologist treats a case of delusional parasitosis, the cosmetic surgeon has an impossible patient wth a dysmorphic delusion, the lawyer does not know what to do with a totally unreasonable litigant, the police officer has to deal with a jealous murderer or an erotomanic stalker, and the personnel officer has an employee who is convinced his fellow workers are persecuting him, etc. How can we draw all this scattered material together and add it to the psychiatric literature to make a whole cloth? The answer is largely by consciousness raising and education.

Kendler, an authority in this field, has said, 'The paranoid disorders may be the third great group of functional psychoses, along with affective disorder and schizophrenia'.[67] If he is correct, it is imperative that we hone our diagnostic and treatment skills in order to improve the help we might offer to delusional disorder sufferers and to facilitate research which is so badly needed.

Mood disorders

Contents

4.5.1 Introduction to mood disorders

John R. Geddes

Mood and disorders of mood

The concept of mood is difficult to define. In psychiatry, it has come to mean a pervasive emotional tone varying along an axis from happiness to sadness—and perhaps anxiety. The boundaries between normal and abnormal mood are equally difficult to define. Nonetheless, there is usually no doubt about the most extreme manifestations of low mood, **depression**, or elevated mood, **mania**.

Early history

Descriptions of variations in mood which go beyond normal limits and are associated with functional impairment are present in the oldest writings of mankind.[1] The ancient Greeks identified that mood disorders were diseases of the body, rather than the effects of supernatural spirits and identified the link between elevation of mood and states of despondency or depression. The Hippocratics also identified that mental disorders were located in the brain. This insight was lost for 2000 years under the influence of Galen's humoral theory which held that melancholia was due to an excess of black bile and mania due to an excess of yellow bile. During this period, attempts to put forward empirical theories in both Western and Eastern civilizations often fell foul of increasingly dominant religious dogma.

Development of modern psychiatric nosology

In Europe, during the Enlightenment of the seventeenth and eighteenth centuries, reason and empiricism once again emerged. In *Anatomy of Melancholy*, published in 1632, Richard Burton provides a comprehensive review of previous writings on mood disorder.[2] Burton, who writes with the penetrating insight of someone with extensive personal experience of mood disorder, clearly makes the link between mood elevation and enhanced creativity, cycling with periods of low mood, when all pleasure is lost:

> When I go musing all alone
> Thinking of divers things fore-known.
> When I build castles in the air,
> Void of sorrow and void of fear,
> Pleasing myself with phantasms sweet,
> Methinks the time runs very fleet.
> All my joys to this are folly,
> Naught so sweet as melancholy.
> When I lie waking all alone,

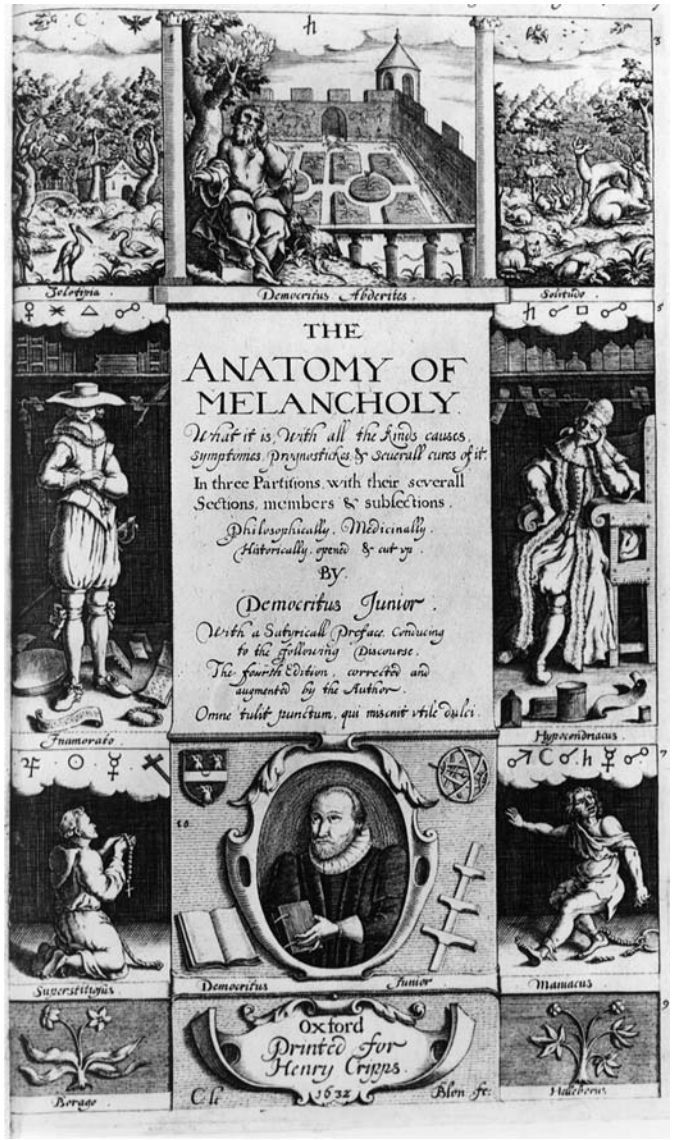

Fig. 4.5.1.1 Frontispiece to Burton's *Anatomy of Melancholy.*

Recounting what I have ill done,
My thoughts on me then tyrannise,
Fear and sorrow me surprise,
Whether I tarry still or go,
Methinks the time moves very slow.
All my griefs to this are jolly,
Naught so mad as melancholy.

(extract from The Author's Abstract of Melancholy, *Anatomy of Melancholy*)

Burton's work is an erudite and comprehensive review of the work on mood disorders until the early seventeenth century, although of course not systematic in the modern sense. Following Burton, Thomas Willis (1621–1675), Sedleian Professor of Natural Philosophy at Oxford University, perhaps better known for his description of the eponymous circle of Willis, is now recognized as one of the first to (re)localize psychiatric disorders within specific body organs, primarily the brain, rather than due to the circulation of bodily humours. In *Cerebri anatomi* (1664) Willis writes[3]:

> Melancholy is a complicated distemper of the brain and heart. For as melancholick people talk idly, it proceeds from the vice or fault of the brain and the inordination of the animal spirits dwelling in it, but as they become very sad and fearful, this is deservedly attributed to the passion of the heart. But we cannot here yield to what some physicians affirm, that melancholy doth arise from a melancholick humour. Melancholy being a long time protracted, passes oftentimes into stupidity, or foolishness, and sometimes into madness.

This identification of the physical brain as the location of the involved pathological processes initiated the modernist project of the scientific study of serious mood disorder, using contemporarily available scientific methods to generate insights into diagnosis, aetiology, course, and treatment. The first steps in this project were diagnosis and classification. Modern psychiatric diagnostic systems can be traced to post-Enlightenment Europe—in particular, France. The development of the mental hospital system throughout Europe provided the populations of patients for the early psychiatrists to study, as they created and refined diagnostic systems. In 1854, Esquirol described *la folie circulaire* which remains a recognizably modern description of bipolar disorder.[4] Despite this, the prevalent view throughout the nineteenth century was that manic and depressive states were separate entities. At the turn of the twentieth century, Kraepelin distinguished *dementia praecox* from *manic-depressive insanity*[5] Kraepelin emphasized the episodic course of the latter, the relatively benign prognosis and the family history of mood disorder.

Expanding the scope of mood disorder and recognition of diagnostic heterogeneity

In the twentieth century, diagnostic systems that had derived from the populations of large mental hospitals were challenged by the recognition that mental disorders were widespread in milder forms in the general population. Under the influence of Freud, Bleuler expanded Kraepelin's original concept of dementia praecox to include some of the less severe forms that he identified in the general population and renamed the disorder *schizophrenia* to reflect his views of the fundamental psychology of the psychosis.[6] A similar process to this occurred with the mood disorders, eventually leading to the recognition that milder, albeit still severe enough to cause impairment of function, forms of depression, and anxiety were the commonest forms of mental disorder in the general population. Indeed, after the World Health Organization and World Bank's Global Burden of Disease study in the 1990s, it became clear that unipolar depression was the among the most important causes of disability worldwide.[7] With the expansion in the scope of mood disorders, it was recognized that there is also heterogeneity in the way in which mood disorders manifest themselves. There was debate about existence of subtypes of depression, often based on the severity of symptoms and hypothesized links to an underlying brain process. For example, Gillespie's *reactive depression* in which the depressive disorder develops in response to external circumstances and remains subject to influence by external influences during its course, can be contrasted with *endogenous* and *melancholic* subtypes which were held to arise from a primary neurobiological abnormality.

The distinction between unipolar and bipolar disorders

Despite having some descriptive clinical utility, most postulated depressive subgroups have remained of uncertain status. The distinction between unipolar and bipolar disorders, however, has become accepted and is included in modern diagnostic systems. Initially, during the twentieth century, diagnostic systems continued to maintain the Kraepelinian approach to mood disorder with *manic-depressive insanity* including both severe mania and depression.—i.e. illnesses that were characterized only by depressive episodes and illnesses which included both poles.

The school of Kleist and Leonhard identified the heterogeneous nature of patients with manic-depressive illness—some had both manic and depressive episodes while others had only depressions. They coined the terms bipolar and unipolar to describe these two forms. Carl Perris and Jules Angst later provided some empirical validation for the separation on the basis of family history.[8,9]

Modern diagnostic systems—the birth of diagnostic criteria

Under the influence of psychoanalytic thought, psychiatric diagnoses had become very vague and unreliable by the 1960s—particularly in the United States where psychoanalysis was particularly influential. Following the observation that schizophrenia was more prevalent in the United States than in United Kingdom, the US–UK Diagnostic project showed conclusively that the apparent differences appeared to be due to the differences in diagnostic practice rather than true differences in prevalence.[10] The US–UK Diagnostic project highlighted the unacceptable reliability of psychiatric diagnoses which fuelled the arguments of critics of psychiatry. It was recognized that more reliable diagnostic systems were required which were explicitly based on evidence of validity. The defining feature of these systems was the use of explicit diagnostic criteria and, historically, the most important of these was the third edition of the Diagnostic and Statistical Manual of the American Psychiatric Association.[11]

International classification systems were based on compromise between national views rather than evidence and were therefore slower to change. The ninth edition of the World Health Organization's International Classification of diseases retained the concept 'Manic-Depressive Illness' which included both unipolar and bipolar disorders. However, the distinction was finally made in the 10th edition in 1993.[12]

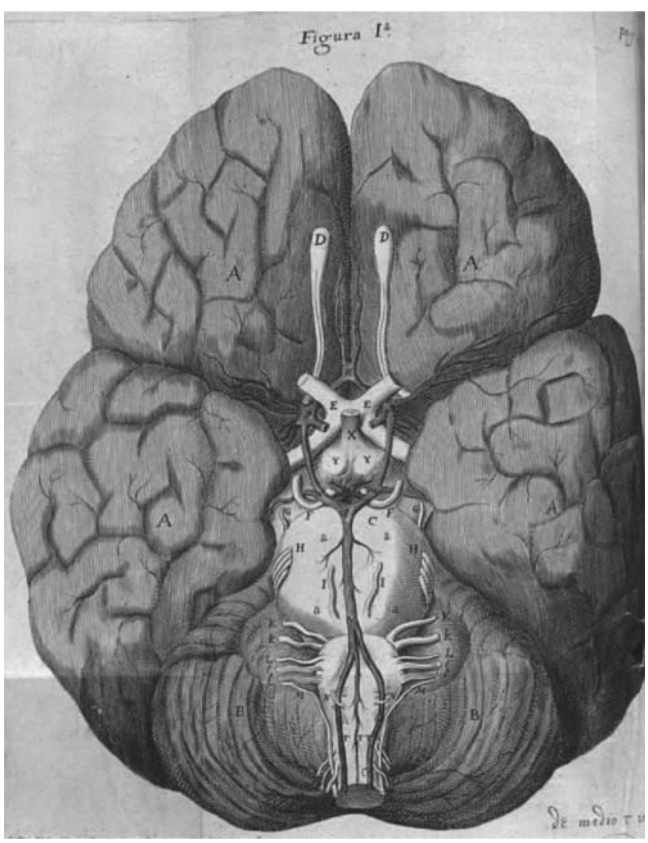

Fig. 4.5.1.2 Illustration by Christopher Wren from *Cerebi anatome* by Thomas Willis.

Refining the concept—subgroups of unipolar and bipolar disorder

As well as the fundamental Kraepelinian distinction between mood disorders and schizophrenia and the subsequent distinction between unipolar and bipolar mood disorders, there have been several attempts to subclassify mood disorders.

Unipolar disorder

A crucial distinction has been made between *endogenous* and *reactive* forms of unipolar depressive disorder (see above). Current classifications do not emphasize the distinction because it is now recognized that both typical endogenous and reactive clinical pictures can be related to external stressors. Nonetheless, the concept of a melancholic subtype remains.

Bipolar disorder

As more is known about the epidemiology of bipolar disorder, it has become apparent that some people do not experience manic episodes, but nonetheless do experience episodes of mood elevation that are clearly noticeable to themselves and others (hypomania)- as well as depressive episodes. To accommodate these heterogeneous clinical pictures, bipolar disorder has been divided into bipolar disorder, type 1 (mania ± depression) and bipolar disorder, type 2 (hypomania + depression). A focus of intense current research is the concept of bipolar spectrum disorder—in other words, the recognition that there is probably a continuum of mood phenomena from normal mood through to extreme mania.

Future developments in the classification of mood disorders

We can expect more changes in the diagnostic classification as knowledge continues to accrue. Our current classifications remain entirely descriptive, based on cross-sectional clinical symptoms and longitudinal course. As such, the classifications have been therapeutically useful—we now have increasing evidence for the diagnosis-specific effects of treatments. In the future, as out knowledge of the basic neurobiology of mood disorder increases, incremental or fundamental changes may be required.

4.5.2 Clinical features of mood disorders and mania

Per Bech

Introduction

The clinical features of mood disorders are dimensional, i.e. distributed according to their severity.[1] The categorical approach as manifested in the DSM-IV or ICD-10 does not, however, preclude dimensional descriptions, because in DSM-IV as well as in ICD-10 the categories or diagnoses are essentially defined by minimum and maximum cut-off scores on the symptomatic states.

Fig. 4.5.2.1 shows a coordinate system in which the ordinate represents the dimension of manic states and the abscissa the dimension of depressive states. The cut-off scores refer to the standardization of the isometric rating scales for mania and depression.[1–3] Jamison[4] has argued that the term 'bipolar' perpetuates the notion that: '. . . depression exists rather tidily segregated in its own pole, while mania clusters off neatly and discretely on another. This polarisation of two clinical states flies in the face of everything that we know about the fluctuating nature of manic-depressive illness . . . and it minimises the importance of mixed manic-depressive states'. William James referred to the stream of consciousness to emphasize its continuity in contrast to its conception as a series of discrete states. However, William James actually confessed that during his own depressive episodes, his mood states,[5] to a large extent, blocked his own stream of consciousness.[6] In the perspective outlined by Jamison,[4] polarity in the clinical world is not two opposites that contradict each other by a logical relationship of juxtaposition. Polarity should rather, as shown in Figs. 4.5.2.1 and 4.5.2.2, be considered at a level of psychological intercorrelations in which clinical mania and depression exist by virtue of each other involving both negative and positive correlations.

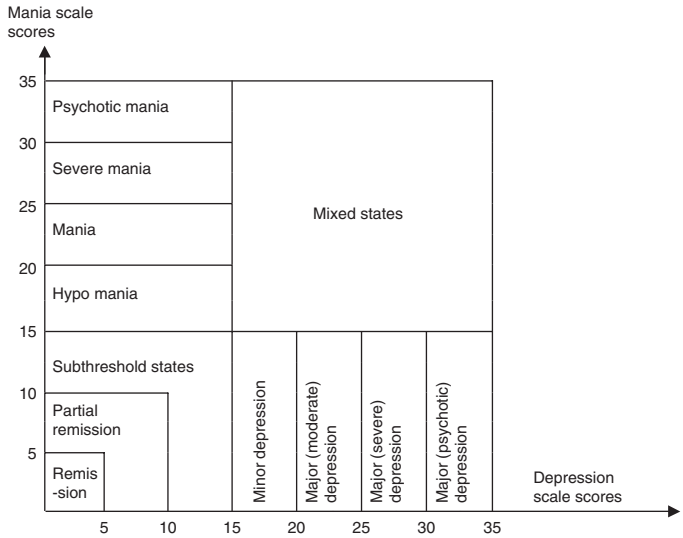

Fig. 4.5.2.1 Patient state fluctuations within the spectrum of mood states from the subthreshold states over minor mood states (hypomania or minor depression) to major states (mania/psychotic mania or major depression without or with psychotic symptoms) and to the mixed states.

The symptom rating scales shown in Fig. 4.5.2.1 measure the severity of mania, depression, or mixed states and have a time frame of 3 days. Clinically, this is the minimum for the measurement of the spectrum of mood states ranging from subthreshold states to states of psychotic severity.

Ultrashort states of mood swings are often seen without any reference to mood disorders. In one of Henry James' masterpieces, The Ambassadors, his autobiographical hero has a tendency towards being introverted in the morning, while in the afternoon and evening he is more extraverted, like a man ' . . . who, elately finding in his pocket more money than usual . . . ', though without spending a lot. This 24-h 'cyclothymia' between introversion and extraversion displays too mild a symptomatology to be part of a 'bipolar' disorder and might be referred to as a temperamental neuroticism. Thus, Eysenck's original questionnaire for measuring neuroticism included items of being moody without any apparent reason or being inclined to having frequent ups and downs in mood.[7] Neuroticism now seems to include subclinical, temperamental, low, negative affectivity (worrying, gloomy, dysphoric, and hostile).

Fig. 4.5.2.2 shows another coordinate system in which the ordinate is representing the dimension of mania severity and the abscissa the dimension of depression severity, but covering the lifelong correlation of the courses of manic and depressive episodes,

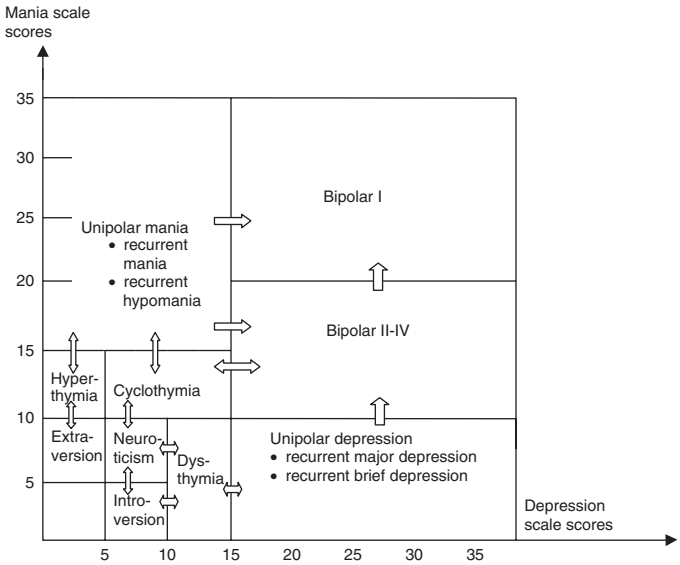

Fig. 4.5.2.2 Patient state lifetime fluctuations within the spectrum of mood polarity syndromes or disorders from the temperamental neuroticism over minor disorders (dysthymia or cyclothymia) to major unipolar disorders (hypomania/mania or brief/major depression) and to the various bipolar disorders.

i.e. the longitudinal diagnosis of mood polarity disorders. While a unipolar course of manic episodes without any depressive episodes is very rare,[8] the course of unipolar depressive episodes without manic episodes is much more frequent. Angst[9] has criticized the DSM-IV definitions of depressive episode disorders (a duration of at least 2 weeks) and of manic episode disorder (a duration of at least 1 week). Thus, Angst has shown that these episode duration criteria are not only too narrow (not sensitive enough), but they also lack empirical evidence (not validated). The spectrum of mood polarity as shown in Fig. 4.5.2.2 is an attempt to refer to the DSM-IV definitions, though modified with reference to Angst.[9] The mood polarity disorder as shown in Fig. 4.5.2.2 is defined by the highest score a given patient has obtained in the coordinate system at any time. Unipolar depression, however, with a score of 10 or less on the mania scale, as shown in Fig. 4.5.2.2, remains a lifelong uncertain diagnosis. Thus, Angst[9] has demonstrated a persistent risk of 1–2 per cent per year of a diagnostic change from unipolar to bipolar disorder.

The dimensional approach has been valid also in regard to personality disorder. As discussed by Angst,[9] only around 15 per cent of the general population seem to report no lifelong personality disorders, and he therefore calls these persons 'supernaturals'. Thus, nearly everyone has some kind of personality disorder, and within the spectrum of mood personality disorders, extraversion, introversion, neuroticism, hyperthymia, dysthymia, and cyclothymia are to be considered subthreshold disorders as shown in Fig. 4.5.2.2.

It has recently been argued that when taking into account both the subthreshold levels of symptoms and the short states of 2–3 days' duration rather than the whole DSM-IV episodes, there appears to be a linear correlation between mania and depression in the course of illness in many patients with mood disorders.[10]

The depressive episode: duration and severity

Table 4.5.2.1 shows the DSM-IV and ICD-10 depressive symptoms for the diagnosis of major depression, which to a large extent covers the rating scale dimension in Fig. 4.5.2.1. Thus, the individual symptoms should be present most of the day and nearly every day during an episode. Kendler and Gardner[11] have shown that the risk of developing a new major depressive episode (i.e. of a duration of 14 days or more) is as high for patients with major depressive symptoms lasting from 5 to 13 days as for patients with symptoms lasting from 14 to 59 days.

The study by Kendler and Gardner[11] has also demonstrated that patients with a subthreshold quantity of depressive symptoms (i.e. just below five out of the nine DSM-IV symptoms listed in Table 4.5.2.1 or minor depression in Fig. 4.5.2.1) had the same risk of developing a new major depressive episode as patients fulfilling the symptomatic criteria of major depression. It has been shown that approximately 50 per cent of the patients fulfilling the ICD-10 category of mild depression also fulfil the criteria for DSM-IV major depression.

To illustrate how a major depressive episode often develops on a continuum of depressive symptoms from the first prodromes of decreased positive well-being (introversion) to the major depressive episode, a layman's description is shown in Box 4.5.2.1. These autobiographical notes of the late William Styron (1925–2006) describe his first episode of depression at the age of 60.[12] As indicated, the symptom of anxiety (not included in DSM-IV or ICD-10) is a very important symptom of major depression from its very onset. When suicidal impulses developed, he was admitted to Yale New Hospital.

Table 4.5.2.1 Depression symptoms as included in DSM-IV and ICD-10

	Symptoms of depression	DSM-IV	ICD-10
1	Depressed mood most of the day, nearly every day	+	+
2	Markedly diminished interest or pleasure in all, or almost all, activities most of the day, nearly every day	+	+
3	Loss of energy or fatigue nearly every day	+	+
4	Loss of confidence or self-esteem	–	+
5	Unreasonable feelings of self-reproach or excessive or inappropriate guilt, nearly every day	+	+
6	Recurrent thoughts of death or suicide, or any suicidal behaviour	+	+
7	Diminished ability to think or concentrate, or indecisiveness, nearly every day	+	+
8	Psychomotor agitation or retardation nearly every day	+	+
9	Insomnia or hypersomnia nearly every day	+	+
10	Change in appetite (decrease or increase with corresponding weight change)	+	+

+ indicates that the symptom is included; – indicates that the symptom is not included.

Box 4.5.2.1 The stages from decreased positive well-being through mild depression to major depression without psychotic features

- The shadows of nightfall seemed more sober, my mornings were less buoyant, walks in the woods became less zestful, and there was a moment during my working hours when a kind of panic and anxiety overtook me, just for a few minutes, accompanied by a visceral queasiness . . .
- . . . As the disorder gradually took full passion of my system, I began to conceive that my mind itself was like one of those outmoded small-town telephone exchanges, being gradually inundated by flood-waters.
- . . . I particularly remember the lamentable near disappearance of my voice . . . The libido also made an early exit . . . food, like everything else within the scope of sensation, was utterly without savor.
- . . . My few hours of sleep were usually terminated at three or four in the morning, when I started up into yawning darkness . . . I'm fairly certain that it was during one of these insomnia trances that there came over me the knowledge that this condition would cost me my life, if it continued on such a course . . . I had not conceived precisely how my end would come. In short, I was still keeping the idea of suicide at bay . . . What I had begun to discover is that the grey drizzle of horror, induced by depression, takes on the quality of physical pain . . .

(from W. Styron (1990), *Darkness visible. A memoir of madness*, Random House, New York.)

Major depression with or without melancholia

Negative beliefs such as 'loss of self-esteem' or 'inappropriate guilt' are among the most specific core symptoms of major depression. Inappropriate guilt can be experienced as a punishment for past misdeeds (prior to the current episode of depression). The prevailing element of negative beliefs is a sense of loss which is associated with lower self-esteem experienced retrospectively. The symptom which discriminates best between anxiety states and major depressive disorder is guilt.

However, also states of anxiety with worrying and panic are important symptoms of depression. Anxiety is among the core items of the Hamilton Depression Scale.[13] Patients suffering from subthreshold depression experience less anxiety than patients with major depression. Another important symptom of depression included in the depression dimension of Fig. 4.5.2.1, but not in Table 4.5.2.1, is emotional and social withdrawal. Within the flux between mania and depression, this is probably another specific symptom (the emotionally intrusive behaviour in mania is its opposite pole).

Both in DSM-IV and ICD-10, major depressive states can be further specified as melancholic or somatic syndromes. In earlier descriptions (including Freud's 'Mourning and melancholia'), endogenous or somatic depression is distinguished from psychogenic or reactive depression by 'early morning awakening' and 'depression regularly worse in the morning'. These two signs are the only features of somatic or melancholic depression not included in the list of symptoms in Table 4.5.2.1. Strictly speaking, diurnal variation of symptoms is not a symptom itself, but rather a description of the fluctuation. The most 'somatic' symptom in Table 4.5.2.1 is change in body weight (Styron had lost 20 to 25 pounds over a period of 6 weeks, when the illness developed into a major depression).[14]

Styron's depression (Box 4.5.2.1) included the somatic feature of early morning awakening and suicidal thoughts. The latter are not just a consequence of the other symptoms. Styron described how during depression he could still keep '…the idea of suicide at bay…'. At a later stage (not shown in Box 4.5.2.1), just before he was admitted to hospital, Styron tried to write a suicide letter. Suicidal thoughts were often present late at night, when anxiety symptoms had lifted.

Measurements of social behaviour and subjective distress have shown that acute major depression is one of the most disabling and distressing of medical disorders.[6] The constant mental pain and the suicidal symptoms seriously affect quality of life. The suicidal risk in major depression is especially high when psychomotor retardation is improving in the course of treatment. The treating physician or the relatives typically observe improvement in the depressive symptoms before the patient does, because psychomotor retardation improves before mood state or hopelessness do. The risk is especially high in socially isolated people. Major depression has the highest risk of suicide of all mental disorders, and all patients with major depression should be assessed for the risk of suicide. It has been shown that patients with unipolar depression have higher suicide rates than patients with bipolar I and bipolar II disorders. However, concerning the core items of severe depressive states, no differences in the intensity of symptoms have been seen between unipolar and bipolar patients.

Major depression with psychotic features

According to DSM-IV or ICD-10, the term 'psychotic depression' is not synonymous with endogenous or melancholic depression. This agrees with Hamilton[13] who used the term 'psychosis' to refer to the severity of symptoms. As stated by Hamilton:[13] ' . . . a schizophrenic patient, who has delusions is not necessarily worse than one who has not, but a depressive patient who has is much worse . . . '.

Recurrent depression

Recurrent major depression

After a single episode of major depression, around 85 per cent of patients experience recurrent episodes. While the first episode of major depression is often provoked by a negative life event such as loss of job, retirement, marital separation or divorce, subsequent episodes are often unprecipitated (but positive life events can also provoke depression). Depressive episodes typically increase in frequency and duration as they return.[3]

Recurrent brief depression

The symptoms of recurrent brief depression, first described by Angst, are similar to those of major depression (Table 4.5.2.1) with regard to both number and severity. Recurrent brief depression is a

state of major depression lasting 2–3 days. Its diagnosis has not been adopted fully in DSM-IV, but it is included in ICD-10. It should be distinguished from recurrent suicidal behaviour, for example in patients with borderline personality disorder.

Seasonal depression

Seasonal depression is seen most frequently in winter, and less frequently in summer. In DSM-IV, seasonal depression has been adopted as a specifier (rather than a diagnostic category) which can be applied not only to recurrent depression but also to bipolar disorder. The seasonal episodes (e.g. winter depression) have to outnumber any non-seasonal depressive episodes in the same patient. In ICD-10 only seasonal depression is briefly mentioned, but only in an annex for disorders under consideration.

According to DSM-IV, the symptoms of seasonal depression are similar to those of major depression. However, it has been shown that the symptoms differ from those of major depression, with hypersomnia, overeating, carbohydrate craving, and weight gain (often referred to as atypical depression).

Atypical depression

DSM-IV atypical depression has a specifier which can be applied both to major depression and to bipolar I and bipolar II, but also to dysthymia. The core item is mood reactivity (i.e. the mood brightens in response to actual or potential positive events), while the associated symptoms are hypersomnia, overeating, and weight gain, leaden feelings in arms or legs, and interpersonal rejection sensitivity. It has been shown that mood reactivity is more often seen in bipolar II disorders than in unipolar depression disorders.

The manic episode: duration and severity

Table 4.5.2.2 shows the symptoms of mania according to DSM-IV and ICD-10, which to a large extent covers the rating scale dimension in Fig. 4.5.2.1. The episode criteria for hypomania and mania are shorter than those for major depression. For hypomania, the symptoms should have lasted at least 4 days, and it has been suggested to accept as little as 2 days (e.g. for states of hypomania).[15] In DSM-IV, but not in ICD-10, the category bipolar II disorder has been adopted (Fig. 4.5.2.2), referring to patients with a major depressive episode, who previously have experienced episodes of hypomania. It has been shown that patients with cyclothymia have the same risk of developing bipolar II depression as patients with hypomania. It has been proposed to extend the bipolar spectrum to include a category of bipolar III to refer to depressed patients who have developed hypomania episodes during treatment with antidepressant medication,[16] while bipolar IV refers to depressed patients having a substance-induced hypomania.

Table 4.5.2.2 Manic symptoms as included in DSM-IV and ICD-10

	Symptoms of mania	DSM-IV	ICD-10
1A	Elevated mood	+	+
1B	Irritable mood	+	+
2	Increased self-esteem or grandiosity	+	+
3	Decreased need for sleep	+	+
4	Increased talkativeness	+	+
5	Flight of ideas	+	+
6	Distractibility	+	+
7A	Increased social activities or contacts	+	+
7B	Psychomotor agitation	+	+
8	Risk taking behaviour	+	+
9	Increased sexual activities	–	+

+ indicates that the symptom is included; – indicates that the symptom is not included.

Patient-reported questionnaires have recently been published to identify previous episodes of hypomania in depressed patients. It has been shown that the Hypomania Checklist[17] is superior to the Mood Disorder Questionnaire in identifying patients with bipolar II disorder.

The problem with self-reported questionnaires to measure manic symptoms is that many patients do not perceive their hypomanic symptoms as pathological. They may describe themselves as 'normal' or their response pattern may show that they play 'the manic game'.

Studies with clinician-rated mania scales have shown that the various symptoms in Table 4.5.2.2, when quantified, can be rank-ordered in one single dimension of severity, analogously to the depressive symptoms in Table 4.5.2.1. This is illustrated by Box 4.5.2.2, which lists the three stages of mania from the longitudinal study by Carlson and Goodwin[18] on hospitalized patients in the untreated stage of their illness.

Hypomania

Hypomania can be the first stage of a spiralling upswing of mood (Box 4.5.2.2). According to DSM-IV, hypomania is more in concordance with the following description by Jamison[4] than with Box 4.5.2.2: ' . . . When you're high it's tremendous. The ideas and feelings are fast and frequent . . . Shyness goes, the right words and gestures are suddenly there, the power to captivate others a felt certainty . . . Sensuality is pervasive and the desire to seduce and be seduced irresistible'. The shyness or introversion seen in mild depression or dysthymia contrast with the lack of shyness and extraversion seen in the hypomanic patient.

As described in Box 4.5.2.2, the dysphoric or irritable mood is often a core symptom of hypomania, which in the next stage of mania develops further, to cooperation difficulties and impulsive hostility. Although hypomania might cause hyperactiveness in social functioning,[15] the more or less hidden hostility often causes marked impairment in the hypomanic individual's ability to pursue some necessary task or to maintain an acceptable contact with family members. In this respect, therefore, dysphoric hypomania may cause as much clinically significant impairment in social functioning as cyclothymia.

Mania without psychotic features

In mania, the elevated spirit seen in hypomania is often mixed with irritability and hostility. Jamison[4] has described the change: 'Humor and absorption on friends' faces are replaced by fear and concern. Everything previously (in the hypomanic state) moving with the grain is now against—you are irritable, angry, frightened, uncontrollable . . . '.

Box 4.5.2.2 The three stages of the acute manic episode as observed in untreated inpatients

- **Hypomania**

  Increased well-being and/or irritable mood, more busy, pressured speech, makes more telephone calls, seductive

- **Mania**

  Nearly always pleasant and cheerful. Occasionally losing insight and cooperation, impulsive, angry, very hyperactive, less sleep, more pressure of speech, makes repeated telephone calls, racing thoughts, more expansive, some grandiosity

- **Mania with psychotic features**

  Emotionally labile, can be very angry, very intrusive. Uncooperative, severely agitated, no sleep, very talkative, loud, flight of thoughts, grandiosity, religious delusions 'hearing God', sexually very preoccupied

(modified from G.A. Carlson and F.K. Goodwin (1973), The stages of mania. A longitudinal analysis of the manic episode, *Archives of General Psychiatry*, **28**, 221–8.)

The psychomotor symptoms of mania are restlessness and less need for sleep. There is pressure of speech; the patient talks more and in a louder voice. There is intrusive behaviour, arguments, and attempts to dominate others. Expansiveness is manifested as increased self-esteem; for example, the patient clearly overestimates his or her own capacities or hints at unusual abilities. Jamison[4] has described how in periods of mania she did not worry about money: 'The money will come from somewhere; I am entitled; God will provide. Credit cards are disastrous, personal cheques even worse . . . mania is a natural extension of the economy . . . So I bought precious stones, elegant and unnecessary furniture, three watches within an hour (in the Rolex rather than Timex class) . . . '.

To be diagnosed as a manic episode, the disorder should last at least a week. The criteria for mania are elevated or clearly irritable mood, and at least three of the symptoms listed in Table 4.5.2.2. These symptoms should be severe enough to cause marked impairment of occupational functioning. Hospital admission is often needed to prevent the patient from harming him/herself or others.

The psychomotor restlessness and the pressured speech in the dysphoric hypomanic state present a clinical picture of agitated depression, i.e. a mixed state (Fig. 4.5.2.1). The taste for talking is observed more frequently in females than in males, but otherwise no significant differences are seen between males and females in the manic dimension (Fig. 4.5.2.1).

Mania with psychotic features

Psychotic states of mania are characterized by greater pressure of speech, more open hostility, severe agitation, no need for sleep, flight of thoughts, severe distractibility, and grandiose delusions. In younger people, psychotic mania is often misdiagnosed as schizophrenia.

In hospital, the increased social contact of manic patients is clearly different from the emotional bluntness of schizophrenics. The intrusive behaviour seen in severe mania is of an extremely dominating and manipulative nature, out of context with the setting. Hamilton found this to be one of the most important mania symptoms. Secondary persecutory delusions often develop. The expansive religious delusion 'hearing God' should be differentiated from the schizophrenic patient's religious hallucinations.

Both DSM-IV and ICD-10 differentiate between mood-congruent psychotic symptoms (such as grandiose delusions of religion and voices supporting the patient's superhuman powers) and mood-incongruent psychotic symptoms (which are often the secondary delusions of persecution mentioned above).

Mixed states

The mixture of manic and depressive symptoms is the essential feature of mixed states (Fig. 4.5.2.1). It is not necessarily a bipolar course of symptoms, but the mixture of depressive and manic symptoms nearly every day. DSM-IV requires that the duration of a mixed episode should be at least 1 week; ICD-10 requires at least 2 weeks.

Kraepelin described transitory moods of depression in acute manic states. Transitory moods of depression have been recorded in manic patients by use of a rating scale administered by the nursing staff. Such short-lived states of 'depression' in patients with acute mania should be referred to as 'microdepressions' and not mixed episodes. Winokur described 'microdepressions' very clearly:

> . . . If one allows a manic patient to talk, one will note that he shows fleeting episodes of depression embedded within mania (microdepressions). He may be talking in grandiose and extravagant fashion and then suddenly for 30 seconds breaks down to give an account of something he feels guilty about . . . His eyes will fill with tears but in 15 to 30 seconds he will be back to talking in his expansive fashion.

Rapid cycling

DSM-IV has a specifier for rapid cycling, which refers to patients with bipolar I or bipolar II disorders, who have experienced at least four episodes during the previous 12 months. The episode has to be demarcated by partial or full remission for at least 2 months or a switch to an episode of opposite polarity.

Conclusion

The clinical spectrum of the states of depression and mania has been described in Fig. 4.5.2.1 by the symptomatic dimensions of severity as validated by clinician-rated scales. Thus, symptom severity is a key issue of the spectrum of mood states.

The spectrum of mood polarity disorders covering the longitudinal diagnosis of manic and depressive episodes is shown in Fig. 4.5.2.2. Recent research has demonstrated how important it is to recognize subthreshold states of mania and depression, as they can have a major impact on both social functioning and quality of life, since many patients with mood disorders spend much time in subthreshold disorders, i.e. cyclothymia, dysthymia, or neuroticism.

While the severity spectrum of the states of mania and depression has been accepted as evidence-based, we still lack a validation of the mood polarity spectrum in long-term follow-up studies.

Acknowledgement

I wish to thank Jules Angst and Rasmus W. Licht for their valuable comments and suggestions during the revision of this chapter.

4.5.3 Diagnosis, classification, and differential diagnosis of the mood disorders

Gordon Parker

Introduction

Varying expressions of mood disorders make for difficulties in definition, diagnosis, and classification. DSMIV and ICD10 formal classifications with decision rules (see Chapter 1.9) provide a structure but their underlying models may or may not be valid. This chapter therefore considers how mood disorders can be variably conceptualized and structured—an issue of intrinsic importance but also influencing identification of causes and management. Some definitional and boundary issues are first detailed prior to considering sub-typing and differential diagnostic issues.

Definitions

(a) Depression

The term *depression* is extremely broad, variably defining an affect, mood states, disorders, or syndromes—as well as disease states. A depressed 'affect' usually occurs in response to a specific situation and is defined as a transient and non-substantive state of feeling 'depressed', 'sad', or 'blue'.

A *depressed mood* is more pervasive, more likely to be experienced as unusual or atypical, associated with negative ideation (e.g. hopelessness, helplessness, pessimism about the future), and may influence behaviour. Its quintessential construct is lowering of the individual's intrinsic level of self-esteem, with the extent of self-esteem lowering roughly equating to the severity of the mood state. Experienced by most people, it generally lasts only minutes to days in non-clinical situations.

A *depressive condition* (be it a disorder, syndrome, or disease) is generally distinguished by a longer duration, more clinical (and more pathological) features, and distinct social impairment. A duration criterion ensures that a transient depressed mood state does not alone establish psychiatric 'case' status, with a minimum duration of 2 weeks capturing most conditions other than the so-called 'adjustment disorders'. Additional clinical features (detailed shortly) inform us about severity (e.g. 'major' and 'minor' depressive disorders) and sub-typing, while the social impairment criterion further cleaves 'normal' mood states from clinical depressive conditions.

At times, depressive conditions are described as *primary or secondary*, a distinction necessarily imprecise. We comfortably concede 'secondary depression' when depression emerges during the course of a substantive psychiatric condition (e.g. schizophrenia) or medical condition, or following certain aetiologically defined triggers (e.g. substance abuse). However, as depression is commonly contributed to by other psychiatric disorders (e.g. severe anxiety states) and primary psychosocial factors, it might be logical to also call these 'secondary' depressive disorders, and yet this rarely occurs. The term 'secondary depression' therefore generally imputes a substantive primary condition with depression as a clear-cut consequence.

(b) Bipolar/unipolar depression specifics

Turning from cross-sectional to longitudinal definition, the course specifier 'bipolar' is applied to those having had at least one manic or hypomanic episode, whether preceded or not by a depressive episode. Originally, Leonhard[1] introduced the concept of 'monopolar' (or 'unipolar') depression to distinguish those who had episodes of the melancholic sub-type of depression, but no manic episode. Regrettably, the term 'unipolar' depression is now used to define a residual (i.e. non-bipolar) category, so heterogeneous as to be of limited meaning and utility.

(c) Mania/hypomania

As described in Chapter 4.5.2, such conditions are the converse of depression and fundamentally represent hedonistic, high energy states. Here self-esteem is almost invariably increased, the mood generally infectious, the individual energized or 'wired', disinhibited, with creativity and religiosity often enhanced, while psychotic features may be present.

Distinguishing 'hypomania' and 'mania' is imprecise in the formal classificatory systems, as noted shortly. To some theorists, the presence of psychotic features determines manic (as against hypomanic) status. Others subscribe to a dimensional model. For example, Goodwin and Jamison[2] suggest that hypomania and mania differ little in mood components, but that cognition, perception, and behaviour differ in severity and manifestation.

(d) Bipolar categories

In recent years, bipolar disorder has been principally sub-categorized into bipolar I and bipolar II expressions, with 'manic' and 'hypomanic' episodes, respectively, defining the 'highs'. The term 'bipolar III' refers to a manic or hypomanic 'switch' on exposure to—or cessation of—an antidepressant drug and may reflect a pure drug effect and/or a vulnerability to switching in those with a latent bipolar condition. Numerous other bipolar categories (e.g. IV, V, and VI) have been proposed in the last few decades.[3] Many describe a 'hyperthymic' bipolar type (where the individual tends to be frequently cheerful, overly talkative, extroverted, self-assured, and full of ideas). Whether this is merely an exuberant personality style or a mild or sub-clinical expression of bipolar disorder remains to be clarified. The growth in bipolar sub-types has led to the dimensional concept of a 'bipolar spectrum'.

(e) 'Mixed states'

Here the individual with a bipolar disorder shows depressive features during a manic episode or manic features during a depressive episode. While sometimes used to describe the transition from one polar mood disturbance to another, it more commonly refers to the coterminous presence of manic and depressive features. Clinically, such patients more tend to report perturbing agitation rather than elevated mood in conjunction with depressive symptoms.

Depressive disorders: contrasting models

Unitary or binary?

The extended debate as to whether the depressive disorders are best conceptualized as comprising one or more distinct disorders warrants overview. The 'unitarian' model presupposes one depressive disorder, varying essentially by severity. The strict 'binarian' view postulated two separate types (i.e. 'endogenous'/'psychotic' versus 'neurotic'/'reactive'). There were a number of ascriptions to the 'endogenous' (now termed 'melancholic') type. Firstly, as indicated by its naming, its determinants weighted genetic and other biological factors rather than exogenous psychosocial factors. Secondly, that it had a distinctive pattern of ('endogeneity') symptoms and signs—noted shortly. Thirdly, that it showed a preferential response to physical treatments (e.g. antidepressant drugs and ECT) and less responsivity to psychotherapy. By contrast, the second 'neurotic' or 'reactive' depressive type was viewed as more reflecting depression emerging as an interaction of a predisposing personality style and precipitating life-event stressors.

The debate was strongly influenced by Lewis's clinical study[4] finding no clear demarcation between depressive types, examined both cross-sectionally and longitudinally, thus delivering support to the unitarian view. The introduction of multivariate statistical approaches led to the debate being reactivated in the 1960s, with the so-called Newcastle School arguing strongly that their analyses supported a binary view. In a representative paper, Kiloh and Garside[5] used a factor-analytic strategy to argue for separate 'endogenous' and 'neurotic' depressive conditions. However, factor analysis is not ideal for developing a typology, in that it produces dimensions (here of symptoms) rather than groupings of patients. Subsequently, more appropriate strategies have been used, such as cluster analysis[6] and latent class analysis,[7] and with those studies providing some support for separate classes. Critics suggest, however, that such classes or subgroups could still be determined by severity or, even if sub-types can be identified, question whether sub-classification has any management importance.[8–10]

This latter challenge is fundamental, taking us to the heart of any consideration of the diagnosis and classification of the depressive disorders. To the unitarians, as depression essentially varies only by degree, treatment choices (e.g. electroconvulsive therapy (ECT), antidepressant drugs, psychotherapy, or cognitive behavioural therapy) are commonly decided on the basis of severity. The opposing argument—for conceding sub-types—was well put by Kendell,[11] who drew on historical analogies. For example, he noted that distinguishing between cardiac and renal forms of 'dropsy' allowed prediction of those who would respond to digitalis.

Thus, if there are valid depressive sub-types, the contribution of putative psychosocial and biological risk factors may vary across each, and exert differential responses to differing treatment modalities. If the sub-typing model is valid, forcing homogeneity by creating dimensionally based categories such as 'major depression' will ensure muddied results. As noted by Hickie,[12] numerous studies of patients with DSM-defined 'major depression' have failed to demonstrate any coherent pattern of neurobiological changes, replicate key biological correlates, and demonstrate any specific pattern of treatment response outside inpatient treatment settings.

Approaches in the classificatory systems

How then have the official classificatory systems addressed such a substantive issue? In developing the DSM-III system,[13] the working group was required to make a decision on the competing unitarian or binarian models. While the binarians were at the door, they had, until then, failed to prove their case and the DSM-III committee chose a compromise. Thus, DSM-III depression classification was predicated on an initial dimensional component (i.e. 'major' versus 'minor' disorders). If criteria for a major disorder were met, second-order and more categorical decisions about the

presence of melancholia or psychotic depression were specified. This model proved unsatisfactory for melancholia. For example, Zimmerman and colleagues[14] noted that the DSM-III melancholia criteria set, unlike the definition provided in the predecessor (DSM-II), 'did not predict treatment response'. Thus, the DSM-III-R[15] criteria set for melancholia was revised to include complete recovery after previous episodes, previous good response to somatic treatments, and no significant personality disturbance, to overcome the lack of predictive validity by building into the definition some of the 'givens' held by many clinicians about melancholia. However, the criteria set for melancholia developed for DSM-IV returned essentially to the DSM-III set, with limitations considered below. The contrasting system, ICD-10, is essentially based on a stricter dimensional or unitarian view of the depressive disorders—comprising 'severe', 'moderate', and 'mild' disorders.

During the extended debate as to whether a categorical and more 'biological' type of depression exists—it was variably termed 'endogenous', 'endogenomorphic', 'autonomous', and 'melancholic' depression. The last is probably preferable as numerous studies have quantified few or no differences in the likelihood of those with 'endogenous' and 'non-endogenous' depression reporting antecedent life events, so arguing against any term weighting 'internal' or 'external' causes.

Whether psychotic (or delusional) depression is a 'severe' form of melancholia or a separate entity also remains problematic. DSM-III had a category 'major depression with psychotic features' for use when delusions or hallucinations are present or when there is 'depressive stupor (the individual is mute and unresponsive)', thus viewing 'psychotic depression' as a sub-type of the generic 'major depression' category rather than a sub-type of melancholia. While 'depressive stupor' may be a useful marker or proxy for the condition, this criterion was not retained in DSM-III-R or DSM-IV, but is included in ICD-10. Two points argue for psychotic depression as a distinct entity: the presence of psychotic features, and its poor response to antidepressant medication alone and to neuroleptic medication alone in comparison to high responsiveness to their combination.[16]

A strict interpretation of the 'binary' view would place the non-psychotic, non-melancholic depressive conditions in a pure second class. However, rather than view this as a pure 'type', this class is best regarded as a heterogeneous residue category (i.e. non-melancholic depression), with its heterogeneity expressed widely—across aetiological factors, clinical expression, and natural and treated history.

Classification of affective mood disorders

Formal classification—depressive disorders

Both ICD-10 and DSM-IV have multiple conditions and specifiers. The ICD-10 system allows mild and moderate depressive episodes (with or without a 'somatic syndrome' conceptualized as reflecting 'melancholic' features), and severe depressive episode (with or without psychotic symptoms). There are separate codes for a similar set of 'recurrent' disorders, while several 'persistent' mood disorders (including cyclothymia and dysthymia) and residual conditions are listed. DSM-IV has two principal 'stem' disorders (major depressive episode and dysthymia), with the first having a number of optional specifiers including 'with' melancholic, catatonic, psychotic, or atypical features, as well as including disorders showing longitudinal patterns of rapid cycling or a seasonal pattern. Both systems have categories for affective disorders secondary to organic disease, while DSM-IV includes mood disorders due to a general medical condition or substance use, or occurring in the post-partum period. Both classificatory systems include adjustment disorders with depression.

Formal classifications are therefore built principally on severity, features of current episode, patterns of disorder expression over time, as well as persistence and recurrence. Few diagnoses are consistent across the ICD-10 and DSM-IV systems and, while each provides definitions that allow a 'shared language' to be used by clinicians and researchers, the extent to which their severity-weighted groupings capture 'meaningful' depressive sub-types remains problematic.

For example, and as detailed elsewhere,[17] 'major depression' has come to be viewed as an entity, sufficient in and of itself for testing antidepressant therapies and to generate treatment recommendations. Limitations to such a model become apparent if we consider the analogy of 'major breathlessness', which could be a transient consequence of acute exercise, or reflect quite differing pathological processes (e.g. asthma, pneumonia, or a pulmonary embolus) benefiting from quite differing treatment approaches. Thus, a diagnosis of 'major depression' or 'clinical depression' is, in reality, a first-level domain diagnosis, and benefiting from secondary specification. The latter tends to proceed on the basis of severity, but alternative and more categorical models have long been proposed as considered elsewhere in this chapter.

Formal classification—bipolar disorders

The DSM-IV definition effectively requires an initial or previous manic episode for bipolar I disorder, while bipolar II disorder requires hypomanic episodes and one or more previous episode of major depression.

To meet DSM-IV diagnostic status, manic episodes must have lasted 7 days and hypomanic episodes 4 days. Both ICD-10 and DSM-IV have course specifiers for bipolar disorder containing 10 and 4 subgroups, respectively. In addition to the number of subgroups, differences include a greater emphasis on distinguishing bipolar I and II in DSM-IV, and cyclothymia being listed as a 'bipolar disorder' in DSM-IV as against being a 'persistent' mood disorder overlapping with a personality style in ICD-10. Distinguishing 'hypomania' and 'mania' is regrettably imprecise in the formal classificatory systems. Both DSM-IV[18] and ICD-10[19] disallow a diagnosis of hypomania if psychotic features are present but, conversely, do not require psychotic features for a diagnosis of mania. DSM-IV lists essentially similar clinical criteria (and criteria number cut-off) for hypomanic and manic episodes, but distinguishes mania by the presence of marked impairment in social functioning (risking subjective judgement), requirement for hospitalization (which is logically more a consequence than a defining criterion although it may have some proxy value), and the presence of psychotic features in a manic episode. As noted earlier, ICD-10 views hypomania as 'an intermediate state without delusions, hallucinations, or complete disruption of normal activities'.

Thus, formal 'cleavage' between bipolar I and II (and constituent manic and hypomanic states) is largely dimensional in relation to clinical features and with some logical fallacies. Further, duration

criteria (i.e. at least 7 days for mania and at least 4 days for hypomania in DSM-IV) do not appear sustainable. In recent years there have been many studies[20] indicating that clinical definition of bipolar disorder is not dependent on the duration of the highs, and that imposing DSM-IV duration criteria for both mania and hypomania may exclude a significant percentage of those with true bipolar disorder.

A sub-typing model for classifying depression

As detailed earlier, there are intrinsic difficulties in classifying depression according to any single model when it is a term encompassing normal mood states through to possibly categorical diseases, and when any imposition of a severity-based model raises problems about how to differentiate meaningful groups (e.g. 'cases' from 'non-cases'). A personal mixed model is now detailed for consideration—one shaped by clinical experience and supported by research findings. It is described in line with the 'reasoning steps' that a clinician might employ in assessing a potential depressive disorder.

(a) Step 1: Is a depressive disorder present?

For all the depressive disorders, the first building block generally requires evidence of a depressed mood (although some with a melancholic or psychotic depression may deny 'depression'). Useful questions include the following: 'Do you feel depressed'?, 'Has there been any change in your self-esteem or from the way you generally value yourself'?, and 'Are you being more self-critical or harder on yourself than usual'?

The next clinical priority is to determine if the depression is sufficiently severe as to warrant 'case' status, and here the DSM-IV criteria for a major depressive episode have common acceptance in terms of representative symptoms and duration criteria. That criteria set lists the following:

- four mood items (depressed mood, loss of interest or pleasure, feelings of worthlessness or inappropriate guilt, recurrent thoughts of death, and suicidal ideation)
- weight changes
- sleep disturbance
- fatigue
- impaired concentration
- psychomotor disturbance

A positive diagnosis requires five or more of the nine, evidence of functional impairment, and a minimum duration of 2 weeks.

(b) Step 2: If a depressive disorder is present, what sub-type?

If 'caseness' criteria are met, the next decision should be to determine the diagnostic sub-type. We favour a three-class hierarchical model (i.e. respectively psychotic, melancholic, and a heterogeneous non-melancholic class)—hierarchical in the sense that those in the two highest classes have class-specific features as well as possessing features of the subordinate classes. Clinical assessment then allows a sequencing process to diagnosis.

In essence: does this individual have a melancholic or non-melancholic depression; are there psychotic features indicative of a psychotic depression? That sequence will now be detailed. The left half of Fig. 4.5.3.1 details the so-called 'structural model'. A shared

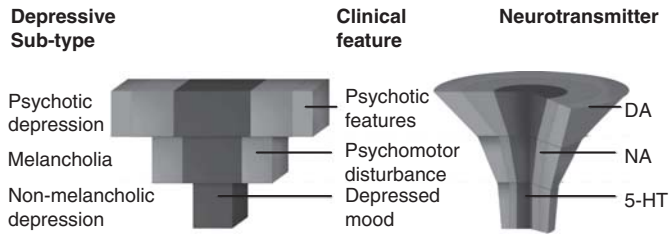

Fig. 4.5.3.1 The structural and functional model of three depressive classes. DA = dopamine; NA = noradrenalin; 5-HT = serotonin.

mood disorder component is present and varying in severity across the three principal sub-types. However, sub-type distinction proceeds on the basis of two class-specific components—psychomotor disturbance and psychotic features.

(c) Step 3: Differentiating melancholic and non-melancholic depression

In DSM-IV, the 'melancholic features specifier' requires, in addition to a base diagnosis of major depression, either one of two A criteria and three (or more) of six B criteria, with most of the latter comprising so-called 'endogeneity symptoms'. However, some such DSM criteria have limitations. Firstly, criterion A (loss of pleasure and/or lack of mood reactivity) is generally met by both 'melancholic' and 'non-melancholic' patients. Secondly, some criterion B features are vague. For example, 'distinct quality' is defined as a mood different to that experienced after 'the death of a loved one', and is a negative definition (akin to defining 'psychiatry' as 'not cardiology'). A second, 'excessive or inappropriate guilt', is a concatenated descriptor, subsuming the excessive expression of normal guilt, as well as guilt held at an overvalued or delusional level. Others are non-specific (e.g. early morning wakening, significant anorexia, or weight loss), being common in other psychiatric conditions (e.g. anxiety disorders) as well as in other expressions of depression. Further, as DSM-IV-defined major depression and melancholia share several similar features (e.g. anhedonia, psychomotor disturbance, weight loss), even those two conditions are poorly cleaved.

Features of melancholia: Any improvement on DSM-IV distinction of melancholia would benefit from identification of features specific to—or distinctly over-represented in—melancholia. Nelson and Charney[21] undertook a review of 33 studies using multivariate statistical approaches to identify melancholic or 'endogeneity symptoms'. They found no support for appetite/weight loss and insomnia, little support for early morning wakening and 'distinct quality', but some support for a severely depressed and non-reactive mood, loss of interest in pleasurable activities (or anhedonia), and psychotic features. The most strongly associated feature was psychomotor change (with retardation more consistently associated than agitation). When Rush and Weissenburger[22] examined nine diagnostic systems for diagnosing melancholia or endogenous depression, the only common criterion in all nine was psychomotor retardation (with psychomotor agitation included in six). Our research[23] has established that the specificity of psychomotor disturbance to 'melancholia' is dependent on measuring it as a sign, with that diagnostic weighting more recently detailed and endorsed by others.[24] Thus, and returning to a hierarchical model,

differentiation between the non-melancholic and melancholic disorders (on the basis of clinical features) appears assisted principally by the specific feature of behaviourally evident psychomotor disturbance. As measured by the sign-based CORE system,[23] psychomotor disturbance is reflected along three dimensions—impaired cognitive processing and motor retardation and agitation, although components are not mutually exclusive. For example, those with significant agitation may have it present for much of the time or, and more commonly, have a base of retardation with intermittent epochs of agitation.

In younger individuals with true melancholia, overt psychomotor disturbance is less distinctive, although they still tend to report distinct concentration problems. In addition to such 'signs', symptoms seemingly over-represented in melancholia include: distinct anergia often preventing the individual from getting out of bed to bathe; anergia and mood distinctly worse in the morning (i.e. diurnal variation); and an anhedonic and non-reactive mood.

The non-melancholic disorders have no specific features—apart from some (e.g. mood reactivity) that are the converse of their expression in melancholic disorder (i.e. non-reactive mood). Thus, these conditions are effectively diagnosed by excluding the two higher order conditions of melancholic and psychotic depression.

(d) Step 4: Implications of the distinction

Classification should never be sterile. It should at least provide us with a lexicon and, ideally, inform us about management nuances. We suggest that there are important treatment implications associated with distinguishing melancholic and non-melancholic disorder. The right half of Fig. 4.5.3.1 offers a 'functional model' that operates in parallel with the 'structural model'. As detailed,[25] it assumes that if there is any neurotransmitter perturbation underpinning the non-melancholic disorders, then it is principally serotonergic in origin, shaping the hypothesis that there is no advantage in proceeding beyond a narrow-action Selective Serotonin Reuptake Inhibitor (SSRI) antidepressant. It further assumes a greater noradrenergic contribution (and possibly dopaminergic contribution) to melancholia, and shapes the hypothesis that broad-action antidepressants will overall be more effective than SSRI antidepressants—and any psychotherapy—for melancholic depression. Both hypotheses have been supported in a number of trials and naturalistic studies[26] arguing the importance of distinguishing the melancholic sub-type.

(e) Step 5: Distinguishing psychotic depression

In psychotic (or delusional) depression, the central mood component is generally even more severe than in melancholic depression but many will deny or minimize a depressed mood. A number of 'endogeneity symptoms' are also frequently more severe (particularly non-reactive mood, anhedonia, and constipation). One frequent feature in melancholic depression (i.e. diurnal variation of mood) is, however, rarely present at episode nadir, as the patient is more likely to be persistently depressed across the days. Observable psychomotor disturbance is present and generally distinctly more severe than in melancholic depression. In some, the combination of the cognitive processing problems and motor change (retardation in particular) can give the impression of a dementing process, and provides an example of 'pseudodementia'.

The key class-specific feature, however, is the presence of psychotic features. Delusions are almost invariably present while hallucinations (auditory most commonly) are present in 10 to 20 per cent. DSM-IV subdivides delusions and hallucinations as 'mood congruent' (where themes of guilt, disease, death, nihilism, and personal inadequacy dominate) and 'mood incongruent' (where psychotic features appear independent of the depressive theme and might include persecutory themes, delusions of control, as well as thought insertion and thought broadcasting) states. It is important to emphasize that mood-incongruent states are common and do not, by themselves, necessarily challenge a diagnosis of delusional depression or argue for a schizophrenic illness of necessity.

A significant percentage (approximately one-third) of patients with psychotic depression develop constipation. In many it is a primary feature (not merely a side-effect of psychotropic medication), and may serve as a nidus of delusional interpretation (e.g. the depressed patient who believes that their bowels have turned to concrete, or that they have a bowel cancer).

When psychomotor disturbance is extremely severe, it may not be possible for psychotic features to be elicited, particularly if the patient is mute. Many patients are diffident about revealing psychotic material, and here indirect questions can often be useful. In particular, pursuing the presence of 'guilt' can assist, with guilt here defined as a sense of self-blame and not merely self-criticism, together with a sense of remorse for wrong acts or omissions that are independent of any concern about potential evaluation by others. In psychotic depression, the guilt is more likely to be held at the level of an overvalued idea or at a formally delusional level. If direct inquiry does not elicit delusional material, then asking 'Do you feel any sense that you deserve to be punished'? can help elicit previously unexpressed psychotic material.

Our 'functional model' (Fig. 4.5.3.1) argues that there is likely to be a greater dopaminergic (than noradrenergic and serotonergic) contribution to psychotic depression, a hypothesis supported by meta-analyses[16,27] quantifying this condition as showing a 25 per cent response to an antidepressant alone, 33 per cent to an antipsychotic alone, and 80 per cent to their combination and to ECT.

(f) Step 6: If a non-melancholic depressive disorder, can this class be sub-typed?

There is no generally accepted sub-typing system for this residual group, and where symptoms reflecting the lower order mood construct dominate the clinical picture. In the absence of any class-specific features, any categorical sub-typing model is unlikely to be valid, and dimensional models more appropriate. But what are the salient constructs for dimensionalizing? DSM-IV and ICD-10 proceed largely on a severity dimension for the mood disorder (e.g. 'major' and 'minor') but also on patterns of recurrence and persistence, all appropriate candidate dimensions.

Historically, terms such as 'neurotic depression' and 'reactive depression' were used, with the former emphasizing a pre-morbid style of neuroticism and high anxiety, and the latter defining depression developing largely in response to life-event stressors. This suggests another set of candidate constructs, dimensionalizing both personality and severity of stress components—and modelling their interaction.

Several earlier studies argued for some clinical utility emerging from such a model. Thus, an early factor-analytic study[28] suggested both a 'hostile' type (evidenced by irritability as well as anxiety) and an 'anxious-tense' type. Blashfield and Morey[29]

reviewed 11 cluster analytic studies suggesting separate 'hostile' and 'anxious' depressive subgroups. In an extensive review of the then published studies, Roth and Barnes[30] suggested three principal subgroups, with depression associated with a personality disorder, in addition to 'hostile' and 'anxious' depression.

While such 'hostile' and 'anxious' subgroups have been identified for a lengthy period, clear and consistent descriptions are lacking. Grinker *et al.*[31] described those with 'hostile' depression as unappreciative, actively angry, provocative, and making excessive demands of—and complaints about—their therapists, suggesting a personality disorder contribution. The second ('anxiety') subgroup is variably interpreted as defining either those with an anxious personality or temperament, or the presence of significant coterminous anxiety symptoms when primarily depressed.

The model we favour is one that respects historical description (i.e. 'reactive' versus 'neurotic') but develops the 'personality' contribution beyond the simple diagnostic allocation of 'neurotic depression'.

Terms such as 'reactive depression' or 'situational depression' (or as used in DSM-IV and ICD-10, 'adjustment disorder') concede that some individuals develop a non-melancholic depressive disorder largely or purely as a consequence of a stressful life event, which may produce, trigger, and/or maintain depressive episodes. In an empirical study,[32] the authors were unable to establish clinical, family history, and even life-event stress differences between those with 'situational' and 'non-situational' major depression. Our research[33] indicated that for the acute reactive 'disorders', the impact emerged less from the severity of the stressor and more from its perceived 'meaning' or 'salience'. We suggested a cognitive 'lock and key model', whereby individuals may be predisposed by perturbing developmental events such as a highly judgemental parent (creating 'locks'). In adult life, exposure to a mirroring situation (e.g. a judgemental boss) might act as a 'key' for precipitating a 'reactive' depression. For more chronic 'situational depression' scenarios, here we presume that the stressor is a chronic one and/or that the stressor induces a 'learned helplessness' mind set in the individual, where they believe that it does not matter what they do or attempt to do—there will be no impact on outcome—and they develop a sense of 'powerlessness' along with depressive symptoms.

A spectrum model

In modelling non-melancholic disorders reflecting a personality contribution, we suggest the utility of a 'spectrum' model, a term variably used but which argues for a continuum between temperament/personality style and symptom states,[34] or some level of inter-dependency. This spectrum model views certain biological factors as shaping temperament and personality style—which then shape surface marker symptoms during a non-melancholic depressive episode. An earlier research report[35] identified those presenting with an 'irritable/hostile' depression as being more likely to have a cluster B personality and to report 'acting out' behaviours when stressed (i.e. demonstrating a 'short fuse' response to stress). By contrast, those with an 'anxious depressive' spectrum disorder appeared more likely to internalize anxiety. They tended to have shown shyness and behavioural inhibition in childhood, to have high rates of lifetime anxiety disorders, score high on trait anxiety, view themselves as 'worriers', 'nervy', or 'tense', and to rate as having a cluster C personality style. When stressed, they were somewhat more likely to 'act in' by becoming quiet, retiring to their room, crying, and 'stewing'. Thus, anxiety was evident both in the temperament pattern and in the prominent symptom profile when depressed—demonstrating the 'spectrum'. The suggested profile of these spectrum disorders is not only important for clinical consideration, but in facilitating research into possible neurobiological determinants and to consider any treatment specificity. For example, Blashfield and Morey[36] reviewed studies indicating that 'anxious depressives respond well to major and minor tranquillizers but not to tricyclics, while hostile depressives show little improvement with conventional drug therapies'. Further, Fava *et al.*[37] reported that anxious depressives were more likely to be responders to a selective serotonin reuptake inhibitor (SSRI) than other depressive expressions (including 'hostile depression').

We have more recently pursued the 'spectrum model' for non-melancholic disorders beyond the two candidate groupings (i.e. hostile/irritable and anxious depressive) considered above. Both clinical observation and literature review indicated eight predisposing personality styles[38] but an application study[39] suggested that the spectrum model could be supported up to a six-factor personality model. The latter spectrum model is now detailed.

Those who scored high on the personality measure of 'anxious worrying' were, when depressed, indecisive, and self-blaming, as well as feeling anxious and tense. Those high on the 'irritability/snappiness' personality dimension were likely, when depressed, to be irritable and impulsive. Rather similar personality dimensions of 'personal reserve' and 'social avoidance' identified some differential coping responses apart from a shared social withdrawal response, with the former avoiding others and losing interest in people, while those high on social avoidance reported avoiding pleasurable activities. Those high in 'perfectionism' were more likely to focus on trying to solve the problem and to seek distraction. The sixth personality style benefits from more detailed consideration as it informs us about the nature of 'atypical depression', a condition which—while listed in DSM-IV and held to show a specific response to monoamine oxidase inhibitor antidepressant drugs—has been quite variably interpreted over time.[40] In that review, we argued for the primacy of the personality style of 'rejection sensitivity'. In our spectrum study,[39] those high on 'rejection sensitivity' were distinctly more likely to report some of its characteristic features (e.g. food cravings, hypersomnia), but also a set of cognitive extensions of their personality style (e.g. a tendency to feel abandoned, rejected, and put down) as well as distinct self-consolatory strategies (e.g. spending money, seeking support, and even crying).

While such a spectrum model is not a categorical one (in circumscribing 'pure' depressive conditions) nor sufficiently consistent in expression to deserve endophenotypic status, such 'fuzzy set' patterning may have clinical implications in terms of assisting a richer diagnostic formulation and in providing therapies that address any predisposing personality style, rather than merely treat the surface marker of non-melancholic 'depression'. Much research will be required to determine if candidate expressions show any differential response to contrasting antidepressant strategies, necessary to ensure that classification has clinical utility.

A sub-typing model for classifying bipolar disorders
