As considered earlier, the formal official classificatory systems fail to provide pristine cleavage between bipolar I and bipolar II disorders. We briefly describe a model that supports an historical approach to this issue (by preserving the definition of mania—and bipolar I status—to those who have had psychotic features during a 'high') and which links the bipolar disorders with psychotic and melancholic depression.

The 'isomer model' illustrated in Fig. 4.5.3.2 builds on studies suggesting that 'bipolar depressive episodes' are highly likely to be psychotic or melancholic in type, albeit with some differences in that individuals not infrequently report 'atypical features' of hypersomnia and food cravings rather than more characteristic melancholic features of insomnia and appetite loss. The model was further shaped by findings derived in one clinical sample.[41] Firstly, bipolar patients who had experienced a psychotic 'high' had a 50 per cent chance of having a depressive episode with psychotic features. Secondly, of the bipolar patients who had never been psychotic during a high, none had experienced psychotic features.

The 'isomer model' therefore posits two contrasting 'mirror image states'. Those with bipolar states oscillate across parameters of energy and mood (elevated in highs, depressed in lows). More specifically, individuals with bipolar II disorder oscillate between non-psychotic depression and hypomania—never experiencing psychotic depression or psychotic mania. By contrast, those with bipolar I disorder have had psychotic manic episodes (by definition) and, when depressed, are at increased risk of having psychotic episodes.

The advantage to the model is that it respects and formalizes the historical view of regarding the presence or absence of psychotic features during a high as distinguishing mania and hypomania (and respective bipolar I and II disorders). Further, it suggests that aetiological studies might well focus on pursuing the nature of two oscillators—one of mood and energy, and one of psychotic features. Thirdly, it offers a template for pursuing management options for the two differing bipolar disorders. Currently, there are many treatment guidelines for managing bipolar I—but only informal templates for managing bipolar II disorder[42]—and it may be unwise to extrapolate such bipolar I guidelines for managing bipolar II disorder.

Differential diagnosis and ascertainment difficulties

Depression

The three key features of lowered self-esteem, increased self-criticism, and a depressed mood distinguish depression phenomenologically from states such as grief or bereavement—where there is a distinct sense of 'loss' of something valued, but no primary 'loss' of self-esteem. They also assist phenomenological differentiation from anxiety, where the individual is more likely to report a sense of insecurity, fear, apprehension, worry, panic, or of 'going mad'. Subsequent questioning of clinical symptoms and observation should clarify if a clinical syndrome exists, its diagnostic sub-type and—from a longitudinal perspective—whether the individual has a unipolar or bipolar course.

At the practical level, such a definitional approach may fail in certain groups. A percentage of those with psychotic or melancholic depression appear more emotionally blunted and 'flat' rather than depressed. They may deny depression, self-blame and worthlessness, and instead note a lack of feeling (or vitality), sluggishness, enervation, or emphasize physical states, such as anergia. Less commonly, they may evidence 'corporization' by Schneider,[43] with reports of pain or physical sensations in the head, chest, or stomach. As noted earlier, others may have such profound psychomotor disturbance that they do not respond to questioning and appear as if they have a dementia (here a so-called 'pseudodementia'). In such instances, pursuit of proxy items (severe psychomotor disturbance, pathological guilt, overvalued ideas) may assist. If unsuccessful, the diagnosis may require corroborative reports and clinical observation, as well as certain investigations (e.g. CT or MRI scans, single-photon emission CT scans, EEG) to exclude a dementia. In a percentage of the elderly, however, a depressive episode and dementia may coexist (particularly a vascular dementia), and reflect a shared aetiological process.

Secondly, there are some patients and certain cultures where psychological issues are either denied or expressed somatically, although careful and directed questioning about central depressive descriptors will usually clarify the possibility. If unsuccessful, diagnostic clarification may require corroborative reports and clinical observation.

Thirdly, it is commonly difficult to define 'clinical depression' in those with a medical illness. Here, general depression criteria sets risk false-positive diagnoses by including certain features which may be secondary to the medical illness (e.g. fatigue, insomnia, anorexia) rather than reflecting depression *per se*. Common corrective strategies include the 'aetiological approach', where only symptoms viewed as independent of the medical condition are counted, the 'exclusive approach', eliminating potentially confounded items such as anorexia, the 'inclusive approach', where all symptoms are counted irrespective of their origin, and the 'substitutive approach', excluding features that could be due to the medical illness and substituting features such as social withdrawal and crying.

In some cases where depression has been established, the salient clinical difficulty is in determining whether depression is or is not the primary disorder in those with concomitant major medical problems, excessive alcohol intake, organic central nervous system disease, and certain psychiatric conditions (e.g. anxiety states, depressive personality disorder). Clinical judgement is generally

required with two alternate logical approaches: either weighting the disorders hierarchically or sequentially. The hierarchical approach assumes that the more severe disorder is the primary one, while the sequential approach weights the antecedent condition (e.g. organic disorder, schizophrenia, anxiety). Acceptance of one approach does not logically bind the clinician to any therapeutic consequence (such as necessarily treating only the more severe or primary condition).

Mania/hypomania

The differential diagnoses for manic states essentially include other psychotic conditions (e.g. schizophrenia, drug-induced psychosis) and, rarely, a primary organic state. While cross-sectional dissection of the phenomenology can be helpful, there is wisdom in also weighting the longitudinal course. Thus, those with manic states are more likely to describe complete restoration of function between episodes (of mania and/or depression), while this is less likely for those with schizophrenia. Definitive distinction is not always possible, and a diagnosis of 'schizoaffective' disorder may then be appropriate. In severe mania, an 'organic' picture may be suggested, and require exclusion of a dementia or delirium.

The differential diagnosis of hypomanic states is often quite difficult. Questioned about having 'highs' often elicits defensive response from those with true states, while some depressed people will present a remission to a euthymic state as a 'high'. Highly creative people may affirm many hypomanic descriptors when possessed by the muse (e.g. less need for sleep, feeling creative, and overconfident, being enthused and energized), as may those with a distinctly extroverted or cyclothymic personality when stimulated. Some patients with a cluster B personality style (especially of the borderline type) may also describe mood states that approximate to hypomania. Clarification is probably best assisted by a sequence of strategies, including asking the individual about times when, neither depressed nor feeling normal, they have states of feeling overly 'energetic and wired', that they have an appropriate number of concomitant criterion features during such highs, that there was a 'trend break' where 'highs' became a new phenomenon (most commonly mid-adolescence or later), and that—during their highs—any usual level of anxiety melts away, and by interviewing a corroborative witness.

Conclusions

Current formal classificatory systems list a large number of mood disorders, with criteria designed to assist diagnostic reliability. Most reflect attempts to create classes on the basis of severity-weighted dimensional models. Terms such as 'major depression' and 'unipolar depression'—as well as 'bipolar spectrum disorder'—have achieved acceptance in recent years, for such diagnoses are easily made (and easily reified), but the limitations inherent to their heterogeneity should not be ignored. Until the dissonance between the formal classifications and clinician-derived models has been resolved, practitioners should proceed by recognizing the advantages and limitations to competing approaches. A functional classificatory system should have clinical utility, going beyond mere description and informing the clinician about treatment differentiation.

4.5.4 Epidemiology of mood disorders

Peter R. Joyce

The Global Burden of Disease, which is a comprehensive assessment of mortality and disability from diseases and injuries in 1990 and projected to 2020, highlights the importance of mood disorders for the world. Using the measure of disability-adjusted life years, it was determined that unipolar major depression was the fourth leading cause of disease burden in the world. It was also projected that, in the year 2020, unipolar major depression would be the second leading cause of disease burden in the world. Disability-adjusted life years is based on both mortality and disability. If one looks at disability alone, then unipolar major depression was the leading cause of disability in the world in 1990, and bipolar disorder was the sixth leading cause. Across the world, 10.7 per cent of disability can be attributed to unipolar major depression and, in developed countries, unipolar major depression contributes to nearly 20 per cent of disease burden in women aged from 15 to 44 years.[1]

The mood disorders have received considerable attention in psychiatric epidemiology over the last 25 years. These received particular attention in the five-site United States National Institutes of Mental Health Epidemiologic Catchment Area Study (**ECA**), as well as in the epidemiological studies in other countries around the world that used the ECA methodology. Mood disorders also received particular attention in the National Comorbidity Survey (**NCS**) in the United States, in the National Psychiatric Morbidity Survey of Great Britain, and most recently in the World Mental Health Survey (**WMH**) across many countries. Thus, there is substantial data from around the world on the epidemiology of these disorders. In addition, many of the population-based twin registries, such as in Virginia (USA), have also paid particular interest to mood disorders and have the additional advantage of being able to consider genetic as well as environmental risk factors.

Bipolar disorders

Diagnostic issues

While classical bipolar disorder with episodes of euphoric mania interspersed with episodes of depression is one of the clearest clinical syndromes in psychiatry, the boundaries of bipolar disorder remain contested. As case definition is central to epidemiology, all the contested boundaries of bipolar disorder could influence prevalence rates and our understanding of risk factors. Some of the major boundary issues for bipolar disorder include the overlap of bipolar disorder with psychotic features, with schizoaffective disorder and schizophrenia, and the overlap of bipolar disorder with unipolar major depression when patients who present primarily with depression have brief or mild episodes of hypomania. There is also an overlap of bipolar disorder with apparent personality disorder, especially Cluster B personality disorders such as borderline and narcissism, and the issue of when hyperthymic personality merges into bipolar disorder.[2,3] When bipolar disorder is comorbid with substance abuse there are also important diagnostic issues.

Another important issue in determining caseness of bipolar disorder for epidemiological surveys is symptom pattern and duration. A number of the diagnostic instruments for assessing bipolarity in population surveys limit the questions on mania to a type of symptom profile characterized by euphoria, grandiosity, increased energy, and decreased sleep. Whether the commonly used epidemiology interviews adequately detect those individuals who have manic episodes characterized by irritability, anger, and activation is very debatable. The other key diagnostic issue is what criteria are used to categorize the minimum duration for hypomania; is four days too long, is even two days too long? Furthermore, as insight is sometimes impaired in hypomania and mania, and as these are low prevalence disorders, the accuracy of case detection of bipolar disorders in populations remains an issue for further research.[4]

Prevalence

Population studies such as the ECA, and its related cross-national studies, and the NCS reported that the lifetime prevalence of bipolar disorder varies from 0.3 to 1.5 per cent. The NCS data include only bipolar I data, while the ECA includes bipolar I and bipolar II disorder.[4,5] In all studies, the six-month prevalence is not much lower than the lifetime prevalence of bipolar disorder. These findings reflect the high degree of chronicity and/or recurrence associated with bipolar disorder. Broader definitions of mania/hypomania have resulted in lifetime prevalence rates increasing to about 4 per cent.[6]

In these population studies, the mean age of onset of bipolar disorder has varied from 17 to 27 years. However, as age of onset is not normally distributed, the mean is a slightly misleading variable; in clinical samples, while the mean age of onset may be in the twenties, the most common age of onset are the teenage years.

In bipolar disorder, the prevalence in males and females is similar. This is in contrast to the reasonably consistent female excess found in major depression.

Comorbidity

In the NCS, all identified bipolar I individuals suffered from at least one, and often up to three or more, comorbid disorders. The most common comorbid disorders included the full range of anxiety disorders, alcohol and drug dependence, and conduct disorder or other antisocial behaviours.

Alcohol and drug abuse and/or dependence are commonly comorbid with bipolar disorder. Old studies found that binge drinking was especially common in bipolar individuals and that this binge pattern of drinking was more associated with manic episodes than with depressive episodes. Clinical studies find that bipolar patients with comorbid substance dependence are less compliant with prescribed mood stabilizers and have more frequent hospital readmissions. Stimulant abuse/dependence rates are especially increased in bipolar disorder.

Individuals with bipolar disorder have the full range of anxiety disorders, including phobias, panic disorder, and obsessive–compulsive disorder. Perhaps surprisingly, comorbid rates of these anxiety disorders tend to be higher in bipolar disorder than in major depression.

Another area of high comorbidity with bipolar disorder is that of childhood conduct disorder and attention deficit disorder. One of the issues in understanding this high rate of comorbidity is whether childhood conduct disorder and/or childhood attention-deficit disorder are sometimes the first manifestations or precursors of bipolar disorder. Certainly, if the pattern of conduct-disorder symptoms or attention-deficit symptoms is episodic rather than consistent over time, the issue becomes whether these are not early manifestations of bipolar disorder rather than truly independent comorbid conditions. The other key diagnostic controversy in this area is the status of juvenile or childhood bipolar disorder.

Use of health services

In the ECA study, 39 per cent of those with bipolar I or bipolar II disorders received outpatient psychiatric treatment within 1 year and about 10 per cent would receive inpatient treatment within a 6-month period. In the NCS study, 45 per cent of those with bipolar disorder had received psychiatric treatment in the previous 12 months; although 93 per cent reported lifetime treatment for their bipolar disorder. However, both of these studies suggest that more than half the individuals with bipolar disorder are not currently in psychiatric treatment and, given the high morbidity and mortality associated with bipolar disorder, this is of major concern.[4]

Risk factors for bipolar disorders

In considering the risk factors for bipolar disorder, it is useful to separate risk factors into those that are risk factors for lifetime vulnerability (for example genetic factors) and those that are risk factors for the onset of an episode of depression or mania (for example, life events). Thus, in determining risk factors for lifetime vulnerability, genetic factors constitute the largest single risk factor. However, if one is considering who is vulnerable to an episode of mania over the next six months, genetic factors will play a relatively smaller part and predictions may be best based on other factors such as past history, childbirth, being treated for depression with antidepressant medication, and the approach of spring or summer. Genetic risk factors are discussed further in Chapter 4.5.5.

Although organic factors, such as some type of central nervous system damage, are unusual risk factors in young adults, in late-onset bipolar disorder (age of onset more than 50 years) organic disease of the central nervous system is an increasing factor for the development of mania. In younger adults, AIDS and head injury are two important aetiological factors in a limited number of cases of bipolar disorder.

Risk factors for manic episodes in people with bipolar disorder

A range of other biological factors are particularly relevant risk factors to the onset of episodes of illness, but they may contribute a relatively small part to lifetime vulnerability. Many women have their first episode of depression or mania in the postpartum period. While a limited number of women may have manic episodes limited to the postpartum period, postpartum episodes of mania are more commonly part of a long-term bipolar disorder and these women will have episodes both precipitated by childbirth and at other times in their life. Indeed, in the postpartum period, having a history of bipolar disorder is one of the strongest risk factors for the development of a postpartum psychosis.

There is substantial evidence that seasonal patterns influence the onset of manic and depressive episodes. There are consistent

findings of an excess of manic episodes in late spring and early summer. To date, however, the nature of the environmental factors that influence this late spring, early summer peak of manic episodes is less clear.

There is also substantial evidence that disruptions of normal biological rhythms may precipitate the onset of manic or depressive episodes. This has been documented in relation to international travel involving east–west or west–east travel with disruption of circadian rhythms. Disruption of circadian rhythms through shift-work or other factors, which disrupt the normal sleep cycles, may also be important triggers to the onset of episodes of mania. These findings have led to the development of a social rhythm metric, as an adjunct to interpersonal psychotherapy (interpersonal social rhythms therapy) as a treatment for individuals with bipolar disorder.

Adverse life events have been well documented to be precipitants of manic episodes, as well as depression. It appears that life events are more likely prior to the first or second episode of mania and are less likely later in the course of illness. The critical factor in life events triggering mania may be whether there is associated sleep disruption, rather than the 'psychological' meaning of the event.

Depressive disorders

Diagnostic issues

A key issue for the epidemiology of depressive disorders is defining the boundaries of major depression and dysthymia. Depressive symptoms in the community are common, and defining both the symptom count and the duration at which depressive symptoms count as part of a clinical disorder is arbitrary. When Kendler and Gardner[7] examined the boundaries of major depression as defined by DSM-IV in a population-based twin sample of women, they found that, if a twin had four or fewer depressive symptoms, syndromes composed of symptoms involving no or minimal impairment, and episodes lasting less than 14 days, then the individual's co-twin was still at an increased risk of major depression. Kendler and Gardner concluded that they could find no empirical support for the DSM-IV requirement of duration for two weeks, five symptoms, or clinically significant impairment. These authors suggested that major depression, as articulated by DSM-IV, may be a diagnostic convention imposed on a continuum of depressive symptoms of varying severity and duration. Wainwright *et al.*,[8] using data from the National Psychiatric Morbidity Survey of Great Britain, have also suggested that research should move beyond a binary decision of case versus non-case, and utilize a probablistic measure of psychiatric case status, replacing the arbitrary threshold with a smooth transition. This type of approach allows the benefits of syndrome diagnosis to be retained, while not falling into the dilemma of an arbitrary threshold that lacks validity.

Provided that one accepts the arbitrary definition of major depression, then determining the rates of current depressive disorders is not especially problematic. However, there are major methodological issues involved in determining whether an individual has ever had a lifetime episode of major depression. Lifetime prevalence rates vary from 4.4 per cent in the United States ECA study, to 17.1 per cent in the NCS, and to over 30 per cent in Kendler's Virginia twin sample of women. In part, subjects in the community may forget or fail to report past episodes of major depression (recall bias), and the manner in which the questions are asked may importantly influence lifetime rates of depression. In the Diagnostic Interview Schedule, which was used in the ECA, respondents were asked about lifetime symptoms, a lifetime diagnosis was made, and then recency of the lifetime diagnosis was determined. More recent diagnostic interview schedules, such as the Composite International Diagnostic Interview, first ask about current depressive symptoms and then, having 'primed' individuals about depressive symptoms, go on to enquire about past depressive episodes. Interviews that follow the schedule of 'priming' before asking about past episodes appear to obtain considerably higher rates of lifetime major depression. Determining lifetime rates of depression with greater precision is an important task, as the vulnerability to depression conferred by risk factors such as genetic factors and childhood experiences may be wrongly estimated if lifetime rates of major depression are imprecise. For instance, when Kendler *et al.*[9] examined the heritability of major depression and corrected for the moderate reliability of a lifetime diagnosis of major depression, the heritability estimate increased from 40 per cent to over 70 per cent. As concluded by Kendler, major depression is not a disorder of high reliability and moderate heritability, but is a diagnosis of moderate reliability and high heritability.

DSM-IV allows major depression to be further subclassified into subtypes, such as melancholia, atypical, psychotic, and by severity and recurrence. Most of the traditional epidemiology studies have tended to ignore the issue of subtyping major depression. Recently, however, the issue of the atypical depression subtype has received particular attention in the study of the Virginia twins and in the NCS. In both these studies, latent class analysis suggests that atypical depression is a distinct subtype with several distinctive features, such as higher rates of parental alcohol- and drug-use disorders, higher interpersonal dependency, and higher rates of conduct disorder. If risk factors for atypical depression are, in part, distinct from risk factors for other subtypes of major depression, then for epidemiology to contribute to an understanding of aetiology it will be important to undertake further work on depressive subtypes.[10]

Prevalence

In the ECA, the six-month prevalence of major depression across five sites was 2.2 per 100. In ECA equivalent studies the six-month prevalence rate ranged up to 5.3 per 100. In the NCS, the 1-month prevalence of a major depressive episode was 6.1 per 100.[11] In the National Psychiatric Morbidity Surveys of Great Britain, the one-week rate of a depressive episode was 2.1 per 100.[12] Together, these studies would suggest that the current rate of major depression is in the realm of two to five per cent.

The estimates of the lifetime rate of major depression are much more variable. The lowest rate reported is 4.4 per 100 from the ECA study, while, in the study of Virginia twins, the lifetime rate of major depression is over 30 per cent. It is reasonable to believe that the true lifetime rate of major depression is probably in the realm of 10 to 20 per 100, but caution should be exercised in expressing lifetime rates of depression with undue precision.

These rates of major depression may also be lower if the rate of bipolar disorder is higher. Isolated clinical studies have found that one in two, not one in ten, individuals presenting with depressive disorders have features of bipolar spectrum disorders. If these

figures are correct, then this would presumably lower the rates of major depression, but would correspondingly increase the rates of bipolar disorders.

Over the past decade, one of the controversial findings in the epidemiology of major depression has been whether the rates of depression are increasing, and whether it is occurring at a younger age. Despite methodological concerns about the reliability of lifetime major depression, studies across countries have reasonably consistently documented an increasing rate of major depression with an earlier age of onset.[13] As mood disorders are the single largest risk factor for suicide, it is also of note that, in most Western countries, the rate of suicide, especially in young adults, increased considerably from the 1970s to 1990s, although the suicide rate is now declining in many countries. This could, however, reflect better recognition and treatment of depression.

Risk factors

(a) Genetics

There is now substantial evidence that genetic factors are of major importance as risk factors for vulnerability to major depression. While traditional estimates have put the heritability at about 40 per cent, when Kendler *et al.*[9] allowed for the moderate reliability of the diagnosis of major depression, the heritability estimate increased to 70 per cent. Of greater interest is that the genes for major depression do not appear to be unique for depression, but overlap with the genes for anxiety and the genes for neuroticism.[14, 15] The greater prevalence of depression in women may be due to the strong association of anxiety and neuroticism with depression, and that the higher rates of anxiety and neuroticism in women lead to higher rates of depression.

(b) Gender

One of the most consistent findings in the epidemiology of major depression is that the ratio of women to men is approximately 2:1. This increased rate of major depression in women arises during puberty, as in childhood there is a slightly higher prevalence of depression in boys than girls. The timing of this transition in rates by gender is related to biological puberty rather than just to age.

(c) Childhood experiences

Early theorizing suggested that the loss of a parent in childhood increased the later risk for major depression; although many studies have examined this issue, they have inconsistently found it to be a risk factor for adult depression. However, studies that examine the nature of child–parent attachment using a measure such as the Parental Bonding Instrument have consistently found that a lack of parental care is associated with increased rates of depression.[16] More recently, childhood sexual abuse has been established as a risk factor for adult major depression.

However, cumulative childhood disadvantage almost certainly poses a greater risk to later depression than any single childhood variable in isolation. Thus, if studies only look at single childhood risk factors, they may miss the full impact of global childhood adversity. The converse of childhood risk factors is childhood resilience, and it is probable that one good relationship with an adult and high intelligence in the child may, in part, protect from other adversities.

(d) Personality

There has been a long history of interest in the likelihood that people with certain personality traits are more vulnerable to depression than others. It is likely that those individuals who are unduly anxious, impulsive, and obsessional may have increased rates of later major depression. The best data exists for neuroticism, which emerges as a clear risk factor for the later development of depressive and anxiety disorders. However, as already mentioned, the same genes seem to contribute to the development of neuroticism and to later anxiety and depressive disorders.

(e) Social environment

There has been considerable interest in the role of marital status as a risk factor for major depression. For men, it appears clear that married men have the lowest rate of depression, while separated or divorced men have the highest rates of major depression. In women, the association is slightly less clear, but in the ECA study the same findings applied for women as for men. Understanding the nature of the association between marital status and rates of depression is more problematic. If personality is a risk factor for depression, then the same traits could interfere with the ability to marry or to stay married. There is little doubt that depression sometimes contributes to marital maladjustment and separation or divorce. Finally, the stresses associated with divorce and separation could increase the likelihood of an episode of depression occurring.

In the classic and influential work of George Brown on working-class women, having three or more children, a lack of paid employment, and the lack of a confident were risk factors for the development of an episode of depression. Subsequent studies have inconsistently replicated the risk factors of having children or lack of paid employment, but have supported the finding that the lack of a confident increases the risk of depression.

It is well established that adverse life events, particularly those characterized by loss, increases the risk of an episode of major depression. Interestingly, however, the life events which may constitute the greatest risk may be 'dependent' rather than 'independent' life events. The increased vulnerability to an episode appears to last for a period of two to three months following such an event.

Early thinking about depression suggested that there would be those depressions that occurred for largely biological reasons and those precipitated by adverse life events; however, it is now clear that such a dichotomous view is incorrect. Kendler *et al.*[17] showed that there is a significant genotype by environment interaction in the prediction of onset of major depression. They proposed that genetic factors influence the risk of onset of depression, in part, by increasing the sensitivity of individuals to the depression-inducing effects of stressful life events.

(f) Physical illness

Having a chronic or severe physical illness is associated with an increased risk for depression. The mechanisms behind this increased risk may vary depending upon the physical disorder. In disorders such as Parkinson's disease, it is possible that there are shared neurotransmitter abnormalities between Parkinson's disease and depression. In post-stroke depression, there is good evidence that the location of the lesion, at least in part, contributes to the rate of depression, which suggests a neuroanatomical/neurotransmitter connection between the physical illness and the likelihood of depression. For non-central nervous system

disorders, such as acute myocardial infarction, diabetes, and cancers, the mechanism for this association is less clear. However, at least in the case of patients with cancer, most do not suffer from major depression and, if they do, the key risk factors are family history and a past history of depression. This suggests that the stress associated with a serious or chronic physical illness may act by bringing out an individual's lifetime vulnerability to depression.

An integrated aetiological model

The ultimate purpose of studying risk factors for depressive disorders is to contribute to the development of an integrated aetiological model. The most promising research in this area has been performed by Kendler and colleagues on twins from the Virginia Twin Register.[18] In this study, both female–female and male–male twin pairs of known zygosity have been assessed on a series of occasions at longer than one-year intervals. A range of predictor variables; including genetic factors, parental warmth, childhood parental loss, childhood disorders, lifetime traumas, neuroticism, self esteem, social support, past depressive episodes, recent difficulties, and recent stressful life events have been examined to see how they contributed prospectively to the development of an episode of major depression over the next 12 months. In considering the results from this study, it is important to bear in mind the limitations of this landmark study, especially the fact that they were predicting the onset of an episode over 12 months and not predicting lifetime episodes. However, despite these caveats, Kendler and colleagues developed a model that predicted over 50 per cent of the variance in the liability to develop major depression in the next twelve months. The strongest predictors to depression were as follows:

- stressful life events
- genetic factors
- previous history of major depression
- neuroticism

It is of note that some of the risk factors exerted these effects directly, while other effects were largely indirect. Thus, 60 per cent of the effect of genetic factors on liability to depression was direct, but the remaining 40 per cent was indirect and largely mediated by past episodes of depression, stressful life events, and neuroticism. Variables such as perceived parental warmth had no direct effect on liability to develop an episode of major depression, but did impact upon neuroticism, a history of a past depressive episode, recent difficulties, and lifetime traumas.The most comparable prospective studies looking at risk factors for the development of major depression have been undertaken during the postpartum period, which is a time of increased risk of depression. In this special case, the most consistent risk factors are family history and a past history of depression, and there is lesser support for a lack of social support, neuroticism, and complications during childbirth.

As one of the key tasks of epidemiology is to contribute to an understanding of aetiology, models that integrate risk factors are important strategies for further research. They provide clinicians with predictive power, and can also guide intervention studies to prevent the onset of episodes of depression.

Comorbidity

One of the important contributions of epidemiology to the study of mood disorders over the past twenty five years has been the recognition of the extent to which depression and other psychiatric disorders are often comorbid. In both the ECA study and NCS, over two-thirds of all individuals identified as having an episode of major depression also met the criteria for one or more other psychiatric disorders. Not surprisingly, the most common comorbid disorders are anxiety disorders and substance-abuse disorders. In the NCS, the anxiety disorders with the highest odds ratios indicating comorbidity were generalized anxiety disorder, panic disorder, and post-traumatic stress disorder. It is also important to note that for most anxiety disorders, with the exception of panic disorder, the anxiety disorder usually predates the onset of the depressive disorder.[19] This is of considerable importance, as the risk factors for pure major depression differed from the risk factors for comorbid major depression. Furthermore, the cohort effects of increasing rates of major depression were largely attributable to increasing rates of comorbid major depression, rather than to increasing rates of pure major depression. These results raise important issues for prevention, as it may well be that targeting young people with anxiety disorders and could be a major step to the prevention of the development of later major depressive disorders.

The second key area of comorbidity with major depression is with alcohol dependence. Data from the Virginia Twin Register suggest that part of this comorbidity is due to shared genetic factors, although there is also a smaller common environmental risk factor to both disorders.

Another area of considerable comorbidity with major depression is the personality disorders. The comorbidity between major depression and these disorders is receiving considerable attention in clinical samples but, to date, there are only limited data in epidemiological samples on the importance of these patterns of comorbidity.

Use of health services

One of the major challenges for psychiatry presented by epidemiological studies of depression has been the consistent finding that the majority of cases of depression in the community are not recognized, diagnosed, nor treated. In the ECA study, it was found that 65 to 70 per cent of people with depression had visited a health professional in the last 6 months, but only 15 to 20 per cent had had a visit for a mental health reason and only about 10 per cent had seen a mental health specialist. Ormel *et al.*[20] found that patients with depression who present with largely somatic rather than psychological symptoms are extremely unlikely to be recognized by general practitioners. Even if major depression is recognized in the primary care setting, it is often not adequately treated.[21]

4.5.5 Genetic aetiology of mood disorders

Pierre Oswald, Daniel Souery, and Julien Mendlewicz

Introduction

Advances towards the understanding of the etiological mechanisms involved in mood disorders provide interesting yet diverse hypotheses and promising models. In this context, molecular genetics has now been widely incorporated into genetic epidemiological research in psychiatry. Affective disorders and, in particular, bipolar affective disorder (BPAD) have been examined in many molecular genetic studies which have covered a large part of the genome, specific hypotheses such as mutations have also been studied. Most recent studies indicate that several chromosomal regions may be involved in the aetiology of BPAD. Other studies have reported the presence of anticipation in BPAD and in unipolar affective disorder (UPAD).[1–3] In parallel to these new developments in molecular genetics, the classical genetic epidemiology, represented by twin, adoption and family studies, provided additional evidence in favour of the genetic hypothesis in mood disorders. Moreover, these methods have been improved through models to test the gene-environment interactions.

In addition to genetic approaches, psychiatric research has focused on the role of psychosocial factors in the emergence of mood disorders. In this approach, psychosocial factors refer to the patient's social life context as well as to personality dimensions. Abnormalities in the social behavior such as impairment in social relationships have been observed during episode of affective disorders, and implicated in the etiology of affective disorders. Further, gender and socio-economic status also emerged as having a possible impact on the development of affective disorders. Finally, the onset and outcome of affective disorders could also be explained by interactions between the social life context and the individual's temperament and personality. The importance of temperament and personality characteristics in the etiology of depression has been emphasized in various theories, although disagreement exists with regard to terminology and the etiology.

While significant advances have been done in these two major fields of research, it appears that integrative models, taking into account the interactions between biological (genetic) factors and social (psychosocial environment) variables offer the most reliable way to approach the complex mechanisms involved in the etiology and outcome of mood disorders. This chapter will review some of the most promising genetic and psychosocial hypotheses in mood disorders that can be integrated in interactive models.

Genetic epidemiology of mood disorders

The various strategies available to investigate genetic risk factors in psychiatric disorders belong to the wider discipline of genetic epidemiology. This combines both epidemiological and genetic investigations and has the primary objective of identifying the genetic and non-genetic (environmental) causes of a disease. Genetic epidemiological data in affective disorders has come mostly

from family, twin, adoption and segregation (within families) studies. Family, twin and adoption studies are the mainstay in establishing the genetic basis of affective disorders. These methods firstly demonstrated that genetic factors are involved in the aetiology of these disorders.[4] Twin and adoption data may also be used to investigate the relative contributions of genetic and environmental factors to the aetiology of a disease.[5] The exact contribution of these factors is not yet firmly understood for affective disorders but some studies provide contributing findings. The study of adoptees who are separated from their biological parents has consistently favoured the gene-environment hypothesis in the aetiology of diverse psychiatric disorders.[6] In adoption studies, both UPAD and BPAD have been described to be more frequent in biological relatives of the adopted subject, suffering from affective disorders than in adopted relatives.[7]

The diagnostic validation and the structure of the genetic and environmental risk factors in mood disorders are also approached in twin studies.[8] From the landmark study of Rosanoff *et al.* in 1934 to more recent works from Mc Guffin *et al.*[9] and Kieseppa *et al.*,[10] concordance rates for BPAD are higher in monozygotic twins (20–100 per cent) than in dizygotic twins (0–38 per cent).

Molecular genetics in affective disorders

The rapid advance in molecular genetic techniques over the last decade has generated a large database of DNA markers across the whole human genome and has enabled chromosomal regions throughout almost the entire genome to be studied in affective disorders. These studies have been performed mainly using linkage and association methodologies. Current linkage and association methods investigate heritable factors at a molecular genetic level, and enable genes to be mapped.[11] These approaches are mostly applied to BPAD, which is considered to be the 'core' phenotype in affective disorders. Linkage analysis tests the hypothesis that a linkage relationship exists between a known genetic marker and a trait which is known to be genetically determined but has not yet been mapped on a chromosome.[12] Two genetic loci are linked if they are located closely together on a chromosome. In linkage analysis, the distance between a marker locus and the gene under investigation is used for gene mapping. This method was originally designed to explore a major single genetic transmission and to evaluate the extent of co-segregation between genetic markers and the phenotype investigated in pedigrees. The major problems which linkage methodology face when applied to affective disorders are the complex aetiology and inheritance patterns. More than one locus are probably involved in susceptibility to these disorders, and the exact mode of transmission is not known. Mis-specification of the genetic parameters of the phenotype may lead to errors in linkage studies.[12] Furthermore, the linkage approach fails to detect minor gene effects which contribute to genetic susceptibility to the disorder.[13] More recently, genome-wide linkage studies have been performed on samples of families with multiply affected members.[14]

The association method offers an alternative strategy of studying genetic factors involved in complex diseases in which the mode of transmission is not known.[15] The association strategy does not require genetic parameters to be known (non-parametric method). The purpose of association studies is to compare frequencies of genetic marker alleles in patient and control populations in order to detect linkage disequilibrium. Linkage disequilibrium between the disease locus and the marker tested is defined as a level of concordance between the two loci which is higher than would be expected by chance. The major reason for this is their proximity on a chromosome. The major advantage of association studies is that they can detect genes with minor effects other than a single major locus (SML). The major limitation of this approach is that spurious associations between a genetic marker and a disorder may result from variations in allele frequency between cases and controls observed if the two populations are ethnically different (population stratification). It is important in this case to compare populations which are homogenous in their ethnic background. A further major difficulty in association studies is the interpretation of the precise meaning of the association observed.[16] The result may be interpreted as linkage disequilibrium between the disease locus and the associated marker allele(s). Alternatively, the associated marker may be interpreted as a susceptibility factor which is directly involved in the disease. The candidate gene approach in association studies is a useful method to investigate linkage between markers and diseases. A candidate gene refers to a region of the chromosome which is potentially implicated in the aetiology of the disorder concerned. The possibility of false positive results must be taken into account, as a very large number of candidate genes now exist. The probability that each of these genes is involved in the aetiology of the disorder is relatively low.

Linkage studies in affective disorders (See[17] for review)

From more than two decades of linkage studies, it seems that several chromosomal locations have been associated with affective disorders, sometimes with conflicting results. Mendlewicz *et al*[18] first reported possible genetic linkage between manic depression and coagulation Factor IX (F9) at Xq27 in 11 pedigrees. Another region of interest seems to be the chromosome 18 where the pericentromeric region was suggested to carry susceptibility genes. The chromosome 11 has been thoroughly investigated in AD but showed contradictory results. Chromosomes 4, 6, and 10 were also investigated with conflicting and/or unreplicated results. Darier's disease (keratosis follicularis), a rare autosomal dominant skin disorder associated with increased prevalence of epilepsy and mental retardation, whose gene was mapped on chromosome 12 (12q23–24.1), was found to cosegregate with BPAD in one pedigree. This result was replicated in several family studies. Genome-wide linkage analyses provide an accurate tool to study regions of interest. In BPAD, early positive and promising results were contradicted by further analyses. This fact is not surprising, since these studies were performed on small samples sizes, insufficient to replicate modest linkage signals.[19] Meta-analyses were thus performed on BPAD to increase the power to detect modest linkage signals.[14] Bipolar loci with evidence of linkage were found on the following arms: 4p, 6p, 6q, 9p, 10q, 12q, 13 q, 14q, 17q, 18p–q, 21q, 22q.[14,20] McQueen *et al.*[21] found susceptibility loci on chromosomes 6q and 8q by using a combined analysis of eleven linkage studies. A recent study from Schumacher *et al.*,[22] in four European samples, confirmed previously reported loci, 4q31 and 6q24, and provided evidence for a new linkage locus, 1p35-36.

Candidate genes in affective disorders

Serotonin markers

Dysfunction of the serotoninergic system has long been suspected in major depression and related disorders. Depression can successfully be treated with selective drugs which target serotonin receptors. The serotonin transporter may also be involved in susceptibility to affective disorders and in the response to treatment with these drugs. Most recent replication studies did not support these initial positive findings. This has been the case for 5HTT.[17] The tryptophan hydroxylase (TPH1) gene, which codes for the rate limiting enzyme of serotonin metabolism, is also an important candidate gene for affective disorders and suicidal behavior. Bellivier *et al*[23] reported a significant association between genotypes at this marker and BPAD, no association was found with suicidal behaviour. In a previous study in depressed patients suicidal behaviour has been associated with one variant of this gene.[24] The tryptophan hydroxylase isoform (TPH2) showed an association between BPAD and suicidality.[25]

Other candidate genes

Among other pathways, DRD2, DRD3, DRD4 and DAT1 were largely studied and replicated. Unfortunately, results remain conflicting. Recent studies have implicated neurotrophic factors in the underlying disease processes of affective disorders. Brain-derived neurotrophic factor (BDNF), the most abundant of the neurotrophins in the brain, enhances the growth and maintenance of several neuronal systems, serves as a neurotransmitter modulator, and participates in plasticity mechanisms such as long-term potentiation and learning.[26] Although promising, BDNF did not confirm its role in the pathophysiology of affective disorders.[27,28] Several new candidate genes from the well-known molecular cascades have been tested: PIK3C3 in the intracellular signalling pathway; PCDH11Y, a proto-cadherin and GSK3β, a target molecule of lithium. Finally, studies of circadian rhythm-related genes showed promising results in BPAD, such as ARNTL.[29,30]

Anticipation and expanded trinucleotide repeat sequences

Anticipation implies that a disease occurs at a progressively earlier age of onset and with increased severity in successive generations. This may explain the non-Mendelian pattern of inheritance observed in some inherited diseases. Anticipation has been found to correlate with specific mutations in these syndromes: expanded trinucleotide repeat sequences. An expanded repeat sequence is unstable and may increase in size between family members, leading to increased disease severity of the disorder.

Anticipation has been described in BPAD and in UPAD.[1,3] One study highlighted an association between Cysteine-Alanine-Glycine (CAG) trinucleotide repeats and BPAD illness in Swedish and Belgian patients with affective disorder.[31] CAG repeats have been detected by the Repeat Expansion Detection method (RED-method). This hypothesis has also been tested in a family sample of two-generation pairs with BPAD.[32] A significant increase in CAG repeats between parents and offspring generations was observed however, when the phenotype increased in severity, i.e. changed from major depression, single episode or unipolar recurrent depression to BPAD. This is the first evidence of genetic anticipation in BPAD families and should be followed by the identification of loci within the genome containing triplet repeats. CTG 18.1 on chromosome 18q21.1 and ERDA 1 on chromosome 17q21.3 are two repeat loci recently identified but were not found to be associated with BPAD.[33] A newly identified CTG/CAG repeat was found to be associated with BPAD.[34]

Phenotype definition

Facing the heterogeneity of results, it has been hypothesized that genetic factors could explain some symptoms or clinical features of the syndromes, such as severity of the disease, age at onset or gender predominance. Early-onset, and more specifically pediatric-onset, BD has been suggested to have its own pattern of genetic susceptibility factors. Family studies have consistently found a higher rate of BD among the relatives of early-onset BD patients than in relatives of later-onset cases.[35] Among the most recent studies, Faraone *et al.*[36] found, in a genome-wide scan, 3 regions of interest that may influence age at onset of mania in BPAD. Geller *et al.*[37] found an association between BDNF and BPAD with early-onset. Massat *et al.*[38] provided evidence for the influence of HTR2C in early-onset BPAD

More specific neurophysiologic, neuroimaging, neurocognitive, or neurochemical trait measures might identify homogeneous groups of patients. These 'traits' are called 'endophenotypes' and are believed to represent the genetic liability of the disorder among non-affected subjects.[39] Endophenotypes in BD are difficult to define. Circadian rythms, stress reactivity and appetite regulation have been proposed. Bipolar patients are also suggested to show inappropriate emotional responsiveness. Using emotional facial stimuli, depressed BD patients show impaired recognition of happy and sad facial expressions.[40] These findings confirm a particular pattern of characteristics in BD, and suggest that genetic factors may explain these characteristics, rather than the whole clinical picture.

Shared genetic predisposition between BPAD and schizophrenia

If BPAD and schizophrenia (SCZ) are distinguishable, they may share some characteristics. Indeed, family studies show partial overlap in familial susceptibility for these two conditions.[41] Evidence for linkage of both BPAD and SCZ were found on 18p11, 13q32, 10p14, 22q11–13 and 6p22.2.[42–44] More interestingly, two genes showed promising results in molecular genetic studies in these two conditions. From the first report from Hattori *et al.*,[45] G72, found on 13q34 and encoding d-amino acide oxidase activator (DAOA), was found to be associated with delusion or psychosis, rather than with the entire bipolar or schizophrenic clinical pictures.[46] Although robust, these results were confirmed in a recent meta-analysis from Detera-Wadleigh *et al.*[47] Largely distributed in neurones, DISC1 (Disrupted in Schizophrenia 1) interacts with many proteins and is related to several neuronal functions. Thomson *et al.*[48] found a robust association between DISC1 and BPAD, but this result needs confirmation. Theses cases of shared genetic predisposition emphasizes the need, in future classification systems such as DSM-V, to focus on classification that may more closely represent expression of underlying biologic systems.[49]

Pharmacogenetics

One of the main difficulties in clinical practice is the inability to know *a priori* which psychotropic drug will be best suited for each case. Therefore, several groups worldwide try to overcome that obstacle by searching genetic markers that might be predictive of treatment response.

BPAD

The first studies on the relationship between response to lithium and family history have been published in the 1970s, supporting an association between a family history of BPAD and satisfactory response to treatment. Mendlewicz *et al.*[50] first reported a study of 36 patients through a double blind study of lithium prophylaxis. They found that 66 per cent of the responders to lithium had at least one first-degree relative with BPAD, and that only 2–1 per cent of the lithium nonresponders had a first-degree relative with BPAD. Lipp *et al.*[51] first reported an association between DRD2 and non-response to lithium. Several studies have followed (See[52] for review). Positive results were found in TPH and 5HTT.[53,54]

UPAD

Previous studies of an association between poor antidepressant response in depressive patients and 5HTT were largely replicated and could be considered as a robust finding (see[55] for exhaustive review and discussion). Among more recent findings, GNB3 (beta3 subunit of G protein) and DAT1 were found to be associated with treatment response. Binder *et al.*[56] found an association between FKBP5, which plays an important role in the glucocorticoid receptor function, and rapid response to antidepressant. Interestingly, this group of patients was characterized by a high rate of relapses. Finally, the large STAR*D (Sequenced Treatment Alternatives to Relieve Depression) project provided recent promising data for HTR2A 5HTT and GRIK4, which codes for the kainic acid-type glutamate receptor KA1 and treatment response.[57–59]

Psychosocial factors in affective disorders

Impairment in social relationships, dysfunctional cognition, gender, economic status, and temperament has been suggested as involved in the emergence of mood disorders. However, empirical studies on psychosocial factors of patients with affective disorders examine psychosocial features assessed after recovery from or/and at the time of episodes of affective disorders. These retrospective studies might not be able to distinguish between premorbid psychosocial patterns and those which result from previous episodes of illness. Further, longitudinal studies focusing on the role of psychosociological factors have involved predictions of recurrence or exacerbation of symptomatology in previously affected people, but not regarding the onset of the diseases. Thus, the demonstration of temporal antecedence to the initial onset of affective disorder is extremely difficult.[60] Thus, the conclusions in terms of etiological psychosocial factor are limited.

Impairment in social and familial relationships

Difficulties in social functioning are concomitant to depressive disorders.[61] The concept of social support has been widely used to predict general health and more specifically psychiatric symptoms.[62] Previous research revealed that the degree of integration in a social network, or structural support, have a direct positive effect on well-being, reducing negative outcomes in both high and low stress life events. Among depressed individuals, dysfunction in social activities has been found to persist long time after remission from the depressive episode.[63] The social dysfunctioning concerns more specifically marital relationships, parental, and familial relationships.

The relationship between marital disturbance and affective disorders has received increased attention over the past decades. First, descriptive studies have suggested that marital conflict correlates highly with concomitant depression,[64] and marital therapy has been found to be effective in reducing the symptoms of depression, alone as well as in combination with pharmacotherapy. Further, previous research found dysfunctional patterns of communication in couples with a depressed spouse.[65, 66] The lack of a confiding and intimate relationship leaves individuals vulnerable to depression.[67, 68] Finally, marital distress may also exacerbate difficulties experienced in extramarital relationships,[69] thereby increasing introverted behavior and social isolation. In similar manner, the absence of a marital partner may hasten the onset of depression among vulnerable individuals.[70]

The parental relationships seem also to have a great impact in the course of affective disorders. A variety of authors have emphasized the importance of the quality of early experiences with parents in the development of adult depression. Beck first, explicitly attributes the development of negative cognition and negative schemata of self to critical, disapproving parents.[71]

Dysfunctional cognition

According to the helplessness model of depression[73] vulnerability to depression derives from a habitual style of explaining the causes of life events, known as attributional style. A large body of research found that individuals suffering of depression think more negatively than healthy individuals. Specifically, depressed patients have a tendency to make internal, stable, and global causal attributions for negative events, and to a lesser extent, the attribution of positive outcomes to external, specific, and unstable causes. In other words, depressed patients have a low self-esteem.[74,75] Thus, when thinking about the self, past, current and future circumstances, depressed patients emphasize the negative, and this process is likely to contribute to the perpetuation of their depressed mood.

Gender

Evidence for sex differences in responses to depression comes from a large number of studies. Women are consistently reported to have greater prevalence of affective disorders than men.[76,77] First, women may experience two important periods, known to be associated with higher rates of depression: pregnancy and post-partum. The prevalence of major or minor depression among pregnant women ranges from 7 per cent to 26 per cent.[78] Depression during pregnancy is a strong predictor of postpartum depression. The prevalence of postpartum depression ranges from 10 per cent to 15 per cent in the first year after childbirth.[79] Besides these two specific conditions, the reasons for this sex difference are unclear, and are as likely to be social as biological.

Divergences in the number and quality of social and occupational roles have been proposed to explain the greater prevalence of affective disorders among women. In the context of marital relationship, previous research has indicated that for men, marriage confers a protection against illness, while it appears to be associated with higher rates of depression for women.[80] There has been some evidence that within the marriage the traditional female role is limiting, restricting, which may lead to depression.[81,82] For example, the role of child caretaker has consistently been shown to be associated with both high levels of stress and a higher incidence of depression for women.[83]Women are found to have more depressive symptoms when there are young children in the home, and this tends to increase in an almost linear fashion according to the number of children in the household.[84] Further, since women who are employed outside the home also tend to be responsible for household chores,[85] the notion that differentiation in occupational roles could partially explain the prevalence of depression for women is supported.

Socio-economic status

Many studies have reported that low socio-economic status is associated with high prevalence of mood disorders.[86] Since a long time, in social psychiatry, the 'social causation' and 'social selection' hypotheses have been formulated to explain the role of the low socio-economic status in the disease. The causation hypothesis suggests that the stress associated with low social position, that is exposure to adversity and lack of resource to cope with difficulty, may contribute to the development of the affective disorder[87] while the social selection hypothesis argued that genetically predisposed persons drift down to or fail to rise out of such positions.[88,89] Thus, the social selection hypothesis emphasizes the genetic interpretation of cause, while social causation hypothesis focuses on the etiologic role of the environment. Few longitudinal data sets are available to test the causal hypothesis. Nevertheless, there is evidence that disadvantaged socio-economic status, poverty, or education and occupation can be considered as risk factors for mood disorders.[90,91] Nevertheless, Bruce and Hoff found that the effect of poverty is substantially reduced when controlling for degree of isolation from friends and family, suggesting that social isolation mediates some of the relationships between economic status and mood disorders.[92]

In summary, a positive relationship has been found between socio-economic status and vulnerability to affective disorders, with higher rates of vulnerability found among individuals with lower educational and social achievement levels.

Temperament and behaviour

Temperament has been defined in terms of differences in the adaptative systems, that is differences in reactivity and self-regulation to the social context.[93–95]

The model of temperament developed by Eysenck approaches temperament in terms of cortical arousal.[96] Eysenck suggested that individuals differ in their basic arousability and therefore, in their optimal level of stimulation. These physiological differences give rise to the primary personality dimension of introversion-extraversion. Introverts are said to possess relatively reactive reticular systems, and thus to attain their optimal level of cortical arousal at relatively low level of stimulation. As a result of their low optimal arousal level, introverts are expected to prefer and seek out mild forms of stimulation and to avoid more intense and novel forms of stimulation. In contrast, extraverts are said to possess relatively unreactive reticular systems, to have correspondingly high optimal levels of cortical arousal, and to therefore, approach more intense and novel forms of stimulation.

The differences between the Cloninger's model and other models are that Cloninger assumes relationships between biogenic amine neurotransmitters (norepinephrine, serotonin, and dopamine) and personality dimensions. Specifically, Cloninger defined temperament dimensions in terms of individuals' differences in associative learning in response to novelty, danger or punishment, and reward. Further, he hypothesized a positive correlation between serotoninergic activity and harm avoidance, dopaminergic activity and novelty seeking, and finally between noradrenergic activity and reward dependence. According to this author, these aspects of personality denote traits that are usually considered temperament factors because they are heritable, manifest early in life, and apparently involved in learning. The possible tridimensional combinations of extreme (high or low) variants on these basic stimulus response characteristics correspond closely to the traditional descriptions of personality disorders. The specific relationship between temperament and mood disorder is not yet understood satisfactorily. Studies have been done regarding the Tridimensional Personality Questionaire (TPQ) scores in relation to mood disorder, the data available suggest that depressed patients have elevated harm avoidance scores.[97–100]

The possible role of candidate genes has been investigated in personality. Association between a personality trait (Novelty Seeking) and the 7 repeat allele in the locus for Dopamine receptor D4 gene (DRD4) has been observed in a group of 124 unrelated Israeli normal subjects.[101] Novelty Seeking was assessed from the Tridimensional Personality Questionnaire (TPQ).[102] An association was also observed between similar personality traits and long alleles of DRD4 gene in 315 subjects, mostly male siblings from United States.[103] This last study utilized the NEO Personality Inventory (NEO-PI-R)[104] from which TPQ Novelty-Seeking scores can be estimated. More recent studies also suggest a pattern of influence on temperamental dimension exerted by serotonergic and dopaminergic genes.[105] They studies, even not definitive, suggest that the contribution of these polymorphisms to the clinical presentation of mood disorders could be mediated by an influence on personality differences.

The gene-environment hypothesis

The availability of molecular genetic findings in affective disorders offers new directions in this research field. It is now possible to consider the gene-environment hypotheses using the DNA as the genetic liability variable. In primate models, early experiences of maternal separation were found to confer increased risk of depression during adult age.[106] Barr *et al.* found that infant rhesus monkeys showing a specific polymorphism in 5HTT were more likely to engage in rough play than were individuals without this polymorphism.[107] In humans, a landmark study demonstrated that a functional polymorphism in the promoter region of 5HTT gene moderated the influence of stressful life events on depression and suicidal behaviour.[108] This study was replicated

with conflicting results using different methodologies.[109–112] However, these results support the notion that a combination of genetic predisposition and specific life events may interact to facilitate the development of affective disorders.

Conclusion

The complexity and heterogeneity of affective disorders is a major limitation for gene-environment studies.This could be attributed to their non-Mendelian mode of inheritance. BPAD and UPAD are, in fact, phenotypes which do not appear to exhibit classic Mendelian recessive or dominant inheritance involving a single major locus. The presence of both environmental as well as genetic factors and phenotypic diversity also represent important problems when dealing with these diseases. After the era of enthusiasm due to first results from linkage and association studies, the lack of replication and the identification of potential methodological biases led to a period of pessimism. However, recent technological advances allow for the analysis of hundreds of components in a biological system simultaneously. Gene expression micro-arrays may analyse the expression of hundreds of genes in a specific tissue. More specifically, micro-array technologies measure levels of messenger ribonucleic acid (mRNA), an intermediate product between gene and protein.[113] The levels of these 'transcripts' are compared between a population suffering from a specific disease and control subjects. The analysis of mRNA transcripts, instead of DNA regions, may provide additional information on genetic regulation processes of illness. Ultimately, the understanding of neurobiological processes underlying affective disorders may help developing therapeutic and prevention strategies.

4.5.6 Neurobiological aetiology of mood disorders

Guy Goodwin

Introduction

Neurobiology provides an explanation of behaviour or experience at the level, either of systems of neurones or individual cells. The current era of progress is driven by contemporary cognitive neuroscience and a rapid evolution in the platform technologies of imaging and genetics. These will allow us to improve our accounts of the functional anatomy of the component elements of mood and its disorder, their functional neurochemistry and, in all probability, give meaning to what a cellular account of depressive illness may eventually describe. This chapter will offer a partial and personal view of these developments to date.

There are now authoritative models of causation in mood disorder, established from well designed, large-scale twin studies (see Chapter 4.5.5). These inform the classical formulation of mood disorder as requiring a vulnerability, a precipitating factor or factors, and maintaining factors which prevent spontaneous recovery. Neurobiology will be addressed under these headings.

Vulnerability to mood disorder

The key vulnerability factors appear to be genes, temperament (also in substantial part genetic), and early adversity. There has been limited work on the neurobiology of these risk factors, as opposed to the vast effort to understand the depressed phenotype. However, for potential prevention either of onset or relapse, such factors appear more logical targets for current research effort and will be covered first. Success in depression would parallel that seen in moving the management of heart disease from the acute episode of infarction to the treatment of metabolic risk factors.

(a) Genetics

Neurobiology has informed the genetic search for candidate genes, starting with the human serotonin transporter (SERT) gene (see Chapter 4.5.5). There has been a terrific proliferation of possible genetic effects deriving from neurobiological theories designed either to explain elements of the actions of psychotropic drugs, the depressed phenotype or from animal experiments. The latter are limited by the validity of animal models of depression per se. Some of the former will be noticed below.

Genes making small contributions to the risk of psychiatric disorder are emerging from direct analysis of the genome (see Chapter 2.4.2). Consistent findings must inform biological investigations in future. At this point it is uncertain whether insights will come from studying variation in individual genes, as has often been assumed, or from a much more complex understanding of cellular function regulated only in part by genetic variation. On the latter assumption the role of genetic hits is to direct attention to processes which may go wrong in the relevant disease. For mood disorder, these seem likely to be developmental or related to stress regulation.

(b) Temperament

The way in which genes may regulate the expression of vulnerability traits is suggested by animal studies. For example, when animals are selected for differences in emotional behaviour they also show different hypothalamic–pituitary–adrenal (HPA) axis function. Specifically, Roman high- and low-avoidance rats differentially acquire a two-way active avoidance response in a shuttle box. High-avoidance animals show greater prolactin and HPA axis responsivity to stress compared with low-avoidance animals. However, young Roman strain rats show identical HPA axis reactivity, although prolactin responses and behaviour are different.[1] In other words, reactivity to the environment may share a measure of common genetic control across physiological and behavioural domains, but HPA abnormality per se develops secondary to emotional experience, or at least is magnified by it.

In human studies, neuroticism is an old psychological construct often criticized as reflecting an average or habitual mood state rather than a truly independent risk. We have studied extremes of the dimension (high and low N) in young subjects before the onset of depression and in older groups who may or may not have experienced depressive episodes. Interestingly, high neuroticism with or without a history of depression is associated with increased awakening cortisol[2] in mature subjects, but not in subjects under 20 years of age, echoing the rodent finding. Thus, N has a purely biological consequence that develops with emotional experience, but is independent of depression per se.

What the neuroticism construct has also lacked hitherto has been a plausible psychological dimension. Cognitive bias relevant to the onset of depression can be detected in young high N subjects. In emotional categorization and memory tasks, high N volunteers were faster to classify dislikeable self-referent personality characteristics and produced fewer positive memory intrusions. They also had a higher threshold for identifying happy faces. This suggests the hypothesis that risk for depression is largely manifest as reduced positive processing of emotional information[3]; increased negative processing appears to develop only after the actual experience of depression. Neural biases underlying this behaviour are even more readily detected.[4] Our hypothesis is that high neuroticism is not just an habitual low mood but is **biologically** founded in negative biases in attention, processing, and memory for emotional material. Indeed, there is now genetic evidence favouring a common genetic locus in human beings and rodent.[5] How emotional bias translates into either low-level symptoms or a full mood episode will be of great interest. Furthermore, depressive episodes per se appear to have an impact on brain function, and increase the risk of further relapse (see below).

(c) Early adverse experience

Adverse childhood experience was identified in genetically uncontrolled studies as a risk factor predisposing women to subsequent

depression (Chapter 4.5.5) and has been confirmed in genetically informative designs.[6] In a clinical context, such developmental or social effects are usually viewed as separable from biology. Indeed, their very existence is usually taken to validate a 'social' approach to psychiatry. From a more unified point of view, however, one would predict measurable neurobiological consequences. In fact, such effects have proved to be more profound than most biologists anticipated.

Variations in maternal care produce individual differences in neuroendocrine responses to stress in rats. The offspring of mothers that exhibited more licking and grooming of pups during the first 10 days after birth showed, in adult life, reduced plasma ACTH and corticosterone responses to acute stress.[7] In addition, there was increased hippocampal glucocorticoid-receptor messenger RNA (**mRNA**) expression, enhanced glucocorticoid feedback sensitivity, and decreased levels of hypothalamic corticotrophin-releasing hormone (**CRH**) mRNA. Greater early maternal attention also substantially reduced subsequent behavioural fearfulness in response to novelty, increased benzodiazepine receptor density in the amygdala and locus coeruleus, increased α_2-adrenoreceptor density in the locus coeruleus, and decreased CRH receptor density in the locus coeruleus. Thus, maternal care serves to programme behavioural responses to stress in the offspring by altering the development of the neural systems that mediate fearfulness.

When BALB/cByJ mice were raised by an attentive C57BL/6ByJ dam, their excessive stress-elicited HPA activity was reduced, as were their behavioural impairments. However, cross-fostering the more resilient C57BL/6ByJ mice to an inattentive BALB/cByJ dam failed to elicit behavioural disturbances. In other words, vulnerable offspring may have their problems exacerbated by maternal behaviour, while early-life manipulations may have less obvious effects in relatively hardy animals.[8] Whether separation or stress paradigms in rodents can be taken as precise models of the mechanisms underlying the risk of mood disorder or other psychiatric problems cannot yet be decided, but their general relevance to the human case seems obvious. At present, data in human subjects is limited but findings that relate to the better characterized animal models are emerging.[9]

In fact, epidemiological data have linked increased risks of cardiovascular, metabolic, neuroendocrine, and psychiatric disorders in adulthood with an adverse *foetal* environment as well. Glucocorticoid excess may be the mechanism.[10] Low-birthweight babies have higher plasma cortisol levels throughout adult life, which suggests a permanent change in HPA function. Whether such effects and later effects of environmental stress in childhood can in part mediate co-morbidity between a range of psychiatric and physical disorders is of growing contemporary interest. It is unclear how, over- or underactivity in stress regulation contributes to psychiatric disorder: both appear to be implicated since awakening cortisol responses may be blunted in subjects with early adversity[9] or enhanced in at risk neurotic individuals.

Gene–environment interaction is the likely basis of the neurobiology of mood disorder. In general terms this must be correct. Either the genetic/biological or the environmental factors could be targets for prevention. Whether the genetic mechanisms can be brought into sufficient focus to allow specific new pathways to be identified remains the major current challenge. It is often assumed that mediating characteristics or the endophenotype may have a simpler genetic architecture than the disease itself: unfortunately, the evidence so far gives reason for caution. This debate is currently very polarized between optimists (see Chapter 2.5.3 by Meyer-Lindenberg & Goldberg) and pessimists (see Chapter 2.4.2 by Flint). The genetic and developmental routes into distal common pathways regulating stress responses may be very numerous. Disorders that are both common and very variable in expression, such as depression, may turn out to have little specificity that is worth talking about. Every illness may be an ensemble of many specific factors, none of which is individually going to lead to a more focused treatment or a better prediction of treatment response.

Precipitating factors: the neurobiology of life events

Like early adversity, the role of life events in depression has been affirmed in genetically controlled studies. Life events are relevant to almost all first episodes of depression, but are less significant in its recurrence. The biology of life events is subsumed in the biology of stress, at best a clumsy term. In human studies it will be always difficult to isolate the critical ingredients of a particular psychological stress from the individual differences that stressed individuals bring to their experience. There have been few recent contributions to the field of direct relevance to depression.[11] However, a key clinical feature of the illness course in depression is the association of life events most strongly with first episodes of depression. Subsequent episodes appear to need a less substantial environmental trigger, as if the patient becomes sensitized.[12] Patients with a strong family history may effectively be presensitized. Accordingly the effect of life events and the brain changes that occur with repeated or chronic illness is of great relevance to prevention and reduction of the risk of future episodes.

Maintaining factors: biological studies of the depressed state

In the majority of biological studies of affective disorder, patients have been studied when ill and compared with normal controls. Over the years, this kind of design has produced a range of positive findings, usually of modest effect. It remains true to say that no biological changes have ever been found that distinguish between depressed patients and controls better than does the clinical assessment of the patients. What is also curious, and not a little tantalizing, is the impression that some symptoms may, in part, represent biological adaptations directed to put things right. Thus, on the one hand, there may be consistent effects upon hormone secretion or sleep that represent phenomena of illness. On the other, deliberate changes in hormone status or sleep deprivation may modify the state of depression. Depression is also so common in its less severe forms, that it is tempting to see it as a biologically adaptive mechanism in response to loss or social defeat. Informative animal analogues might be expected to exist, but theoretical comparisons with other biological models such as early separation in primates or hibernation in bears are limited by the species gap.[13]

However, what makes depression the clinical burden it is, remains its tendency to persist and sometimes become chronic. The biological factors contributing to this are still poorly understood, but they would provide an obvious target for novel drug development. In general it is not yet obvious which symptoms of acute depression are related to this key biology and which are either irrelevant or even adaptive. If there is now a consistent interest, it has been

stimulated by the gradual acceptance that some cells divide to produce neurones in the mature brain, especially in the hippocampus. It is very tempting to suppose that the plastic effects maintaining the unwanted brain state in depression may be related to neurogenesis or its failure, which is a beautiful hypothesis requiring confirmation by direct evidence.

(a) The depressed state: functional anatomy

Perfusion or metabolic imaging can indirectly detect changes in neuronal activity (see Chapters 2.3.6 and 2.3.8). Signals can be well localized, but their meaning is ambiguous. They may reflect either reversible changes in function or a semi-permanent loss of neuronal connectivity. Reductions in function in anterior brain structures have been typical in major depression. Hypoperfusion tends to be greatest in frontal, temporal, and parietal areas and most extensive in older patients; high Hamilton scores tend to be associated with reduced perfusion.[14] Reductions in frontal areas may be more likely in patients with impoverished mental states. Thus, neuropsychological testing in major depression shows evidence of slowing in motor and cognitive domains, with additional prominent effects on mnemonic function that are most marked in the elderly. These effects are correlated with reduced frontal perfusion in the elderly. In younger patients, there may actually be increased perfusion in the frontal and cingulate cortex. Metabolic increases in the cingulate gyrus have been associated with a good treatment response.[15] Highly localizing findings have been unusual, however. The only exceptions have been within-subject changes on recovery in the mesial frontal cortex and perhaps the basal ganglia.[14]

There has been a dramatic expansion of imaging studies of emotional processing in normal volunteers, now usually with fMRI (see Chapters 2.3.8 and 2.5.4). It is well summarized by meta-analysis of over 300 such emotion induction and cognitive task. Emotion induction resulted in inferior medial activation and cognitive tasks resulted in dorsolateral activation.[16] However, the broad spread of precise loci of activation means that localization within the frontal lobes has proceeded little further. It may explain the diffuse reports typical of the depression literature. Nevertheless, a focus on limbic activity has led to quite specific, quasi-neurological hypotheses about connectivity in frontal areas and to treatment innovation: deep brain stimulation adjacent to subgenual cingulated cortex (Brodmann area 25).[17] How effective, and how localized this treatment effect really is, will be an important challenge to the field. However, it underlines that 'functional imaging' of brain perfusion primarily informs anatomy.

Isotope-based imaging of receptor occupation could more plausibly offer mechanistic understanding of psychiatric disorder. In depression, it has progressed with the availability of suitably informative ligands. However, the field generally tends to employ small sample sizes, and fundamental advances are difficult to identify. Single-photon emission tomography (**SPET or SPECT**) with the dopamine $D_{2/3}$ ligand [123I]IBZM showed increased binding in the striatum.[18] There were significant correlations between IBZM binding in the left and right striatum and measures of reaction time and verbal fluency, but not of mood as such. This finding has been confirmed with a PET ligand.[19] Increased $D_{2/3}$ binding in the striatum probably reflects a reduced dopamine function, whether due to a reduced release or secondary upregulation of receptors. Binding to the 5-HT1a receptor appears to be reduced in unipolar depression, an effect also present in recovered atients.[20]

In recent years, new SPET and PET ligands for the serotonin and dopamine transporter have become available (see Chapter 2.3.6 by Grasby). For the serotonin transporter in acute depression, the story is not consistent.[21,22] Binding to the dopamine transporter appears to correlate with depressive symptoms in healthy volunteers.[23] Hence trait effects may confound state effects and vice versa. Isotope-based imaging has been slow to develop a wide choice or availability of ligands, hence its role has been largely to follow rather than stimulate new ideas. Its specificity does mean that it can critically test hypotheses about specific receptors.

Such ligands have not yet made an impact on treatment strategies, as dopamine receptor ligands have for the antipsychotics. However, there are interesting preliminary conclusions: for example, drugs that bind to the serotonin transporter appear to saturate the site at therapeutic doses and increase the availability of dopamine reuptake sites.[24]

In summary, functional imaging has served to implicate frontal and limbic rather than posterior brain areas, in broad confirmation of anatomical conclusions derived from observing the effects of lesions or brain stimulation. Relevant neuropsychological challenges are now being incorporated into imaging protocols and we have the first example of an imaging-led treatment innovation—deep brain stimulation. Finally, 'functional' abnormalities may importantly predict structural abnormality in depression.

(b) Neuroendocrine challenge tests

Secretion of hormones in the anterior pituitary is under control, both direct and indirect, of central neuronal cell bodies that may project relatively widely within the brain. The secretion of a given hormone in response to specific precursors or agonists for individual neurotransmitter receptors has been proposed as a way of testing the security of such connections. Hormone secretion provides a bioassay of the system of interest. There is a measure of consensus about the findings in major depression, which, indeed, forms the most consistent basis for our understanding of disturbed neurotransmission in depression. However, the approach no longer leads the neurobiology, and merits consideration instead, in the more specific context of neuroendocrine function (see Chapter 2.3.3). The main findings are described below.

Neuroendocrine drug challenge suggests attenuated serotonergic function and increased cholinergic function in depression. Reduced responses to adrenergic and dopaminergic challenge also suggest impaired neurotransmission. Interpretation of tests with agonists is always difficult, because blunting may occur in an overactive system that has been downregulated. In addition, if the secretion of the assay hormone itself is actually directly affected by the state of depression, interpretation in terms of specific neurotransmitter abnormalities may be misleading. This is a particular problem for ACTH/cortisol responses (see below). In fact, enthusiasm for neuroendocrine surrogate markers of monoamine transmission within the brain has probably diminished in recent years, but the paradigm of drug challenge nevertheless remains interesting. We must assay brain responses of the monoamine projections more centrally involved in mood regulation.

(c) Hypercortisolaemia

About half of all patients with major depression have a raised cortisol output, which tends to return to normal on recovery. It is most consistently associated with an 'endogenous' pattern of

illness (see Chapter 4.5.3). While cortisol is always regarded as a 'stress' hormone, and is secreted in response to various types of acute stress, the stresses that commonly result in long-term hypercortisolaemia are poorly understood. The idea that there is a relatively specific link between chronic high cortisol levels and mood disorder is notably persistent. In major depression there is peripheral hypertrophy of the adrenal glands, measurable in MRI body scans, and an enhanced response to corticotrophin. The MRI change, like the hypercortisolaemia itself, reverses on recovery.[25]

Suppression of cortisol secretion occurs normally via glucocorticoid receptor-mediated inhibitory feedback to the hypothalamus; it is readily produced by dexamethasone, which is a potent exogenous glucocorticoid (the dexamethasone suppression test (**DST**)). For example, Non-suppression of endogenous cortisol after dexamethasone occurs in Cushing's disease. It implies either reduced feedback and/or enhanced central drive to release cortisol. It was initially observed that the 1-mg DST showed high specificity (96 per cent) and sensitivity (67 per cent) as a putative diagnostic test for melancholia.[26] At this point of time the result attracted intense interest, but has since proved difficult to generalize. The high specificity established against normal controls was less against other patient groups. Thus, DST non-suppression has not been accepted as a diagnostic test. This failed effort to give medical respectability to psychiatric diagnosis came to devalue what remains an important observation. Non-suppression usually reflects hypercortisolaemia, which is itself a robust phenomenon of mood disorder that requires explanation like any other core biological symptom. Other symptoms that we identify as part of the depressive syndrome lend themselves less easily to investigation. The DST also has potential clinical uses beyond diagnosis. DST non-suppression predicts a low placebo response rate to drug treatment,[27] and hypercortisolaemia predicts a low rate of clinical response to psychological intervention.[28]

It remains unclear whether cortisol contributes to the clinical state of depression by a direct action on the brain. Exogenous cortisol administration is associated with affective symptoms, and chronic excessive cortisol secretion commonly appears to produce depressive symptoms in Cushing's disease. An HPA axis programmed to hypersecrete cortisol under stress could be a pathogenic mechanism explaining why depression or mania develops. This view has provoked efforts to treat mood disorder by inhibition of cortisol synthesis with metyrapone or blocking the post-synaptic receptors. The effects of such manipulations appear primarily, and unexpectedly, to influence cognitive function more than mood per se. Thus the anti-glucocorticoid, mifepristone improved spatial working memory in bipolar depression[29] and the anti-mineralocorticoid, spironolactone significantly impaired selective attention and delayed recall of visuospatial memory in healthy volunteers without effects on CCK-induced panic anxiety.[30]

There is a final twist: when depressed patients are given large doses of cortisol they tend to show acute mood enhancement[31] and oral dexamethasone has been reported to elevate mood in major depression, especially in hypersecretors.[32] This leads to the converse hypothesis that an HPA axis appropriately adapted to chronic stress early in development might be unable to mount a normal effective response to acute stress later in life. Cortisol may then be seen as a euphoriant (or antidepressant), and hypercortisolaemia as an antidepressant response of the stress-regulating mechanisms of the brain. Based on this view, all cortisol levels seen in depression may be set inappropriately low for the ongoing stress, however high or low they are compared with the normal range.

Whether one supposes cortisol levels to be set too high or too low in depression, it remains inconvenient that either a suppression or an augmentation of steroid effect seems, initially at least, to elevate mood. A way out of this complication may lie in cortisol's action on two receptors in the brain (the glucocorticoid and mineralocorticoid receptors) that may have opposite actions. However, we still need better-controlled replicated data on the effects of steroid manipulations, both in at-risk subjects and in major depression. It is also possible that peripheral cortisol levels are largely irrelevant to the brain and that receptor regulation may critically modulate their central action: one challenging hypothesis is that antidepressants work through changing receptor disposition.[33]

An increased cortisol production is associated with an increased release of hypothalamic β-endorphin and probably a pulsatile increase in ACTH. The paraventricular nucleus of the hypothalamus represents the highest level of dedicated neurones in the HPA axis. The neurosecretory cells of the paraventricular nucleus release the peptides CRH and AVP into the portal hypophyseal blood. These hormones in turn stimulate the release of ACTH from the anterior pituitary. Major depression is characterized by a blunted ACTH response to CRH, an elevated level of CRH in the cerebrospinal fluid, and increased numbers of neurones expressing CRH mRNA in the paraventricular nucleus of the hypothalamus postmortem.[34] CRH is not confined to the paraventricular nucleus, but is expressed in a variety of other central nuclei whence it can produce anxiogenic behavioural effects. CRH receptors, which exist in two forms, are widely distributed in the hypothalamus and cortex. A related peptide, urocortin, has a similar pharmacology. Knocking out the CRH-1 receptor gene in mice impaired the HPA stress response and reduced anxiety-like behaviour. Non-peptide antagonists of CRH action, and of other peptide hormones implicated in stress responses have been taken very seriously as putative anxiolytics or antidepressants.[35] If effective, they will be among the first of a new generation of truly novel treatments based on peptide neurotransmission. The failure to see new compounds of this general kind by now is disappointing, and in the case of a neurokinin antagonist, aprepitant, there has been a high profile failure in major depression.[36]

(d) Thyroid abnormalities

In unselected major depression, thyroid hormone levels are usually normal, but there may be abnormalities of the thyrotropin (thyroid-stimulating hormone) response to thyrotropin-releasing hormone. The thyrotropin response is blunted in a significant number of patients, but this effect is poorly understood and has few accepted clinical associations. In contrast, a subgroup of patients may show an enhanced thyrotropin response with normal thyroid hormone levels (referred to as grade II hypothyroidism). These associations and the use of thyroid hormones in treatment suggest that there is more to be learned in this area (see Chapter 4.5.8).

(e) Sleep disturbance

Sleep is often disturbed in depression but in a variety of ways. Early-morning waking is the most typical in endogenous or melancholic depression, with the sleep patterns in such patients being similar to those seen in patients with mania. Trouble getting to sleep, frequent awakenings, and unsatisfactorily prolonged sleep

are also commonly seen in depression. Like other biological manifestations of the disorder, the extent to which sleep is simply a consequence of the state of depression or a contribution to its biology is uncertain. Patients with severe depression or mania may respond to sleep deprivation with a transient elevation in mood. It implies that the sleep–wake cycle is directly involved with mood regulation and its disorder.

In severe depression (melancholia) the typical effects are a reduction in the total length of slow-wave sleep and a shortened latency in the appearance of rapid eye movement (**REM**) or dreaming sleep.[37] The cholinergic projections from the hindbrain may be REM-ON cells, while serotonergic and noradrenergic cells may be REM-OFF cells. The disturbed sleep of depression could be due to an increased cholinergic and/or a decreased serotonergic/noradrenergic drive; simplistic though it sounds, the experimental evidence is supportive. Depressed patients challenged with a cholinergic agonist in the second non-REM period enter REM significantly faster than psychiatric and normal control subjects. The reduced sensitivity of the noradrenergic system is suggested because clonidine fails to suppress REM in depressed patients compared with controls.[38] Tryptophan depletion (to attenuate 5-HT function) partially mimics the changes seen in depression in recovered patients.[39]

Sleep tends to recover on recovery from depression, and the tricyclic antidepressants in particular suppress REM sleep. However, sleep disturbance may be an early predictor of relapse, and disturbed sleep parameters predict a poor response to cognitive behaviour therapy.[40] Indeed, depressed patients may have inherently weak slow-wave sleep processes because unaffected subjects with a family history of depression show reduced slow-wave sleep and increased REM density in the first sleep cycle[41].

Interest in sleep as a fundamental key to understanding mood disorder has waned in the last two decades. However, its neurobiology is increasingly well understood, and its time may come again.

(f) Monoamine metabolite turnover

The earliest studies to investigate the actions of tricyclic antidepressants highlighted their actions on the turnover of the monoamine metabolites in animal brain. The 'monoamine theory of depression' proposed the reduced functioning of monoamine transmission in depression. Therefore it was natural to seek relevant measures of monoamine chemistry in the cerebrospinal fluid of patients and controls. The study of what became irreverently known as 'neural urine' and indeed of urine itself, since peripheral measures of monoamine turnover are also potentially relevant, virtually defined a decade of biological psychiatry in the 1970s and 1980s. Drugs had similar effects on neurotransmitter turnover as seen in animal studies, demonstrating that the human techniques were sufficiently sensitive. Indeed the monoamine theory is, at its best, a theory about drug action because the monoamine and metabolite changes produced by illness in patients have proved remarkably unconvincing.[42] The findings for the noradrenaline metabolite MHPG and the 5-HT metabolite 5-hydroxyindoleacetic acid were negative. The dopamine metabolite homovanillic acid did show the predicted decrease, but only significantly in women. There were trends to modest increases in all the major metabolites in mania. Although disappointing, cerebrospinal fluid studies could never reflect the activities of smaller groups of neurones localized in areas critical for the modulation of mood. Such a focus is only possible in isotope imaging (PET or SPET) or better post-mortem studies of the brain.

(g) Tryptophan depletion

The most convincing evidence that 5-HT is intimately involved in mood disorder has come from depletion of tryptophan, the amino acid precursor of 5-HT. The level of tryptophan in both peripheral blood and the brain can be driven to very low levels by a short-term low-protein diet and subsequent loading with large neutral amino acids. These compete with tryptophan for access to the brain amino acid transporter and also increase its peripheral metabolism, which results in the reduced synthesis and release of 5-HT. Initial observations appeared to bear primarily on the mechanism of drug action. Thus, patients who had recovered from major depression while taking a serotonin-selective reuptake inhibitor experienced a clear-cut return of severe symptoms lasting for several hours after tryptophan depletion. This finding has now been critically extended to patients with a history of recurrent major depression who were euthymic but not taking any medication.[43] Prominent objective symptoms of retardation and cognitive distortion returned in a stereotyped and severe way, reflecting previous symptoms. The effects on mood in patients who have had a previous episode of depression are qualitatively different from the more minor changes seen in normal female controls or even subjects with a strong family history. This may imply the formation of a form of neurobiological template, which increases the vulnerability to subsequent relapse or recurrence. The immediacy of the link between neurotransmitter function and symptoms may be the reason why patients with recurrent major depression need long-term treatment with antidepressant drugs to remain well.

(h) Does mood disorder have a functional neuropathology?

Severe mood disorder is virtually defined by its frequent recurrence or its chronicity. The first episodes of severe depression occur more frequently with increasing age and tend to be more refractory to treatment. Severe mood disorder is associated with ventricular enlargement and sulcal prominence.[44] Late-onset depression is characterized by pronounced impairments in most areas of cognitive function, in particular executive function and processing speed and is increasingly regarded as having a quasi-neurological quality. Indeed, there is an increased rate of white matter lesions, perhaps related to vascular disease, in older patients.[44] The relationship between cognitive deficits and underlying neuropathological changes requires further examination. Elderly patients with early-onset depression demonstrate greater preservation of executive functioning and processing speed, which may reflect partially distinct disease processes possibly mediated by different neuropathological mechanisms.[45] The key hypothesis must be that it is the particular pattern of functional disruption resulting from any cellular pathology that increases the risk of depression. It may be reasonable to describe such a change as a functional neuropathology.

In younger patients, the issue is whether depression per se leads to a functional neuropathology. In patients with unusual refractoriness and chronicity, MRI scanning again suggested reduced grey matter parameters, most significantly in the left hippocampus but also more diffusely in the left parietal and frontal association cortices. Left hippocampal grey matter density was correlated with measures of verbal memory, supporting the functional significance

of the imaging changes. In contrast, patients with severe illnesses fully responsive to treatment showed no differences from controls. Any finding in the chronic group could predate the onset of depression, or be the result of the illness process or its treatment. It is fashionable to attribute structural changes in depression to hypercortisolaemia, but in this study that was not the explanation.[46] A failure of BDNF, related neurogenesis or loss of synaptic plasticity is also a possibility. Reduced hippocampal volume is a relatively consistent finding in many studies of modest size which have also implicated inter-linked structures in basal ganglia and thalamus.[47]

Rather surprisingly, a correlation between lifetime duration of illness and memory performance was also seen in a very large outpatient sample studied after recovery from a discrete episode.[48] It favours a toxic link between the burden of depression and cognition, which has implications for public health. It also means that the mechanisms associated with very severe depression are also relevant in less severe ambulant forms.

Post-mortem studies of the brain in mood disorder have been rare and are limited by tissue availability. Such studies in elderly depression have greater potential validity than the much more numerous investigations of schizophrenia. The Stanley Neuropathology consortium has made samples of tissue widely available from small but well-characterized patient series. In the hippocampus, the most consistent findings are of reduced GABA function and abnormal measures of synaptic density or neuronal plasticity.[49] Such studies have seldom focused on other 'candidate regions' such as the inferior frontal or cingulate cortex or amygdale.[50] Several studies suggest a particular involvement of glial cells.[51] Since glia support the energy requirements of neurones, and their deficient function could account for aspects of the imaging abnormalities found in these disorders: elevated levels of glucocorticoids acting on glia could change their function, or glial changes could represent responses to primary neuronal withdrawal (see also Chapter 2.3.5).

Post-mortem studies can also address the neurochemistry, perhaps more directly and completely than other methods. Normal ageing is accompanied by a decline in a variety of indices of monoamine function including presynaptic markers of 5-HT innervation. In a small series of depressed suicides, there were 54 per cent fewer neurones in the dorsal raphe nucleus expressing SERT mRNA compared with controls.[52] Whether a reduced serotonergic innervation is the critical change that increases the vulnerability to mood disorder of patients with advancing years is not yet established. If so, the potential for MDMA to have long-term effects in heavy users is real and worrying.[53]

In suicide, post-mortem findings have broadly paralleled those in depression, with an important emphasis on 5-HT metabolism and neurotransmission (see Chapter 4.15.3). Whether 5-HT neurotransmission, perhaps like that involving the other monoamines, represents a functional domain implicated independently in a variety of psychiatric syndromes and behaviours remains to be well established.

Conclusions

Mood disorder has an important neurobiological basis. This stretches from a vulnerability, which seems to be attributable to polymorphism in genes critical to stress regulation, through the impact that early experience has on the subsequent programming of the brain for stress responses, to the final responsiveness when encountering particular personal adversity in later life. Biological studies have highlighted the role of key brain areas within the limbic system such as the cingulate cortex and amygdala. We are still a long way from understanding, with any precision, the critical connections and cellular mechanisms, but the function of monoamine neurones generally, and of serotonergic projections in particular, is closely associated with mood regulation. Peptide neurotransmitters have long seemed likely to play a central role in stress regulation, but their potential as targets for antidepressant drug action are yet to be fulfilled. Finally, observations in the most chronic illnesses and in the elderly with depression have highlighted the possibility of a functional neuropathology underlying severe mood disorder. Depression seems to be critically related to the evolving story around neurogenesis in the brain. It is perhaps appropriate that its resolution will require fundamental advances in brain science: psychiatry has always posed, or anyway implied, the most demanding of scientific questions: how does the brain work?

4.5.7 Course and prognosis of mood disorders

Jules Angst

The importance of course

Ever since Kahlbaum's monograph 1863[1] the course and outcome of mental disorders have played important roles as criteria and validators of psychiatric classification. The prognosis is fundamental for doctor and patient when deciding whether to start long-term prophylactic medication and, at a later stage, whether to stop a successful long-term treatment. Course is a crucial factor in estimating the social consequences, costs, suicide risk, and mortality associated with mood disorders.

The description of course includes the age of onset, episode length, recurrence of episodes, residual symptoms between episodes and outcome (remission, chronicity, death). These aspects are covered in this chapter.

Stability of the diagnoses of mood disorders

Mood disorders can be roughly sub-classified into unipolar mania, bipolar disorder, and unipolar depression.[2] The three groups differ significantly as regards family history, personality, course and outcome, including mortality. Unipolar mania has not yet been studied extensively, and for this reason will not be dealt with here.

Distinguishing between bipolar disorder and unipolar depressive disorder is hampered by the fact that the diagnosis of unipolar depression is always uncertain. Many depressives are hidden bipolar patients: a long-term follow-up study over 27 years showed a constant rate of diagnostic change from depression to hypomania of 1.25 per cent per year of follow-up. As a consequence of this diagnostic instability, the exact ratio of bipolar to unipolar depressive subjects in the population is unknown; modern estimates range from 1:5 to 1:1. The discussion of bipolar disorder has therefore to take account of its unipolar counterpart.

Bipolar disorder

Onset

In patients admitted to hospital between 1913 and 1940 and not treated by electroconvulsive therapy or modern psychotropic drugs, bipolar disorder clearly manifested earlier than unipolar depression; this finding is confirmed by modern community studies. In most patients bipolar disorder begins during adolescence but in some cases may already manifest in childhood. Unfortunately pediatric psychiatry cannot yet provide prospective data from large representative community studies on the onset and course of bipolar disorder starting in childhood or adolescence.

In the offspring of bipolar parents social functioning up to the age of 18 develops normally before the onset of their illness.

Bipolar disorders usually begin as depression, and it takes a further 5 years on average until the first manic syndrome manifests.[3] There may be unspecific prodromal symptoms in the form of mood lability, vegetative lability, somatization, or being hyper-alert or easily excited; there may also be discrete cognitive impairment present before the onset of the affective disorder.[4] After the onset of the disorder social functioning often begins to be impaired.

The first depressive and manic manifestations are commonly mild, brief, or uncharacteristic, and are often only diagnosed in retrospect after years.

Prospective epidemiological studies in adolescents and young adults found the onset of bipolar disorder to occur in the teens (with means and medians around 15 years or later), whereas studies of hospitalized patients date its onset in retrospect in the early 20s or in the 30s.

Bipolar-I illness manifests earlier than bipolar-II and psychotic bipolar disorder. Late-onset bipolar disorder is extremely rare but does occur and may be associated with specific neuropathology. An early age of onset of the disorder, usually manifesting as depression, is correlated with suicidality, comorbid substance-use disorder and a rapid cycling course.

A two-peak distribution of the age of onset has sometimes been described for both bipolar disorder and depression in men and women, with no specific association in women between the second peak and the menopause.

Duration of episodes

Most episodes are short, but 10 to 20 per cent become chronic (lasting more than 2 years); the distribution of episode length is log normal, and therefore percentiles and not averages should be used as parameters. Using data collected a century ago on the natural length of episodes of mania and bipolar disorder, mainly among hospitalized patients, it is possible to compute a median length of 4 to 6 months for mania and 5 to 6 months for bipolar disorder. These figures do not differ from those obtained today despite a wide range of antimanic and antidepressant treatments. Among hospitalized bipolar patients episode length (median) was 4.2 months; 25 per cent of bipolar episodes lasted more than 7.3 months.

About 20 to 30 per cent of episodes are *biphasic* (mania with subsequent switch into depression, or depression with subsequent, switch into hypomania/mania); such high switch rates were already observed before the introduction of electroconvulsive therapy and antidepressants. An effective treatment does not induce a switch but increases (compared to placebos) the rates of responders; and the response is a precondition for the natural switch.

Recurrence of episodes

Recurrence is typical of mood disorders. It can be described by the number of episodes, the length of intervals (measured from remission to the onset of a new episode), and the length of cycles

(measured from the beginning of one episode to the beginning of the next). In prospective studies, time to the onset of a new episode is frequently used as a parameter for survival analyses and frailty analyses of recurrence.

In both bipolar disorder and unipolar depression the time from the first to the second episode is on average much longer than from the second to the third episode and so on. This progressive shortening of cycles and free intervals then levels off and fluctuates around a certain (but still variable) individual limit. Most published data on interval length or cycle length are methodologically flawed because they have not been corrected for the number of episodes/cycles observed. Nonetheless, multiple episodes obviously follow each other in more rapid succession than a few episodes distributed over a lifetime. Statistically, a normal distribution of cycle length can be obtained by log *n* transformation. Even after taking episode numbers into account, there is a clear intra-individual trend to a progressive shortening of cycle length, as demonstrated by frailty analyses[5] dimming the prognosis for both bipolar disorder and unipolar depression. Initial cycle length tends to be shorter in late-onset than in early-onset mood disorders, increasing the risk of recurrence in the elderly.

Precipitating events play an important role in the onset of the first few affective episodes; thereafter recurrence seems to become gradually autonomous with stressful events contributing little or nothing to the process. Stressors may not only precipitate episodes but also increase a pre-existent vulnerability, sensitizing the individual and thereby making him or her more vulnerable to further episodes (kindling effect). In bipolar illness there is no difference in the quality or quantity of stressors precipitating depressive and manic episodes; a legacy or the loss of a relative can induce depression or mania. The sensitivity to stressors has also a genetic component.

Over a patient's lifetime his condition continuously fluctuates on a dimension of severity, which ranges from psychotic, via major and minor syndromes (cyclothymic and minor bipolar disorders), cyclothymic temperament within the norm, symptomatic to symptom-free.

The NIMH Collaborative Depression Study with annual assessments of outpatients over an average of 13 years, demonstrated that bipolar-II patients spent slightly more time with symptoms/syndromes (33 per cent) than bipolar-I patients (27 per cent). In both subtypes of bipolar disorders depressive periods were three times more common than manic periods[6] but bipolar-I patients suffered more from psychotic features. In a 25-year follow-up study of hospitalized mood disorder patients, manic and depressive episodes were about equally present in bipolar-I patients, whereas in bipolar-II patients the course was dominated by depression.

Daily assessments of the course by the life-chart methodology over more than 3 years confirmed that bipolar outpatients spent a three-fold greater amount of time in depression than hypomania. But it was also shown that bipolar-I patients spent significantly more time in hypomania than their bipolar-II counterparts but an equal time in depression; in more than half the time the patients were euthymic.

Over lifetime bipolar patients experience twice as many episodes as unipolar depressives, a difference which is not explained by the manifestation of manic episodes in addition to depression. The total number of episodes observed depends on the length of observation. In a 22- to 26-year follow-up study, bipolar patients experienced a median of 10 episodes, but depressive patients only four. A family history of mood disorders increases recurrence. The proportion of mania to depression remains fairly stable across multiple episodes, but over their lifetime patients spend more time in depression than in mania.

Outcome

(a) Incomplete remission of episodes

Remission after bipolar episodes is frequently incomplete in terms of symptomatic and functional recovery. Residual symptoms are common in patients in both psychiatric and general practice settings and bipolar subjects identified in community studies. Residual depressive symptoms are more impairing than hypomanic symptoms, which may even enhance functioning.[7] The chronic residual symptoms are mainly depressed mood, anxiety, and somatic disturbances, such as insomnia, hypersomnia, headaches, neurasthenic complaints, reduced libido, and gastrointestinal symptoms. Functional recovery was found to develop later than symptomatic recovery. Short-term outcome is less favourable in patients with agitation, rapid cycling, poor premorbid functioning, comorbidity with anxiety disorders, social phobia, substance use, OCD, obesity, personality disorders, sexual trauma, abuse, and behaviour disorders in childhood.[8] Manic versus mixed episodes do not differ in outcome after 1 year.

(b) Long-term course and outcome

The long-term course and outcome of bipolar disorders is characterized by high recurrence rates, frequent residual symptoms between episodes; compared to depression they carry a higher risk of suicide attempts but lower risk of suicides.

Bipolar disorder has a poorer outcome than depression and there is no burn-out with age. After a follow-up of 22 to 26 years, definitive recovery (at least 5 years with good social adaptation) was found in 25 per cent of 186 depressive subjects, whereas the figure was only 16 per cent of the 220 bipolar patients; a chronic course lasting at least 2 years without remission was present in 12 to 14 per cent of depressive and bipolar patients. A chronic course is associated with early life adversity, including sexual and physical abuse.

Comorbidity with alcoholism, a factor known to correlate with poorer outcome and increased mortality, was found in 30 per cent of the bipolar patients. Modern treatment has improved the outcome of mood disorders by reducing chronicity and rehospitalization.

Recurrence (number of hospital admissions) may increase the risk of dementia.

Mortality

Mortality is expressed by the standardized mortality ratio (**SMR**) in comparison with the normal population (SMR = 1.0). Data on hospitalized psychiatric patients in Sweden[9] give an overall SMR for bipolar men of 2.5 and for women 2.7. The high mortality is a consequence not only of suicides (SMR = 15.0 for males and 22.4 for females) but of most other causes of death (excluding cancer): infections, endocrine, cardiovascular, cerebrovascular, respiratory and gastrointestinal disorders, homicides, accidents, traffic accidents and secondary substance-use disorders (mainly alcohol use disorder), etc. This is true for both men and women.

Consequences for treatment

Incomplete recovery and high recurrence are the main problems in the treatment of bipolar disorders. In the treatment of an acute episode the primary goals are full recovery and the prevention of relapses. The length of treatment of an acute episode depends on its estimated spontaneous duration, which may be derived from earlier episodes. In case of doubt, 6-months' maintenance treatment after recovery is the rule. Long-term prophylaxis should be maintained lifelong.

Most time is spent in depression, therefore a combination of a mood stabilizer with an antidepressant is often indicated. The same is true for the long-term medication of the disorder, where combined treatments are the rule.

Special attention should be given to suicidal bipolar patients, who should preferably be treated with drugs shown to be antisuicidal (lithium or clozapine combined often with antidepressants). A lifelong study demonstrated a three- to five-fold reduction of suicides. Comorbidity with alcohol use disorder increased the mortality but not the suicide rate.

Major depressive disorder (MDD)

Onset

Unlike bipolar disorder, depression may start at any time of life and has therefore a later mean age of onset. In the United Kingdom a mean age of onset of 33 years was found in hospitalized patients. In a large United States study of outpatients the mean was 29.4 years, but in 53 per cent of cases the onset was before the age of 21. The distribution of the age of onset is bimodal, with peaks in the 30s and 50s.

Prospective data suggest that MDD very often begins as subthreshold depression; this is especially true for late-onset cases, where the full MDD episodes also tend to last longer and to become chronic more often. Age of onset and earlier episodes assessed in retrospect are subject to dramatically false recall.

There is no true dichotomy between early-onset and late-onset depression but a continuous distribution accompanied by a systematic decrease in genetic vulnerability (morbid risk among first-degree relatives) and an increase in precipitation by environmental factors. The correlation of age of onset with the genetic component was found in both patient and community samples. Childhood traumata create a vulnerability which promotes earlier onset and higher comorbidity.

Duration of episodes

The length of depressive episodes is log normally distributed; therefore simple mean values are meaningless. Compared to bipolar disorder, episodes of depressive disorders last about 1 month longer (median duration of 5.4 months); and about 18 to 25 per cent of patients develop chronic depression with a minimum duration of 2 years. In the general population, among whom there are many untreated cases of depression, episodes were found to be shorter; the 25th, 50th, and 75th percentiles were 4, 8, and 16 weeks respectively for recurrent episodes.

Chronicity is clearly correlated with age and persistent cognitive deficits; it is common in the elderly but relatively rare in adolescents. As is in bipolar disorder chronicity is associated with early life adversity, including sexual and physical abuse.

Recurrence of episodes

Major depression is recurrent in about 85 per cent of cases; compared to bipolar disorders, however, depressive patients experience only half as many episodes over their lifetime. The cycle length (time from the start of an episode to the start of a subsequent episode) is consequently longer than in bipolar disorders. There is also a systematic shortening of cycle length with the increasing number of episodes, as shown by frailty analyses. The precipitation of episodes by life events—frequent initially—decreases as the number of episodes grows; the periodicity becomes increasingly autonomous. A twin study suggests that undesirable life events play a significant role in the recurrence of depression in women with a low genetic risk.

In a recent large representative record study in Denmark (N = 20 350 first admissions) unipolar depressives had strikingly lower recurrence rates (hospitalizations) than bipolars, the rates for both correlating with the number of previous episodes.[10] The authors concluded: 'The course of severe unipolar and bipolar disorder seems to be progressive in nature despite the effect of treatment and irrespective of gender, age and type of disorder'. Risk factors for recurrence are previous recurrence, long duration of episodes, late onset, age, severity, and incomplete remission.

Residual symptoms represent a strong risk factor for further recurrence; a survival analysis by Paykel *et al.*[11] found a three-fold higher risk of recurrence (76 per cent) in patients with residual symptoms than in those without (25 per cent). This sub-threshold depressive morbidity is clinically relevant and a clear risk factor for future recurrence and suicidality, especially in the elderly.

Outcome

In long-term follow-up studies, 43 to 52 per cent of depressed outpatients became symptom-free between their episodes, and the other half continued to suffer from dynamically fluctuating residual syndromes or symptoms. The corresponding cross-sectional status may be diagnosed as dysthymia, recurrent brief depression, minor depression, residual syndromes and symptoms, or as full recovery. Initial severity and comorbidity are positively correlated with poor outcome in terms of poorer functioning and incomplete remission. In a British study residual symptoms of major depression, defined by a score of eight or more on the 17-item Hamilton Depression scale, were found in 32 per cent of 60 patients 12 to 15 months after remission.[11] In a large cross-cultural study (N = 968) conducted over 9 months, between 25 and 48 per cent of cases experienced complete remission,[12] rates which also depended on the severity of the depression and comorbidity. Severe residual symptoms correlate with long-term morbidity, impaired social functioning at work and in relationships and suicidal behaviour, especially in the elderly, amongst whom remission is present in only about one third of cases.

Recent evidence from a 30-month prospective community-based cohort study of 75-year-old subjects suggests that a history of depression may increase the risk of senile dementia,[13] which is compatible with findings from Denmark that recurrence (number of hospital admissions) increases the risk of dementia.[14]

Mortality

Unipolar depressives have twice the mortality risk of the general population. The SMR (standardized mortality ratio) for suicide is

21 for males and 27 for females;[9] these figures are higher than those for bipolar disorder. Many other causes of death are also more common among unipolar depressives than in the general population but to a lesser extent than among bipolar patients.

The frequently quoted suicide rate of 12 to 19 per cent is only valid for selected hospitalized patient samples, which, by definition, include many suicidal patients. In community and outpatient samples, suicides account for a considerably smaller percentage of deaths; but long-term data is not available yet.

A lifelong follow-up study showed a suicide-preventive effect of administering low-dose antidepressant medication to severe unipolar depressives.

Course of other subtypes of mood disorders

Dysthymia

Subjects with a depressive personality disorder are especially prone to develop dysthymia. Dysthymia is by definition a chronic form of depression; nevertheless dysthymic patients have a similar outcome to major depressives: in outpatients the 5-year recovery rate was 53 per cent. Dysthymia is highly comorbid with other psychiatric disorders, especially with major depression (which it may precede or follow), so worsening the prognosis.

Minor depression

In the general population the recurrence rates of minor depression are comparable to those of major depression, a fact confirmed by survival analyses.[15] A diagnostic change from minor to major depression, or the reverse, is frequent during the course of mood disorders. Minor depression increases about five-fold the risk for the development of major depression. Primary minor depression, like depressive symptoms in general, is a significant risk factor for major depression. It can also represent a residual state of major depression and is a strong risk factor for further recurrence.

Among the elderly minor depression is common as a residual state. Both minor and major depression should be considered seriously as a target for preventive intervention and treatment; full recovery should be the goal.[15]

Seasonal affective disorder

Many patients experience depressive episodes mainly in autumn and winter; mania tends to occur more often in summer. Seasonal affective disorder (SAD) remained seasonal in 70 per cent of 43 cases followed up over 2 to 5 years and in 42 per cent over 8.8 years.[16] The diagnostic stability of SAD was fairly good (26 to 57 per cent). A large number of patients developed seasonal subthreshold (subsyndromal) depression, whereas full remission was present in only 15 to 20 per cent.

Rapid cycling mood disorder

There is no generally accepted definition of rapid cycling; it is usually defined by the occurrence of at least four episodes per year, counting arbitrarily a biphasic episode as two episodes. Rapid cycling occurs almost exclusively in bipolar disorder; it is more frequent in females and in the bipolar-II subtype. Rapid cycling often manifests at an early age and increases the risk of suicide attempts but does not appear to represent a final course pattern of bipolar disorder: it is often a transient, non-familial manifestation of the disorder. In a prospective follow-up conducted over approximately 3 years the diagnosis was stable in about half the cases and the other half became simply recurrent (non-rapid cycling); in a control group 10 per cent of the non-rapid-cycling patients converted to rapid cycling.[17] Studies on the long-term prognosis are inconclusive.

Consequences for treatment

Antidepressant treatment can shorten the time to recovery. Therapeutic decisions on the length of acute treatment will depend on the length of the individual's previous episodes and on the average episode length observed in follow-up studies. The length of affective episodes has probably not changed in 100 years. Antidepressants cannot shorten the episodes but can minimize the symptoms. Treatment should be maintained for the full duration of episodes, which are frequently masked, otherwise relapses must be expected. Full symptomatic and functional remission to the premorbid level should be the goal of treatment.

As with acute treatment, the choice of a long-term prophylactic medication should take into consideration the previous individual course of the disorder plus the general scientific knowledge of course and prognosis, and keep in mind the increased mortality, especially the high suicide risk associated with depression. Recurrence is also a feature of mild cases, but in contrast to severe cases the suicide mortality is probably low.

Over a patient's lifetime, each new recurrence is associated with a new risk of suicide and requires long-term prophylaxis with lithium, combined with low-dose antidepressants. This is especially necessary in the presence of suicidality in the previous or in the family history. If further studies confirm that the recurrence of affective episodes increases the risk of dementia, such a long-term prophylaxis may become even more important.

Conclusions

Bipolar disorder and depression are serious illnesses responsible for most suicides in the population and are recurrent lifelong in most cases. The remission between episodes is often incomplete, increasing the risk of recurrence. Compared to depression bipolar disorder is twice as recurrent and complicated by higher comorbidity with multiple somatic and psychiatric disorders, especially with substance-use disorder which shortens life expectancy even more. Most patients spend about half their lifetime in good health but the other half in largely depressive mood states fluctuating on the broad severity spectrum. Sub-diagnostic morbidity has been recognized as clinically very relevant and in need of permanent treatment. Great progress in the study of continuous fluctuations has been made by the introduction of the life-chart methodology and by computer-assisted daily assessments, methods which hold further promise.[18] Treatment should focus on all manifestations of the illness, including minor morbidity, in order to achieve full recovery to the premorbid level of functioning; in a long-term perspective the primary goal remains the prevention of recurrence, secondary substance-use disorders and suicides.

Future studies should also try to reduce the dementia associated with affective disorders.[13,19,20]

4.5.8 Treatment of mood disorders

E. S. Paykel and J. Scott

Evidence

Medication and physical treatments

(a) Acute treatments for depression

(i) Antidepressants: general issues

The first modern antidepressants became available in the late 1950s, coinciding with introduction of randomized controlled trials in psychiatry. Tightening of licensing requirements has ensured good efficacy for new antidepressants. Overall efficacy and speed of response of most antidepressants are similar. In addition to meta-analyses of specific antidepressant classes, there have been meta-analyses confirming efficacy in specific patient groups or disorder subtypes, including dysthymia[1] and the elderly.[2]

There are moderate, but not very large, effect sizes. About 30 per cent more subjects respond well on antidepressants than on placebo, partly because good response is often seen in placebo groups, probably not due to the placebo but to spontaneous improvement and non-specific treatment effects such as those of seeing a helping figure, supportive psychotherapy, and hospitalization. Non-specific outcome tends to be worse among severely ill patients, but here also antidepressants may be less effective. Placebo-controlled trials are still mandated by regulatory authorities for new antidepressants, since comparisons between active drugs have high risk of type 2 error.

Table 4.5.8.1 lists the principal antidepressants and recommended doses, omitting minority drugs limited to a small number of countries. Some of the antidepressants listed are not available in all countries. Recommended doses depend partly on national authorities and readers should check the situation in their own country.

(ii) Reuptake inhibitors

Tricyclic antidepressants. In addition to the tricyclics listed in Table 4.5.8.1, maprotiline and amoxapine are available in some countries. There have been many older efficacy reviews, with

Table 4.5.8.1 Antidepressant medications*

Drug	Usual dose range (mg/day)**
Reuptake inhibitors	
Tricyclics	
Amitriptyline	75–300
Clomipramine	75–300
Desipramine	75–300
Dosulepin (dothiepin)	75–225
Doxepin	75–150
Imipramine	75–300
Lofepramine	70–210
Nortriptyline	75–150
Proptriptyline	15–60
Trimipramine	75–300
Serotonin and noradrenaline reuptake inhibitors (SNRIs)	
Duloxetine	60
Venlafaxine	75–375 (check)
Selective serotonin reuptake inhibitors (SSRIs)	
Citalopram	20–60
Escitalopram	10–20
Fluoxetine	20–80
Fluvoxamine	50–300
Paroxetine	20–60
Sertraline	50–200
Selective noradrenaline reuptake inhibitor (NARI)	
Reboxetine	4–12
Monoamine oxidase inhibitors	
Irreversible monoamine oxidase inhibitors	
Isocarboxazid	30–60
Phenelzine	45–90
Tranylcypromine	20–30
Reversible monoamine oxidase inhibitor (RIMA)	
Moclobemide	300–600
Others	
Bupropion	200–450
Mianserin	30–90
Mirtazepine	15–45
Trazodone	150–600

*This list is not fully comprehensive because of new developments and national differences.

**Official dose recommendations vary between countries and should always be checked.

further studies accumulating as tricyclics have been included in placebo-controlled trials of new antidepressants.

Earlier views that tricyclics were more effective in endogenous and psychotic depressives have not been confirmed and effects extend across a broad spectrum of depressives, extending more widely into anxiety disorders, panic disorder, and obsessive-compulsive disorder. Tricyclic use has lessened in recent years in favour of antidepressants with fewer side effects.

Serotonin and noradrenaline reuptake inhibitors (SNRIs). Selective SNRIs share the proposed therapeutic mechanisms of tricyclics but with fewer and different side effects, including the serotoninergic effect of nausea, and for venlafaxine at high dose, risk of blood pressure elevation and cardiac arrhythmia, with toxicity in overdose. There is good efficacy evidence for venlafaxine, with possible superiority over SSRIs,[3] and emerging evidence for duloxetine.[4] A further SNRI in some countries is milnacipran.

Selective serotonin reuptake inhibitors (SSRIs). Meta-analyses of SSRIs[5] show efficacy comparable with tricyclics, but lower rates of side effects and discontinuation. There is conflicting evidence as to whether SSRIs are less effective than tricyclics and SNRIs in severe depression. SSRIs and clomipramine, the most serotoninergic tricyclic, are more effective than noradrenergic tricyclics in obsessive-compulsive disorder.

There have been vigorous debates regarding effects of antidepressants, particularly SSRIs, on suicidal behaviour, with many studies.[6] Actual suicide does not appear to be increased and may be reduced. There is some evidence that suicidal feelings and attempts may be increased in the early weeks after starting, particularly for SSRIs, with development of tension or agitation, and in children and adolescents. On the other hand SSRIs and other newer antidepressants are considerably safer in overdose than tricyclics and SNRI. Warnings were issued by regulatory authorities in the United States and the United Kingdom when the evidence started to emerge. Most strongly the findings argue for careful clinical surveillance of patients prescribed antidepressants, particularly in the early phases of treatment when risk of suicidality has long been recognized as increased. This is in any case important in depressed patients.

Noradrenaline reuptake inhibitors. Only one newer selective NARI is available, reboxetine. It is clearly superior to placebo.[7]

(iii) Monoamine oxidase inhibitors (MAOIs)

Irreversible MAOIs. There are few MAOIs available, reflecting hypertensive and other interactions and limited use. The older MAOIs bind irreversibly to the enzyme, and new enzyme needs to be synthesized over 1–2 weeks to reverse the effect. Controlled trials[8] show superiority to placebo in depression, and in anxiety disorders. Often high doses are necessary and the hydrazine MAOIs, phenelzine, and isocarboxazid, show better clinical response in slow acetylators. Tranylcypromine has additional stimulant effects, and has been viewed as more effective but with more risk of interactions.

From the late 1950s, there were suggestions of particular efficacy in atypical depression, variously regarded as non-endogenous depression, anxiety disorder with depression, or as a pattern of reversed vegetative symptoms with increased appetite, increased sleep, evening worsening, reactivity, and other features, a meaning currently predominant in the United States. Evidence is not strong, but comparative trials of phenelzine and tricyclics point to better effects than tricyclics with anxiety disorders and reversed vegetative symptoms.[8] On the other hand MAOIs are mostly used as second-line drugs by psychiatrists, where other antidepressants have failed, irrespective of clinical picture.

Reversible competitive inhibitors. The reversible MAO-A selective drug moclobemide can dissociate from the enzyme and be displaced by substances with higher affinity, including tyramine. It shows superiority to placebo,[9] but not at doses below 450 mg daily, and evidence is best for 600 mg. Many clinicians view moclobemide as less effective than older MAOIs.

(iv) Other antidepressants

Bupropion. Bupropion is relatively stimulant and is epileptogenic. It is licenced for depression in the United States, and in some other countries as an aid to smoking cessation.

Mianserin. Mianserin, an older drug which blocks alpha-2 autoreceptors, is sedative in side effects and carries a definite although low risk of agranulocytosis.

Mirtazepine. Mirtazepine blocks alpha-2, 5HT2, and 5HT3 receptors. It has been shown superior to placebo and is also a sedative.[10]

Trazodone. Trazodone, an older drug is relatively sedative carries a risk of priapism in males.

New classes of antidepressants, not yet licenced, are continually being sought.[11] Agomelatine, an agonist at melatonin MT1 and MT2 receptors and a 5HT2C antagonist has shown evidence of efficacy. Efforts have been made to develop drugs, which inhibit cortisol secretion. Development pathways for new antidepressants are long and failures due to weak treatment effects or major adverse effects are common.

(b) Electroconvulsive therapy (ECT)

ECT, the earliest of modern treatments, is still the most effective in severe depression. In a meta-analysis.[12] It has been found more effective than simulated ECT in blind trials, and more effective than pharmacotherapy. Bilateral ECT appears more effective than unilateral but this may not be true at adequate stimulus intensity. Best effects occur in psychotic depression with delusions or psychomotor retardation. There is also some evidence, which is not conclusive, that ECT may benefit mania.

Other physical treatments

(a) Bright light

Bright light, reviewed in Chapter 6.2.10.2 is the established treatment for seasonal affective disorder. Several studies in non-seasonal depressions as adjunctive treatment have suggested some benefit, although the effect may not be sustained.[13]

(b) Repetitive transcranial magnetic stimulation (TMS)

TMS is reviewed in Chapter 6.2.10.3. There is clear evidence of superiority of left prefrontal TMS compared with sham therapy but the degree of benefit appears weak. There is still uncertainty regarding optimal stimulation parameters. At present the evidence is not sufficient for widespread use of TMS in clinical practice.

(c) Vagus nerve stimulation

Stimulation of afferent left cervical vagus nerve fibres by a stimulator implanted in the chest wall is approved by regulatory authorities in a number of countries for resistant epilepsy and in the United States for resistant depression. Controlled evidence is still limited.[14]

(d) Deep brain stimulation

Chronic stimulation of white matter tracts adjacent to the subgenual cingulate region by implanted electrodes has been reported to produce striking remission in a small number of patients with resistant depression, associated with marked reduction in local cerebral blood flow.[15] Further experience is still needed.

Longer-term treatment

(a) Continuation treatment

In recent years, it has become apparent from follow-up studies that the long-term outcome of depression is still often problematic. It is customary to distinguish between relapse, or early symptom return, and later recurrence of a new episode.[16] In parallel, drug treatment after the acute episode has been divided into earlier continuation treatment, to prevent relapse, and longer-term maintenance treatment to prevent recurrence.

There have been many controlled trials of continuation treatment on active drug for 6 to 8 months after the acute episode against withdrawal to placebo, showing substantial benefit from continuation.[17] A fluoxetine study with staged withdrawal showed benefit of continuation for 24 and 38 weeks, but not 62 weeks, suggesting that routine continuation should be for 9–12 months rather than 6 months.[18] A controlled trial of early lithium withdrawal after augmentation showed very high relapse rate indicating a need for lithium continuation[19] and there is evidence for continuation drugs after ECT.

(b) Maintenance treatment

Longer-term studies in unipolar depression have shown clear benefit from maintenance antidepressants,[17] although recurrence rates in drug-treated patients may be high.

Withdrawal reactions requiring temporary restarting can occur if antidepressants are stopped abruptly, particularly after high doses for long periods, with malaise, coryza-like symptoms, vomiting, and diarrhoea. This may occur with a variety of antidepressants including SSRIs, tricyclics, and SNRIs.

Trials of lithium in maintenance treatment of severe recurrent unipolar depressives also show benefit over placebo.[20] Comparative efficacy against antidepressants is not clear.

(c) Acute treatments for bipolar disorder

In the treatment of bipolar depression there is a good evidence for efficacy of antidepressants.[21] The major risks are precipitation of mania and rapid cycling, which appear to occur more with tricyclics and venlafaxine than with other antidepressants, suggesting the preferential use of SSRIs, MAOIs, or ECT and covering with lithium. Lamotrigine has also been found effective.[22] For lithium alone as an antidepressant the evidence is less clear-cut.

In the treatment of acute mania, lithium has been extensively reviewed and the evidence is good.[23] Anticonvulsants have been increasingly evaluated, with good controlled trial evidence in mania for valproate and carbamazepine, but not lamotrigine or other anticonvulsants.[22] There is also controlled trial evidence for antipsychotics, both older and newer.[24] Available trials do not clearly point to choice of treatment.

(d) Maintenance treatment of bipolar disorder

Controlled trials of maintenance lithium against placebo in bipolar disorder show clear reduction of recurrences, particularly of mania, with weaker effects on depression.[25] There is also reduction of suicide in mood disorder more generally.

There are high rates of early recurrence, particularly of mania, when lithium is discontinued after long-term use, particularly if discontinuation is rapid.[26] This mandates slow withdrawal in practice. One study.[27] has indicated greater benefit on residual

symptoms for doses producing blood levels 0.8 to 1.0 mmol/l than for 0.4 to 0.6 mmol/l. This is important since follow-up studies of bipolar patients show that subsyndromal symptoms are common.

There have been fewer long-term studies of anticonvulsants.[22] For valproate evidence is suggestive rather than conclusive. For lamotrigine two controlled trials have confirmed prophylaxis of bipolar depression. Although carbamazepine has been used for longer, evidence from placebo-controlled trials is mainly for acute treatment of mania.

Several manufacturer-sponsored trials have indicated prophylactic effects of olanzapine in maintenance. Older antipsychotics have long been used as adjunctive treatment in bipolar maintenance.

Psychological treatments

There is high public demand for psychotherapies. Guidelines are less well developed and less robustly based than for pharmacotherapy. The concept of empirically supported psychotherapies (EST) assists definition of the evidence base.[28]

(a) Acute treatment of depression

(i) Psychological treatments: general issues

The therapy models can broadly be divided into 'process-orientated' therapies such as psychodynamic or supportive–expressive therapies, and 'outcome-orientated' therapies, such as cognitive behaviour therapies (CBT) and interpersonal therapy (IPT), which primarily focus on symptom reduction. The latter EST are protocol or guideline driven, with a manual describing the therapy in detail. In large-scale randomized controlled treatment trials (RCTs) they have been found superior to pill or psychological placebo-controlled treatments or efficacious as antidepressants or other established treatments.[28] The EST are usually brief (12–20 sessions), delivered by a trained therapist, establishing a working alliance and using an individualized case formulation to focus on specific 'here and now' problems, encouraging between session 'homework' tasks to enable development of new coping skills.

(ii) Meta-analyses

The two best-evaluated therapies are CBT (including behaviour therapies) and IPT, with many meta-analyses of a large number of RCTs. There are fewer studies of dynamic therapies. Early outcome studies and resultant meta-analyses were hampered by use of 'completer' samples rather than 'intent-to-treat' analyses, but found specific psychological therapies, particularly CBT, more effective than other verbal therapies or waiting-list controls. A meta-analysis of 29 carefully selected controlled trials,[29] using intent to treat analyses, found efficacies of individual CBT (response rate, 50 per cent), behavioural therapy (55 per cent), and IPT (52 per cent) in the treatment of the acute episode were not significantly different to pharmacotherapy (58 per cent). Brief dynamic psychotherapies, mainly group therapies, were less effective (35 per cent) and only marginally superior to waiting-list controls (30 per cent). CBT was less effective in a group format, behavioural therapy was equally effective, and IPT was more beneficial when a significant other took part in therapy.

A recent meta-analysis[30] found CBT and IPT equally effective in reducing depressive symptoms in heterogeneous groups of patients with depressive symptoms and syndromes, and both were superior to counselling, other therapies or control treatments in primary care. When compared in meta-analyses to an active treatment, however, CBT and IPT show only equivalent efficacy or marginal superiority. Almost all RCTs of psychological therapies have been in outpatient depressives, not above moderate severity and comparisons with pharmacotherapy do not represent severe or inpatient disorder.

(iii) Cognitive therapy

Earlier CBT studies suggested it was effective over a range of severity and endogenicity. However, in the three-centre NIMH study,[31] which sought to overcome earlier methodological flaws, a secondary analysis found CBT less effective than pharmacotherapy in the more severe disorders within the outpatient range studied. Another study found that individuals with mild or moderately severe depression did equally well with either 8 or 16 sessions, but those with severe depression showed better response with 16 sessions. A large RCT in subjects with severe major depressive disorder[32] found no difference overall between antidepressants and CBT, but also significantly greater effects for antidepressants at the trial centre where the CBT therapists were less experienced.

(iv) IPT

IPT Has been found effective in moderate numbers of RCTs, in a variety of situations, including combination studies with antidepressants and some situations where medication as a first-line treatment for depression is not easily feasible (pregnancy, postpartum, adolescence, and in a developing country).[33] The NIMH study[31] is the only one that has compared IPT with a pill-placebo control. Interpersonal therapy was nearest to the effectiveness of imipramine but a little weaker, and IPT was more beneficial than CBT in patients with more severe outpatient depression.

(v) Other psychotherapies

Fewer acute controlled trials of other therapies have been published. Two large-scale RCTs of individual behavioural therapy found respectively greater efficacy than insight-orientated therapy, which disappeared by 3 months follow-up, and no differences from several other treatments.

The only published RCTs on marital therapy mainly draw on behavioural approaches with behavioural marital therapy or CBT both more effective than waiting-list controls in one study and an advantage for behavioural marital therapy over CBT one study of depressed individuals with marital discord. Couples therapy was more effective than pharmacotherapy in a study of depressed patients living with a critical partner. An RCT of family therapy in inpatients with affective disorder[34] found benefit on role function for female patients on discharge, and for bipolars but not unipolars on follow-up.

Counselling is often offered alone or in combination with medication, particularly in primary care or non-specialist mental health settings. Recent meta-analyses[30] suggest limited benefits, with superiority over treatment as usual or waiting-list control conditions lost beyond about 3 months. Individuals who are socially isolated and lack a confidante may particularly benefit.

(vi) Combined psychotherapy and pharmacotherapy

Data on whether combination of psychotherapy and pharmacotherapy bestows additional benefit over either treatment alone are not conclusive, but some studies suggest a small advantage at the

level of severity usually studied, both for CBT and for IPT. However, in a meta-analysis of eight outcome studies, neither CBT, behavioural therapy, nor IPT added to antidepressants were any more effective than pharmacotherapy alone.[35]

In a large RCT of antidepressant and cognitive behavioural analysis system of psychotherapy (CBASP) given alone, or in combination for major depressive episode persisting for longer than 1 year[36] the group receiving the combined treatment had significantly greater overall reduction in depressive symptoms and attainment of remission as compared with single therapies.

In other studies, treatment with an antidepressant alone or in combination with IPT has been found more effective than IPT alone in dysthymics, and greater benefit of combined treatment has been reported in an RCT of group CBT and medication. These studies indicated that combined treatments improved quality of life over and above individual treatments. There is also some evidence that social adjustment is particularly benefited by IPT.

(b) Longer-term psychological treatment

(i) Continuation and maintenance trials

Psychological treatments are more expensive than antidepressants, but the balance could change if they reduced relapse rates.[37] Naturalistic follow-ups suggest this, but are hard to interpret because the original RCTs were not designed or powered to evaluate long-term outcome.

The use of continuation and maintenance psychotherapy is a relatively new concept. The key maintenance trial for IPT[38] assigned subjects with recurrent depression to imipramine, placebo, or monthly IPT with or without medication. There was a highly significant effect for antidepressants on recurrence rates and a modest effect (at the end of year 1 and year 3) for IPT. The first study of IPT, by its originators 15 years earlier, did not find it reduced relapse, compared with antidepressant continuation.

Five longer-term RCTs have now shown relapse and recurrence reduction with CBT.[37] Three of these, in individuals in remission using mindfulness or other techniques have only found benefit in subjects with a previous history of repeated episodes.

At least 20 per cent of people with an initial episode of major depressive disorder do not recover within 2 years, and those with residual depressive symptoms have a high risk of relapse. In a RCT[39] in 158 subjects with persistent residual depressive symptoms following major depression assigned to antidepressant continuation or antidepressant plus CBT, at 18-month follow-up relapse rates in the CBT plus antidepressant group were reduced by 45–50 per cent compared with the control group. Relapse prevention persisted for 3.5 years. Similar findings have been obtained in three small RCTs.[40]

(c) Bipolar disorder

Until very recently, research in psychological treatments for bipolar disorder was limited. Prior to 1995 a number of small studies, few of them randomized trials, suggested that adherence to medication was improved.[41] More recently good RCTs have been completed. The earlier of these found some benefit from psychological treatments in preventing relapse, with a hint that the briefer interventions are more effective in preventing mania than depression. A meta-analysis of relapse rates[42] found an odds ratio (OR) for relapse in the intervention as compared to the control group of 0.31. Three recent large efficacy trials used CBT, family therapy, or group psycho-education, respectively. A separate meta-analysis of these[42] found a similar odds ratio for relapse, with more benefit for depressive than manic/hypomanic relapses.

The MRC multicentre RCT in the United Kingdom[43] was one of the few pragmatic effectiveness trials, with over 250 subjects randomized to CBT plus usual psychiatric treatment or usual treatment alone. Over 50 per cent of the sample had a recurrence by 18 months, with no overall significant differences between groups, but a significant interaction with number of previous episodes such that CBT was significantly more effective than treatment as usual in subjects with fewer than 12 previous episodes, but less effective in those with more episodes.

One variant of IPT has been evaluated in a large RCT, interpersonal and social rhythm therapy (IPSRT), which includes an approach to stabilize social rhythms.[44] It was found to reduce bipolar relapse rates more than did IPT. The full advantages and disadvantages of different forms of psychotherapy for bipolar disorders are yet entirely clear, but further evidence is expected to emerge soon.

Management

Treatment of unipolar disorder

(a) General aspects: where to manage

The goals of depression treatment are to alleviate acute symptoms, to restore psychosocial functioning, and to prevent relapse and recurrence. Crucial decisions are the selection of an intervention and treatment setting. These involve four key issues: severity of the disorder including risk of self-harm, availability of treatments (specific antidepressants, trained therapists), patient preference, and nature of any associated difficulties. Recent guidelines include those of the UK National Institute for Health and Clinical Excellence[45] and of CANMAT.[46]

(b) Treatment setting

Very severe depression with definite suicidal risk is best managed in inpatient facilities to allow careful monitoring. With less suicidal risk and good social support severe cases can be managed with intensive community support, partial hospitalization, day care, or combined outpatient and home-based care. Moderate or mild depression should be managed in outpatient settings, unless treatment is complicated by severe physical illness, or non-response requires more detailed assessment.

(c) Primary or secondary care

Worldwide, most depressed patients are treated in primary care or general medical settings. Cases are referred to specialist mental health services because the disorder is more severe, chronic, treatment resistant, or because other difficulties, such as alcohol misuse or marital problems, complicate the clinical picture.

(d) Medication or psychological therapy

Although severe depression may respond to psychotherapy alone, recovery is slower than with drugs or ECT. Psychotherapy may be used in addition, rather than alone. In milder depressions, choice depends partly on patient preference and availability of psychotherapies, although when major depression criteria are reached antidepressants should preferably not be withheld. In the complex situations requiring specialist referral it is often necessary to use

combinations of drugs and psychosocial approaches. Although physical and psychological treatments are described separately in this section, treatment rarely involves only prescribing, but education and support of patient and family are important aspects of any clinical management.

Medication

(a) When to treat

The most important indications for use of medication are severity and persistence. A severity threshold has been shown a little below major depression at which tricyclic antidepressants start to show superiority over placebo.[47] SSRIs may show benefit in minor depression.[48] Antidepressants are also superior to placebo in dysthymia. In mild depressive episodes highly reactive to major stress, and in acute grief, prognosis for spontaneous resolution is often good, and medication may be delayed, provided that improvement is occurring. Impairment of function and suicidal feelings are other indications to treat. Recent guidelines recommend use in depression of moderate severity, major depression, or ICD-10 depressive episode.

(b) What antidepressant to choose

Since SSRIs are comparatively free of side effects and are not costly if out of patent, they are generally recommended as first choice antidepressants. Where there is a previous history of response to a specific drug or class, the best first choice is that antidepressant.

With few exceptions, symptom pattern is not a good guide to treatment. Effects of antidepressants extend widely across the spectrum of depression and in to anxiety disorders. The place of SSRIs in very severe depression is still debated. MAOIs or SSRIs or are a reasonable first choice in atypical depression. With comorbid obsessive-compulsive disorder the SSRIs, SNRIs, or clomipramine are preferable to noradrenergic antidepressants. Light therapy is indicated for seasonal affective disorder, alone or with antidepressant.

(c) How to use an antidepressant

There is a delay in clinical antidepressant effects of 1 to 3 weeks or longer, although some improvement may be seen earlier. An antidepressant needs to be continued for a minimum duration of 6 weeks at adequate or high dose before being regarded as ineffective.

Since side effects often occur more in the early weeks, with later tolerance, build-up of dose over 2 to 3 weeks is useful. For fluoxetine, the exceptionally long half-life of the active metabolite means that blood levels build-up for some weeks, even on a standard dose. Standard dosage regimes fail to allow for the considerable interindividual variability in pharmacokinetic mechanisms that occurs. Low doses are usually ineffective. Where response is not occurring and there are only minor side effects doses should be increased towards maximum, except in the elderly, who are vulnerable to poor elimination and to side effects.

Dose division during the day can be based on pharmacology. Half-lives of most antidepressants, combined with delay in therapeutic effects, mean that one dose per day may be adequate, but for most, two doses per day are better and three doses may be useful for some patients. Moclobemide, which is easily displaced from MAO and metabolized, should be given in three doses daily. For sedative antidepressants, administration of two-thirds of the dose at night may avoid hypnotics. Doses at bedtime of the more stimulant antidepressants, including SSRIs and older MAOIs, should be avoided.

Common side effects of SSRIs and SNRIs are nausea, and other gastrointestinal disturbances, insomnia, and sometimes tension and restlessness. Blood pressure should be monitored with high dose venlafaxine and it should not be used with hypertension or risk of ventricular arrhythmias. Common side effects of tricyclics clinically are sedation and anticholinergic side effects of dry mouth, blurred near vision, urinary retention, orthostatic hypotension, and confusion in the elderly. Dose-limiting side effects of MAOIs are hypotension, insomnia, and ankle oedema and tyramine containing foods and interacting drugs must be avoided.

(d) What to use if the first choice does not work

The evidence base for second choice of antidepressant after poor response to the first is weak. The large non-blind partially randomized STAR*D study,[49] has shown few differences between different choices after weak first response to citalopram.

The major pragmatic options are switch to a different antidepressant or combination. Switch should be to an antidepressant of a different class, or to a broad action SNRI. If this is not adequate, lithium augmentation is the best-supported change. Where depression is severe ECT is an alternative second choice.

(e) What to use in special situations

(i) Suicidal risk

Major suicidal risk requires consideration of lethality of particular antidepressants in overdose. Tricyclics and SNRIs should be avoided. SSRIs and most other newer antidepressants are comparatively safe in overdose, with careful monitoring for increased risk early in treatment.

(ii) Psychotic depression

Evidence as to choice of antidepressant is weak, but suggests SNRIs or tricyclics, rather than SSRIs. Combination with an antipsychotic may be useful, but antipsychotics are not adequate alone.[50] ECT is an alternative.

(iii) Medical illness

Antidepressant treatment with medical disorders is often difficult, because of toxicity due to illness, high blood levels from impaired metabolism, side effects, and drug interactions. Cardiac problems indicate use of an SSRI or other newer non-tricyclic non-SNRI antidepressant, and treatment after myocardial infarction may enhance survival. MAOIs lower blood pressure as a dose-related effect and should be avoided.

Concomitant epilepsy may be controlled by adjustment of anticonvulsant dose. Tricyclics and bupropion are epileptogenic and should be avoided. Epileptic potential is usually less with newer antidepressants but is often not clear, and the only antidepressants established not to be epileptogenic are older MAOIs.

(iv) The elderly

The elderly are particularly liable to side effects. SSRIs and newer antidepressants are preferable to tricyclics.

(v) Children

Antidepressants are not first choice treatments for depression in children and adolescents, for whom psychological therapy is preferable. Where the depression is not improving and is severe, an

antidepressant may be needed. Tricyclics are not effective.[51] There is more evidence for SSRIs, best for fluoxetine,[52] but the risk-benefit ratio is argued. For adolescents combination of SSRIs with CBT may be useful. The risk of increased suicidality early in treatment mandates careful observation. The FDA issued an Advisory in 2004 but not a contraindication.

(vi) Pregnancy and lactation

Tricyclics have been used in pregnancy for many years and do not carry risk of foetal malformation. For SSRIs the current evidence is contradictory and for some newer drugs evidence is lacking. Lithium and anticonvulsants carry some risk of foetal malformation and are contraindicated in the early months of pregnancy. Psychotropic drugs used at the time of delivery may produce complications of anaesthesia and foetal sedation and if possible should be withdrawn temporarily. Most psychotropic drugs appear in breast milk in small quantities. Breast feeding should be discussed with the patient.

Electroconvulsive therapy

Use of ECT varies internationally. Many psychiatrists use it as a first choice treatment in severe depression with psychomotor retardation or mood-congruent depressive delusions, or where an antidepressant has failed, and for moderately severe depressions which have not responded to one or two courses of antidepressant.

The UK National Institute for Clinical Excellence has recommended use only to achieve rapid improvement where a trial of other treatment has failed or the condition is potentially life threatening, in severe depression, catatonia, and prolonged or severe mania.[53] Detailed recommendations on how ECT should be administered also can be consulted.[54]

Non-response and resistant depression

Controlled trials of treatments for depressives who do not respond to first or second treatments are limited. There is good evidence for lithium augmentation of antidepressants[55] and limited evidence for potentiation by triiodothyronine (T3).[56] A variety of other augmenters have been tried including tryptophan, pindolol, buspirone, and combinations of antidepressants such as SSRI-bupropion, SNRI-mirtazepine, tricyclic-MAOI, with weak evidence.

We therefore depend on clinical experience.[57] If there is still limited response after several antidepressant treatments, a systematic approach to resistant depression should be adopted:

1 Reassess the situation thoroughly, with full history, assessment, and laboratory investigation of thyroid function to ask the following questions: (a) Is the diagnosis correct? Wrong diagnosis is in practice unusual. (b) Are there perpetuating factors in personality, family environment, or the social setting? Commonly, where depression has been long-term, secondary role loss (including work), and family adaptations to a non-functioning member mean there are no roles or relationships for the patient to return to and remission cannot occur, or is transient, unless psychotherapy, family therapy, and rehabilitation are employed to change the situation. (c) Is hypothyroidism impairing response? This may develop as a result of earlier use of lithium.

2 Consider previous treatment. Failure to use high or maximal doses of antidepressants when response is not occurring can lead to apparently resistant depression.

3 Employ drug and other physical treatments.

4 As remission occurs, introduce psychotherapeutic, cognitive, and rehabilitative interventions.

The treatment decisions depend on what has been used before. Start with the most promising antidepressant suggested by the history and push to a very high dose. If there is no good clue venlafaxine may be useful, with monitoring of blood pressure for elevation as high doses are reached.

The next intervention is augmentation. Lithium is easiest and best. Blood levels required for augmentation are not established. If response occurs, the lithium should be continued for some months, although not as long as antidepressant. Care should be taken to monitor for a serotonin syndrome (excitability, restlessness, temperature elevation), with serotoninergic antidepressants.

T3 may produce fewer side effects than lithium but evidence is weaker and care must be exercised if there are cardiac problems. L-tryptophan may potentiate MAOIs and the more serotoninergic uptake inhibitors. Its effect is weak, but may be combined with lithium. Pindolol, which blocks 5-HT_{1A} autoreceptors, can accelerate speed of antidepressant response but increased amount of response is less clear.

At one time tricyclic-MAOI combinations were often used and occasionally still have a place, combined with lithium. SSRIs, SNRIs, and clomipramine risk of serotonin syndrome and are contraindicated. Doses should be increased gradually. More ordinarily 1 to 2 weeks should intervene between stopping an older MAOI and starting a reuptake inhibitor.

When vigorous medication regimens have still not produced a response, it is often helpful to add bilateral ECT to maximal drug therapy, even when ECT alone has not previously helped. The practical places for vagus nerve stimulation and deep brain stimulation are not yet clear. In intractable severe chronic depression, psychosurgery still has an occasional place, followed by active rehabilitation.

Longer-term treatment

(a) Continuation treatment: a routine

Continuation antidepressant for 9–12 months should be routine following response to acute treatment. Antidepressant or lithium are also advisable after ECT. The continuation dose should initially be the same as the acute treatment dose. After 2 to 3 months this may be reduced if side effects are a problem, but only by a small amount, to avoid symptom return.

Before the antidepressant is withdrawn the patient should also be completely free of residual symptoms for at least 4 months. These symptoms or history of previous relapse or recurrence suggest longer continuation. Withdrawal should then be carried out slowly, over 2 to 3 months, to minimize the risk of relapse, and of withdrawal symptoms.

In some patients, after withdrawal, or achievement of a low dose, depressive symptoms return. Full dose should be resumed, followed by continuation for a further period of 9 months to a year. Some of these patients relapse again on later drug withdrawal, and long-term maintenance should then be considered.

(b) Maintenance treatment

Longer-term maintenance is indicated where there have been several recurrences, such as two episodes in the last 2 years, or three

episodes in 5 years.[16,45] This also depends on the severity of episodes, their potential impact on personal life, family life, and career, and the patient's preferences. Discussion is required, to reach a joint decision.

For most unipolar depressives the maintenance treatment choice will be whichever antidepressant has been effective and well tolerated. Where antidepressants have not been fully effective, lithium or combination are required. Antidepressant doses should be the same or a little lower than those needed for acute treatment in the particular patient. The length of maintenance is harder to specify, and it depends on the history. Two to three years will be a minimum, longer where remission has been difficult to achieve or recent episodes more frequent, 5 years or more where risk is greater, and indefinite or lifelong where two or three attempts to withdraw have been followed by another episode within a year.[16] Withdrawal of antidepressants, lithium, or other drugs after long-term maintenance should always be gradual. Where withdrawal is followed soon after by a recurrence, longer-term maintenance is indicated, and where this sequence has been repeated, lifelong treatment.

Psychological treatments

The psychological management of acute depression ranges across basic clinical management, psychoeducation for the individual and partner or family, supportive psychotherapy, to formal psychotherapy.

(a) Clinical management

Clinical management is a key component of the care of all individuals with depression regardless of the specific treatment. It includes education about the nature of the disorder, its polarity, course and prognosis, treatment options, their advantages and disadvantages, delay in benefits, probable side effects and how to manage these, and planned length of treatment. This dialogue can help build a strong treatment alliance, overcome misconceptions such as fears of addiction to antidepressants, and improve medication adherence. Involving 'significant others' also in some sessions facilitates information and engagement in the treatment process, clarifies what aspects of care are the clinician's responsibility, and can help reduce tension in interpersonal relationships resulting from the patient's depression. For many depressed individuals the reduction in symptoms from this basic approach and medication restores the previous level of functioning. They are again able to use their coping skills to resolve personal problems and no other form of psychological input is needed.

(b) When to use psychological therapies

If additional strategies are needed, a number of factors should guide their choice, including treatment setting, severity, chronicity, complexity, patient preferences, and availability of therapists. Most management approaches are multifaceted and in a dynamic state so the divisions below, structured by severity of depression, although useful may be somewhat artificial.

(i) Mild depression

For individuals with milder depression, usually treated in primary care, psychological approaches can be used alone as alternatives to medication, and there is little advantage in combined treatment. Many patients express their own treatment preferences. Some primary care physicians offer extended treatment sessions for depression, but many utilize counsellors. A course of counselling, lasting 8–10 sessions, is particularly useful to patients who lack a confidante. Benefits appear in the first 3 months, but there is no evidence of longer-term benefits compared to other treatments or 'watchful waiting'[45] (regular appointments with a clinician offering monitoring and support without medication or other interventions).

The next option may be CBT or IPT. There are no robust predictors of differential response to these as opposed to medication so choice often depends on availability of a suitable therapist. Difficulties in timely access have led to development of computerized CBT and of self-help approaches. The individual is offered a computer version of therapy or a written manual to guide self-therapy (bibliotherapy), with possible 1–3 sessions from a therapist to explain the process and overcome hitches. In other circumstances, including management of depressed pregnant women, telephone versions of IPT have been developed. There is not yet consensus on the efficacy of these alternatives but a trial may be used in mild depression.

(ii) Moderate depression

Formal psychotherapy may be offered to individuals with moderate depression as the only treatment, or preferably combined with medication. Usually this comprises 15–20 sessions of individual therapy, but since more than 20 per cent of couples report marital discord in association with depression, marital or family approaches should also be considered. Psychological treatments may also be required where medical conditions or needed medications contraindicate antidepressants, or the patient refuses medication. Other important considerations include previous coping skills, premorbid stressors requiring problem-solving approaches, ability to articulate emotions and difficulties. If there are doubts regarding suitability, referral may be offered for assessment. Patient preference for therapy does not imply benefit, and dropout rates are about similar to those for medication. Also consider whether needs can be met through a time-limited input or if longer-term support is preferable through day services or a community support worker. Therapists adherence to the therapy model, their level of expertise and skill and the provision of regular and adequate supervision to the practitioner are other factors and may account for some 30 per cent of the variance in patient's improvement.[58]

(iii) Severe depression or complex presentations

Research evidence suggests that CBT or IPT may be used alone in severe depression if delivered by an expert therapist. However improvement is slower than with antidepressants and in practice these are usually combined with medication, which is commenced first. In severe depressions it may be difficult for an individual to concentrate until the mental state has been stabilized by medication. Patients who fail to respond adequately to antidepressants alone require reassessment. In many instances medication has improved the vegetative symptoms of depression, but the individual manifests psychological vulnerabilities, such as Axis II comorbidity or long-standing, low self-esteem, or social stressors, acting as maintenance factors and amenable to therapy. The evidence suggests that IPT or CBT are the most useful therapies to combine with antidepressants in unipolar disorders, but the more severe or complex the case, the more important therapist factors become.[58] More severe or chronic disorders also require more prolonged therapy.

Continuation and maintenance therapy

Some patients may benefit from regular but less frequent sessions of continuation or maintenance CBT or IPT to prevent relapse, with about eight additional sessions over the course of a year, to explore whether the techniques learnt in therapy are being used well and to identify potential triggers of relapse or recurrence. It is unrealistic to offer this to all those who receive an acute course of IPT or CBT, but it may be considered for those at high risk of relapse or recurrence due to residual symptoms, history of highly recurrent episodes, ongoing severe psychosocial stressors, refusal to take continuation medications. A full course of CBT may also be offered now, rather than during the acute illness, if remission is partial with residual symptoms.

Treatment of bipolar disorder

Recent guidelines on treatment of bipolar disorder, providing supporting evidence, include those from the UK National Institute for Health and Clinical Excellence,[59] the CANMAT consensus statement,[60] and the APA Practice Guideline.[61]

(a) Treating acute mania

Most mood stabilizers and antipsychotics have acute antimanic effects, but lithium or valproate are the drugs of first choice. Since response may take 7 to 14 days, an antipsychotic is also often required, with effects within days in controlling the acute manic symptoms. The older antipsychotic, haloperidol should not be used with lithium due to risk of neurotoxicity syndrome. Benzodiazepines such as lorazepam and clonazepam may also be used temporarily to treat hyperactivity, insomnia, and agitation. The loss of insight, impaired judgement, hyperactivity, and disinhibited behaviour of manic patients often mean that hospitalization is required to ensure patient safety and commence treatment. For severe mania, ECT may occasionally be used.

(b) Treating bipolar depression

Treatment of bipolar depression is in principle similar to unipolar, but with mood stabilizer cover. If severity indicates antidepressant use, an SSRI, bupropion, or MAOI should be used, but not a tricyclic or SNRI, because of higher risk of mania and cycling. A mood stabilizer should be used in addition. Lamotrigine may produce benefit alone. If cycling occurs in spite of this, an antipsychotic may be added, and the antidepressant cautiously reduced. ECT may be indicated, as in unipolar depression, and does not appear to lead to rapid cycling.

(c) Continuation and maintenance treatment for bipolar disorder

Continuation treatment is needed after acute bipolar episodes, using the single medication or combination that has been used in acute treatment. Bipolar disorder is more recurrent than unipolar disorder, and mania can have catastrophic effects on personal life. The threshold for maintenance treatment is therefore lower and it should be used for 1 to 2 years following a first episode of mania and longer after bipolar recurrences.

Choice of mood stabilizer includes an increasingly wide range. Probably lithium is still the first choice, in the absence of major side effects. Doses should achieve blood levels 12 h after the last dose of 0.4 to 0.8 mmol/l, but sometimes higher levels are needed to prevent recurrences, and to reduce residual symptoms. After some months blood levels are often very stable and only require occasional monitoring. Advice needs to be given on circumstances, which may disturb levels such as dehydration, gastrointestinal upset, travel, hot climates. Thyroid function should be monitored for hypothyroidism every 6 to 12 months.

Poor or partial responses are not uncommon, and valproate is a first choice alternative. Lamotrigine may be helpful where depression is a main feature. In treatment-resistant cases, two mood stabilizers may be required, particularly lithium and valproate. Antipsychotics, particularly olanzapine, may also be added or substituted if response is poor.

Antidepressants can often be withdrawn slowly after mood stabilizers are well established, but may be necessary to prevent chronic or recurrent depression. Antidepressants should not usually be used alone for maintenance in view of the risk of mania. A few patients require multiple combinations of mood stabilizers, an antipsychotic, and an antidepressant.

Length of maintenance treatment varies, from a few years, to lifelong where several recurrences have followed withdrawal. Withdrawal of lithium should always be slow, over 3 to 6 months, to avoid rebound mania. It is best to do the same for the anticonvulsants.

(d) Rapid cycling

Treatment of established rapid cycling may be difficult. It is important to avoid a cycling alternation of antidepressant and antimanic medication, following too late after mood changes. The patient should be established on mood stabilizers, usually in high dose and often more than one in combination. Antipsychotic may be added. Antidepressants are better avoided but may be needed in addition, used cautiously and with slow dose increase and an effort to establish a constant dose. Thyroid function should be checked initially and regularly.

(e) Pregnancy

Management in pregnancy is complicated by the risk of foetal malformations with lithium and anticonvulsants. These should be withdrawn for the first trimester. Antipsychotics and antidepressants may be used if necessary. Olanzapine may be appropriate but safety of newer antipsychotics and antidepressants is less well established than for older ones. In later pregnancy lithium and anticonvulsant mood stabilizers may need to be reinstituted. Medication should be withdrawn at the time of delivery to avoid effects on the foetus, but started again as soon as possible thereafter, as risks of relapse are increased postpartum.

Psychological treatments

(a) Acute treatment of mania

Psychotherapy has not been evaluated in manic patients and the evidence for benefit in bipolar disorders is for relapse reduction when delivered during euthymia. Access to therapy in most countries is limited and it is important to use clinical management, supportive therapy, and psychoeducational sessions as part of general treatment. Use should be made of systematic care packages to address psychosocial problems, to facilitate recognition of early warning symptoms of relapse, and to implement self-monitoring and self-management strategies.[59] Support should also include education about the disorder and treatment options, and help in

adjusting to the diagnosis and should, if possible, include the patient's 'significant others'. About six sessions of family therapy may have beneficial effects extending beyond discharge.

Therapy with individuals with bipolar disorders can be challenging, requiring skilled and experienced therapists who also understand aetiology and pharmacology. There is a trend towards more cost-efficient group approaches, which allow individuals to observe the strengths and weaknesses of coping strategies employed by peers. However, a key study of group psychoeducation found benefits only with a structured group with a coherent treatment plan and not with unstructured groups without expert professional leadership.

The therapies currently found effective to treat acute bipolar depressive episodes or to reduce the risk of future relapse in RCTs do not differ markedly in either their overall efficacy or their core content. They incorporate four key components: psychoeducation and adjustment to the disorder, lifestyle regularity and 'harm reduction' (reducing substance misuse), enhancing medication adherence, and developing self-management skills to reduce the risk of relapse by recognizing potential triggers or prodromal signs or symptoms.

There are no consistent predictors of therapy response. There is some consensus that patients with Axis I or II comorbidity, particularly substance misuse or borderline personality disorder will benefit from an extended course of therapy. Likewise, where there have been many previous episodes of bipolar disorder, patients are unlikely to be able to assimilate and implement all the problem-solving and coping strategies being offered, in a time-limited therapy. Even where therapy does not clearly reduce relapse, many recipients value the opportunity to discuss their problems in detail, reporting improved quality of life and social functioning. Clinically, if the goal is relapse prevention, it may be appropriate to particularly target for therapy those individuals at an earlier stage of their 'bipolar career', whom evidence suggests may benefit more.[43]

Longer-term treatment of bipolar disorders

Supportive or other psychological therapies may extend over considerable periods of time. People with affective disorders also form 15 to 20 per cent of the long-stay patient populations of United Kingdom and United States mental hospitals. Rehabilitation techniques, as applied to schizophrenia and other severe mental disorders, are important for instilling hope and developing day-to-day living skills in people with chronic or recurrent affective disorders. Lastly, individuals with chronic health problems are at high risk of non-adherence with medication. There is an important role for psychotherapy in enhancing the acceptance of long-term medication[23,62] and there is emerging evidence that psychological interventions targeted directly or indirectly at enhancing medication adherence can have a beneficial impact on outcome in bipolar disorders.

4.5.9 Dysthymia, cyclothymia, and hyperthymia

Hagop S. Akiskal

Subthreshold affective conditions, personality, and temperament

Long before psychiatry moved to the outpatient arena in the latter part of the twentieth century, psychiatrists had observed milder mood disturbances among the kin of patients hospitalized for endogenous or psychotic depressions or mania. Some were described as sullen, morose, or otherwise moody, without discrete episodes; others reported self-limited episodes, but often went untreated. With the advent of modern treatments, practitioners are being increasingly consulted by patients presenting with attenuated affective disturbances. Although the relationship of these ambulatory mood states and more classical severe affective disorders has not been resolved, there is emerging sleep electroencephalography (**EEG**) and familial-genetic evidence[1–3] that a continuum exists between them. Along the same lines, studies conducted in the United States and Germany[4,5] into what were once described as 'neurotic' depressions have revealed a progression to more endogenous, psychotic, or bipolar switching. For these and related reasons, current official classification systems such as the ICD-10 and DSM-IV, have dropped the neurotic-endogenous dichotomy. Sceptics would perhaps argue that the new categorization of depressive disorders into dysthymic and major subtypes is not much of an improvement. Nonetheless, the new terminology has drawn attention to a large universe of human suffering that had been neglected in the past, and the conceptualization of dysthymia as a variant of mood disorder has had a far-reaching impact on diagnostic and therapeutic habits of clinicians worldwide.[6] The emerging concept of the bipolar spectrum, which does include manic, cyclic depressive (bipolar II), cyclothymic, hyperthymic and related conditions, is beginning to have a similar impact on practice.[7]

The subthreshold mood disorders are not only in continuum with more pathological mood states, but they also provide a bridge with normal affective conditions. In this context, temperament, as a construct encompassing affective personalities, is currently enjoying a renaissance as one of the possible substrates for the origin of mood disorders. Temperament classically refers to an adaptive mixture of traits which, in the extreme, can lead to illness or modify the expression of superimposed affective states. The subthreshold conditions covered in this chapter represent the extreme expressions of these temperaments. A new self-administered instrument, the TEMPS-A,[8] now validated in 10 language versions, is being used internationally to measure the classical constructs of depressive, cyclothymic, hyperthymic, and irritable, as well as anxious temperaments.

In the current literature, various terms such as 'minor affective states', 'intermittent depression', 'hysteroid dysphoria', and 'atypical depression' are often used for subthreshold disorders.[9] These terms are avoided here, because in contemporary practice these conditions are at least as 'typical' as major mood disorders: their impact on the sufferer is not time-limited, nor minor, and involves more than a state of demoralization and moral foible. The following passage from Sir Aubrey Lewis[10] is *à propos*:

> . . . Severe emotional upsets ordinarily tend to subside, but mild emotional states . . . tend to persist, as it were, autonomously. Hence the paradox that a gross blatant psychosis may do less damage in the long run than some meager neurotic incubus: a dramatic attack of mania or melancholia, with delusions, wasting, hallucinations, wild excitement may have far less effect on the course of man's life than some deceptively mild affective illness which goes on so long that it becomes inveterate. The former comes as a catastrophe and when it has passed the patient takes up his life again . . . while with the latter he may never get rid of his burden.

It is a curious fact that most subthreshold affective conditions, while symptomatologically attenuated, tend to pursue a chronic course. This raises the question, partially addressed in this chapter, whether these conditions in their trait expressions might serve some useful function, even as they burden the individual with cares and instability which could predispose to full-blown affective disease. By their very chronicity, these subaffective conditions pose difficult conceptual and clinical questions about their differentiation from personality disorders.[11] Sceptics might argue that subthreshold affective conditions are nothing more than personality disorders and/or expressions of 'neuroticism'. Actually, a close examination of the Eysenck personality inventory, which ranges over a large terrain of depressiveness, anxiousness, emotionality, and mood lability among others, reveals low-grade intermittent affective symptomatology.[12] And at least one genetic investigation has reported that neuroticism and major depression in women share substantial genetic underpinnings.[13] Nonetheless, clinicians have always preferred categorical constructs, because neuroticism and related personality constructs do not do justice to the rich clinical phenomenology of disorders within the subaffective realm. I finally wish to point out that terms like 'neurotic', 'psychopathic', or 'personality disorder' used as epithets to describe a person have pejorative connotations. They tend to describe what is negative about someone, whereas 'temperament' refers to the optimum mixture of both liabilities and assets regarding a human being, thereby rendering therapeutic work possible with relatively little countertransference. This is particularly relevant when we consider the distinct possibility that the many dysthymic and cyclothymic individuals might otherwise be labeled 'borderline.'[11]

The dysthymic spectrum

History

The term 'dysthymia' (meaning 'bad mood') originated in classical Greek and is still in current use in that country with the same connotation.

In the Hippocratic School, it was considered as part of the broader concept of melancholia (meaning 'black bile'). A temperament predisposed to melancholia was also delineated, and referred to individuals who were lethargic, brooding, and insecure. It was not until the early nineteenth century that dysthymia was reintroduced into medicine by the German physicians, Stark and Fleming to describe depressions in inpatients that pursued a chronic course.[14] Eventually, dysthymia came to subsume all mood disorders. The major residue of dysthymia in the latter sense in Europe today is the French rubric of *les dysthymies*, as a synonym for *troubles de l'humeur*; the DSM-IV or ICD-10 'dysthymic disorder' in that country is translated as *le trouble dysthymique*.

The more direct lineage of our current usage of the term dysthymia is to be found in the latter part of the nineteenth century in the work of Kraepelin, who delineated the depressive disposition as one of the constitutional foundations of affective episodes. The condition often began early in life, such that by adolescence many showed an increased sensitivity to life's sorrows and disappointments: they were tormented by guilt, had little confidence in their abilities, and suffered from low energy. As they grew into adulthood, they experienced 'life with its activity [as] a burden which they habitually [bore] with dutiful self-denial without being compensated by the pleasures of existence'. In some, these temperamental peculiarities were so marked that they could be considered 'morbid without the appearance of more severe, delimited attacks . . .' (clearly foreshadowing the modern concept of trait dysthymia). In other cases, recurrent melancholia arose from this substrate without definite boundaries (again anticipating the concept of 'double-depression').

Subsequently, Kurt Schneider in his opus *Psychopathic Personalities* devoted considerable space to a depressive type whose entire existence was entrenched in suffering. Building on this rich phenomenological tradition, our research in Memphis[15] helped in operationalizing the core characteristics of such patients encountered in contemporary practice: gloomy, sombre, and incapable of having fun; brooding, self-critical, and guilt-prone; lack of confidence, low self-esteem, preoccupation with failure; pessimistic, easily discouraged; easy to tire, sluggish, and bound to routine; non-assertive, self-denying, and devoted; shy and sensitive. These traits have excellent internal consistency and discriminatory ability.[16] Similar concepts have also appeared in the Japanese literature,[17] with particular emphasis on self-critical attitudes, persistence in work habits, and devotion to others. Finally, the French construct of *la depression constitutionelle*[18] has emphasized the lethargic aspects with a sense of inadequacy. A self-rated scale in all of these languages[8] now can assist in reliable and valid assessment of depressive temperament traits.

The classical tenet in psychiatry has been that affectively ill patients recover from their acute episodes with relatively little symptomatic residua and dysfunction. Community psychiatry, which has given renewed visibility to the temperamentally expressed low-grade fluctuating depressive disorders, has challenged this classic view. With the advent of DSM-III, such patients are now officially designated as 'dysthymic.' In the ICD-10 classification, the low-grade depressive baseline is considered the main pathology; only an occasional superimposed depressive episode is permitted, provided that it is mild. In DSM-IV, at least two patterns have been described: pure dysthymia uncomplicated by major depression and a more prevalent pattern of dysthymia complicated by major depressive episodes that could be even moderate or severe in intensity (and which has been dubbed 'double depression').

The mystery of this incapacitating depressive subtype—long recognized, but only recently sanctioned in official diagnostic manuals—is that, in their habitual condition, sufferers lack the classical 'objective' or 'major' signs of acute clinical depression, such as profound changes in psychomotor and vegetative functions. Instead, patients consult their doctors for more fluctuating complaints consisting of gloominess, lethargy, self-doubt, and lack of *joie de vivre*; they typically work hard, but do not enjoy their work; if married, they are deadlocked in bitter and unhappy marriages which lead neither to reconciliation nor separation; for them, their entire existence is a burden: they are satisfied with nothing, complain of everything, and brood about the uselessness of existence. As a result, in the past those who could afford it were condemned to the couch for what often proved to be interminable analysis. The legitimization of dysthymia as a clinically significant variant of affective disorder in both the United States and WHO classifications has helped the cause of more cost-effective treatments.

To sum up, for nearly 2500 years physicians have described individuals with a low-grade chronic depressive profile marked by gloominess, pessimism, low enjoyment of life, relatively low drive, yet endowed with self-critical attitudes and suffering for others.[19]This constellation is as much a virtue as it is a disposition to melancholy, and many dysthymic patients presenting clinically have various admixtures of major depression. This is compatible with a spectrum-concept of depressive illness, which defines various degrees of severity.

Clinical picture and diagnostic considerations[20]*

Diagnostic criteria for dysthymia in both DSM-IV and ICD-10 stipulate a two-year duration of low-grade depressive symptoms, exclusive of such indicators of severity as suicidality and psychomotor disturbances. Dysthymia is distinguished from chronic major depressive disorder by the fact that it is not a sequel to well-defined major depressive episodes. Instead, patients often complain that they have always been depressed. Most are of early onset (less than 20 years). A late-onset subtype first manifesting after the age of 50 is much less prevalent and has not been well characterized clinically, but it has been identified largely through studies in the community.

At their best, dysthymic individuals invest whatever energy they have in work, leaving none for leisure or social activities. According to Tellenbach, such dedication to work represents overcompensation against depressive disorganization. Kretschmer had earlier suggested that such persons were the 'backbone of society,' devoting their lives to jobs that require dependability and great attention to detail. These features represent the obsessoid facet of dysthymia. Such individuals may seek outpatient counseling and psychotherapy for what some clinicians might consider 'existential depression': individuals who complain that their life lacks lustre, joy, and meaning. Others present clinically because of an intensification of their gloom to the level of clinical depression; history of lifelong low-

* Unless otherwise specified, in the remainder of this chapter, references to concepts, historical developments, and research covering dysthymia and cyclothymia through the year 2000 can be found in this centenary review of Kraepelinian psychiatry.[20]

grade depressive symptoms would distinguish them from episodic major depressive patients.

The proverbial dysthymic patient will often complain of having been 'depressed since birth'. In the eloquent words of Kurt Schneider, "they view themselves as belonging to an 'aristocracy of suffering". These hyperbolic descriptions of suffering in the absence of more objective signs of depression earn such patients the label of 'characterological depression'. The description is further reinforced by the fluctuating depressive picture that merges imperceptibly with the patient's habitual self, leading to the customary clinical uncertainty as to whether dysthymic disorder belongs to the affective or personality disorder domains.

At their worst, patients with low-grade depression having an intermittent course can present such instability in their life, including suicidal crises, that some clinicians would entertain the diagnosis of borderline personality disorder. This is not consistent with the classic picture of dysthymia arising from a temperamental type with more mature ego structure described above. Depressives with unstable (that is to say, 'borderline') personality structure more often belong to the irritable cyclothymic–bipolar II spectrum.

The greatest overlap of dysthymia is with major depressive disorder, but differs from it in that symptoms tend to outnumber signs (more subjective than objective depression). Thus, marked disturbances in appetite and libido are uncharacteristic, and psychomotor agitation or retardation is not observed. Nonetheless, subtle 'endogenous' features are not uncommonly reported: inertia, lethargy, and anhedonia that are characteristically worse in the morning. Because many patients with dysthymia presenting clinically fluctuate in and out of a major depression, the core DSM-IV criteria for dysthymia tend to emphasize vegetative dysfunction, whereas the alternative criterion B for dysthymia in a DSM-IV appendix lists cognitive symptoms; although the latter appear more characteristic of trait dysthymia, the DSM-IV field trial could not demonstrate their specificity for dysthymia.

A Milan-San Diego collaboration of a large sample from community and primary-care medical settings revealed that negative mood (by definition), along with low energy, poor concentration, low self-esteem, sleep and appetite disturbance, and hopelessness (in descending order) were the most common symptoms of dysthymia. These data suggest that the cognitive and somatic symptoms are not easily separable in practice. None the less, this study did raise the possibility that factors could be discerned along two different axes: 'negative affectivity' and 'lassitude with poor concentration'. In our experience, patients loading on the latter factor often complain of hypersomnia and may exhibit subtle bipolar signs; alternatively, they might have some link to the poorly defined constructs of neurasthenia, chronic fatigue syndrome, and fibromyalgia. In terms of differential diagnosis, patients with chronic fatigue syndrome present with disabling fatigue and, typically, deny depressive symptoms; patients with fibromyalgia complain of pain; by contrast, the typical patient with dysthymia cannot stop relating to the physician his or her litany of depressive symptoms. Polysomnography, though not yet definitive, may shed some light on differentiating fibromyalgia from dysthymia proper.

Although dysthymic disorder represents a more restricted concept than does its parent, neurotic depression, it is still quite heterogeneous. Anxiety is not a necessary part of its clinical picture, yet dysthymia is sometimes diagnosed in patients with anxiety and neurotic disorders. That clinical situation is perhaps to be regarded as a secondary or 'anxious dysthymia' or, as some British authors seem to prefer, as part of a 'general neurotic syndrome' (an implicit partial return to the now defunct concept of neurotic depression).

Table 4.5.9.1 The core characteristics of dysthymia

Long-standing subthreshold depression of a fluctuating or persistent nature
Gloomy and joyless disposition
Brooding about the past and guilt prone
Low drive and lethargy
Low self-esteem and preoccupation with failure
Identifies suffering as part of the habitual self

Summarized from Akiskal.[19]

The clinical picture of dysthymic disorder that emerges from the foregoing descriptions is quite varied, with many who fluctuate in and out of major depression, whereas in others the pathology is woven into the habitual self. Prospective follow-up supports a continuum between temperament, dysthymia and major depression. These considerations suggest that a clinically satisfactory operationalization of dysthymia must include both symptoms and trait characteristics (Table 4.5.9.1). The following vignette illustrates this more prototypical form of dysthymic suffering.

Case Study: This 37-year-old never-married male teacher presented with the complaint that he was 'tired of living' and was considering 'ending it all'. He said that much of his life had been 'wasted', he had never known any joy, and that all human existence for him was a 'tragic mistake of God'. He was known to be a dedicated and talented teacher, but he felt all his efforts had been 'useless and in vain'. He said he probably was 'born depressed', because he had not known any happiness and that the only utility he could have for mankind was 'to serve as a specimen to be researched—to shed light on human misery'. Although he conceded that some women found him interesting, even intellectually stimulating, he said he could not enjoy physical intimacy, that even orgasm lacked passion; nonetheless, he masturbated frequently, fantasizing about married female teachers—only to feel guilty. We could not document any major affective episodes. He stated that he had always functioned at a 'mediocre level' (which was at variance with the good feedback students had given him year after year); but did admit he 'appreciated work, because there was nothing else to do'. He denied alcohol and drug habits. There had never been any periods of hypomania, but one of his maternal aunts had been treated for a 'cyclical depression' and was apparently doing well on lithium. The patient's mother was a sombre serious work-oriented woman who had raised three children and had done voluntary work for the church, but had no depressive complaints. His father had died from a coronary attack, but his side of the family was otherwise unremarkable.

Although both DSM-IV and ICD-10 omit suicidal preoccupations in their diagnostic criteria for dysthymia, as testified by the above case, this is what often brings patients to clinical attention.

Course[20]

An insidious onset of depression dating back to late childhood or the teens, preceding any superimposed major depressive episodes by years, even decades, is the most typical developmental

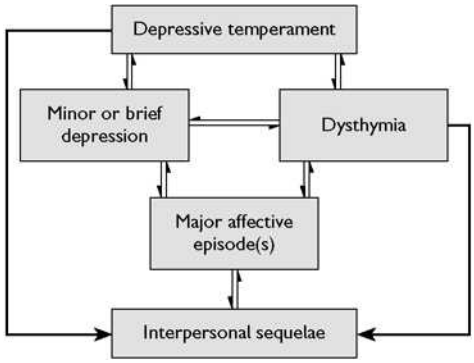

Fig. 4.5.9.1 Diagram to show putative relationships within a broad depressive spectrum.

background of dysthymic disorder. A return to the low-grade depressive pattern is the rule following recovery from superimposed major depressive episodes, if any, hence the designation 'double depression'.

Few studies have studied the phenomenology of dysthymia in childhood. DSM-IV does not seem to distinguish between childhood and adult dysthymia, yet current clinical experience indicates that the main symptoms in childhood dysthymia include irritability, low self esteem, fatigue, low mood, guilt, poor concentration, anhedonia, and hopelessness; as in adults, comorbid anxiety disorders were prevalent; suicidality was more common in adolescents. These findings should be useful in dysthymic children in future studies. A long-term prospective Pittsburgh study of prepubertal children has revealed an episodic course of dysthymia with remissions and exacerbations, and eventual complication by major depressive episodes, as well as hypomanic, manic, or mixed episodes postpubertally. Persons with dysthymic disorder presenting clinically as adults tend to pursue a chronic 'unipolar' course, which may or may not be complicated by major depression: they rarely develop spontaneous hypomania or mania. However, when treated with antidepressants, some adult patients with dysthymia may experience brief hypomanic switches that typically disappear when the antidepressant dose is decreased. Although ICD-10 and DSM-IV would not 'allow' the occurrence of such switches in dysthymia, systematic clinical observation have verified their occurrence in between 10 and 30 per cent of dysthymic patients. In that special dysthymic subgroup, the family histories are typically positive for bipolar disorder. Such patients, often conforming to the double depressive pattern, represent a clinical bridge between major depressive disorder and bipolar II.

A 12-year NIMH prospective study has shown that patients with major depressive disorder spent 44 per cent of their course in low-grade depression (versus 15 per cent of time in major depressive episodes). This suggests that major depression, dysthymia, or otherwise subsyndromal depression constitute somewhat artificial conventions on the threshold and duration of depressive illness, representing alternative manifestations of the same diathesis. In this context, residual intermorbid depressive symptoms have been confirmed as being strongly predictive of a rapid relapse into a new major depressive episode. Various 'major' and 'minor' depressive conditions described in DSM-IV and its appendix must not be viewed as distinct depressive subtypes, but part of a symptomatic continuum. Fig. 4.5.9.1 shows a diagram of these putative relationships within a broad depressive spectrum.

Epidemiology[20]

From 1966 to 1980, *Index Medicus* listed no more than 10 articles on chronic depressions. Since 1980, when dysthymia was first introduced in DSM-III, at least 500 articles have appeared on chronic depression, mostly on dysthymia. This phenomenal growth in research interest parallels the increasing public health significance of this disorder. It is estimated that 3–5 per cent of the world population is suffering from dysthymia. Like major depressive disorders, dysthymia is twice as common in women as in men. Because of its chronicity, dysthymia is among the most prevalent psychiatric conditions in clinical practice. Dysthymia is more disabling, as far as quality of life in social and personal areas, work, and leisure, than depression in the setting of a severe anxiety disorder like agoraphobia. Celibacy is also common in early-onset dysthymia, but not for long; modern successful treatments often lead to a change in marital status!

UCLA research in primary care has focused on depressive symptoms falling short of the major depressive threshold, as far as symptom intensity is concerned, as well as falling short of the two year duration criterion for dysthymia. Despite its chronicity, 50 per cent of people remain unrecognized by general practitioners. Despite the low-grade nature of their depressive complaints, these patients report high degrees of morbidity and impairment in a variety of health domains and quality of life, including 'bed days' (namely, the number of days per year they stayed ill in bed). Actually, these impairments are generally more pronounced than those of patients with a variety of medical conditions, such as hypertension, diabetes, arthritis, and chronic lung disease; only coronary artery disease exceeded the disability of low-grade depression in several domains. Stroke has recently been added on this list.

In light of the foregoing developments, both the World Psychiatric Association[21] and the World Health Organization[22] have developed programmes to address the challenges of educating general practitioners in the proper recognition and treatment of dysthymia.

Aetiological considerations[20]

Some sensitivity to suffering, a cardinal feature of the depressive temperament, represents an important attribute in a species like ours, where caring for young and sick individuals is necessary for survival. This temperament, historically the *Anlage* of dysthymia, in the extreme often leads to clinical depression. The constitutional viewpoint, while dominant in the early part of the twentieth century, gradually disappeared from psychiatric thinking. One reason was that Kurt Schneider preferred to conceptualize such conditions as 'psychopathy', by which he meant abnormal personality development. Independently, Freud's disciples took this one step further and, eventually in outpatients, all milder depressions with a tendency to chronicity came to be considered as the expressions of a character neurosis. In support for this position, these authors could point to the long-standing nature of the interpersonal difficulties in the lives of these individuals. When, and if, antidepressants were prescribed, they were given in homeopathic doses; worse, many patients received stimulants or benzodiazepines rather than genuine antidepressants. Failure to respond to these incorrectly chosen pharmaceutical agents seemed to further reinforce the notion of a 'character' defect.

Several lines of observation during the latter part of the 20th century have challenged the concept of 'character neurosis' as an explanation for low-grade depression, and thereby forced a return to the more classical European concept of temperament with its biological underpinnings. First, in a 1980 Memphis study of rapid eye movement (REM) latency (normally 90 min, measured from sleep onset to the first REM period) conducted in 'depressive characters' who were not in a state of major depression, we reported that REM latency was less than 60 min, and REM was redistributed to the early part of the night (which was the reverse of what we observed in chronic anxious patients). Moreover, a family history for major affective illness (including bipolar) was significantly high in short-REM latency patients. (The reverse was true for those with familial alcoholism and sociopathy.) The sleep findings were so reminiscent of those seen in major affective illness that we were compelled to give our patients systematic open trials with desipramine and nortriptyline (the best-tolerated secondary amine tricyclics in those days) or lithium carbonate if antidepressants failed (based on the observation of familial bipolar disorder in some). Nearly 40 per cent remitted, of whom one out of three developed brief hypomania. The sleep findings have been replicated in other laboratories. Furthermore, a Hungarian study has shown that patients with dysthymia experience transient lifting of their mood with sleep deprivation. Other studies have shown high rates of affective illness in a systematic familial investigation of dysthymic probands. There also exist dysthymic patients whose lifelong suffering and discontent appear, in retrospect, a legacy of an unsatisfactory childhood marked by deprivation or abuse at the hands of alcoholic and/or sociopathic parents or step-parents. Although it is clinically attractive to invoke the notion of 'learned helplessness' secondary to such inescapable childhood traumata, an alternative hypothesis is that the helplessness of these individuals might develop secondary to an inherited diathesis which biases these children's early experiences in a dysphoric direction.

As for neuroendocrine markers, thyroid-releasing hormone-thyroid-stimulating hormone challenge and electrodermal activity similar to those with major depressive disorders are the main findings; by contrast, dexamethasone suppression and catecholamine metabolism are essentially unaltered in dysthymia. These observations, along with the REM latency findings, suggest that dysthymia represents trait depression. Coupled with the family history data, this traitness can be postulated to be of constitutional origin. Certainly, the occurrence of major affective episodes in the long-term course of dysthymia, in both community and clinical samples, is in line with this position. It is, therefore, of great theoretical and practical significance that shortened REM latency has been reported in the offspring of the affectively ill. More recently a variety of other biological findings have been reported in dysthymia, further strengthening the link with major depression: low testosterone and adrenal-gonadal steroid levels,[24] neuro-immune abnormalities,[25] effects of prenatal maternal dysthymia on foetal growth,[26] as well as small genual corpus callosum volume[27] and enlarged amygdalar volume.[28] Coupled with s-allele polymorphism of the serotonin transmitter,[29,30] that subthreshold depression, however defined, is not a 'neurotic' phenomenon in the traditional psychodynamic sense of the term, but part of the spectrum of depressive illness! Table 4.5.9.2 summarizes the foregoing links between dysthymia and major depressive disorder, and which support its inclusion within the family of mood disorders.

Table 4.5.9.2 Evidence for considering dysthymia as a variant of major depressive disorder

Familial affective loading
Phase advance of rapid eye-movement sleep
Diurnality of inertia, gloominess, and anhedonia
Thyroid-releasing hormone-thyroid-stimulating hormone challenge test abnormalities
Low testosterone
Lowered interlukin-1-beta production
Amydalar enlargement
s-allele in serotonin transporter gene
Prospective course complicated by recurrent major depressive episodes
Positive response to selected thymoleptics
Treatment-emergent hypomania

Updated from Akiskal.[19]

There are also exist medical and neurological factors that may contribute to dysthymic symptom formation. Actually, joint medical-neurological and non-affective psychiatric disease is often contributory to extreme refractoriness among the chronic depressive states of these patients. Such patients are at risk for suicide, especially those with epilepsy or progressive degenerative neurological disease. Interestingly, living with a medically disabled spouse or family member, too, can be associated with some chronicity of depression.

The emergence of pathogenetic understanding, as outlined above, is all the more impressive, given the controversies on the very nature of dysthymia and its legitimacy as a nosological entity.[31]

Treatment[20]

The trait nature of dysthymia can be further observed in the fact that dysthymia often pursues an unrelenting course towards chronicity. Thus, spontaneous recovery has been shown to occur in no more than 13 per cent of subjects in the community over 1 year. In outpatient clinics, the outcome is somewhat better, but this is probably due to the treatment received and a longer follow-up.

Most classes of antidepressants have been shown to be effective in dysthymia in double-blind studies (Table 4.5.9.3). The rationale for using classic antidepressants such as tricyclic compounds in our mood clinic was our observation of shortened REM latency in

*Summarized from references[19,20]

dysthymic subjects in our sleep laboratory. Irreversible monoamine oxidase inhibitors such as phenalzine were used because of the belief that non-classical depressions respond preferentially to this class of drugs; the same can be said for the reversible inhibitors of type A monoamine oxidase. Amisulpride was tried, because it reverses 'negative' symptoms in schizophrenia and, by analogy, it was hypothesized that the low motivation and lethargy seen in some patients with dysthymia reflected a shared underlying dimensional transnosological pathology. The selective serotonin re-uptake inhibitors (SSRIs) were used empirically, because of good tolerance compared with the tricyclic antidepressants, and later it was suggested that improvement in dysthymia correlates with normalization of serotonergic indices. The foregoing trials, conducted in different countries during the past 12 years represent the most eloquent evidence for the increasing worldwide acceptance of the concept of dysthymia as a clinically significant variant of affective disorder.[21,22]

The treatment of dysthymia should continue in most cases for 2 years or more. Tricyclic antidepressants have too many side-effects in clinically effective doses (desipramine equivalent of 150 mg or more per day). Given dietary and medication prohibitions, monoamine oxidase inhibitors are also not practical as first-line drugs. Overall good tolerance in long-term use, despite sexual side-effects, has made the SSRIs first-line intervention treatment for dysthymia; given that many people with dysthymia are young individuals who should be eager to form families, their acceptance of long-term SSRI use is an indication that the alleviation of the depressive suffering of dysthymia is genuine and far outweighs the sexual dysfunction. However, 75 to 150 mg bupropion-SR can be taken in the morning on the desired day of sexual union, but preferably no more than once a week. Moclobemide also spares sexual function, but seems more effective in anxious and milder cases of dysthymia. Amisulpride, which rarely causes amenorrhoea and/or galactorrhoea, is otherwise well tolerated in dysthymia in the more lethargic forms of the illness seen in general medical practice.

The dosage of nearly all antidepressants in dysthymia is in the full range for that recommended for major depression (20–40 mg for fluoxetine). In the case of amisulpride, the dosage is low (25–50 mg), because at this dosage the drug is a dopamine agonist, believed to be the necessary ingredient for its mechanism of action in dysthymia. Both dysthymia and double depression respond equally well, and the duration of underlying dysthymia does not seem to matter. The main difference in treatment for these two course patterns is that dysthymia need not be treated for a lifetime, but double depression should probably be treated indefinitely. Women seem to have a preferentially better response to SSRIs, which have the added benefit of treating the premenstrual accentuation of dysthymic symptoms. Borderline thyroid function (e.g. a high baseline thyroid-stimulating hormone level) preferentially occurs in women with dysthymia, so that these women would benefit from thyroid augmentation (levothyroxine 175 mg/day) of the antidepressant. In those patients who oversleep in the morning, terminal sleep deprivation and/or morning phototherapy represent useful adjuncts to antidepressants. Although there are no controlled studies in children, our clinical experience indicates that SSRIs often prove effective in this population, with the appropriate dosage reduction for body-weight. In adults, concurrent personality disturbances (for instance, obsessoid, avoidant, dependent, and hostile features) do not compromise therapeutic responses. Indeed, more often than not, such personality disturbances recede with the successful alleviation of dysthymic suffering; social function improves in tandem. (However, extremely hostile patients, who may meet symptomatological criteria for 'dysthymia' but whose irritable dysphoria more appropriately belongs to the cyclothymic domain, are best managed with mood-stabilizing anticonvulsants, for example divalproex 600 to 1200 mg/day.)

In a Memphis study, we have shown that, with the judicious use of the foregoing modalities in private practice, three out of four patients with dysthymia engulfed in gloom for much of their lives had sustained remissions for five or more years. Depressive episodes *and* suicidal preoccupation and/or crises were prevented, in tandem with the alleviation of the dysthymia. Approximately 15 per cent experienced 'overcorrection' of their dysthymia in the direction of mild hypomania; this is particularly likely in the presence of inhibited-social phobic traits as part of dysthymia, and when the family history is bipolar. The hypomania is typically short-lived, and tends to disappear when the antidepressant dose is reduced; in some cases, it is necessary to provide lithium (600–900 mg/day) or valproate augmentation (500–750 mg/day). The question has been raised whether selective serotonin-reuptake inhibitors, in particular fluoxetine, change the personality in a hyperthymic direction. In our experience, most observed changes are compatible with adaptive behaviour that emerge as a result of alleviation of depressive suffering; the more distinctly protracted hypomanic changes nearly always require familial bipolar diathesis. It is, nonetheless, true that with SSRIs we have entered an era of 'dimensional psychopharmacology', whereby the clinician could dose the patient to a desired end from a functional standpoint. Many become care-less rather than careless. The present author has also encountered some patients treated with SSRIs who view a life without cares as negative; in such cases, one should opt for very low doses and a more gradual lifting of the dysthymia, and help the patient adjust to a new self-image of normalcy.

As for psychotherapy, there is little credible evidence for its efficacy as monotherapy in the treatment of dysthymia. Actually, some female mental health experts have argued that exploration of one's mental inadequacies, in the 'passive' psychoanalytical situation, is particularly negative for women; the more 'active' cognitive behavioural approaches, which encourage thinking, and behaviours reinforcing for the individual, are preferable. Many clinicians profitably use the latter strategy along with pharmacotherapy to boost the self-esteem of the patient. In a more practical vein, there are clinical management strategies that are specifically useful for both the patients and their clinicians (Table 4.5.9.4).

Table 4.5.9.4 Psychotherapeutic principles in dysthymia*

Provide a believable dose of optimism
Optimize compliance to pharmacotherapy
Limit destructive expression of negative feelings
Address accumulated conflicts
Combat postdepressive resignation and inertia
Provide support for patient and significant others
Be aware of countertransference feelings
Consult experts with extensive experience in treating chronic depression
Gradually mobilize patient's skills and resources

*Updated from Akiskal.[6]

It is particularly important for the clinician not to be submerged by the negative thinking of the patient, and it is even more crucial for the therapist to recognize that a relative lack of progress can generate feelings of 'impotence' and countertransference; periodic consultation with more experienced clinicians in the treatment of chronic depression would be desirable.

Interpersonal psychotherapy has been used in medication failures. This is best viewed as a more practical abbreviation of psychodynamic psychotherapy, with a strong emphasis on support and encouragement for patients with dysthymia who seek help at a time of loss or role transition in their lives. Knowledge of the interpersonal context of depression is obviously important in formulating how the clinician would stage the psychological recovery process from dysthymia. Nonetheless, there are some suggestions that SSRIs often lead to improved coping behaviour, even without formal psychotherapy. Indeed, Canadian studies have shown that a successful response to SSRIs is often associated with decreased emotion-focused coping and decreased perception of daily hassles, as well as alleviation of the sense of loneliness one experiences in chronic depression.

No matter what the active ingredients in antidysthymic treatments, there is little doubt that for the first time in the history of psychiatry we have potent practical treatments to alleviate a major source of chronic human suffering, including what were once deemed depressive characterological attributes inseparable from the habitual self. Helping patients attain a new homeostasis of the self is an art unparalleled in the history of medical science. In our view, it does not constitute what Kraemer has erroneously labeled 'cosmetic psychopharmacology'.[32]

Prevention opportunities[20]

Community subjects with pure dysthymia have been found in two prospective studies to be at risk for major depressive episodes. Because dysthymia often makes its first appearance in juvenile years, identifying the disorder at this early stage represents a special opportunity for prevention in child psychiatry and paediatrics. 'Pure' dysthymia, even without major depression, responds better to pharmacotherapy better than to placebo in 8 out of 9 social domains. St. John's Wort, on the other hand, does not appear to be effective in dysthymia![33]

In still another group of patients, low-grade chronic depressive developments occur in the setting of disabling systematic medical and neurological disorders, and are best categorized as 'secondary dysthymias'. For instance, poliomyelitis may not only lead to deformities in musculoskeletal structures in children, but could permanently scar the sufferer's sense of enjoyment, fulfillment, and outlook of life. Likewise, low-grade chronic depressive development often complicates neurodegenerative cerebrovascular disease later in life. In both situations, psychological factors might be operative, yet the contribution of specific cerebral lesions to the subthreshold mood disturbance may be substantial. This group as a whole is not well captured by the conventional depressive categories in ICD-10 and DSM-IV. In these subacute dysthymic-like conditions, the affective state is often disabling, yet symptomatologically less severe than major depression; it is low grade, yet not as chronic as dysthymia. 'Minor depression' would not capture the clinical significance of their condition. Indeed, there is emerging data that treating these subacute dysthymias may improve the prognosis of the underlying neurological disorder.[22]

In concluding this review of the legitimacy of dysthymia from clinical, biologic and therapeutic standpoints, it is relevant to point out that dysthymia—properly defined—may well serve as a behavioral endophenotype for depressive illness.[34] Such a conceptualization highlights its potential as a target for preventing strategies for major depressive illness.

Cyclothymic disorder and labile-irritable variants[20]

History

Kraepelin included the cyclothymic disposition as one of the temperamental foundations from which manic-depressive illness arose. Kretschmer went one step further and proposed that this constitution represented the core characteristic of the illness: some patients were more likely to oscillate in a sad direction, while others would more readily resonate with cheerful situations; these were merely viewed as variations in the cyclothymic oscillation between these two extremes. Kurt Schneider, who did not endorse the concept of 'temperament', instead referred to 'labile psychopaths' whose moods constantly changed in a dysphoric direction, and who bore no relationship to patients with manic depression. To confuse matters further, Schneider used the term 'cyclothymia' as a synonym for all manic depressive illness, from the mildest to the most severe psychotic forms. Today, 'cyclothymia' is still sometimes used in this broader sense in Germanophone psychiatry. But in much of the rest of the world, cyclothymia (short for 'cyclothymic disorder') is reserved for a form of extreme temperament related to bipolar disorder.

Cyclothymia, which in ICD-9 and DSM-II was subsumed under the affective personalities, was first introduced into DSM-III and DSM-IV and subsequently into ICD-10 as a form of attenuated chronic mood disorder. The diagnosis is not commonly made in clinical practice, because it is almost always seen when a patient presents with major depressive episodes, warranting the designation of 'bipolar II'. Indeed, Hecker used cyclothymia as a synonym for what today we call bipolar II; his short monograph has recently been translated into English.[35] Nonetheless, systematic clinical and familial validation studies conducted in Memphis[36,37] have shown that the construct of cyclothymic temperament is of great theoretical, psychometric and practical significance as one of the possible substrates for major mood disorders. Moreover, it could shed light on social and occupational maladjustment and/or addictive behaviours that could otherwise be misattributed to personality disorder.

Clinical features and diagnostic considerations[20]

By definition, individuals with cyclothymia report short cycles of depression and hypomania that fail to meet the sustained duration criterion for major affective syndromes. At various times, they exhibit the entire range of manifestations required for the diagnosis of depression and hypomania, but only from a few days at a time up to 1 week, rarely longer. These cycles follow each other in an irregular fashion, often changing abruptly from one mood to another, with only rare interposition of 'even' periods. The unpredictability of mood swings is a major source of distress for cyclothymes, as they do not know from moment to moment, how they will feel. As one patient put it, 'my moods swing like a

Table 4.5.9.5 Discriminatory biphasic characteristics of cyclothymic disorder*

Lethargy alternating with eutonia
Shaky self-esteem alternating between low self-confidence and overconfidence
Decreased verbal output alternating with talkativeness
Mental confusion alternating with sharpened thinking
Introverted self-absorption alternating with uninhibited people-seeking

*Summarized from Akiskal *et al.*[36,37]

pendulum, from one extreme to another'. The rapid mood shifts, which undermine the patients' sense of self, may lead to the misleading diagnostic label of borderline personality. But unlike a personality disorder, the mood changes in cyclothymes have a circadian component. One patient described it as follows: 'I would go to bed in a cheerful mood and wake up down in the dumps'. This observation is in line with NIMH psychophysiological data on mood-switching occurring out of the rapid eye movement sleep phase, as reported in more typical cases of manic depression.

The mood swings of cyclothymes are biphasic: eutonia versus anergic periods; people-seeking versus self-absorption; sharpened thinking versus mental paralysis. Table 4.5.9.5 provides an empirically tested set of criteria. In addition, the following presentations characterize their roller-coaster biography.

Irritable periods. At one time or another, labile angry or irritable moods are observed in virtually all these patients. Cyclothymes, unlike patients with epilepsy, are aware of their 'fits of anger', which lead to considerable personal and social embarrassment after they subside. The patients often feel 'on edge, restless, and aimlessly driven'; family and friends report that during these periods patients seem inconsiderate and hostile toward people around them. The contribution of alcohol and sedative-hypnotic drugs to these moods cannot be denied, but the moods often occur in the absence of drugs. Electroencephalography typically reveals no seizure or subseizure activity. The interpersonal costs of such unpredictable interpersonal explosiveness can be quite damaging. One of our patients reported frequent periods where he would start unprovoked fights with very close friends, only to shift into periods of prolonged 'soul-searching, guilt, shame, and embarrassment'. In other patients, outbursts of anger are 'reactive' to minor interpersonal disputes—but once in full force, they are like emotional avalanches with the distinct potential to destroy relationships. Should they dominate the clinical picture, especially among young women who hurt themselves in response to interpersonal contexts, the problematic diagnosis of borderline personality disorder is often invoked (more so in North America than elsewhere). Although controversial, contemporary research suggests that many 'borderline' patients represent a severe labile-irritable variant of cyclothymia on the border of manic-depressive psychosis.[38] On the other hand, bizarre episodes of self-harm with features of post-traumatic stress are uncharacteristic of cyclothymia, and suggest other diagnoses.

Romantic–conjugal failure. It is easy to understand how individuals with mercurial moods would charm others when in an expansive people-seeking mode, and rapidly alienate them when dysphoric. In effect, the life of many of these patients is a tempestuous chain of intense but brief romantic liaisons, often with a series of unsuitable partners. Some rationalize their behaviour on the grounds that their spouse or partner is 'too conservative in sex, too unimaginative, too unaware of the intensity' needed to stimulate them. As expected, frequent marital separations, divorces, and remarriage to the same person occur.

Financial extravagance. One patient in our case series reported going to bars and buying people drinks because he wanted everybody to feel like him. Another patient intermittently showered his lovers with expensive jewellery. In general, however, the extravagance of the cyclothymic group reflects gregariousness and tends to occur on a smaller scale compared to the psychotic manner in which manic patients bring financial ruin to themselves and their families.

Uneven school and work record. Repeated and unpredictable shifts in work and study habits occur in most people with cyclothymia, giving rise to a dilettante biography. Although some do better during their 'high' periods—for example, one car salesman would sell cars only 'when up'—for others, the occasional 'even' periods were more conducive to meaningful work. It is sometimes unappreciated by clinicians inexperienced with bipolarity that the hypomanic period can be one of disorganized and unpatterned busyness that could easily lead to a serious drop in net productivity. For instance, one insurance salesman related that he was less successful when 'high', because he tended to enter into unproductive arguments with his clients. When 'down', productivity obviously abates, although two creative individuals in our case series—one inclined poetically, the other towards painting—produced their better work when coming out of mini-depressions.

Alcohol and drug abuse. An alternating pattern of the use of 'uppers' and 'downers' occurs in at least 50 per cent of patients. We have clinically evaluated at least five cyclothymes who 'sold dope' to maintain their habit: two went to prison. These and other observations suggest that a proportion of substance-abusing, especially stimulant-abusing, patients might be suffering from subtle or cryptic forms of bipolar disorder. The bipolar nature of mood swings in alcohol- or substance-abusing individuals can be documented by demonstrating mood swings well past the period of detoxification; in some cases, escalating mood instability makes its first appearance following abrupt drug or alcohol withdrawal. The DSM-IV criteria for drug-induced or drug withdrawal-induced mood disorder are, in our opinion, biased against the diagnosis of otherwise treatable bipolar spectrum disorders. New evidence suggests that the temperamental disorder might serve as the anlage for self-enhancement or augmentation with cocaine, other stimulants and heroin.[39,40] These features might raise differential diagnostic questions from adult attention deficit hyperactivity disorder (ADHD). The social warmth observed among most people with cyclothymia distinguishes them from ADHD. Also, elation and inflated self-confidence, which occur periodically in cyclothymia, are uncharacteristic of ADHD; the moodiness in the latter is largely depressive in nature. Finally, antidepressants and stimulants typically worsen the moods in cyclothymia; they treat ADHD. In rare cases, however, cyclothymia and ADHD can coexist.

Course patterns

In cyclothymia, hypomania and mini-depression alternate with each other from adolescence. For instance, the optimistic, over-

confident, people-seeking phase can give way to self-absorption, self-doubt, pessimism, and a sense of futility, emptiness, and suicidal ideation. More commonly, depressive periods dominate the clinical picture, interspersed by 'even', 'irritable', and occasional hypomanic periods. Indeed, most people with cyclothymia who present clinically do so because of depression. These depressions are typically short-lived, yet unrelenting in their cyclic course, creating much interpersonal havoc for the patient. The following vignette illustrates the cardinal clinical features of cyclothymia that has not yet progressed to major depression.

Case Study: This 24-year-old songwriter presented with the chief complaint of 'depression so bad that I become totally dysfunctional—I cannot even get out of bed'. Since her mid-teens she had experienced periods lasting from a few days up to a week, during which she would withdraw into herself, losing confidence and interest, feeling drained of energy, and crying when approached by anybody. These periods were particularly prevalent during the autumn and winter months, but they did not coincide with the premenstrual phase. All she needed sometimes was restful sleep to 'feel alive again'; at other times, she would have little sleep, and would wake up 'wired', 'ready to go', 'open to experience all the joy waiting for me out there'; she would exude confidence, 'sensuality and sexual aroma'. These occurred less frequently than the 'down' periods and usually lasted for 1 to 3 days, but were not associated with creative spurts. The latter came as she was descending from 'highs' into a more 'mellow depression'. Her success in music had been sporadic, paralleling the sporadic nature of her 'muses' that visited her on the descending limb of 'hypomania merging with tears'. However, the major toll of her mood swings had been in her personal life, the intensity of her moods had driven away most men she had loved, of whom she had lost count. She described periods of such intense sexual arousal, that sometimes she would go to bed 'with anybody, including women of all ages, shapes, and description'. But, she added: 'I am not a lesbian—oral love is just one way of relating to these women—why not?' She had also experimented with drugs, such as stimulants, which had made her moodiness worse. More recently, she had been prescribed at least two SSRIs, which after a period of 'success' for a few months, had made her depressive swings more frequent and lower in amplitude, leading to the present consultation in our clinic.

As documented in this case, sexual excesses with both sexes are often readily admitted by patients. Winter accentuation or clustering of depressive periods, as exemplified here, is not uncommon in cyclothymia. We also would like to point out the special relationship of the moods to artistic productivity which occur in up to 8 per cent of cyclothymic depressions.[41] The 4-day threshold for hypomania in the official diagnostic manuals is too conservative; as shown in this case, most patients with cyclothymia (and bipolar II disorder) report a threshold of 1 to 3 days (though on occasion, one would observe a hypomanic duration of 1 week or longer). It is also noteworthy that the episodes are short-lived and do not reach the duration threshold for rapid cycling. Sometimes, the term 'ultra rapid cycling' is used for these patients, but we prefer to reserve this for extremely severe cases who require hospitalization. The short cycle length in cyclothymia is, in part, a selection artifact: the universe of patients with bipolar disorder is composed of an extreme variety of overlapping patterns.

The relationship of a cyclothymic temperament to the bipolar spectrum is more complex than that of dysthymia to major depressive disorder. Although cyclothymia can be observed in some patients with full-blown manic-depressive illness (bipolar I with severe or hospitalized mania), it is more commonly associated with the bipolar II pattern (of recurrent major depression with self-limited hypomanias). In a recent French national study of patients with major depression, 88 per cent of those with a cyclothymic disposition belonged to the bipolar II subtype. (Mania, by contrast, has been reported to more likely represent either an extension of hyperthymic traits, or a reversal from a depressive temperamental baseline.)

One-third of patients with cyclothymia studied by us on a prospective basis, progressed to spontaneous affective episodes with more protracted hypomanias and clinical (major) depression.[36,37] Thus, 6 per cent of the original cyclothymic cohort could be reclassified as bipolar I, and 30 per cent as bipolar II. The tendency to switch to hypomania was further augmented by the administration of antidepressants. A larger National Institute of Mental Health study of patients with major depression who switched to bipolar II during a prospective observation period of up to 11 years, found that a temperamental mix of 'mood-labile', 'energetic-active', and 'daydreaming' traits (reminiscent of Kretschmer's concept of the cyclothymic temperament were the most specific predictors of such outcome. Actually such temperamental factors predict who among the offspring of bipolar probands will progress during prospective course to clinical episodes.[42] New data further indicate that cyclothymia might be one of the pathways to suicidality among adolescents.[42]

The foregoing clinical and course characteristics suggest that a cyclothymic temperament leading to major depressive recurrences represents a distinct longitudinal pattern of 'cyclothymic depression', and which appears to capture the core features of bipolar II disorder in contemporary clinical practice. Because hypomanic episodes cannot be easily ascertained by history, assessing cyclothymia in clinically depressed patients represents a more sensitive and specific approach to the diagnosis of bipolar II.

Epidemiology

An excess of interpersonal difficulties and psychiatric consultations distinguish people with cyclothymia in the community from controls; excessive use patterns of stimulants, caffeine, nicotine, and alcohol, have also been well documented. Explosive traits, probably representing the irritable component of cyclothymia, have been reported to be prevalent in the community in a British study. More recently, we found that 6.3 per cent of a national cohort of 1010 Italian students between the ages of 14 and 26 years of age scored above two standard deviations for cyclothymia; this was more prevalent in females, with a ratio of 3:2. Overall, the foregoing data testify to the fact that a cyclothymic and/or labile disposition can be accurately measured, is prevalent, and represents a population at risk for affective disorders. Table 4.5.9.6 summarizes the rates in different populations.

Aetiological aspects

The flamboyant behaviour and the restless pursuit of romantic opportunities in cyclothymia suggest the hypothesis that its

*These data derive from interview-based studies. For more recent psychometric data based on cyclothymic and a broader range of sub-bipolar temperaments in a self-reported format can be found in a new monograph.[8]

constituent traits may have evolved as a mechanism in sexual selection.[23] Even their creative bent—in poetry, music, painting, or fashion design—may have evolved to subserve such a mechanism. Cyclothymic traits appear to lie on a polygenic continuum between excessive temperament and manic depression. Indeed, clinically identified cyclothymes have patterns of familial affective illness, as one would expect for a *forme fruste* disorder.

Cyclothymia has also been observed in the offspring of manic-depressive probands, with onset in the postpubertal period. Finally, family studies of patients with a bipolar disorder have revealed an excess of cyclothymia. Hypothetically, this temperament might represent one of, if not the most important, inherited trait diathesis for bipolar disorder. For instance, moody-temperamental individuals are over-represented in the 'discordant' monozygotic co-twins of Danish manic-depressives. Alternatively, and in a more theoretical vein, manic-depressive illness might be the genetic reservoir for the desirable cyclothymic traits in the population at large.[23,44] In line with these data and considerations, cyclothymia can be considered a behavioral endophenotype for bipolar disorder.[45] This is supported by recent findings from both Europe and the United States which have shown that it is present in the clinically well relatives of bipolar probands. Cyclothymia might also share familial-genetic relationship with alcohol and substance use,[40] bulimic,[46] panic,[47] obsessive-compulsive[48] as well as atypical depressive and borderline conditions.[49]

Clinical management

The proper pharmacological treatment for cyclothymic excesses is low doses of lithium (600–900 mg/day) or valproate (500–750 mg/day). These are based on open systematic studies.[50] There is some data from a controlled trial with lithium about the prevention of depression in cyclothymic individuals. Similarly controlled data exist for a related construct—'labile personality'. Generally speaking, patients with cyclothymia object to the 'overcontrol' that may come from mood stabilizers, and this is particularly the case with lithium. Lamotrigine is also being used on clinical grounds in the unstable dysthymic-cyclothymic spectrum. In those with 'borderline' features, lamotrigine is particularly promising.

Patients should be taught how to live with the extremes of their temperamental inclinations, and to seek professions where they determine the hours that they work. Marriage to a work-oriented or a rich older spouse might sustain them for a while, but eventually interpersonal friction and sexual jealousy terminate such marriages. The artistically inclined among them should be encouraged to live in those parts of a city inhabited by artists and other intellectuals, where temperamental excesses are better tolerated. ltimately, the decision to use mood stabilizers in such individuals should balance any benefits from decreased mood instability against the social and creative spurts that the cyclothymic disposition can bring to them. Their clinical management represents a challenging task for the psychiatrist who is willing to learn about the lifestyle of these individuals, not prejudging them by the more mundane norms of society. But the psychiatrist should also be there to help them during the multiple crises of their lives. Low-dose sedating neuroleptics, both classical (e.g. thioridazine 50 mg at bedtime) and atypical (e.g. quetiapine 25–50 mg at bedtime) may temporarily help to diffuse such crises. It is only when a clinician has earned therapeutic alliance with a patient that the latter will permit limit-setting on his or her extravagant or outrageous behaviour. Parents might also benefit from some counselling, because the dilettante life of their children is often a source of great sorrow for them. Rarely, parents or spouses are rewarded by great artistic or intellectual achievement, which does not necessarily reduce the pain that the volatile cyclothymes bring to their loved ones.

Kurt Schneider admonished the kin of labile individuals (who might approximate the contemporary concept of borderline personality disorder) 'on their bad days . . . to keep out of their way as far as possible'. Cyclothymes with some insight into their own temperament would give the same advice to their loved ones. A cautious trial of anticonvulsants will often prove effective in those distressed enough by their behaviour to comply with such treatment.

Prevention

The offspring of patients with bipolar disorder who exhibit a cyclothymic level of temperamental dysregulation represent a logical population for prevention studies. This is a challenge for the 21st century. Presumably molecular genetic testing will one day identify those moody individuals who carry the genes for bipolar disorder. At present, it would be useful to conservatively follow-up the cyclothymic offspring of people with bipolar disorders and provide them with psychoeducation about the necessity of avoiding stimulants and sleep deprivation. It may not be entirely possible to prohibit the use of occasional alcohol consumption, but benzodiazepines should not be used. It is also imperative, should they get depressed, to protect them from the indiscriminate prescription of antidepressants.

Mood-labile female prisoners, commonly given the diagnosis of antisocial or borderline personality disorder, may represent affective variants with irritable cyclothymic features. Formal studies are needed in prison populations, to assess more precisely the rates of preventable cryptic bipolarity among female and male offenders.

It is finally worthwhile to mention that affective temperaments with irritable, cyclothymic and irritable-hyperthymic traits might predispose to HIV infection. The public health dimensions of this question deserve further research focus.

The hyperthymic temperament[38]*

History and description

Although well described by classical German psychiatrists (e.g. Schneider), the hyperthymic type appears neither in DSM-IV nor in ICD-10. A lifelong disposition, hyperthymia must be distinguished from short-lived hypomanic episodes. Alternatively, this disposition can be characterized as trait hypomania. It derives from the ancient Graeco-Roman sanguine temperament, believed to represent the optimal mixture of behavioural traits. They are full of zest, fun-loving, and prone to lechery: their habitual disposition is one of buoyant action-orientation, extraverted people-seeking, overconfidence, and swift thinking. Typically short sleepers, they possess boundless energy to invest in sundry causes and projects, which often earn them leadership positions in the various professions and politics, yet their carefree attitudes and propensity for risk-taking can bring them to the brink of ruin; this is particularly true for their finances and sexual life, which can be marred by scandal. A hyperthymic lifestyle is so reinforcing that some resort to 'augmenting' it with stimulants such as amphetamines or cocaine. In brief, while a hyperthymic temperament *per se* does not constitute affective pathology—indeed, it represents a constellation of adaptive traits—in excess it could lead to undesirable complications. The latter will be our main focus here.

Epidemiology

The foregoing considerations partly explain why such a temperament has received scant research attention in the community. Extrapolating from studies on intermittent hypomania in the community, if strictly limited to hypomania with early onset and persistent course, the prevalence of hyperthymic temperament can be estimated to be slightly under 1 per cent. On the other hand, the traits that constitute the hyperthymic profile are so desirable that normal individuals tend to endorse them; in a recent Pisa-San Diego collaboration[16] involving 1010 students aged between 14 and 26, of whom 8.2 per cent met the full criteria for hyperthymic temperament, all participants scored between the first and second positive standard deviation. The TEMPS-A tends to validate these findings in Lebanon,[51] Argentina[52] and Hungary.[53] More work needs to be done on the psychometric standardization of this temperamental construct; on the other hand, all studies are consistent in showing marked male predominance.

Diagnostic aspects

On the positive side, hyperthymic individuals are enterprising, ambitious, and driven, often achieving considerable social and vocational prominence. Abuse of stimulants is not so much an attempt to ward off depression and fatigue as an effort to enhance their already high-level drive and, sometimes, to further curtail their already reduced need for sleep. Hyperthymic individuals typically marry three or more times. Others, without entering into legally sanctioned matrimony, form three or more families in different cities; these men are capable of maintaining such relationships for long periods, testifying to their financial and personal resourcefulness, as well as their generosity towards their lovers and the offspring from such unions. Unlike the antisocial psychopath who is predatory on others and neglects or abuses his women and children, these men care for their loved ones. But obviously, the 'arrangement' involving women of different generations is complex, and a fertile soil for jealousy, drama, scandal, and tragedy. Nonetheless, it is not uncommon to see more than three or four women crying profusely and expressing their common grief at the funerals of these men!

Although individuals with hyperthymia optimally enjoy the advantage of their reduced need for sleep (giving more time and energy to invest in work and pleasure), some present clinically because of insomnia. Thus, in a predominantly male sample of executives presenting to a sleep centre,[54] habitual sleep need was 4 to 5 h; however, they had been intermittently bothered by 'nervous energy' and difficulty falling asleep. Now, in late middle age, alcohol was no longer an effective hypnotic. Although they vigorously denied depressive and other mental symptoms—indeed, they had extremely low scores on self-rated depression—spouses or lovers provided collateral information about brief irritable-depressive dips, especially in the morning and, in some cases, more protracted 'fatigue states' of days to weeks during which the subject would vegetate. Despite these depressive dips, these patients were distinguished from the constantly shifting moods of cyclothymic patients by the fact that the depressions arose from a baseline of trait hypomania of a more or less stable course. Our most current diagnostic guidelines for a hyperthymic temperament consist of the following traits on a habitual basis since at least early adulthood: cheerful, overoptimistic, or exuberant; extraverted and people-seeking, often to the point of being overinvolved or meddlesome; overtalkative, eloquent, and jocular; uninhibited, stimulus-seeking, and sexually-driven; vigorous, full of plans, improvident; overconfident, self-assured, and boastful attitudes that may reach grandiose proportions.

A systematic retrospective review of the case records of people with manic depression, whose course was dominated by manic episodes, was recently undertaken in Munich, yielding attributes overlapping with our proposed list: active, vivid, extraverted, verbally aggressive, self-assured, strong willed, engaged in self-employed professions, risk-taking, sensation-seeking, breaking social norms, spendthrift, and generous. The fact that at least 10 per cent of patients with major depression in an Italian study could be characterized as premorbidly hyperthymic, suggests that this temperament has relevance to both major affective poles. This is an important diagnostic consideration, because rather than being considered narcissistic depressions, these should be recognized as a soft bipolar variant.

Aetiological aspects

It is of interest that Gardner's ethological analysis[55] of what constitutes 'leadership' led to a description that overlaps with a hyperthymic profile: cheerfulness, joking, irrepressible infectious quality, unusual warmth, expansive, strong sense of confidence in one's abilities, scheming, robust, tireless, pushy, and meddlesome. Hypothetically, this temperament evolved in primates whose social life required leadership to better face challenges to the group from within and without.

In a sleep electroencephalography study,[54] REM latency was found to be shortened; similar findings have been reported on the sleep of manic patients, thereby supporting the notion of a trait-state continuum at the neurophysiological level. (Although counter-intuitive, this neurophysiological marker appears to be shared between the depressive and hyperthymic poles.) Finally, family

* Unless otherwise specified, this review article contains most of the references to the concepts, history, and research on the hyperthymic type.

history for frank bipolar disorder characterizes many such individuals. The foregoing data, albeit limited, suggest that hyperthymic traits share several key biological underpinnings of affective disorder.

Course and treatment

Little is known about the natural course of the hyperthymic temperament, except what can be reconstructed retrospectively from biographical and clinical studies. Given their overoptimistic and self-assured style of thinking, these individuals feel perfectly fit in all areas of functioning and thus have no need to consult a psychiatrist. They do so only when forced by loved ones. There are no systematic treatment studies on hyperthymia. Anecdotally,[50] low doses of anticonvulsants such as valproate (e.g. 500–750 mg/day) can be useful in reducing drivenness, when deemed appropriate on clinical grounds, such as in the presence of cardiovascular disease, or when enormous sexual appetite places them at risk for social scandals and, in some cases, exposure to HIV infection.[56] Stimulant-abusing subjects with hyperthymia can be detoxified with valproate, carbamazepine, or gabapentin. Clinically depressed subjects with a hyperthymic temperament often respond poorly to antidepressants. In our opinion, the efficacy of lithium augmentation in resistant depression is partly based on the high prevalence of hyperthymia in resistant populations; it would be wise to keep the dose of lithium in augmentation in such individuals to a lower to middle range (i.e. 600–900 mg/day).

People with hyperthymia are action-oriented, and are not inclined to any type of self-examination. Furthermore, their hypertrophied sense of denial makes them poor candidates for psychotherapy. The physician must, nonetheless, attempt psychoeducation about the harm that can come to them and their loved ones because of their temperamental excesses. Alcohol consumption, which is common in these individuals, should not be abruptly interrupted because of the risk of the switch to a suicidal depression. If detoxification is necessary for health reasons, admission to a suitable inpatient facility should be arranged. The occasion might be profitably used for whatever counselling is deemed appropriate for life and health situations confronting them at the time.

Therapeutic and preventive aspects

In clinical practice, hyperthymic individuals are likely to be confused with narcissistic or antisocial types. Otherwise, they rarely present to psychiatrists, except as the premorbid adjustment of manic-depressive illness. Hyperthymic individuals are often the driving force of society in economic and political life and unless they are involved in scandals or suicidal behavior, rarely come to the attention of clinicians. In the rare circumstances they seek psychiatric advice, it is due to exasperated pressure from loved ones; even then, they tend to dictate rather than follow treatment recommendations. Their sense of entitlement derives in part from the fact these individuals have considerable leadership talent and often bequeath large sums of endowments for research, museums and other community projects. Some are performing artists. Others are famed for their erotic life in the tabloid and popular press. Rare biological investigations have been conducted on hyperthymia involving fascinating neurophysiologic and endophenotype studies.[57,58] The preventive potential of such investigations for manic-depressive illness remains uncertain at this time.

Stress-related and adjustment disorders

Contents

4.6.1 Acute stress reactions

Anke Ehlers, Allison G. Harvey, and Richard A. Bryant

Introduction

Exceptionally stressful life events can cause severe psychological symptoms, including anxiety, feelings of derealization and depersonalization, and hyperarousal. In one of the first studies to comprehensively document acute reactions to extreme stress, Lindemann[1] observed that the symptoms reported by survivors of the Coconut Grove Fire included avoidance, re-experiencing scenes from the fire, reports of derealization, and the experience of anxiety when exposed to reminders of the event. Similarly, acute responses reported by soldiers who fought in the First and Second World Wars included re-experiencing symptoms and dissociative responses such as numbing, amnesia, and depersonalization.[2]

The *International Classification of Diseases* has recognized acute stress reactions since 1948 (ICD-6).[3] In the most recent edition (ICD-10),[4] early reactions to exceptionally stressful life events are diagnosed as acute stress reaction, one of the diagnoses in the section headed 'reactions to severe stress, and adjustment disorders'.

In contrast, the *Diagnostic and Statistical Manual of Mental Disorders* did not formally recognize that exceptionally stressful life events are a sufficient cause of psychological symptoms until 1980 when its third edition (DSM-III)[5] introduced the diagnosis of post-traumatic stress disorder (**PTSD**). DSM-III did not stipulate a duration for the symptoms, but the revised third version (DSM-III-R)[6] required that the symptoms of PTSD must be present for more than 1 month after the traumatic event. This stipulation precluded the inclusion of acutely traumatized individuals who instead were diagnosed with adjustment disorder.[7] In 1994 the fourth edition of DSM (DSM-IV)[8] formally recognized acute trauma reactions by introducing the new diagnosis of acute stress disorder into the anxiety disorders section.

The diagnoses of acute stress reactions in ICD-10 and of acute stress disorder in DSM-IV have similarities in that they are caused by extreme stress and have some overlap in symptom patterns. They can be considered as two separate points on a continuum from transient to more enduring symptoms. However, there are also differences in the underlying concepts, as we will discuss in this chapter.

Clinical features

Acute stress reactions, as defined in ICD-10, are transient reactions to exceptional physical and/or mental stress. There is an initial stage of a 'daze', including narrowing of attention, inability to comprehend stimuli, and disorientation. This is followed by a rapidly changing picture of symptoms that may include withdrawal from the surrounding situation, flight reactions, panic anxiety, and autonomic hyperarousal, depression, anger, or despair. Symptoms usually begin to diminish after 24 to 48 h and should be minimal after about 3 days.

In contrast, acute stress disorder, as defined in DSM-IV, is only diagnosed if the psychological symptoms persist for more than 2 days. Dissociative symptoms dominate the disorder. Dissociation refers to a disruption of the usually integrated feelings of consciousness, memory, identity, or perception of the environment. Symptoms include a subjective sense of numbing or detachment, reduced awareness of surroundings, derealization, depersonalization, or dissociative amnesia. In addition, patients with acute stress disorder experience symptoms that are typical of PTSD, namely re-experiencing aspects of the event, avoidance of reminders of

the event, and hyperarousal symptoms. Acute stress disorder is seen in DSM-IV as a precursor of PTSD. If the re-experiencing, avoidance, and hyperarousal symptoms persist for more than 4 weeks, PTSD is diagnosed.

Classification

ICD-10 classifies acute stress reactions (F43.0) among the reactions to severe stress and adjustment disorders (F43) that are primarily caused by stressful events. DSM-IV classifies acute stress disorder (308.3) among the anxiety disorders, like PTSD (see also Chapter 4.6.2).

Diagnosis and differential diagnosis

The main diagnostic criteria for acute stress reactions (ICD-10) and acute stress disorder (DSM-IV) are compared in Table 4.6.1.1.

Stressor criterion

Both ICD-10 and DSM-IV require that acute stress responses must occur in the immediate aftermath of an exceptionally stressful event. ICD-10 uses a broad concept of what qualifies as an 'exceptional mental or physical stressor'. This includes stressors that would be regarded as traumatic (e.g. rape, criminal assault, natural catastrophe) as well as unusually sudden changes in the social position and/or network of the individual (e.g. domestic fire or multiple bereavement). In contrast, DSM-IV uses a narrow definition of stressors that lead to acute stress disorder, which is identical to the stressor criterion of PTSD. It requires (i) that the traumatic event must have involved actual or threatened death or serious injury, or a threat to the physical integrity of self or others, and (ii) that the person's response to the traumatic event must have involved intense fear, helplessness, or horror (or disorganized or agitated behaviour in children) (see Chapter 4.6.2 for the rationale underlying this definition).

Symptom patterns

As shown in Table 4.6.1.1, the diagnostic criteria for acute stress reactions (ICD-10) and acute stress disorder (DSM-IV) overlap, in that they include symptoms of dissociation, anxiety, and hyperarousal. DSM-IV puts a much greater emphasis on dissociation, requiring a minimum of three of the dissociative symptoms specified in Table 4.6.1.1 (Criterion B). According to ICD-10, any combination of a minimum of four symptoms of generalized anxiety disorder (specified in Criterion C, Table 4.6.1.1) would be sufficient to establish the diagnosis of acute stress reaction. In addition, DSM-IV, but not ICD-10, requires the individual to have at least one re-experiencing symptom, to show marked avoidance of reminders of the trauma, and to experience significant distress or impairment of functioning.

In contrast to DSM-IV, ICD-10 distinguishes between mild, moderate, and severe forms of acute stress reactions on the basis

Table 4.6.1.1 Comparison of the criteria for acute stress reaction (ICD-10) and acute stress disorder (DSM-IV)

	Acute stress reaction (ICD-10 research diagnostic criteria)	Acute stress disorder (DSM-IV)
Stressor	Exposure to exceptional mental or physical stress	(1) Exposure to event involving actual or threatened death or serious injury to self or others (2) Experience of fear, helplessness, or horror
Symptoms	*Criterion C: Symptoms of generalized anxiety disorder (at least 4 symptoms)* Palpitations, sweating, trembling, dry mouth, difficulty breathing, choking, chest pain, nausea, dizziness, derealization or depersonalization, fear of losing control, fear of dying, hot flushes, numbness or tingling, muscle tension, restlessness, keyed up, difficulty swallowing, exaggerated startle response, difficulty concentrating, irritability, difficulty getting to sleep *Criterion C: Additional symptoms to determine severity* Social withdrawal, narrowed attention, disorientation, aggression, hopelessness, overactivity, excessive grief	*Criterion B: Dissociation (at least 3 symptoms)* Numbing, reduced awareness, derealization, depersonalization, dissociative amnesia *Criterion C: Re-experiencing* (at least one *symptom)* Recurrent images, thoughts, dreams, illusions, flashbacks, reliving, distress on exposure *Criterion D: Marked avoidance* Avoidance of thoughts, feelings, conversations, activities, places, people associated with the trauma *Criterion E: Marked anxiety or increased arousal* Difficulty sleeping, irritability, poor concentration, hypervigilance, exaggerated startle response, motor restlessness *Criterion F: Clinically significant distress or impairment in functioning*
Time from trauma	Onset within 1 h	Onset within 4 weeks; lasts for at least 2 days
Time course	Transient; symptoms begin to diminish within 48 h	May result in post-traumatic stress disorder
Relationship to post-traumatic stress disorder	Alternative diagnosis	Precursor
Diagnostic group	Reactions to severe stress	Anxiety disorder
Exclusion criteria	No other concurrent (within last 3 months) mental or behavioural disorder, except for generalized anxiety disorder or personality disorder	(1) Not due to effects of a substance or general medical condition (2) Not better accounted for by brief psychotic disorder (3) Not merely exacerbation of pre-existing Axis I or Axis II disorder

of additional symptoms (Criterion C, additional symptoms, Table 4.6.1.1) such as social withdrawal, hopelessness, or excessive grief. A mild severity is stipulated when none of these symptoms are present, moderate when two are reported, and severe when four are reported or when there is dissociative stupor.

Time course of symptoms

The two diagnoses cover distinct periods on a continuum from transient to more persistent symptoms. Specifically, to meet the criteria for an acute stress reaction (ICD-10), symptoms must be manifest within 1 h of the stressor (Criterion B) and begin to diminish after no more than 8 h for a transient stressor and after no more than 48 h for an enduring stressor (Criterion D).

The diagnostic criteria for acute stress disorder (DSM-IV) require that the disturbance must last for a minimum of 2 days and a maximum of 4 weeks post-trauma, after which a diagnosis of PTSD can be considered.

Assessment instruments

There are two recognized clinician-administered and two self-report measures of acute stress disorder (DSM-IV) available. As yet, there are no established standardized assessment instruments for transient acute stress reactions (ICD-10).

(a) Acute stress disorder interview

This structured clinical interview establishes the presence or absence of 19 symptoms of acute stress disorder.[9] The sum of the symptoms scored as being present indicates acute stress disorder severity. This measure has very good internal consistency ($r = 0.90$), and, with clinician-based diagnoses as the criterion, very good sensitivity (91 per cent) and specificity (93 per cent). Test–retest reliability is strong ($r = 0.88$).

(b) Structured clinical interview for DSM-IV (SCID[10])

The SCID interview indexes the presence, absence, or subthreshold presence of each acute stress disorder symptom specified in DSM-IV. An advantage of employing this interview is that it provides a comprehensive assessment of the differential diagnoses and comorbid disorders that can be present in trauma populations.

(c) Stanford acute stress reaction questionnaire[11]

This self-report inventory asks patients to rate the frequency of a range of dissociative, intrusive, somatic anxiety, hyperarousal, attention disturbance, and sleep disturbance symptoms. The questionnaire has very good internal consistency (Cronbach's alpha = 0.90 and 0.91 for dissociative and anxiety symptoms, respectively) and concurrent validity with scores on the Impact of Event Scale ($r = 0.52$ to 0.69).[12,13] It can be employed as a measure of the severity of symptoms, but does not allow the diagnosis of acute stress disorder to be established as it has not yet been validated against clinician diagnoses.

(d) Acute stress disorder scale[14]

This self-report scale is scored on a 5-point scale that reflects degree of severity of 19 acute stress disorder symptoms. The Acute Stress Disorder Scale possesses good sensitivity (95 per cent) and specificity (83 per cent) relative to the Acute Stress Disorder Interview. Test–retest reliability with a re-administration interval of 2 to 7 days is strong ($r = 0.94$).[14]

Differential diagnoses

Both ICD-10 and DSM-IV require that the symptoms are not merely an exacerbation of a pre-existing disorder. In addition, a number of alternative diagnoses need to be considered.

(a) Post-traumatic stress disorder

In ICD-10, PTSD is conceptualized as an alternative diagnosis of acute stress reactions. The definitions of acute stress reaction and PTSD differ in terms of the stressor criterion (exceptionally stressful life event versus exceptionally threatening or catastrophic event), the time course (symptoms start to diminish within 48 h versus no time limit), and symptom pattern (PTSD, but not acute stress reaction, includes involuntary re-experiencing the traumatic event).

In DSM-IV, acute stress disorder can be distinguished from PTSD by the time-frame covered by the diagnoses. Acute stress disorder refers to the period from 2 days to 1 month post-trauma, after which a diagnosis of PTSD can be considered. The primary difference between the symptom criteria for acute stress disorder and PTSD in DSM-IV is the former's emphasis on dissociative reactions.

(b) Adjustment disorder

This diagnosis covers a wide range of emotional or behavioural symptoms indicative of distress, which are judged to be out of proportion to the stressor experienced. This broad coverage can be contrasted with (i) the specific set of symptoms described by the acute stress disorder and acute stress reaction criteria, and (ii) the stipulation that the stressor involves both a threat to life and a subjective response of fear for the acute stress disorder and an exceptional stressor in the case of acute stress reaction.

(c) Brain injury

A number of acute stress disorder symptoms overlap with symptoms of brain injury including reduced awareness, depersonalization, derealization, irritability, and concentration difficulties.[15] While results from neuropsychological and neurological investigations may assist in the differential diagnosis, there appear to be a group of individuals with a mild head injury for whom there are no known tools to differentiate whether the disturbance is due to brain injury or acute stress disorder, or whether both are present.

(d) Brief psychotic disorder

When there is one or more psychotic symptoms present after experiencing an extreme stressor, the brief psychotic disorder diagnosis should be considered.

(e) Dissociative disorders

Given the emphasis on dissociative symptoms in acute stress disorder, it needs to be distinguished from dissociative amnesia and depersonalization disorder. The criteria for these diagnoses stipulate that if the amnesia or depersonalization can be accounted for by acute stress disorder then a dissociative disorder cannot be diagnosed (see Chapter 5.2.4).

Epidemiology

Incidence

There is little research into what proportion of people develop acute stress reactions to severe stress. In a study of accident survivors, 14 per cent experienced a response pattern characterized by

derealization, and a further 17 per cent exhibited strong anxiety or dysphoria.[16]

Estimates of the incidence of acute stress disorder range from about 14 per cent in motor vehicle accident survivors to 33 per cent in witnesses of a mass shooting.[17] Given the variable procedures and assessment tools employed across studies, it is difficult to determine whether the different rates of acute stress disorder detected are attributable to differences in method or in the type of trauma.

Comorbidity

Data on comorbidity are sparse. Given the similarities between acute stress disorder and PTSD it is likely that the conditions found to be comorbid with PTSD, in particular depression and substance abuse, will be applicable to acute stress disorder (see Chapter 4.6.2).

Aetiology

Both psychological and biological theories have attempted to explain the symptoms of acute stress disorder. They overlap largely with theories of PTSD (see Chapter 4.6.2). Given that acute stress reaction describes a transient disturbance, there are no specific theories of acute stress reactions as defined in ICD-10.

Psychological theories

The psychological mechanism that has received the most attention in relation to acute stress disorder is dissociation, as reflected in the DSM-IV criteria. It has been argued that dissociation minimizes the adverse emotional consequences of trauma by restricting awareness of the experience to avoid overwhelming fear and loss of control.[13] Dissociation is thought to prevent recovery because it prevents the integration of the traumatic experience into existing schemas[18] and it prevents the full activation of the trauma memory which is thought to be necessary for its modification.[19] In line with these hypotheses, dissociation during or immediately after a traumatic event predicts PTSD.[20] In contrast, an alternate view posits that dissociation at the time of trauma may serve a protective function because it may limit the encoding of aversive experiences and this may assist adaptation.[21] Consistent with this view, there is evidence that persisting dissociation (which is a form of cognitive avoidance) is more predictive of PTSD than dissociation that occurs at the time of trauma.[22,23]

Psychological theories of acute stress disorder and PTSD focus on the personal meaning of the trauma and its consequences, and characteristics of the trauma memory. Several hypotheses about the problems in memory that are responsible for the characteristic re-experiencing symptoms (i.e. unwanted memories of aspects of the trauma that occur in response to a wide range of stimuli) have been suggested (see also Chapter 4.6.2). Foa and colleagues[24,25] suggested that PTSD is characterized by a pathological network in memory that is particularly large and easily triggered. It contains many stimulus propositions that are erroneously linked to danger, causing fear responses to harmless stimuli that are associated with the traumatic event in memory. Brewin *et al.*[26] postulated that two different representations of the trauma are formed in memory. The first, termed verbally accessible memory, contains the conscious recollection of the trauma. The second memory representation, termed situationally accessible memory, comprises sensory, physiological, and motor aspects of the trauma in the form of codes that enable the re-experiencing of the original experience. Ehlers and Clark[27] suggested three memory processes to explain that a wide range of stimuli can trigger vivid memories and strong emotional responses, which are experienced as if the traumatic event was happening at present. First, trauma memory is thought to be inadequately linked to its context in memory, which leads to poor inhibition of stimulus-driven retrieval. Two other basic memory processes, perceptual priming and associative learning, are thought to further enhance the chances of stimulus-driven retrieval of memories. Consistent with these psychological theories, there is evidence that chronic PTSD is predicted by impaired access to autobiographical memories[28] and the perceived 'nowness' of trauma memories.[29] There is also evidence that maladaptive appraisals such as 'I am inadequate', 'My reactions since the trauma mean I am losing my mind', or 'I have permanently changed for the worse' in the acute phase after trauma exposure predict chronic PTSD.[30,31]

Psychological models also concur that successful adaptation to trauma involves integration of corrective information, and any strategies that minimize this process will contribute to subsequent PTSD. Excessive use of such avoidant strategies (e.g. trying not to think about the trauma, efforts to push intrusive memories out of one's mind, ruminating about how the trauma could have been avoided) prevent recovery.[24–27] There is preliminary empirical evidence supporting this hypothesis.[30–33]

Biological theories

Biological models have focused on fear conditioning and progressive neural sensitization in the weeks after trauma.[34] Specifically, when a traumatic event (unconditioned stimulus) occurs, people typically respond with fear (unconditioned response). It is argued that the strong fear elicited by the trauma will lead to strong associative conditioning between the fear and the stimuli surrounding the trauma. As reminders of the trauma occur (conditioned stimuli), people then respond with fear reactions (conditioned response). It has been hypothesized that extreme sympathetic arousal at the time of a traumatic event may result in the release of stress neurochemicals (including norepinephrine and epinephrine) into the cortex, mediating an overconsolidation of trauma memories. It is possible that sensitization occurs as a result of repetitive activation by trauma reminders and re-experiencing symptoms, elevating sensitivity of limbic networks, and that as time progresses these responses become increasingly conditioned to trauma-related stimuli.[35] In support of these proposals, there is evidence that people who eventually develop PTSD display elevated resting heart rates in the initial week after trauma.[36] There is also evidence that most people with acute stress disorder suffer panic attacks during the traumatic experience, and most of these people continue to suffer ongoing panic attacks in the subsequent month.[37]

Course and prognosis

Time course of symptoms

Whereas the ICD-10 criteria define an acute stress reaction as a disorder that remits within a few days, DSM-IV conceptualizes acute stress disorder as a marker of those vulnerable to the development of PTSD. Evidence relating to these different assumptions was sparse at the time the diagnoses were established. One explicit goal of the acute stress disorder diagnosis is to identify people who

will develop PTSD. This goal is difficult to achieve because most people who initially display acute stress reactions adapt in the following 3 months.[38] Across 12 studies that have assessed the relationship between acute stress disorder and PTSD, most studies have found that whereas most people with acute stress disorder do develop PTSD, the acute stress disorder diagnosis does not capture the majority of people who develop PTSD.[38] It appears that the requirement for dissociative symptoms in the acute phase to be present results in a failure to identify many people who are high risk for PTSD development. It is important to note that similar patterns have been noted in prospective studies of children after trauma.[39–41] Across studies, people who have more severe symptoms of PTSD in the weeks following trauma have a poorer prognosis than those with less severe symptoms.[42,43]

Predictors of acute stress disorder

Little is known about predictors of acute stress reactions. A history of psychiatric disorder, depressive and dissociative symptoms prior to the traumatic event, and previous trauma predict acute stress disorder.[22,44,45]

Treatment

Psychological treatments

(a) Debriefing

Critical incident stress debriefing is a widely practised intervention that has the goal of promoting adaptation to traumatic events. Debriefing is generally conducted in a group within 24 to 72 h of the trauma. However, these parameters have been modified to permit more flexible interventions. Mitchell[46] proposes that debriefing comprises seven phases:

1 an initial outline of the purpose and benefits of debriefing;

2 the fact phase, in which participants relate what happened to them;

3 a thought phase, in which participants relate their initial thoughts after the critical incident;

4 a feeling phase, which requires participants to focus on the worst aspects of the incident and engage in their emotional reactions to the incident;

5 an assessment phase, in which participants are trained to note their physical, cognitive, emotional, and behavioural symptoms;

6 an education phase, which provides information about stress responses and ways to manage them;

7 the re-entry phase, in which the information given is summarized and referral information offered.

These phases may take 1 to 5 h, and are usually coordinated by a trained mental health professional.

Anecdotal evidence and clinical reports attest to the efficacy of debriefing. However, despite its widespread use, few controlled trials have been conducted. These have mainly focused on single session individual debriefing. A Cochrane review of 15 randomized controlled studies of psychological debriefing[47] found that although participants usually found the intervention useful, debriefing did not prevent the onset of PTSD nor reduce psychological distress compared to control. The two studies with the longest follow-up actually found that the debriefing group had a worse long-term outcome than the control group.[48–50] These results suggest that single session individual debriefing is not effective.[47]

In line with these results on individual debriefing, the first two non-randomized controlled studies of the efficacy of group debriefing found that the intervention had no beneficial effects on post-trauma symptoms.[51,52] One of the studies found negative effects of the intervention after 18 months.[52] A large trial of 1050 soldiers on a peacekeeping mission found no differences on all outcomes between a full programme of critical incident stress debriefing, stress education, and no intervention.[53]

(b) Cognitive behaviour therapy

Cognitive behavioural interventions are effective in treating PTSD (see Chapter 4.6.2). The results of randomized controlled studies of rape victims and road traffic accident survivors suggest that a brief five-session version of this treatment is effective in acute stress disorder and prevents the development of chronic post-trauma reactions.[54–58] Treatment involved the following:

1 education about trauma reactions;

2 progressive muscle relaxation;

3 prolonged exposure;

4 cognitive restructuring of fear-related beliefs;

5 graded *in vivo* exposure.

Cognitive behaviour therapy was found to be superior to other psychological therapies such as non-directive therapy or relaxation in preventing chronic PTSD.[59,60]

Psychopharmacological treatment

Little is known about which pharmacological interventions are effective in acute stress reactions/disorder. Preliminary studies report the utility of tricyclic antidepressants, but no or even harmful effects of benzodiazepines.[59–61] Research on PTSD suggests that selective serotonin reuptake inhibitors are, to date, the best pharmacological treatment for persistent reactions to traumatic stress (see Chapter 4.6.2).

There is growing interest in pharmacological interventions in the acute phase following the trauma that may prevent the development of PTSD symptoms.[62] A pilot study attempted to prevent PTSD by administering propranolol (a β-adrenergic blocker) within 6 h of trauma exposure.[63] This approach is based on evidence that propranolol abolishes the epinephrine enhancement of fear conditioning.[64] Although propranolol did not result in reduced PTSD relative to a placebo condition, patients receiving propranolol displayed less reactivity to trauma reminders 3 months later. This outcome accords with an uncontrolled study that found that propranolol administered immediately after trauma resulted in reduced PTSD 3 months later.[65] These preliminary data suggest that propranolol administration shortly after trauma exposure may limit fear conditioning that may contribute to subsequent PTSD development. Two other pilot studies found that high doses of hydrocortisol given to medical patients in an intensive care environment had a beneficial effect on subsequent PTSD symptoms.[62,66] One possible pathway of action is that cortisol contains strong epinephrine responses during stress, and may thus indirectly influence the strength of fear conditioning.[62] However, these experimental studies are as yet too preliminary to suggest clinical application.[60]

Information and self-help booklets

Several studies have evaluated the effectiveness of information or self-help booklets as early interventions after trauma. They consistently found that such interventions are ineffective and do not decrease the risk of chronic PTSD symptoms, although patients report that they find the booklets helpful.[67,68]

Advice about management

As acute stress reactions (ICD-10) are transient, and trials showed that early psychological debriefing is not effective in reducing future symptoms, psychological interventions that focus on recounting the traumatic event and ventilation of feelings are not indicated in the initial days after trauma exposure.[59,60] Instead, clinicians should focus on ensuring trauma survivors' safety and security, providing support and practical assistance, and encouraging them to actively use their social support.[59,60] Although drug treatments are not recommended as a preventative intervention following traumatic exposure,[60] clinicians may consider short-term hypnotic medication or longer term use of antidepressants for the management of significant sleep disturbance in the acute phase after trauma.[59,61] Furthermore, patients may find information about common reactions to trauma and their course, and practical advice about issues such as hospital procedures, police questioning, insurance claims, legal procedures, and media pressure to tell one's story helpful. Clinicians should offer follow-up appointments and monitor trauma survivors for the development of PTSD.[59]

An important clinical task is the early identification of those trauma survivors who are likely to develop chronic and disabling post-trauma symptoms.[47,59] If symptoms persist for 2 weeks or longer, treatment may be indicated. However, patients with low symptom severity at 2 weeks have a good chance of recovering without intervention, and clinicians may want to initially monitor symptom progression for a month to determine whether the patient is recovering naturally.[59] A number of short symptom screening questionnaires have been developed that may provide useful predictive information for this purpose in the future, but still await cross-validation in other samples.[69]

For trauma survivors with more severe acute stress disorder symptoms, a course of cognitive behavioural treatment should be considered.[59,60] This form of intervention is typically not provided within 2 weeks of trauma exposure. If the patient is offered cognitive behavioural treatment, therapists need to be aware that avoidance is a hallmark symptom of acute stress disorder and may reduce the likelihood that an individual will attend treatment sessions regularly. Flexible treatment procedures (e.g. initial contacts by telephone, scheduling sessions around the patient's preferences) and discussions about the ambivalence towards treatment may be helpful. Therapists need to be knowledgeable about the conditions surrounding the traumatic event and be sensitive to the particular socio-cultural background of the patient, which will affect the personal meaning of the event. Other forms of psychological treatment that do not address traumatic memories (such as relaxation or non-directive therapy) should not be routinely offered.[59]

The lack of randomized controlled trials suggests that pharmacological treatment cannot be considered a front-line treatment for acute stress disorder,[59,60] but research on PTSD suggests that selective serotonin reuptake inhibitors and other antidepressants may be helpful (see Chapter 4.6.2).

Possibilities for prevention

Identifying highly symptomatic individuals with acute stress disorder and providing a cognitive behavioural intervention from 2 weeks post-trauma onwards may reduce the risk of chronic PTSD. Additional preventive methods have been explored that prepare individuals 'at risk' (e.g. emergency services and military personnel) for experiencing trauma so as to enhance their coping strategies and reduce the risk of them developing longer-term symptomatology. For those individuals at high risk of experiencing a trauma, providing them with training to remain calm, evaluate the situation objectively,[70] to not identify with victims, to utilize social supports, and to express emotional reactions[71] have all been found to be associated with better coping after the trauma. However, evidence remains preliminary and it remains unclear whether they affect the risk of PTSD.

4.6.2 Post-traumatic stress disorder

Anke Ehlers

Introduction

Clinicians have long noted that traumatic events can lead to severe psychological disturbance. At the end of the nineteenth and the beginning of the twentieth centuries, railway disasters, the World Wars, and the Holocaust prompted systematic descriptions of the symptoms associated with traumatic stress reactions. These include the spontaneous re-experiencing of aspects of the traumatic events, startle responses, irritability, impairment in concentration and memory, disturbed sleep, distressing dreams, depression, phobias, guilt, psychic numbing, and multiple somatic symptoms. A variety of labels were used to describe these reactions including 'fright neurosis', 'combat/war neurosis', 'shell shock', 'survivor syndrome', and 'nuclearism'.[1–3]

Whether the traumatic event can be considered a major cause of these psychological symptoms, has been the subject of considerable debate. Charcot, Janet, Freud, and Breuer suggested that hysterical symptoms were caused by psychological trauma, but their views were not widely accepted. The dominant view was that a traumatic event in itself was not a sufficient cause of post-trauma symptoms, and experts searched for other causes. Many suspected an organic cause. For example, damage to the spinal cord was suggested as the cause of the 'railway spine syndrome', microsections of exploded bombs entering the brain as the cause of 'shell shock', and starvation and brain damage as causes of the chronic psychological difficulties of concentration camp survivors. Others doubted the validity of the symptom reports and suggested that malingering and compensation-seeking ('compensation neurosis') was the major cause in most cases. Finally, the psychological symptoms were attributed to pre-existing psychological dysfunction. The predominant view was that reactions to traumatic events are transient, and that therefore only people with unstable personalities, pre-existing neurotic conflicts, or mental illness would develop chronic symptoms.[1–3]

It was the recognition of the long-standing psychological problems of many war veterans, especially Vietnam veterans, that changed this view and convinced clinicians and researchers that even people with sound personalities can develop clinically significant psychological symptoms if they are exposed to horrific stressors. This prompted the introduction of post-traumatic stress disorder (PTSD) as a diagnostic category in DSM-III.[4] It was thus recognized that traumatic events such as combat, rape, man-made, or natural disasters give rise to a characteristic pattern of psychological symptoms. The diagnostic criteria specified the experience of a traumatic event as a necessary condition for the diagnosis. ICD-10[5] emphasized the causal role of traumatic stressors in producing psychological dysfunction even more clearly, in that a specific group of disorders, 'reaction to severe stress, and adjustment disorders', was created. These disorders are 'thought to arise always as a direct consequence of the acute severe stress or continued trauma. The stressful event . . . is the primary and overriding causal factor, and the disorder would not have occurred without its impact'.

What makes a stressor traumatic?

In everyday language, many upsetting situations are described as 'traumatic', for example, divorce, loss of job, or failing an examination. However, a field study designed to establish what kinds of stressors lead to the characteristic symptoms of PTSD, showed that only 0.4 per cent of a community sample developed the characteristic symptoms of PTSD in response to such 'low magnitude' stressors.[6] Thus, in diagnosing PTSD, it appeared necessary to employ a strict definition of what constitutes a traumatic stressor.

Few people would contest that horrific events such as rape or bombings are traumatic. In an attempt to capture the essence of these stressors, the authors of DSM-IIIR required a traumatic stressor to be 'outside the range of usual human experience' and that it 'would be markedly distressing to almost anyone'.[7] However, epidemiological studies showed that stressors that can lead to PTSD are actually quite common, for example road traffic accidents[8] or sexual assault.[9] Thus, the DSM-IIIR definition appeared too restrictive.

ICD-10 uses a broader definition and characterizes traumatic stressors by their exceptional severity and the distress they would cause for the average person 'a stressful event or situation . . . of an exceptionally threatening or catastrophic nature, which is likely to cause pervasive distress in almost anyone'.[5] Thus, the ICD-10 diagnosis refers to a common sense understanding of which situations are likely to be extremely distressing.

In contrast, the authors of DSM-IV[10] attempted a specific definition. On the basis of research findings that threat to life or physical integrity during the event is one of the most consistent predictors of PTSD,[11] DSM-IV requires that the person 'experienced, witnessed, or was confronted with an event or events that involved actual or threatened death or serious injury, or a threat to the physical integrity of self or others'. The authors of DSM-IV made a further important step, in that they moved away from a purely situational definition and included the person's subjective response to the situation as an additional criterion, requiring that the 'person's response involved intense fear, helplessness, or horror' (or disorganized or agitated behaviour in the case of children).[10] The latter criterion takes into account that there is a large inter-individual variability in the psychological response to the same situation.

The stressor criterion of DSM-IV is still under debate. Recent research suggests that both components of the definition may require extension. First, it may be necessary to include further possible emotional responses to traumatic stressors. There is accumulating evidence that emotional numbing during traumatic events is predictive of PTSD.[12] Furthermore, it has been established that perpetrators of violent crime sometimes develop PTSD. Witnessing or participating in war-related crimes such as torturing or killing prisoners of war and civilians and mutilation of corpses is more closely linked to PTSD in Vietnam veterans than the threat of death associated with combat.[13] The psychological state of the perpetrators during the events that later lead to PTSD has not been studied in detail, but it isdoubtful that they would meet the current DSM-IV definition. Feelings of shame or guilt that were experienced at the time or subsequently, may be predictive of PTSD in this group.[14]

Second, the emphasis on threat to life or physical integrity may omit important dimensions of subgroups of traumatic events. The threat to the perception of oneself as an autonomous human being may be a relevant dimension of traumatic events that involve intentional harm by other people.[15] Mental defeat, the perceived loss of all autonomy, was related to PTSD in political prisoners and assault victims,[15,16] independent of other indicators of trauma severity including threat to life and perceived helplessness.

Clinical features

The most characteristic symptoms of PTSD are the re-experiencing symptoms. Patients involuntarily re-experience aspects of the traumatic event in a very vivid and distressing way. This includes: flashbacks in which the person acts or feels as if the event were recurring; nightmares; and intrusive images or other sensory impressions from the event. For example, a woman who was assaulted kept seeing the eyes of the perpetrator looking through the letterbox before he broke into her house, and a man involved in a severe car crash at night kept hearing the sound of the impact. Despite these vivid memory fragments, intentional recall of the event is often disorganized, and some patients have amnesia for parts of the event (see also Chapter 4.6.3).

Reminders of the trauma arouse intense distress and/or physiological reactions and are consequently avoided, including conversations about the event. Patients try to push memories of the event out of their mind and avoid thinking about the event in detail, particularly about its worst moments. On the other hand, many ruminate excessively about questions that prevent them from coming to terms with the event, for example about why the event happened to them, about how it could have been prevented, or about how they could take revenge.

The patients' emotional state ranges from intense fear, anger, sadness, guilt, or shame to emotional numbness. They often describe feeling detached from other people and give up previously significant activities. Various symptoms of hyperarousal include hypervigilance, exaggerated startle responses, irritability, difficulty concentrating, and sleep problems.

Classification

ICD-10[5] classifies PTSD (F43.1) among the reactions to severe stress and adjustment disorders (F43) that are primarily caused by stressful events. DSM-IV[10] classifies PTSD (309.81) among the anxiety disorders because symptom patterns, psychophysiological responses, family studies, and the efficacy of exposure treatment and serotonergic drugs suggested a relationship with other anxiety disorders. However, some of the symptoms would also suggest a relationship with dissociative disorders (e.g. amnesia) or depression (e.g. loss of interest).[17,18]

Diagnosis and differential diagnosis

Diagnostic criteria in ICD-10 and DSM-IV

Table 4.6.2.1 compares the diagnostic criteria of ICD-10 and DSM-IV.[10] ICD-10 research diagnostic criteria,[19] as well as diagnostic guidelines,[5] are included. The diagnostic systems agree on the core symptoms of PTSD (re-experiencing, avoidance, emotional numbing, and hyperarousal), but differ in the weight assigned to them. DSM-IV criteria are stricter.

Table 4.6.2.1 Diagnostic criteria for PTSD in ICD-10 and DSM-IV

ICD-10 diagnostic guidelines	ICD-10 research diagnostic criteria	DSM-IV criteria
Stressor criterion		
1 Event or situation of exceptionally threatening or catastrophic nature	(a) 1 Event or situation of exceptionally threatening or catastrophic nature	(a) 1 The person experienced, witnessed,or was confronted with an event or events that involved actual or threatened death or serious injury, or a threat to the physical integrity of self or others
2 Likely to cause pervasive distress in almost anyone	2 Likely to cause pervasive distress in almost anyone	2 The person's response involved intense fear, helplessness, or horror (or disorganized or agitated behaviour in children)
Symptom criteria		
Necessary symptom	*Necessary symptoms*	*Necessary symptoms*
1 Repetitive intrusive recollection or re-enactment of the event in memories, daytime imagery, or dreams	(b) Persistent remembering or 'reliving' of the stressor in intrusive 'flashbacks', vivid memories, or recurring dreams, and in experiencing distress when exposed to circumstances resembling or associated with the stressor	(b) The traumatic event is persistently re-experienced in one (or more) of the following ways 1 Recurrent and intrusive distressing recollections of the event, including images, thoughts, or perceptions (or repetitive play in which the themes or aspects of the trauma are expressed in children)
Other typical symptoms		
2 Sense of 'numbness' and emotional blunting, detachment from others, unresponsiveness to surroundings, anhedonia	(c) Actual or preferred avoidance of circumstances resembling or associated with the stressor which was not present before exposure to the stressor	2 Recurrent distressing dreams of the event (or frightening dreams without recognizable content in children)
3 Avoidance of activities and situations reminiscent of trauma	(d) 1 Inability to recall, either partially or completely, some important aspects or the period of exposure to the stressor	3 Acting or feeling as if the traumatic event were recurring (or trauma-specific re-enactment in children)
Common symptoms		4 Intense psychological distress at exposure to internal or external cues that symbolize or resemble an aspect of the traumatic event
4 Autonomic hyperarousal with insomnia		5 Physiological reactivity at exposure to internal or external cues that symbolize or resemble an aspect of the traumatic event
5 Anxiety and depression	*or*	
Rare symptoms		
6 Dramatic acute bursts of fear, panic, or aggression triggered by reminders	2 Persistent symptoms of increased psychological sensitivity and arousal (not present before exposure to stressor), shown by any two of the following (a) Difficulty in falling or staying asleep (b) Irritability or outbursts of anger (c) Difficulty in concentrating (d) Hypervigilance (e) Exaggerated startle response	(c) Persistent avoidance of stimuli associated with the trauma and numbing of general responsiveness (not present before trauma), as indicated by three (or more) of the following 1 Efforts to avoid thoughts, feelings, or conversations associated with the trauma 2 Efforts to avoid activities, places, or people that arouse recollections of the trauma 3 Inability to recall an important aspect of the trauma 4 Markedly diminished interest or participation in significant activities 5 Feeling of detachment or estrangement from others 6 Restricted range of affect 7 Sense of foreshortened future (d) Persistent symptoms of increased arousal (not present before the trauma), as indicated by two (or more) of the following 1 Difficulty falling or staying asleep 2 Irritability or outbursts of anger 3 Difficulty concentrating 4 Hypervigilance 5 Exaggerated startle response
Time frame		
Symptoms should usually arise within 6 months of the traumatic event	Symptoms should usually arise within 6 months of the traumatic event	Symptoms present for at least 1 month
Disability criterion		
N/A	N/A	The disturbance causes clinically significant distress or impairment in social, occupational, or other important areas of functioning

(continued)

Table 4.6.2.1 (Continued) Diagnostic criteria for PTSD in ICD-10 and DSM-IV

ICD-10 diagnostic guidelines	ICD-10 research diagnostic criteria	DSM-IV criteria
Differential diagnoses 1 Acute stress reaction F43.0 (immediate reaction in the first 3 days after event) 2 Enduring personality change after a catastrophic experience F62.0 (present for at least 2 years, only after extreme and prolonged stress) 3 Adjustment disorder (less severe stressor or different symptom pattern) 4 Other anxiety or depressive disorders (absence of traumatic stressor or symptoms precedes stressor)	Same as ICD-10 diagnostic guidelines	1 Acute stress disorder (duration of up to 4 weeks) 2 Adjustment disorder (less severe stressor or different symptom pattern) 3 Mood disorder or other anxiety disorder (symptoms of avoidance, numbing, or hyperarousal present before exposure to the stressor) 4 Other disorders with intrusive thoughts or perceptual disturbances (e.g. obsessive–compulsive disorder, schizophrenia, other psychotic disorders, substance-induced disorders)

- DSM-IV puts a stronger emphasis on the avoidance/numbing cluster of symptoms by requiring a minimum of three of these symptoms.
- DSM-IV states two additional criteria that are not included in ICD-10, namely a minimum symptom duration of 1 month and significant distress or impaired functioning.

A large-scale study[20] found a prevalence of ICD-10 PTSD of 6.9 per cent, and a prevalence of DSM-IV PTSD of 3 per cent.

Differential diagnoses

Differential diagnoses are summarized in Table 4.6.2.1. Distinguishing features include the following:

- the type of stressor (adjustment disorders, enduring personality change)
- the symptom pattern (adjustment disorders, enduring personality change)
- the duration of the symptoms (acute stress disorder, acute stress reaction)
- the question of whether the avoidance, numbing, and hyperarousal symptoms were present before the traumatic event occurred (other anxiety or depressive disorders)
- the nature of the intrusive cognitions and perceptual disturbances (obsessive-compulsive disorder, psychotic symptoms, substance-induced symptoms).

Prolonged repeated trauma, such as captivity or repeated childhood sexual abuse, may lead to a more complex pattern of symptoms, 'complex PTSD', that is characterized by somatization, dissociation, affect dysregulation, poor impulse control, self-destructive behaviour, and pathological patterns of relationships.[21] It was debated whether to include a category 'disorders of extreme stress not otherwise specified' (DESNOS) into DSM-IV to accommodate these cases, but the decision was not to include it.[17] In ICD-10, the diagnosis 'enduring personality changes after catastrophic experience' covers such long-standing consequences of enduring trauma.

Furthermore, it is currently being debated whether an additional diagnostic category 'traumatic grief' should be included into the psychiatric classification systems.[22]

Ongoing research on symptom criteria

Some research has questioned the symptom clusters of DSM-IV. In particular, it may be preferable to assess the emotional numbing symptoms separately from the avoidance symptoms, because these symptoms do not load on the same factor in factor analyses and may have different underlying mechanisms. Furthermore, it may be preferable to include severity criteria for the symptoms rather than relying on counting the presence of symptoms.[23]

Assessment instruments

Several semi-structured interviews assess the DSM-IV criteria for PTSD. The most commonly used diagnostic interviews are the Structured Clinical Interview for DSM-IV (SCID)[24] and the Clinician Administered PTSD scale (CAPS).[25]

The most widely used self-report measure of PTSD symptoms used to be the Impact of Event scale.[26] The original scale contained two scales, an intrusion and an avoidance scale. It has been expanded to include an additional hyperarousal scale (IES-R).[27] The IES-R does not cover all the symptoms of PTSD specified in DSM-IV. This is why new measures that are modelled on the DSM-IV criteria are now commonly used in research studies, for example the Post-traumatic Stress Diagnostic scale (PDS)[28] or the PTSD Checklist (PCL).[29]

Epidemiology

The available epidemiological data so far stem mainly from large-scale studies in industrialized societies such as the United States or Australia. It remains to be investigated whether these data replicate in other countries. One has to bear in mind that the society and natural environment set conditions for exposure to traumatic events. For example, in the last decades, people in developing countries have had a much greater exposure to war and natural disasters than people in industrialized western societies.[30]

How common are traumatic events in the population?

Traumatic events are common. In a large representative United States' sample, Kessler *et al.*[31] found that 60.7 per cent of the men and 51.2 per cent of the women had experienced at least one traumatic event meeting DSM-IIIR criteria in their lifetime. The most common types of trauma were witnessing someone being killed or severely injured, accidents, and being involved in a fire, flood, or natural disaster. Using DSM-IV criteria, Stein *et al.*[32] found a lifetime exposure to serious traumatic events of 81.3 per cent for men, and 74.2 per cent for women. Sudden death of a loved person was one of the most frequent traumatic stressors (DSM-IV criteria).[33]

What types of trauma are associated with high PTSD rates?

PTSD rates depend on the type of traumatic event. Rape was associated with the highest PTSD rates in several studies. For example, 65 per cent of the men and 46 per cent of the women who had been raped met PTSD criteria in the Kessler *et al.*[31] study. Other traumatic events associated with high PTSD rates included combat exposure, childhood neglect and physical abuse, sexual molestation; and for women only, physical attack and being threatened with a weapon, kidnapped, or held hostage. Accidents, witnessing death or injury, and fire or natural disasters were associated with relatively low-lifetime PTSD rates of less than 10 per cent.[31] Other research has shown high PTSD rates for torture victims,[34] survivors of the Holocaust,[35] and prisoners of war.[36] The emphasis in DSM-IV on threat to life or physical integrity has led to increasing awareness that medical illness and treatment (e.g. waking up during anaesthesia) can lead to PTSD.[37]

What proportion of people develop PTSD in response to a traumatic stressor?

Kessler *et al.*[31] found that the risk of developing PTSD after a traumatic event is 8.1 per cent for men, and 20.4 per cent for women. For young urban populations, higher risks have been reported; Breslau *et al.* found an overall risk of 23.6 per cent[38]; 13 per cent for men and 30.2 per cent for women.[39]

The figures reported in these studies may be influenced by two types of biases that have opposite effects on probability estimates. First, Breslau *et al.*[33] have pointed out that previous studies overestimated the PTSD-risk imposed by traumatic events because participants reported on the worst trauma that they had experienced. When assessment focused on the symptoms induced by a traumatic event that was randomly selected from the ones that a person had experienced, the conditional risk of PTSD following exposure to trauma was found to be 9.2 per cent, using DSM-IV criteria.

Second, the retrospective methodology used in the epidemiological studies may have led to underestimation of PTSD rates due to selective recall. For example, the prevalence of PTSD 3 months after road traffic accidents was found to be around 20 per cent in prospective longitudinal studies,[40,41] whereas the retrospective studies found prevalences below 10 per cent.

How prevalent is PTSD in the population?

Kessler *et al.*[31] estimated that the lifetime prevalence of PTSD is 7.8 per cent, using DSM-IIIR criteria. Women had a higher prevalence than men (10.4 versus 5.0 per cent). This was due to both a greater exposure to high-impact trauma (rape, sexual molestation, childhood neglect, and childhood physical abuse) and a greater likelihood of developing PTSD when exposed to a traumatic event. Other studies using DSM-IIIR criteria have yielded similarly high prevalence rates.[9,39] Estimates for the 12-month prevalence range between 1.3 per cent in an Australian study[42] and 3.6 per cent in an US study.[43] A study using DSM-IV criteria and found a past-month PTSD prevalence of 2.7 per cent for women and 1.2 per cent for men.[32]

Earlier studies using DSM-III criteria had reported lower lifetime prevalences of about 1 per cent. Besides differences in procedures and sampling methods, the low PTSD prevalence in these earlier studies may be due to the use of an interview schedule with low sensitivity in detecting PTSD.[44] In particular, the early interviews asked global questions about the occurrence of traumatic events and lacked the repeated probing for specific events or event categories that seems to be necessary in eliciting relevant experiences.

Partial PTSD

Several studies have found substantial levels of distress and disability for traumatized people who met some, but not all, of the PTSD criteria specified in DSM-IV.[32] These people may be at greater risk of developing the full PTSD syndrome than people with fewer symptoms.[40,41]

Comorbidity of PTSD with other disorders and symptoms

PTSD shows a substantial comorbidity with affective disorders, other anxiety disorders, substance-use disorders, and somatization. In the study by Kessler *et al.*,[31] 88.3 per cent of the men and 78.1 per cent of the women with PTSD had comorbid psychiatric diagnoses. Studies of veterans with PTSD have also indicated an enhanced level of problems in family and marital adjustment and violent behaviour,[45] and heavy smoking.[46] Furthermore, reports of poor health and increased rates of various diseases, in particular infectious and nervous system diseases, are associated with PTSD.[47]

Is PTSD primary or secondary to the comorbid diagnoses? There is, as yet, little research into this question. The retrospective accounts obtained by Kessler *et al.*[31] suggested that PTSD was primary to comorbid affective or substance-use disorders in the majority of cases, and PTSD was primary to comorbid anxiety disorders in about half of the cases. Similarly, Breslau *et al.*[39] found that PTSD increased the risks for first-onset major depression and alcohol-use disorder. Conversely, pre-existing major depression also increased vulnerability to the PTSD-inducing effects of traumatic events and risk for exposure to traumatic events. A prospective study confirmed that PTSD increased the risk of subsequent pain, conversion symptoms, and somatization symptoms.[48]

Most of the comorbidity research has concentrated on the nature of the relationship between PTSD and alcohol or drug abuse. The majority of studies found that PTSD precedes the development of alcohol-abuse problems. There are probably several mechanisms for this relationship. In the short-term, alcohol is used to self-medicate the symptoms of PTSD, but paradoxically intoxication and withdrawal symptoms may intensify the symptoms in the long-term.[49]

Summary of main findings from epidemiological studies

- The majority of people will experience at least one traumatic event in their lifetime.
- In assessing PTSD history, interviewers should probe for specific events.
- Assault, in particular sexual assault, and combat have a higher impact than accidents and disasters.[31,32]
- If the frequency and impact of traumatic events are considered together, sudden unexpected death of a loved one[33] and road traffic accidents[8] can be considered important causes of PTSD in western industrialized societies.
- Men tend to experience more traumatic events than women, but women experience higher impact events.[31,32]
- Women are at least twice as likely as men to develop PTSD in response to a traumatic event. This enhanced risk is not explained by differences in the type of traumatic event. The estimated lifetime prevalence for women is approximately 10 to 12 per cent, and for men 5 to 6 per cent.[9,31,38,39]
- Comorbid depression and substance-use disorders appear to be secondary to PTSD in the majority of cases.

Aetiology

There is no single accepted theory of PTSD. Theoretical explanations have focused on psychological and biological mechanisms that are not mutually exclusive.

Psychological processes

(a) Fear conditioning

Mowrer's two-factor conditioning theory of phobias has been applied to PTSD.[50–52] It is suggested that through classical (Pavlovian) conditioning, stimuli that were present at the time of the trauma (unconditioned stimulus) become associated with fear and arousal responses. Subsequently, the conditioned stimuli trigger similar (conditioned) responses when presented on their own. Through stimulus generalization and higher-order conditioning, a wide variety of stimuli become triggers of distress in the aftermath of trauma. Quite naturally, the person will try to avoid the conditioned stimuli and the associated distress. The avoidance behaviour is negatively reinforced (operant or instrumental conditioning) because it leads to a reduction in psychological and physical discomfort. In the long-term, however, avoidance prevents extinction of the conditioned fear responses to reminders of the traumatic event, and thus maintains the problem.

(b) Personal meanings of the traumatic event and its aftermath

The persistence of PTSD symptoms has been explained by individual differences in the appraisal of the traumatic event: that is to say, in what personal meaning it has for them.[53–55] Some people are able to see the trauma as a time-limited terrible experience that does not necessarily have negative global implications for their view of themselves, the world or the future. These people are likely to recover quickly. Individuals with persistent PTSD are characterized by *excessively* negative appraisals of the event that go beyond what everyone would find horrific about the event. The nature of predominant emotional responses in PTSD depends on the particular appraisals; for example, appraisals concerning danger lead to fear ('Nowhere is safe'), appraisals concerning others violating personal rules lead to anger ('Others have not treated me fairly'), appraisals concerning responsibility for the traumatic event lead to guilt or shame ('It was my fault', 'I did something despicable'), and appraisals concerning loss lead to sadness ('My life will never be the same again').[55] Such appraisals distinguish between traumatized individuals with and without PTSD, and predict chronic PTSD.[16,56]

Negative appraisals involved in maintaining PTSD do not only concern the traumatic event itself, but also its sequelae such as the initial PTSD symptoms or responses of other people in the aftermath of the traumatic event.[55,57,58] In line with this hypothesis, negative interpretations of intrusive recollections (e.g. 'I am going mad') after road traffic accidents were one of the most important predictors of PTSD at 1 year after the event.[41] Perceived negative responses from other people in the aftermath of trauma predicted PTSD in studies of assault and torture victims.[15,16]

(c) Nature of trauma memories

What exactly distinguishes trauma memories from other memories and what explains the distressing re-experiencing symptoms in PTSD is still under debate.[59,60] Phenomenological observations show that although a wide range of stimuli can trigger unwanted intrusive memories of parts of the traumatic event, people with PTSD show relatively poor intentional recall of details such as the order of events and their recall appears disjointed.[60] Several theories have been put forward to explain re-experiencing symptoms. Foa and colleagues[53,58] explain re-experiencing as spreading activation in a pathological network in memory. This network is thought to be particularly large and easily triggered. It contains many stimulus propositions that are erroneously linked to danger, causing fear responses to harmless stimuli associated with the traumatic event in memory. In addition, the person's reactions during the trauma are linked to the belief that the self is incompetent. Activation of components of the trauma memory (for instance, by confrontation to a reminder, by similar bodily sensations, or by thinking about the event) will activate the whole network, including the emotional responses that the person had during the traumatic event.

Brewin and colleagues[61] have proposed that the symptoms of PTSD can only be explained if one assumes several levels of representation of the traumatic event, namely a verbally accessible memory and a memory that is triggered by situation-specific cues. PTSD is thought to be characterized by easily accessible situationally specific memories that lead to re-experiencing symptoms.

Ehlers and Clark [55] suggested that re-experiencing results from three memory processes, namely, (i) poor inhibition of stimulus-driven retrieval of parts of the trauma memory (re-experiencing) due to insufficient elaboration of the trauma memory (insufficient links to other information that would give the worst moments of the trauma a context such as 'I survived the event' or 'I complied with the requests of the perpetrator because he had threatened me with a knife'), (ii) strong perceptual priming (low perceptual threshold for stimuli with similar sensory characteristics as those present during the trauma), and (iii) strong associations among stimuli present at the time of the event (e.g. footsteps behind me

associated with feeling knife in my back) and between stimuli and emotional responses (e.g. pressure on back associated with fear of death).

(d) Behaviours that maintain PTSD symptoms

Whereas many people will recover from initial PTSD symptoms, some do not get better. This has led researchers to specify possible maintaining behaviours. These include avoidance of reminders, suppression of thoughts and memories connected to the event, rumination, safety behaviours, dissociation, and the use of alcohol or drugs.[57] Ehlers and Clark[55] suggested that these behaviours and cognitive strategies maintain PTSD in three ways. First, some behaviours directly lead to increases in symptoms; for example, thought suppression leads to paradoxical increases in intrusion frequency. Second, other behaviours prevent changes in the problematic appraisals; for example, constantly checking one's rear mirror (a safety behaviour) after a car accident prevents change in the appraisal that another accident will happen if one does not check the mirror. Third, other behaviours prevent elaboration of the trauma memory and its link to other experiences. For example, avoiding thinking about the event may prevent people from incorporating the fact that they did not die into the worst moments of the trauma memory, and they thus continue to re-experience the fear of dying they originally experienced during the event. Several studies have found that avoidance, safety behaviours, thought suppression, and rumination predict maintenance of PTSD.[16,41]

Some of the cognitive processes that maintain PTSD symptoms are not intentional. Patients with PTSD have an unintentional attentional bias to stimuli that are reminiscent of the traumatic event.[6] Involuntary selective attention to reminders may be one of the reasons why these patients have frequent re-experiencing symptoms. Rumination is often described by the patient as unintentional. In particular, patients have problems stopping ruminating once they have started. Rumination may represent a cognitive habit that started as an intentional strategy employed to solve problems and that became more automatic with time.

Biological processes

A number of biological factors have been linked to PTSD symptoms. They have the effect that they make people with PTSD hyperresponsive to stressful stimuli, especially stimuli that are reminiscent of the trauma.[62]

(a) Chronic stress reaction

Patients with PTSD show several abnormalities that are consistent with a chronic stress reaction or an enhanced reactivity to minor stressors. There is evidence for an enhanced secretion of adrenaline (epinephrine) and noradrenaline (norepinephrine) to stress.[63] In psychophysiological studies, patients with PTSD showed enhanced startle responses and higher baseline heart rates and blood pressure than traumatized controls without PTSD. However, these responses may, in part, reflect anticipatory anxiety related to the expectation of trauma cues. Patients with PTSD exhibit greater physiological reactivity to trauma cues (e.g. sounds, pictures, or script-driven imagery) than control subjects without PTSD.[6]

(b) Hypothalamic-pituitary-adrenal axis abnormalities

Patients with PTSD show a different pattern of hypothalamic-pituitary-adrenal response than patients with major depression.[63] Like depressed patients, patients with PTSD hypersecrete corticotrophin-releasing factor (CRF). However, they show *lower* levels of cortisol compared to normal controls, traumatized individuals without current PTSD and depressed patients. When given a low dose of dexamethasone, PTSD patients exhibit *hyper*-suppression of cortisol. Some, but not all findings, suggest that the hypothalamic-pituitary-adrenal axis in PTSD may characterized by enhanced negative feedback.[64] Overall, the hypothalamic-pituitary-adrenal axis in PTSD appears to be set to produce large responses to further stressors.

(c) Hypothalamic-pituitary-thyroid axis

Studies suggest increased hypothalamic-pituitary-thyroid axis activity in PTSD.[63] Patients with PTSD showed increased levels of thyroid hormones, and an exaggerated thyrotropin-stimulating hormone (TSH) response to the standard TSH stimulation test.

(d) Neuroendocrinological abnormalities

Several neurotransmitter systems appear to be dysregulated in PTSD.[63,65] Research suggests exaggerated noradrenergic activity in PTSD in response to stressors.[65] People with PTSD have fewer plaletet α_2-adrenergic receptors, which has been interpreted as a response to chronic elevation of circulating catecholamines. Yohimbine (which blocks α_2-receptors) provokes flashbacks and panic attacks in a substantial subgroup of PTSD patients.[65]

There is also evidence for the involvement of the serotonergic system in PTSD.[63,65] Findings suggest decreased serotonin activity, including decreased serum concentrations, decreased sensitivity of platelet serotonin uptake sites, and blunted prolactin response to D-fenfluramine (indicative of central serotonin hypo-activity). Serotonin-reuptake inhibitors have therapeutic effects in PTSD.

Endogenous opiates have been suspected to mediate the symptoms of emotional numbing and amnesia. In the animal model, uncontrollable stress leads to the secretion of endogenous opiates that induce analgesia. There is some evidence for decreased baseline levels, but increased post-stimulation levels of ß-endorphin.[63]

The dopaminergic and γ-aminobutyric acid (GABA) systems have also been implicated in PTSD, but the evidence for these hypotheses is sparse at this stage.[63]

(e) Neuroimaging

Structural magnetic resonance imaging studies tend to show a reduced hippocampal volume in adults with PTSD, in particular in those with severe and very chronic PTSD, but not in children.[66] Disturbances of hippocampal function may lead to deficits in explicit memory and the appreciation of safe contexts. This line of research was prompted by animal studies showing that high levels of cortisol seen during stress are associated with damage to the hippocampus.[67] However, there is evidence from a study of monozygotic twins that the hippocampal volume of the *unexposed* twins correlated with the PTSD severity of the exposed twins. Thus, small hippocampal volume may be a vulnerability factor for PTSD, an effect of severe or chronic stress, or both. Preliminary evidence suggests that successful long-term treatment with paroxetine increases hippocampal volume in patients with PTSD.[67]

Functional neuroimaging studies have found differences between people with and without PTSD in neurocircuits that are involved in fear conditioning (amygdalae, medial prefrontal cortex, hippocampus). When exposed to trauma reminders or other anxiety cues,[68] people with PTSD tend to show heightened responsivity of the

amygdala and diminished responsivity in the medial prefrontal cortex. The latter plays a role in extinguishing fear reactions, as animal studies established that conditioned fear responses could only be extinguished if the cortex was intact.[69] Recent studies suggest different patterns of responses to trauma reminders for people with PTSD who show high arousal to trauma reminders (involving mainly the anterior cingulate, medial prefrontal cortex, and thalamus) versus those with dissociative reactions (involving mainly the parietal, occipital, and temporal cortex).[70]

(f) Animal models of PTSD

There are biological and psychological parallels between the animal model of inescapable shock and exposure to a traumatic event. The uncontrollability of an aversive event seems to make it particularly traumatic.[71] Inescapable shock leads to changes in the noradrenergic system, the HPA axis, and endogenous opiates that parallel findings in PTSD patients.[51]

However, these effects are usually only observed after repeated exposure to inescapable shock, whereas one traumatic event can be sufficient in inducing PTSD. This is why some authors have suggested that the animal model of kindling or behavioural sensitization is more appropriate in explaining PTSD. Kindling refers to a process whereby intermittent subconvulsive electrical stimulation of the limbic system eventually has the effect that the animal will respond with a seizure to a stimulus that previously was subthreshold. Post *et al.*[72] have suggested that the repeated re-experiencing of the traumatic event may constitute a kindling process, to the effect that PTSD symptoms become more easily triggered with time. Similarly, previous exposure to stressors may sensitize people to respond with PTSD symptoms to a traumatic event.

Animal models suggest that the massive secretion of neurohormones at the time of the trauma, in particular noradrenaline and vasopressin, leads to overconsolidation (long-term potentiation) of the trauma memory. This would have the effect that the conditioned fear responses are particularly difficult to extinguish and that stimuli that resemble those present during trauma are particularly likely to trigger intrusive memories, distress, and/or the corresponding physiological responses.[62]

(g) Genetic factors

Twin studies have found a higher concordance of PTSD among monozygotic than dizygotic twins. There is also an increased prevalence of psychiatric disorders, especially anxiety disorders, affective disorders, sociopathy, and/or substance abuse, among family members of people with PTSD.[73] A study found a higher proportion of the 5-HTTLPR s/s genotype in PTSD compared to controls.[74]

Course and prognosis

Time course of symptoms

For the vast majority of PTSD cases, symptoms begin immediately after the traumatic event. Delayed onset is found in a minority (11 per cent or less) of the cases.[6]

Prospective longitudinal studies suggest that a large proportion of people who initially develop PTSD after trauma will recover on their own. However, between one-third and 50 per cent of those who develop PTSD after a traumatic event will not recover for many years.[31,75] Long-term outcome depends on initial symptom severity and the experience of further traumatic events. People with high initial PTSD severity are more likely to remain symptomatic at follow-up than those with low initial symptom severity.[41,75]

Factors that influence the risk of developing PTSD

Meta-analyses[11,76] have identified several reliable predictors of PTSD. The results are summarized in Table 4.6.2.2. Overall, peri-traumatic factors such as perceived life threat and dissociation during the trauma and post-trauma factors such as low social support appear more predictive of PTSD than pre-trauma variables.

(a) Demographic and pre-trauma variables

Women have consistently shown to have a greater risk of developing PTSD than men, but the mechanisms remain unclear.[11,31,67,76,77] Similarly, it is as yet unclear why people with lower intelligence or education,[76] people with lower socioeconomic status,[76] and people from ethnic minorities[78] have an elevated PTSD risk. Other risk factors include previous trauma, childhood adversity, a personal or family history of anxiety or depression,[76] and neuroticism.[38]

(b) Stressor variables

PTSD risk depends on the severity of the stressor. Prolonged and repeated trauma, exposure to the grotesque aftermath of violence, events that involve intentional harm by another person and abusive violence, and events that involve harm to children are particularly likely to lead to PTSD.[79,80]

Injury severity is only a weak predictor of PTSD. Long-term health problems and loss of function may play a greater role in maintaining PTSD.[41,79] There are some reports that unconsciousness during a traumatic event may decrease the risk of PTSD,[81]

Table 4.6.2.2 Risk factors for post-traumatic stress disorder

	Weighted average effect size *r*
Demographic variables	
Female sex	0.13[76]
Race (minority status)	0.05[76]
Younger age	0.06[76]
Low socio-economic status	0.14[76]
Cognitive ability	
Low education	0.10[76]
Low intelligence	0.18[76]
Psychiatric and trauma history	
Psychiatric history	0.11[76]–0.17[11]
Family psychiatric history	0.13[76]–0.17[11]
Prior trauma	0.12[76]–0.17[11]
Childhood abuse	0.14[76]
Other adverse childhood	0.19[76]
Peri-traumatic factors	
Trauma severity	0.23[76]
Perceived life threat	0.26[11]
Peri-traumatic emotions	0.26[11]
Peri-traumatic dissociation	0.35[11]
Post-trauma factors	
Low social support	0.28[11]–0.40[76]
Further life stress	0.32[76]

(Modified from meta-analyses by Brewin *et al.* (2000) and Ozer *et al.* (2003))

but other studies have found small associations in the opposite direction.[41]

(c) Psychological responses during trauma

PTSD risk depends on the degree of psychological distress the traumatic event caused. The psychological impact of the trauma depends on the perceived threat to life,[11,76] the perceived loss of control (helplessness),[82] and the perceived threat to one's autonomy (mental defeat).[15,16] Among the psychological responses predicting PTSD are feelings of anger, guilt, or shame[83] and dissociation and numbing.[11]

Factors affecting recovery from trauma

(a) Recovery environment

Recovery is facilitated by social support, [11,76] and hindered by perceived negative responses from other people.[15,16] Further stressful or traumatic life events impede recovery from PTSD.[76] This includes the stress caused by long-lasting negative effects of the event on health and personal appearance, financial difficulties, disruptions in everyday life, and ongoing litigation.[41,81,84]

(b) Psychological processes

Excessively negative appraisals of the traumatic event impede recovery (e.g. 'Nowhere is safe', 'I cannot trust anyone', 'I am inadequate').[16,56] If individuals interpret their initial PTSD symptoms as signs that they are going mad or losing control, or as signs of a permanent change for the worse, they are less likely to recover.[16,41]

If individuals engage in behaviours or cognitive coping styles that prevent them from 'working through' and accepting the trauma, they are less likely to recover. Such maladaptive behaviours include avoidance, not talking about the experience, safety behaviours, denial, thought suppression, and rumination.[16,41,80,85]

Treatment of PTSD

Meta-analyses of randomized controlled trials have identified several effective psychological and pharmacological treatments for PTSD.[86–88]

Psychological treatments

Psychological treatments lead, on average, to large improvements in PTSD symptoms. The mean effect size (Cohen's *d* statistic) for the difference between the pre- and post-treatment scores was $d = 1.43$ across 26 studies of psychological treatments.[86] (An effect size $d = 1$ means that the treatment led to improvement by one standard deviation). In interpreting the effect sizes of treatments, one has to bear in mind that pill-placebo or waiting list conditions also lead to some improvement. Mean effect sizes for these conditions were $d = 0.77$ and $d = 0.75$ for observer-rated PTSD symptoms, and $d = 0.51$ and $d = 0.44$ for self-rated PTSD symptoms in 61 treatment-outcome trials.[88]

Not all psychological treatments are equally effective in treating PTSD. According to the meta-analyses, trauma-focused treatments are more effective than other treatments.[86,87] Trauma-focused cognitive behaviour therapy (CBT) and eye movement desensitization and reprocessing (EMDR) were superior to stress management and other therapies such as supportive therapy or hypnotherapy.[87] On average, 67 per cent of patients who complete the trauma-focused treatments (and 56 per cent of those who enter these treatments; intent-to-treat analysis) no longer met diagnostic criteria for PTSD.[86] For supportive therapy, the corresponding recovery rates were 39 per cent among treatment completers and 36 per cent in intent-to-treat analyses.[86] On the basis of these results, recent United Kingdom and Australian treatment guidelines recommend trauma-focused CBT and EMDR as the treatments of choice for PTSD.[89,90] Both treatments address the patient's troubling memories of the traumatic events and the personal meaning of the event and its consequences.

(a) Trauma-focused psychological treatments

(i) Cognitive behavioural therapy (CBT)

All effective CBT programmes for PTSD include an element of psycho-education about common reactions to trauma that normalizes the PTSD sufferer's symptoms, and a rationale for the interventions. Trauma-focused CBT programmes for PTSD include either exposure or cognitive therapy, or a combination of these interventions. Some also include elements of stress management training such as breathing training.

Exposure. Exposure treatment for PTSD comprises two components.[58] In imaginal exposure, patients are systematically exposed to the memory of the trauma. A commonly used procedure is imaginal reliving,[58] where patients relive the traumatic event in their imagination, including their thoughts and feelings at the time. This is repeated until the reliving no longer evokes high levels of distress. Writing a trauma narrative can also be used as a method of exposure to the trauma memory.[54] In vivo exposure[58] involves confronting (safe) situations that patients avoid because they remind them of the trauma (e.g. going to the site of the traumatic event, driving again after a road traffic accident). Exposure is repeated until the patient no longer responds with high levels of distress. The effects of exposure were originally explained as an effect of habituation, but there are probably several mechanisms for its efficacy.[55,58] For example, patients realize that exposure does not lead to a feared outcome (for example, going to the site of an accident will not mean that another accident will happen; thinking about the trauma will not make them go mad) and thus helps in correcting dysfunctional beliefs about danger of the world and the meaning of PTSD symptoms. Second, the repeated exposure helps patients to create an organized memory and facilitates the distinction that intrusive thoughts and images are memories rather than something happening right now.

Whereas exposure treatment is effective in the majority of cases, a minority of patients become worse.[91] In particular, exposure treatment does not appear suitable for patients whose traumatic memories are about being perpetrators rather than victims.[92] It may also have limits in treating survivors of complex and prolonged traumatic events such as torture, war, or captivity.[93]

Cognitive therapy. Cognitive therapy for anxiety disorders focuses on the identification and modification of misinterpretations that lead the patient to overestimate threat. In PTSD, the perceived threat stems from interpretations of the trauma and its aftermath.[54,55] For example, people with PTSD may feel strong guilt or shame related to the trauma: a rape victim may blame herself for the rape; a war veteran may feel it was his fault that his best friend was killed. Others overestimate the current danger they are encountering in everyday life. An accident survivor may become convinced that he is at great risk of having a further trauma.

Others may take the intrusive re-experiencing symptoms as a sign that they are about to go crazy. By discussing the evidence for and against the interpretations, and by testing out the predictions derived from the interpretations with the help of the therapist, the patient arrives at more adaptive conclusions. The patient is encouraged to drop behaviours and cognitive strategies that prevent a disconfirmation of the negative interpretations, e.g. excessive precautions to prevent further trauma or excessive rumination about what one could have done differently during the event. Recent studies have shown that cognitive therapy is effective on its own, without additional exposure treatment.[91,94] However, when verbal challenging of dysfunctional beliefs was used as an additional procedure after a session of imaginal exposure, it did not lead to additional treatment gains.[94] However, cognitive therapy may help reduce the amount of exposure necessary to achieve large treatment effects.[95,96]

(ii) Eye-movement desensitization and reprocessing (EMDR)

Like trauma-focused CBT, EMDR[97] aims to help patients process their traumatic memory and think more positively about their experience. It involves inducing a series of rapid and rhythmic eye movements while the patient focuses on a trauma-related image and related negative emotions, sensations, and thoughts. Patients are instructed to visually track the therapist's fingers as they move back and forth in front of the patient's eyes for sets of about 20 s. After each set, the patient discusses the images and emotions they experienced during the eye movements with the therapist. This process is repeated, and includes focusing on different memories that come up in connection with the trauma. Once distress to the target image is reduced, patients are instructed to focus on the image while rehearsing a positive thought connected to the image. The mechanism of treatment is not yet understood. Several empirical studies have suggested that the eye movements may not be necessary in producing the therapeutic effects observed with EMDR.[98]

(iii) Other psychological treatments

Most other psychological treatments have a small evidence-base. In general, non-trauma focused treatments were shown to be less effective than trauma-focused treatments in randomized controlled trials.[86,87]

Stress management (stress inoculation). The goal of this treatment is to teach the patient a set of skills that will help them cope with stress. Examples include relaxation training, training in slow abdominal breathing, thought stopping of unwanted thoughts, assertiveness training, and training in positive thinking. Stress management is more effective than supportive psychotherapy, but given on its own less effective than trauma-focused treatments.[87]

Psychodynamic therapy. Several different forms of psychodynamic treatments for PTSD have been described.[99] The focus lies on resolving unconscious conflicts provoked by the stressful event by making it conscious in tolerable doses. This is thought to help the patient reengage normal mechanisms of adaptation. The goal of treatment is to understand the meaning of the stressful event in the context of the individual's personality, attitudes, and early experiences. The psychological meaning of the event is explored by a range of methods such as 'sifting and sorting through wishes, fantasies, fears, and defences stirred up by the event'.[99] Treatment strategies include exploratory insight-oriented, supportive, or directive activity. It may also include working with transference, but with the therapist using a less strict technique than that used in psychoanalysis. To date there is only one controlled study of psychodynamic therapy, and the effect size observed in that study is below those observed with trauma-focused CBT or EMDR.[88]

Hypnotherapy. The patient is given instructions to induce a state of highly focused attention, a reduced awareness of peripheral stimuli, and a heightened suggestibility. The goal of this treatment is to enhance control over trauma-related emotional distress and hyperarousal symptoms and to facilitate the recollection of details of the traumatic event. To date there is only one controlled study of hypnotherapy, and the effect size observed in that study is below those observed with trauma-focused CBT or EMDR.[88] Shalev *et al.*[93] raised concerns about the use of hypnotherapy in the treatment of PTSD as it may induce dissociative states.

Supportive therapy. Supportive therapy is primarily non-directive and non-advisory. Through a supportive therapeutic relationship, clients are encouraged to explore their thoughts, feelings, and behaviour to reach clearer self-understanding; and to find and use their strengths so that they cope more effectively with their lives by making appropriate decisions, or by taking relevant action. Supportive therapy is less effective than trauma-focused psychological treatments.[86,87]

Pharmacological treatments

Although recent guidelines[89,90] recommend trauma-focused psychological treatments as the first line treatments for PTSD, they also acknowledge a role for medication. A Cochrane review[100] found an advantage of medication over placebo with response rates of 59.1 and 38.5 per cent, respectively. Indications for medication according to recent guidelines include patient choice, severe ongoing threat, the patient is too depressed or unstable to engage in psychological treatment, and failure to respond to psychological treatment.

(a) Selective serotonin-reuptake inhibitors (SSRIs)

Among the pharmacological treatments, the SSRIs have been most widely studied and are recommended as the first line medication choice for PTSD according to expert consensus[90,101] and a recent Cochrane review.[100] Paroxetine has received the most consistent support for its efficacy.[89,100] SSRIs reduce alcohol consumption; a relevant finding given the high comorbidity of PTSD with substance abuse or dependency.[102]

(b) Monoamine oxidase inhibitors (MAOIs)

There is some evidence that phenelzine is effective in PTSD,[89,100] particularly in reducing re-experiencing symptoms and insomnia.[102] Thus, phenelzine may be considered as one of the treatment options for PTSD by mental health specialists,[89] taking into consideration the risks and necessary dietary restrictions.

(c) Other antidepressants

There is some evidence for the efficacy of tricyclic antidepressants, particularly amitriptyline, in the treatment of PTSD.[89,100] They may be considered as a treatment option for PTSD by mental health specialists.[89,90] Mirtazepine, a noradrenergic and specific serotonergic antidepressant, has shown promise in initial trials and has been recommended as one of the treatment options for PTSD.[89,90]

(d) Benzodiazepines

Benzodiazepines do not appear to be effective in the treatment of PTSD. They do not affect the re-experiencing, avoidance, and numbing symptoms, although they may show some effects on insomnia, irritability, and general anxiety and arousal symptoms.[102]

Advice on management

Diagnosing PTSD

When assessing whether a patient has experienced a trauma, it is important to ask about specific examples of traumatic events. Patients may initially feel too overwhelmed or ashamed to report details of their traumatic experience, and may find it easier to reply to factual questions with 'yes' or 'no' answers. In diagnosing PTSD, clinicians need to ascertain that the patient involuntarily re-experiences parts of the event. In addition, patients will need to have some symptoms of hyperarousal, avoidance, and emotional numbing. Self-report instruments such as the Post-traumatic Stress Diagnostic scale[28] or semi-structured interviews such as the Clinician Administered PTSD scale[25] are useful in assessing the pattern and severity of symptoms. Clinicians should ask about the impact of the symptoms (e.g. distress, restrictions, effect on family and work) on the patient's life. The DSM-IV criterion of a minimum of three avoidance or numbing symptoms appears too strict for clinical purposes. It does not appear justified to withhold treatment if the patient is disabled by the PTSD symptoms but fails to meet this criterion.

Is PTSD the main problem?

As PTSD is often comorbid with other disorders, clinicians need to ascertain whether PTSD is the main problem for which the patient presently needs help at present. The time course of the onset of the comorbid disorders and changes in the severity of symptoms provide useful information. It is also helpful to ask patients whether they believe that they would need professional help for their other problems if the PTSD symptoms are resolved. In cases of comorbid depression, the PTSD should usually be treated first (as comorbid depression improves with successful PTSD treatment), unless the depression is so severe that the patient cannot engage in treatment. In contrast, significant substance dependence usually needs to be addressed before treating the PTSD.[89]

Assessments need to include a risk assessment. If there is a high risk of suicide or harm to others, clinicians will need to concentrate on managing the risk first.[89]

Clinicians will also need to establish whether there is any serious ongoing threat or health, social, and financial problems that may need to be addressed before the patient can engage in psychological treatment.[89]

(a) Choice of treatment

Patients should be informed about effective treatments for PTSD. Information material for patients and carers is available.[103] Trauma-focused psychological treatments are the best treatment option for PTSD to date, given the strong evidence for their effectiveness,[89,90] their established long-term effectiveness,[88] and the lower dropout rates compared to medication. Meta-analyses report that, across studies, 14–21 per cent of the patients can be expected to dropout of psychological treatments,[86,88] compared to 31–36 per cent for medication.[88,100] The advantage of SSRIs and other medications compared to psychological treatments is that they are more readily available.

(i) Psychological treatment

Trauma-focused psychological treatments usually last between 8 and 12 sessions (longer for patients with multiple traumas and comorbid personality disorders). When the trauma is discussed in the session, 90 min should be allowed for the session.[89,90] The treatments require a good therapeutic alliance.[90] Depending on the nature of the trauma and comorbid problems, additional sessions for establishing trust and emotional stabilization may be needed before the trauma-focused treatment commences.[89,90]

(ii) Pharmacological treatment

Clinicians should discuss the benefits and possible side effects of the prescribed medication with the patient, and address common concerns, such as fears of addiction. Patients also need to be informed that the medication needs to be discontinued gradually. Most antidepressants recommended for the use in PTSD need to be discontinued over at least 4 weeks.[89] The risk of self-harm needs to be considered when prescribing antidepressants. Those with high risk should be seen at least weekly until the risk is no longer considered significant.[89,90] Patients receiving SSRIs need to be monitored for akathisia, suicidal ideation, and increased anxiety and agitation. Patients receiving phenelzine require careful monitoring (including blood pressure measurement) and advice about interactions with other medicines and food.[89]

(b) Special problems in the management of PTSD patients

Avoidance is one of the main symptoms of PTSD, and it can thus take years for the patient to seek help for this condition. It is important for clinicians to bear in mind that even those who seek help may find it hard to talk about the traumatic experience, and may show signs of avoidance such as irregular attendance or failure to disclose the worst moments of the trauma initially. Therapeutic techniques to deal with this problem include empathy, gradual encouragement, and giving the patient control over the timing and mode of working through the experience (e.g. writing, talking into a tape recorder, reliving with the support of the therapist).

One of the requirements for change is that the patient feels safe. Therapists therefore have to make sure that they establish a good relationship with the patient, and that the therapeutic setting or their behaviour does not remind the patient of the traumatic event. Sometimes support in changing living circumstances may be necessary if they prevent the patient from being safe (e.g. moving house if assaulted by a neighbour).

Patients with PTSD often suffer from poor sleep and concentration, and find it painful to face reminders of the trauma. For these reasons, they have difficulty in dealing with the aftermath of traumatic events such as legal procedures and continuing treatment for physical injuries, including the long delays that this usually involves. Such ongoing stressors impede recovery, and patients may therefore benefit from problem-solving and practical advice.

4.6.3 Recovered memories and false memories

Chris R. Brewin

Clinicians working with survivors of traumatic experiences have frequently noted the existence of memory loss with no obvious physical cause and the recovery of additional memories during clinical sessions. Indeed, amnesia is described in diagnostic manuals as a feature of post-traumatic stress disorder, although its presence is not necessary for this diagnosis. In the majority of these cases, people forget details of the traumatic event or events, or forget how they reacted at the time, although they remember that the event happened. They typically report that they have endeavoured not to think about the event, but have never forgotten that it occurred. Controversy is centred on memories of traumatic events, particularly concerning child abuse, that appear to be recovered after a long period of time in which there was complete forgetting that they had ever happened. It has sometimes been suggested that many, if not all, of these apparent recovered memories are the product of inappropriate therapeutic suggestion. This argument has been promulgated in particular by the False Memory Syndrome Foundation in the United States, by its counterpart, the British False Memory Society, and by their scientific advisors.

The 'false memory' position

Loftus[1] suggested that at least some of the memories of child sexual abuse recovered in therapy after apparent total amnesia may not be veridical, but may be false memories encouraged or 'implanted' by therapists who have prematurely decided that the patient is an abuse victim and who use inappropriate therapeutic techniques to persuade him or her to recover corresponding 'memories'. The false memory societies have claimed that there are many cases known to them in which previously happy families have been disrupted by accusations of abuse that were only triggered when an adult child entered therapy. Particular scepticism has been levelled at reports of repeated abuse, all of which has apparently been forgotten, and it has been claimed that such reports are contradicted by what is known scientifically about memory. Reports of 'repressed' memories of childhood abuse are generally regarded as clinical speculations and the psychoanalytical concept of repression as one that has no credible scientific support.

Several reviewers claim that there is no empirical support for repression or dissociative amnesia in trauma victims.[2–4]

Lindsay and Read[5] have marshalled evidence to suggest that the creation of false memories within therapy is a possibility that must be taken seriously. For example, they review experimental studies conducted with non-clinical subjects concerning the fallibility and malleability of memory, and note the potential for inaccurate recall involved in techniques such as hypnosis. Experiments have demonstrated that people are sometimes confused about whether a recent event in the laboratory actually happened, or whether they only imagined it happening. Other experiments have repeatedly succeeded in implanting apparent childhood memories of single non-abusive events in approximately 25 to 30 per cent of subjects, particularly in those who score highly on measures of hypnotizability or suggestibility.[6] Further evidence comes from individuals who claim to remember impossible events such as being kidnapped by aliens.[4]

Critics have argued that these experiments are a long way from being evidence that therapists could implant false memories of child abuse, and even the experimental studies have shown that successful suggestion depends on the plausibility of the event subjects are asked to believe in. Nevertheless, although no one has performed experiments in an attempt to implant the notion that abuse occurred, it is reasonable to argue that some patients may be highly suggestible and inclined to go along with the beliefs of therapists who may be their only source of support. If their therapist was convinced that abuse had occurred, put overt or covert pressure on their patient to 'remember' this abuse, and was insufficiently alert to the unreliability of memory, there would be a greatly increased risk of false memories occurring.

In conclusion, the recently developed 'false memory' position goes beyond previous concerns of a general nature about errors in memory, and specifically identifies a process whereby errors arise after a person has been subjected to repeated suggestive influences that the explanation for their symptoms lies in forgotten child sexual abuse. These influences are usually thought to occur in therapy, although it has been proposed that exposure to certain books or broadcast media may have the same effect. This position relies partly on information from the false memory societies about their members, and partly on experimental evidence from non-traumatic procedures in the laboratory. There has been little independent scrutiny of the data from members of false memory societies, and many of their claims, for example that parents have been falsely accused, that accusations only follow entry into therapy, or that there is a 'false memory syndrome', are anecdotal and have not been empirically verified.[7]

Evidence for genuine 'recovered memories'

Over 20 longitudinal and retrospective studies have now found that a substantial proportion of people reporting child sexual abuse (somewhere between 20 and 60 per cent) report periods in their lives (often lasting for several years) when they could not remember that the abuse had taken place.[8,9] Although the rates vary between studies, broadly similar findings have been obtained by clinical psychologists, psychiatrists, and cognitive psychologists in both clinical and community samples. As has been pointed out by critics of these studies, this evidence supports the forgetting of trauma, but does not yet have much to say about the mechanism (for example 'repression') by which it occurs. Thus it would be true to say that while there is evidence for forgetting, there is little evidence for 'repression' as such.

Three main factors support the argument that these apparently forgotten memories are not necessarily false.

1 Surveys have also found recovered memories of other traumatic experiences such as witnessing accidents, experiencing medical procedures, and physical abuse in childhood.[10] It is unclear how these could have been brought about by suggestion.

2 A number of studies have found that apparent recovered memories occur prior to any therapy, and in the absence of any obvious prolonged suggestive influence.[11] Again, it is unclear how these could have been brought about by suggestion.

3 Surveys of psychologists and therapists found that approximately 40 per cent of those with apparent recovered memories reported corroborative evidence for the content of the memories, such as abusers' confessions, testimony from other victims, and court records. Although the quality of this corroboration has been criticized, it seems unlikely that all these cases can be summarily dismissed. There are also substantial numbers of case studies reporting more detailed corroborative evidence for apparent recovered memories, some of this evidence of reasonably high quality.[10–12]

The quality of the research evidence supporting genuine recovered memories is mixed, and almost all the studies can be argued to have some flaws, but taken together the evidence for genuine memories of major traumatic events is far more extensive than the evidence for false memories of such events. Moreover, these observations need not, as has sometimes been claimed, contradict what we know about memory. Cognitive psychology recognizes that ordinary memory relies as much for its efficiency on the ability to inhibit unwanted material as on the ability to gain rapid access to relevant material. Experimental studies clearly demonstrate the inhibition of memory retrieval and the existence of a subgroup of individuals with poor memories for negative experiences.[11]

The intimate neuroanatomical connections between brain circuits involved in emotion and those involved in memory provide a good reason for believing that memory may not behave in the same way under conditions of extreme real-world stress as it does in ordinary laboratory experiments. Whereas high levels of arousal often make events more difficult to forget, it has been argued by several well-known neuroscientists that extraordinarily high levels of catecholamines or other neuropeptides at the time of the trauma, perhaps in combination with a failure to release sufficient cortisol, may produce amnesia. More specifically, it has been suggested that extreme stress produces at the same time both enhanced fear conditioning and impaired autobiographical memory.[13] Much of the evidence is indirect and not yet compelling, but it illustrates that claims concerning recovered memories of trauma need not violate current knowledge concerning the cognitive psychology and neurobiology of memory.

Why the debate?

From a purely scientific point of view, it should be evident that the quality of the available evidence is insufficient to justify any extreme position at present. The questions are extremely difficult to study

empirically, and there has been little new research since the 1990s to suggest that this state of affairs is likely to change. However, scientific considerations have sometimes been secondary to the passionate advocacy practised by parents who claim to be falsely accused, and by accusers who claim that their memories of abuse are being ignored. Psychiatrists and psychologists have in the past become caught up in the debate and in some cases abandoned any pretence at neutrality. In the face of these compelling and intensely painful personal concerns, the quality of much of the argument became debased. Thus, supposedly scientific contributions on both sides of this debate questioned the motives and integrity of people with whom they disagreed and attempted to disparage opponents' professional abilities. Some of these same authors made exclusive claims for the scientific legitimacy of their own perspective, subjecting opposing data to fierce scrutiny while being relatively uncritical of studies that supported their point of view. Much of the literature was obfuscatory and confusing. Logical errors abounded, seen for example in the conclusion that because a memory has been recovered in therapy, the practitioner must have been using 'recovered memory therapy'.

A good example of the debate in action is the article by Pope *et al.*[4] on the evidence for dissociative amnesia in trauma victims and the commentary that followed it.[14] These articles demonstrate how widely differing conclusions can be drawn from the same set of studies, depending on the way terms are defined, on assumptions about what evidence should be given the most weight, and on the rigour with which alternative explanations are evaluated.

An emerging scientific and professional consensus

What should be clear by now is that extreme views, claiming that either false memories or genuine recovered memories are rare or impossible, cannot be supported by the available data. Nevertheless, the dispute continues about whether traumatic events, and particularly repeated traumas, can be forgotten and then remembered with essential accuracy. In my view it is safe to conclude from the evidence reviewed that the hypothesized implantation of false memories by practitioners cannot account for more than a subset of recovered memories (and at present it is entirely unclear how large or small this subset might be). False memories may certainly arise in other circumstances, but as yet there is little pertinent evidence. On the other hand, there is a great deal of plausible evidence supporting the existence of genuine recovered memories.

Most commentators, including some members of the advisory boards of false memory societies,[6] now accept that traumatic events can be forgotten and then remembered. Cognitive psychologists Lindsay and Read[5] summed it up well: 'In our reading, scientific evidence has clear implications . . . memories recovered via suggestive memory work by people who initially denied any such history should be viewed with scepticism, but there are few grounds to doubt spontaneously recovered memories of common forms of child sexual abuse or recovered memories of details of never-forgotten abuse. Between these extremes lies a grey area within which the implications of existing scientific evidence are less clear and experts are likely to disagree'. Similarly, the consensus view among independent commentators, repeated in the 1995 report of the British Psychological Society's Working Party on Recovered Memories and the 1995 interim statement of the American Psychological Association's Working Group on Investigation of Memories of Childhood Abuse, is that memories may be recovered from total amnesia and they may sometimes be essentially accurate. Equally, such 'memories' may sometimes be inaccurate in whole or in part.

In practical terms, the debate has had two major effects. First, proponents of 'recovered memory therapy' are now almost impossible to find within the ranks of leading psychiatrists and psychologists. Despite the small amount of empirical support, there is widespread agreement that situations in which there is sustained suggestive influence, such as therapy, do have the potential to induce false memories. Active attempts to recover suspected forgotten memories may sometimes be appropriate in unusual or extreme cases, but both the client and the therapist must be aware of the risk of false memories. Techniques such as hypnosis and guided imagery should not be used without safeguards against potential suggestive influence. Second, good practice now requires both the therapist and the client to adopt a critical attitude towards any apparent memory that is recovered after a period of amnesia, whether or not this is within a therapeutic context, and not to assume that it necessarily corresponds to a true event. Even highly vivid traumatic memories (sometimes known as 'flashbacks') may be misleading or inaccurate in some cases. Clinical guidelines are now available to help the practitioner avoid the twin perils of uncritically accepting false memories as true or summarily dismissing genuine recovered memories.[9,15]

4.6.4 Adjustment disorders

James J. Strain, Kimberly Klipstein, and Jeffrey Newcorm

Introduction

The psychiatric diagnoses that arise between normal behaviour and major psychiatric morbidities constitute the problematic subthreshold disorders. These subthreshold entities are also juxtaposed between problem-level diagnoses and more clearly defined disorders. Adjustment disorder (AD) would 'trump' problem-level disorders, but would be 'trumped' by a specific diagnosis even if it were in the NOS category. The subthreshold disorders present major taxonomical and diagnostic dilemmas in that they are often poorly defined, overlap with other diagnostic groupings, and have indefinite symptomatology. It is therefore not surprising that issues of reliability and validity prevail. One of the most commonly employed subthreshold diagnosis that has undergone a major evolution since 1952 is AD (Table 4.6.4.1). The advantage of the indefiniteness of these subthreshold disorders is that they permit the classification of early or prodromal states when the clinical picture is vague and indistinct, and yet the morbid state is in excess of that expected in a normal reaction and this morbidity needs to be identified and often treated. Therefore, AD has an essential place in the psychiatric taxonomy.

Many questions prevail with regard to the concept of the AD diagnosis: (1) the role of stressors and the place of specific stressors; (2) the importance of age; (3) the role of concurrent medical morbidity, for example comorbidity of Axis I and/or Axis III disorders; (4) the lack of specificity of the diagnostic criteria; (5) the absence of a symptom checklist; (6) uncertainty as to optimal treatment protocols; and (7) undocumented prognosis or outcomes. Research data regarding these questions will be examined.

The DSM was conceptually designed with an atheoretical framework to encourage psychiatric diagnoses to be derived on phenomenological grounds with an avowed dismissal of pathogenesis or aetiology as diagnostic imperatives. In frank contradiction to this atheoretical conceptual framework, the stress-induced disorders require the inclusion of an aetiological significance to a life event—a stressor—and the need to relate the stressor's effect on the patient in clinical terms. However, the stress-related disorders are unique in that they are psychiatric diagnoses with a known aetiology—the stressor—and thus aetiology is essential for the diagnosis. Four other diagnostic categories also invoke aetiology in their diagnostic criteria: (1) organic mental disorders (aetiology-physical abnormality); (2) substance abuse disorders (aetiology-ingestion of substances); (3) post-traumatic; and (4) acute stress disorders

Table 4.6.4.1 DSM-IV Evolution of the diagnosis for adjustment disorder

(a) The development of emotional or behavioural symptoms in response to an identifiable psychosocial stressor(s), which occurs within 3 months of the onset of the stressor(s)

(b) These symptoms or behaviours are clinically significant as evidenced by either of the following

1 Marked distress that is in excess of what would be expected from exposure to the stressor

2 Significant impairment in social or occupational (academic) functioning

(c) The stress-related disturbance does not meet the criteria for any specific Axis I disorder and is not merely an exacerbation of a pre-existing Axis I or Axis II disorder

(d) The symptoms do not represent bereavement

(e) Once the stressor (or its consequences) has terminated, the symptoms do not persist for more than an additional 6 moths

Specify if:

Acute: if the disturbance lasts less than 6 months.

Persistent/chronic: if the disturbance lasts for 6 months or longer

AD is a stress-related phenomenon in which the stressor precipitates maladaptation and symptoms that are time limited until either the stressor is diminished or eliminated, or a new state of adaptation to the stressor occurs (Table 4.6.4.2). At the same time that AD was evolving, other stress-related disorders, for example, post-traumatic stress disorder and acute stress disorder were described. (Acute stress disorder was formulated by Spiegel during the development of the DSM-IV.[1,2]) Acute stress reactions could result from involvement in a natural disaster such as a flood, or an avalanche, or a cataclysmic personal event, for example, loss of a body part (aetiology-an identifiable stressor).

The diagnosis of AD also requires a careful titration of the timing of the stressor in relation to the adverse psychological sequelae that ensue. Maladaptation and disturbance of mood should occur within 3 months of the patient experiencing the stressor. Until the DSM-IV criteria, the ADs were regarded as transitory diagnoses that should not exceed 6 months in duration. Thereafter, that diagnostic appellation could not be employed and had to be changed to a major psychiatric disorder or discontinued.

Definition and history

With the opportunity in 1994 to develop another evolutionary step of the DSM, i.e. DSM-IV,[3] the authors were asked to re-examine the subthreshold diagnostic category of AD with the goal of

Table 4.6.4.2 ICD-10 definition of adjustment disorder

(a) Onset of symptoms must occur within 1 month of exposure to an identifiable psychosocial stressor, not of an unusual or catastrophic type
(b) The individual manifests symptoms or behavioural disturbances of the types found in any of the affective disorders (except for delusions and hallucinations), any disorders in F40–F48 (neurotic, stress-related, and somatoform disorders) and conduct disorders, but the criteria for an individual disorder are not fulfilled. Symptoms may be variable in both form and severity
The predominant feature of the symptoms may be further specified by use of a fifth character:
Brief depressive reaction Prolonged depressive reaction Mixed anxiety and depressive reaction With predominant disturbance of other emotions With predominant disturbance of conduct With mixed disturbance of emotions and conduct With other specified predominant symptoms
(c) Except in prolonged depressive reaction, the symptoms do not persist for more than 6 months after the cessation of the stress or its consequences. However, this should not prevent a provisional diagnosis being made if this criterion is not yet fulfilled

improving its acknowledged 'shortcomings'. The research included: review of the literature, reanalysis of existing studies of AD and their data sets, and examination of field studies (e.g. minor depression, minor anxiety) to observe if there was sufficient differentiation among these minor disorders from the ADs (e.g. how often was a stressor identified in those patients assigned the diagnosis; minor depression or minor anxiety?). From these three sources and consultations, modifications for DSM-IV and their rationale were formulated based on the best evidence extant.

Changes in the criteria for adjustment disorder in DSM-IV

The review of the literature, the reanalysis of the Western Psychiatric Institute and Clinic data (University of Pittsburgh), and consultations with experts supported the following changes in DSM-IV.

1 Enhance the understanding of the language.

2 Describe the timing of the reaction to reflect the duration of the AD: **acute** (less than 6 months) or **chronic** (6 months or greater).

3 Allow for the continuation of the stressor for an indefinite period; psychological reactions to chronic stress states (e.g. chronic arthritis, HIV, abuse by an alcoholic spouse) do not necessarily terminate at 6 months, nor do they necessarily lead to a major psychiatric disorder.

4 Eliminate the subtypes of mixed emotional features, work (or academic) inhibition, withdrawal, and physical complaints (as they were rarely employed by diagnosticians).

Although it might be argued that ADs could be placed in a new category of 'stress response syndromes', the literature and research reports did not support such a taxonomical organization. Another possibility was that AD could be eliminated altogether, with the advantage of maintaining the atheoretical approach of the DSM conceptual framework, and substitute in its place the appropriate minor or NOS categories as established by the accompanying mood states or behaviours. However, these solutions do not seem appropriate with recent findings that demonstrate AD to be a valid and frequently employed diagnosis.[4] AD was diagnosed in over 60 per cent of burned inpatients,[5] over 20 per cent of patients in early stages of multiple sclerosis,[6] and over 40 per cent of poststroke patients.[7] Furthermore, evaluations of patients in a psychiatric walk-in clinic showed a significant difference in the symptom profile of those assigned AD and the other diagnosis, including minor diagnoses.[8] (The McArthur field trials on the prospective assessment of minor depressive and anxiety disorders which collected data on the occurrence of stressors immediately preceding the outbreak of symptoms are important databases that need further study to establish whether stress per se is a distinguishing characteristic between AD and the other minor mood disorders.)

Problems with the adjustment disorder diagnosis

(a) The symptom profile

Critics of the AD diagnosis argue that the symptom complex is too subjective or 'depends structurally on clinical judgement' as opposed to sound, operational criteria.[9,10] Because of the lack of any quantitative behavioural or operational criteria, the problem of reliability and validity are obvious. Criterion reference was evaluated by Aoki *et al.*[11] who reported that three psychological tests, Zung's Self-Rating Anxiety Scale,[12] Zung's Self-Rating Depression Scale,[13] and the Profile of Mood States,[14] were useful tools for the diagnosis of AD in physical rehabilitation patients. While these measures succeeded in reliably differentiating AD patients from normal patients, they were not able to distinguish them from patients with major depression or post-traumatic stress disorders. Thus, the construct of AD is designed as a means for classifying psychiatric conditions having a symptom profile that is at the time of its application insufficient to meet the more specifically operationalized criteria for the major syndromes but is:

1 clinically significant and deemed to be in excess of a normal reaction to the stressor in question;

2 associated with impaired vocational or interpersonal functioning;

3 not solely the result of a psychosocial problem (V Code) requiring medical attention (e.g. non-compliance, phase of life problem, etc.).

However, field studies are being performed[15] to assess whether a reliable checklist from an elaborate list of symptoms associated with AD can be constructed (Table 4.6.4.3). (The V Codes—a problem level of diagnoses—are understandably devoid of a symptom-based diagnostic schema.)

Table 4.6.4.3 DSM-IV subtypes of adjustment disorders

Adjustment disorder with depressed mood
Adjustment disorder with anxious mood
Adjustment disorder with mixed anxiety and depressed mood
Adjustment disorder with disturbance of conduct
Adjustment disorder with mixed disturbance of emotions and conduct
Adjustment disorder unspecified

(b) The meaning of 'maladaptive'

The imprecision of the diagnostic criteria for AD is immediately apparent in the DSM-IV description of this disorder as a maladaptive reaction to an identifiable psychosocial stressor, or stressors that occurs within 3 months after onset of the stressor. It is assumed that the disturbance will remit soon after the stressor ceases or, if the stressor persists, when a new level of adaptation is achieved.[1] In addition to the problem of no symptom checklist, difficulties are inherent within each of these diagnostic elements.

First, with regard to the 'maladaptive reaction', it is unclear how this concept can or should be operationalized. Is the assessment of maladaptation subjective or objective? Who makes the decision—a third party, a mental health professional, the patients themselves, or an admixture of these? Is this decision 'culture bound'? Succinctly when does an individual cross the threshold into 'patienthood', and who will make the decision? Powell and McCone (2004) make this point in their case report of the treatment of a patient with AD secondary to the stressors of the 11 September terrorist attacks. Since there has never before been a large-scale terrorist attack in United States, how are clinicians to know what a 'normal' response to such an event would be?[16]

(c) The stressor

Most recently, in the DSM-IV text revision (DSM-IV-TR; American Psychiatric Association, 2000),[17] the term psychosocial stressor was changed to the broader concept of stressor. Emotional reactions to physical stress, such as the Chernobyl reactor incident[18] or cardiac surgery[19] are well documented in literature and suggest that psychosocial stressor as a criterion is too restrictive. Moreover, the concept of 'psychosocial' versus 'physical' stressors has led to confusion.[20]

Obviously, the stressor and its effect are central to the AD diagnosis. The second major confound emanates from the fact that the DSM-IV presents no criteria or 'guidelines' to quantify stressors or to assess their effect or meaning for a particular individual at a given time. Furthermore, the assessment of stress is not linked by an algorithm to Axis IV—a statement of stress—during the previous year and so internal consistency or reinforcement within the diagnostic lexicon is not mandated (D. Schafer, personal communication, 1990). Mezzich *et al.*[8] attempted to classify and quantify the psychosocial stressors in 13 specific domains: health, bereavement, love and marriage, parental, family stressors for children and adolescents, other familial relationships, other relationships outside the family, work, school, financial, legal, housing, and miscellaneous. Such specificity has not been defined in DSM-IV and the construct is vague and generic with minimal opportunity to achieve quantification. Despland *et al.*[21] observed that the type of stressor may indeed be of help in diagnosing AD. His study demonstrated that AD with depressed mood and mixed mood was associated with more marital problems than major depressive disorders. AD with anxiety could be distinguished from the major anxiety disorders by the quantity of family and marital problems.

(d) The time course

The time course and chronicity of both stressors and their consequent symptoms were left vague in DSM-IIIR and were not consistent with the clinical situation. The modifications introduced in DSM-IV, which differentiate between *acute* and *chronic* forms of AD, solved the problem of the 6-month limitation of the AD diagnosis in DSM-IIIR and is more in keeping with what is observed in the clinical situation. This change was validated by Despland *et al.*[21] who observed that 16 per cent of patients with AD required treatment longer than 1 year—the mean exceeded the prior limitation of 6 months.

Other problems of definition

Even serious symptomatology (e.g. suicidal behaviour) that is not regarded as part of a major mental disorder requires treatment and a 'diagnosis' under which it can be placed, for example a V Code, 'Phase of Life Problem', AD, acute stress response, etc. De Leo *et al.*[22,23] reported on AD and suicidality. Recent life events, which would constitute an acute stress, were commonly found to correlate with suicidal behaviour in a patient cohort which included those with AD.[24] Spalletta *et al.*[25] observed the assessment of suicidal behaviour to be an important tool in the differentiation among major depression, dysthymia, and AD. AD patients were found to be among the most common recipients of a deliberate self-harm diagnosis, with the majority involving self-poisoning.[26] Thus deliberate self-harm is more common in AD patients,[26] while the percentage of suicidal behaviour was found to be higher in AD patients with depressed mood.[25]

The AD DSM-IV Work Group suggested that suicide and deliberate self-harm could be subtypes of AD. However, there were concerns that patients with other diagnoses, for example major affective disorder, borderline personality disorder, etc. and suicide behaviour, would be assigned the AD diagnosis since there was a specific placement for suicidal ideation and behaviour and that would be a predominant reason to use AD. The final decision was to place the problem of suicidal symptomatology without a psychiatric diagnosis in the DSM-IV F Code section for other problems 'that may be a focus of clinical attention'. Obviously a subthreshold diagnosis, AD, does not necessarily imply the presence of subthreshold symptomatology!

Recognizing some of the limitations of the diagnosis including the aforementioned lack of specificity of symptoms and the lack of clarity of the role of the stressor, the authors of a recent article proposed adding an additional 'A-Criterion' to the DSM IV diagnosis of AD. They studied 328 young conscripts diagnosed by DSM IV with AD secondary to non-combat military stress. The diagnosis was closely associated with undisturbed psychosocial function outside of military life but with marked symptoms within military life.[9] Thus, location-specific stress was associated with location-specific symptoms, a phenomenon that the authors found helpful in distinguishing AD from other psychiatric diagnoses. Whether or not this finding would be consistent in non-military populations requires further evaluation.

'Splitting' and 'lumping' continue, for example, the subthreshold diagnosis of mixed anxiety-depressive disorder is a new category included in the DSM-IV. This disorder is very similar to AD with mixed mood; a boundary between the two is difficult to demarcate. The main difference between the two diagnoses was the chronicity of the mixed anxiety-depressive disorder (as was noted in the mixed anxiety-depression field trial).[27] The change in criterion C for AD—allowing a chronic or recurrent disturbance—confounds the differentiation of these two subthreshold diagnoses. This uncertainty is further complicated by the question of treatment. Is this

an anxiety accompanied by depression, which should be treated with anxiolytics, such as benzodiazepines, or is this a depression accompanied by anxiety, which should be treated with an antidepressant, such as a selective serotonin reuptake inhibitor (SSRI)? Furthermore, it is commonly viewed that the majority of patients with AD should be treated with psychotherapy or counselling as the initial approach.

Another potential mood disorder, subsyndromal symptomatic depression (**SSD**), has been suggested.[28] It joins AD in the grey area of subthreshold diagnoses. However, there are two critical differences between SSD and AD: SSD employs a symptom checklist, and is not associated with a stressor. By definition, SSD is the simultaneous presence of any two or more symptoms of depression, persistent for most or all of the time for a duratio of at least 2 weeks, associated with social dysfunction, and occurring in patients who do not meet the criteria for minor depression (which also requires two symptoms), major depression, and/or dysthymia.[28] In some cases, the SSD diagnosis is the same as the DSM-IV diagnosis for minor depression, termed by the authors 'SSD with mood disturbance', and has to be documented as such. In other cases, the disorder is 'SSD without mood disturbance'.

In a recent study, Casey *et al.* (2006) examined variables that might distinguish AD from other depressive episodes. The patients were screened for depression severity with the Beck Depression Inventory (BDI) and then interviewed with the Schedule for Clinical Assessment in Neuropsychiatry (SCAN) which includes questions assessing the presence of AD. The authors were unable to find any independent variables that distinguished AD from other depressive episodes, including the severity of the BDI score at the outset.[29] Maercker *et al.* conceptualize AD as a stress response syndrome in which intrusions, avoidance of reminders, and failure to adapt are the central processes and symptoms.[30]

Age and medical comorbidity

In contrast with DSM-IIIR, DSM-IV has tried to accommodate the presence of comorbid medical illness. DSM-IIIR was regarded as 'medical illness and age unfair' (i.e. inadequate consideration of age and/or medical illness) (L. George, personal communication, 1981).[31] To enhance reliability and validity, there will need to be a psychiatric taxonomy that takes into account medical illness and symptomatology and developmental epochs (e.g. children and adolescents, adults, 'young' elderly, and 'old' elderly). (Actually, the original DSM did divide the AD by developmental epochs.) It is clear from the Western Psychiatric Institute studies that the symptom profile for children and adolescents is very different from that for adults with regard to the entire spectrum of diagnoses. With regard to age, recent studies report AD patients to be significantly younger compared with those with major psychiatric diagnosis.[21,32] Zarb's study[33] suggests that in cognitively impaired elderly, using individual items of the Geriatric Depression Scale, AD could be differentiated from major depression. In addition, Despland *et al.*[21] showed that patients labelled AD with depressive or mixed symptoms included more women: a sex ratio resembling that seen in major depression or dysthymia. The future evolution of the DSM needs to consider the effect of developmental epochs, gender, and medical comorbidity on symptom profiles in the various diagnostic categories.

Grassi *et al.*[34] investigated psychosomatic symptoms in patients with AD in a hospital setting in order to further characterize the diagnosis of AD in the medically ill. Results showed a considerable overlap between AD and abnormal illness behaviour including health anxiety, somatization, conversion symptoms, and demoralization among others. Only 13 out of 100 AD patients interviewed did not present with psychosomatic symptoms.

Epidemiology

The Epidemiologic Catchment Area Study (ECA) did not include AD in its historic survey of patients in the population of five major settings in the United States. Most studies are of smaller or more discrete samples and have the problem of generalization. Andreasen and Wasek[35] reported that 5 per cent of an inpatient and outpatient sample at the university hospital and clinics in Iowa were labelled as having AD. Fabrega *et al.*[36] reported that 2.3 per cent of a sample of patients presenting to a walk-in clinic (diagnostic and evaluation centre) met criteria for AD, with no other diagnoses on Axis I or Axis II; when patients with other Axis I diagnoses (i.e. Axis I and II comorbidities) were included, 20 per cent had the diagnosis of AD. In general hospital inpatient psychiatric consultation populations, AD was diagnosed as 21.5 per cent, 18.5 per cent, and 11.5 per cent, respectively.[37–39] D. Schafer (personal communication, 1990) noted that up to 70 per cent of children in the psychiatric setting may be given the diagnosis of AD in a variety of mental health care environments. Faulstich *et al.*[40] reported the prevalence of AD for adolescent psychiatric inpatients. Andreasen and Wasek,[35] utilizing a chart review, reported that more adolescents than adults experienced acting out and behavioural symptoms, but adults had significantly more depressive symptomatology (87.2 per cent versus 63.8 per cent). Anxiety symptoms were frequent at all ages.

Mezzich and coworkers[8] evaluated 64 symptoms currently present in three cohorts: subjects with specific diagnoses, those with AD, and those who were not ill. Vegetative, substance use, and characterological symptoms were greatest in the specific diagnosis group, intermediate in the AD group, and least in the group with non illness. The symptoms of mood and affect, general appearance, behaviour, disturbance in speech and thought pattern, and cognitive functioning had a similar distribution. The AD group was significantly different from the non-illness group with regard to more 'depressed mood' and 'low self-esteem' ($p \leq 0.0001$). The AD and non-illness groups had minimal pathology of thought content and perception. A positive response on the suicide indicators was obtained in 29 per cent of AD compared with 9 per cent of the non-illness group. The three cohorts did not differ on the frequency of Axis III disorders.

Associated features of adjustment disorder

Andreasen and Wasek[35] observed that in their AD cohorts 21.6 per cent of the adolescents' fathers and 11.8 per cent of the adults' fathers had problems with alcohol. Greenberg *et al.*[41] report more substance abuse in adults with diagnosed AD compared with all those with other diagnoses. Breslow *et al.*[42] comparing patients with AD and other psychiatric diagnoses, observed that alcohol or substance use/abuse did not help to differentiate between diagnostic groups. Thus, currently the higher rate of substance use does not serve as an incontrovertible predictive factor for the diagnosis of an AD diagnosis.

Aetiology—the role of stress

(a) Nature of the stressor

Andreasen and Wasek[35] described the differences between the chronicity of stressors found in adolescents compared with those in adults: present for a year or more, 59 per cent and 35 per cent; present for 3 months or less, 9 per cent and 39 per cent. Fabrega *et al.*[36] reported that their AD group had greater registration of stressors compared with other diagnoses and the non-illness cohorts. Compared with other diagnoses and the non-illness patients, AD was over-represented in the 'higher stress category'. In their consultation cohort, Popkin *et al.*[37] found that in 68.6 per cent of the cases the medical illness itself was judged to be the primary psychosocial stressor. Snyder and Strain[39] observed that stressors as assessed on Axis IV were significantly higher (p = 0.0001) for consultation patients with AD than for patients with other diagnostic disorders.

(b) Modifiers of stress

Stress has been described as the aetiological agent for AD. Vulnerability to stress is another risk factor. Diverse variables and modifiers are involved regarding who will experience AD following a stress. Cohen[43] argues as follows:

1 acute stresses are different from chronic stresses in both psychological and physiological terms;

2 the meaning of the stress is affected by 'modifiers' (e.g. ego strengths, support systems, prior mastery);

3 manifest and latent meanings of the stressor(s) may be associated with differential impact (e.g. loss of job may be a relief or a catastrophe).

An objectively overwhelming stress may have little impact on one individual, whereas a minor stress could be regarded as cataclysmic by another. A recent minor stress superimposed on a previous underlying (major) stress that has no observable effect on its own may have a significant additive impact (i.e. concatenation of events) (B. Hamburg, personal communication, 1990). Despland *et al.*[21] reported that stressors were present on Axis IV in 100 per cent of those assigned AD with depressed mood, while it was present in 83 per cent of those with major depression, 80 per cent of those with dysthymia, and 67 per cent of those with non-specific depression, which emphasizes the importance of stressors in the AD diagnosis.

Clinical features

Nine different types of AD are listed in DSM-IV.[1] As in DSM-III, AD is classified in DSM-IIIR according to the predominant symptom picture. In DSM-IV, AD has been reduced to six types that, again, are classified according to their clinical features:

1 AD with depressed mood;

2 AD with anxious mood;

3 AD with mixed anxiety and depressed mood;

4 AD with disturbance of conduct;

5 AD with mixed disturbance of emotions and conduct; and

6 AD not otherwise specified.

In their study, Despland *et al.*[21] suggested reducing the subtypes even further, demonstrating identical profiles for AD with depressed mood and AD with mixed mood, and proposing assimilation of mixed mood into the depressed mood category. Fifty-seven per cent of their sample was represented by these two groups; the remainder was accounted for by AD with 'anxiety' and 'other' categories.

Treatment

(a) Evidence regarding treatment

In terms of randomized controlled trials (RCTs), a search of the Cochrane Database revealed only two RCTs on psychotherapeutic treatment of AD. Gonzales-Jaimes and Turnbull-Plaza (2002) showed that 'mirror psychotherapy' for patients suffering from AD with depressed mood secondary to a myocardial infarction was both an efficient and effective treatment. Mirror therapy is described as a type of therapy with psychocorporal, cognitive, and neurolinguistic components with a holistic focus. As part of the treatment, a mirror is used to encourage patient acceptance of his/her physical condition that resulted from past self-care behaviours. In this study, mirror therapy was compared to two other treatments, Gestalt psychotherapy or medical conversation in addition to a control group. Depressive symptoms improved in all treatment groups compared with the control group, but mirror therapy appeared significantly more effective than the other treatments in decreasing symptoms of AD at post-test evaluation.[44]

In a second RCT, an 'activating intervention' was carried out for the treatment of AD which had resulted in occupational dysfunction. A total of 192 employees were randomized to receive either the intervention or care as usual.[45] The intervention consisted of an individual cognitive behavioural approach to a graded activity, similar to stress inoculation training. Goals of treatment emphasized the acquisition of coping skills and the regaining of control. The treatment proved to be effective in decreasing sick leave duration and shortening long-term absenteeism when compared to the control group; both intervention and control groups, however, showed similar amounts of symptom reduction. This study formed the basis for the Dutch Practice Guidelines for the treatment of AD in primary and occupational health care.[46] These guidelines were prepared by a team of 21 occupational health physicians and one psychologist and subsequently reviewed and tested by 15 experts, including several psychiatrists and psychologists and 21 practicing occupational health physicians.

Though no other RCTs involving the psychotherapeutic treatment of pure cohorts of patients with AD could be found, many RCTs exist that studied an array of depressive and anxiety disorders and that included AD in their cohorts. For example, a recent trial comparing brief dynamic therapy (BDT) with brief supportive therapy (BSP) in patients with minor depressive disorders, including AD, was found in the Cochrane Database. Though both therapies proved efficacious in reducing symptoms, BDT was more effective as demonstrated in a 6 months follow-up.[47]

Another therapeutic modality, eye movement desensitization and reprocessing (EMDR) has been recently studied in patients with AD.[48] EMDR, a psychotherapeutic technique shown to be effective in the treatment of post-traumatic stress disorder, was carried out on nine patients suffering from AD. Results showed significant improvement in patients with anxious or mixed features but not in those with depressed mood. Additionally, those with ongoing stressors did not show improvement.

Hameed *et al*. in a retrospective chart review sought to determine if there was a difference in antidepressant efficacy in the treatment of major depressive disorder versus AD in a primary care setting. Patients had been prescribed mostly SSRIs. DSM-IV symptoms, Patient Health Questionnaire-9 (PHQ-9) depression rating scale scores, and functional disability reports were systematically used to assess patients' response. Results showed that neither depressed, nor AD patients demonstrated a difference in clinical response to any particular antidepressant. Patients with a diagnosis of AD, however, were twice as likely to respond to standard antidepressant treatment as depressed patients. This study suggests that antidepressants are very effective in treating depression in the primary care setting and may be even more effective in the treatment for AD with depressed mood.[49]

In another recent double-blind RCT, the efficacies of etifoxine, a non-benzodiazepine anxiolytic drug, and lorazepam, a benzodiazepine, were compared in the treatment of AD with anxiety in a primary care setting.[50] Efficacy was evaluated on days 7 and 28 using the Hamilton Rating Scale for Anxiety (HAM-A). The two drugs were found to be equivalent in anxiolytic efficacy on day 28. However, more etifoxine recipients responded to the treatment. Moreover, 1 week after stopping treatment, fewer patients taking etifoxine experienced rebound anxiety, compared to those given lorazepam.[50]

Management

(a) Psychotherapy and counselling

Though brief therapeutic interventions are usually all that are needed, ongoing stressors or enduring character pathology that may make a patient vulnerable to stress intolerance may signal the need for lengthier treatments.[51]

Treatment of AD initially focuses on psychotherapeutic and counselling interventions to reduce the stressor, enhance the capacity to cope with a stressor that cannot be reduced or removed, and establish a system of support to maximize adaptation. The patient needs to be made aware of the significant dysfunction that the stressor has caused and consider strategies to manage the disability. Some stressors, for example taking on more responsibility than can be managed by the individual or putting oneself at risk (e.g. unprotected sex with an unknown partner), can be avoided or minimized. Other stressors may elicit an overreaction on the part of the patient (e.g. abandonment by a lover). The patient may attempt suicide or become reclusive, damaging his or her source of income. In this situation, the therapist would assist the patient to verbalize his or her disappointed feelings and rage rather than behaving destructively. The role of verbalization in minimizing the discomfort of the stressor and enhancing coping cannot be overestimated. It is necessary to clarify and interpret the meaning/reality of the stressor for the patient. For example, if a mastectomy has devastated a patient's feelings about her body and herself, it is mandatory to articulate that the patient is still a woman, capable of having a fulfilling relationship, including a sexual one and that recurrence of the cancer may not occur. Without the correction of distortions, the patient's pernicious fantasies—'all is lost'—may occur as sequelae to the stressor (i.e. the mastectomy) and intensify incapacitation at work and/or sex, as well as contribute to a profound disturbance of mood.

Counselling, psychotherapies, crisis intervention, family therapy, and group treatment are utilized to encourage the verbalization of fears, anxiety, rage, helplessness, and hopelessness to the stressors imposed upon a patient. As mentioned above, the goal of treatment is to expose the concerns and conflicts that the patient is experiencing, identify means to reduce the stressor(s), enhance the patient's coping skills, clarify the patient's perspective on the adversity, and enable the establishment of supporting relationships. The primary treatment for AD is talking.

(b) Psychopharmacotherapy

Should drugs be used in the treatment of AD? The pharmacological studies are not conclusive. The diagnostic dilemmas of the AD present sufficient difficulty in and of themselves.[52–54] It would be preferred that cautious psychotropic drug administration be employed, to avoid subjecting the patient to the risk of unfavourable medical drug-psychotrophic drug interaction(s). Psychotrophic drug treatment will not be necessary if the condition resolves. If it evolves into a major psychiatric illness then drug treatment needs to be actively entertained. And, for a refractory AD treatment with psychopharmacological agents should be considered. Small doses of antidepressants and anxiolytics may sometimes be appropriate for AD patients when dysphoria remains profound despite several sessions of psychological treatment.

Although formal psychotherapy is presently the treatment of choice, psychotherapy combined with benzodiazapines are utilized, especially for patients with severe life stress(es) and an unrelenting anxious component. Tricyclic antidepressants or buspirone were recommended in place of benzodiazapines for AD patients with current or past excessive alcohol use because of their greater risk of dependence.[55] The use of antidepressants may assist some patients if their maladaptation is debilitating and the accompanying mood is pervasive, especially if a trial of psychotherapy has been shown to be ineffective.

Adults and adolescents

Andreasen and Hoenk[56] report that the long-term outcome of AD has a good prognosis for adults, but that a majority of adolescents eventually have major psychiatric disorders. Follow-up at 5 years after original diagnosis of AD revealed that 71 per cent of adults were completely well, 8 per cent had an intervening problem, and 21 per cent had developed a major depressive disorder or alcoholism. However, in adolescents at 5-year follow-up, only 44 per cent were without a psychiatric diagnosis, 13 per cent had an intervening psychiatric illness, and 43 per cent went on to develop major psychiatric morbidity (e.g. schizophrenia, schizoaffective disorders, major depression, bipolar disorder, substance abuse, and personality disorders). In contrast with the adults, the chronicity of the illness and the presence of behavioural symptoms in the adolescents were the strongest predictors for major psychopathology 5 years after the initial AD diagnosis. The number and type of symptoms were less useful than the length of treatment and chronicity of symptoms as predictors of future outcome.

As Chess and Thomas[57] have reported, it is important to note that AD with disturbance of conduct, regardless of age, has a more guarded outcome. In agreement with the findings of Andreasen and Wasek,[35] Chess and Thomas[57] emphasize that:

> a significant number [of AD adolescents] did not improve or even grew worse in adolescence and early adult life. It was not possible to predict the developmental course of the disorder in the early period after its first identification. Hence, we would suggest active appropriate

therapeutic intervention in all cases but especially adolescents [and adequate follow-up].

Spalletta *et al.*[25] report that suicidal behaviour and deliberate self-harm are important predictors in the diagnosis of AD. As mentioned before, these are obviously not subthreshold symptoms; they can lead to the most dire consequence—death. This outcome, when reached, can be neither corrected nor resolved. These behaviours mandate immediate and protective interventions. The diagnosis of AD may suggest that the patient has minor symptomatology. Such erroneous assessment may be life-threatening. There needs to be a definite split from viewing a diagnosis as subthreshold, and therefore assuming the attendant symptoms to be subthreshold. It is similar to labelling a patient with hypochondriasis, which in some settings can influence a more casual physical assessment, when such a patient could have serious physical morbidity concomitant with their hypochondriacal Axis I pathology.

Although most studies do point to a more benign prognosis for the AD, it is important to realize that the risk of serious morbidity and mortality still exists. Several recent studies investigating the association between suicide and AD underscore the importance of monitoring patients closely for suicidality, especially in younger populations. Portzky *et al.* conducted psychological autopsies on adolescents with AD who had committed suicide and found that suicidal thinking in these patients was brief and evolved rapidly without warning.[60] A slightly different profile was found in two other studies that looked at suicide attempters with a diagnosis of AD. These patients were more likely to have poor overall psychosocial functioning, prior psychiatric treatment, personality disorders, substance abuse histories and a current 'mixed' symptom profile of depressed mood and behavioural disturbances.[61,62] A study of the neurochemical variables of AD patients of all ages who had attempted suicide revealed biologic correlates consistent with the more major psychiatric disorders. Attempters were found to have lower platelet MAO activity, higher MHPG activity, and higher cortisol levels than controls. Though these findings differ from the lower MHPG and cortisol levels found in patients with major depression and suicidality, they are similar to findings in other major stress-related conditions.[63]

As mentioned earlier, the diagnosis of an AD may be in the early phase of an evolving disorder that has not yet developed to the extent that full-blown symptoms are evident to reach threshold for a major psychiatric disorder. If a patient continues to worsen, becomes more symptomatic, and does not respond to treatment, it is critical to review the diagnosis for the presence of a major disorder.

A recent report by Jones *et al.* (2002) looked at 10 years of readmission data for various psychiatric diagnoses including the AD. They found that admission diagnosis was a significant predictor of readmission and that AD had the lowest readmission rates.[58] Furthermore, initial psychological recovery from an AD may in large part be attributable to removal of the stressor. This was found to be the case in prisoners who developed AD after being placed in solitary confinement and whose symptoms resolved shortly after their release.[59]

The domains of diagnostic rigour and clinical utility seem at odds for AD. Studies that employ reliable and valid instruments (e.g. depression or anxiety rating scales, stress assessments, length of disability, treatment outcome, family patterns, etc.) would enhance more exact specification of the parameters of the AD diagnosis. Identification of the time course, remission or evolution to another diagnosis, and the evaluation of stressors (characteristics, duration, and the nature of adaptation to stress) would enhance the understanding of the aetiology, mechanisms, and mediators of a stress-response illness.

Studies with adequate symptom checklists rated independently from the establishment of the diagnosis would clarify the threshold between major and minor depression and anxiety, as well as guide an entry threshold to employ the AD diagnosis. Although the upper threshold is established by the specified criteria for major syndromes, the entry threshold between an AD and problem-level diagnoses and normality is undesignated with operational criteria. The careful examination of associated demographic and treatment outcome variables would also enable clinicians to describe more specifically the boundaries among subthreshold diagnoses, problem-level diagnosis, and normal behaviour. Associated features such as family history, biological correlates, treatment response, long-term course, and so forth, are all critical to establishing the validity of a diagnosis. The theory and practice of medicine have demonstrated the need for a comprehensive multidimensional formulation of all these physiological and functional variables to describe an illness and develop the most appropriate working diagnosis.

Subthreshold syndromes can encompass significant psychopathology that must not only be identified but treated (e.g. suicidal ideation/behaviour). Cross-sectionally, AD may appear to be the incipient phase of an emerging major syndrome. Consequently, AD, despite its questionable reliability and validity, serves an important diagnostic function in the practice of psychiatry. Problem- and subthreshold-level diagnoses are critical to the function of any medical discipline. Because this may be the initial phase, or a mild form, of a dysfunction that is not yet fully developed, there is a need to describe the relationship of this incipient state to other potential diagnoses. This lack of specificity and questionable reliability and validity are the hallmark of interface disorders and subthreshold phenomena, whether they are in diabetes mellitus, hypertension, or depression.

As mentioned earlier, the characteristics of a mental disorder vary over the life cycle, and this is clearly illustrated by the AD. Certain developmental epochs may be associated with a particular symptom profile, as seen with acute myocardial infarction or appendicitis. The effect of the stressor may vary, and the assessment of functioning must be 'measured' according to the demands of the developmental stage (e.g. school [adolescents], work [adults], self-care and maintenance [elderly]). The symptom characteristics and functional assessment of other diagnoses may also vary along the developmental schema from birth to senescence; illnesses such as major depressive disorders, organic mental disorders, sexual dysfunctions, and eating disorders need to be 'recast' in another hierarchy to incorporate the stage of the life cycle extant at the time of the assessment, and symptom profiles adjusted accordingly. The normal variations across developmental epochs would make AD and the other psychiatric disorders more reliable and valid across the life cycle. Similarly, there needs to be a consideration of a possible concomitant state of medical illness. The result would be a taxonomy tempered by the vicissitudes of development and medical illness.

A taxonomy which considers the development epoch and the presence of medical illness would be more useful to child

psychiatrists, paediatricians, geriatricians, geriatric psychiatrists, and primary care specialists, who are often convinced that a patient does not conform with today's psychiatry lexicon. A significant number of their patients remain at the problem level of diagnoses with their somatic complaints as well. It is not uncommon for a fever of unknown origin to not be diagnosed, or for a chest pain to remain unspecified. It is the art of medicine that makes it a profession, and a most difficult one, at the interface of medicine and psychiatry, or at the interface of normality and pathology. Freud[64] has emphasized the difficulty of understanding normality and pathology in her assessments of childhood. This important advice would obtain across the life cycle and be an important challenge to the developers of the subthreshold diagnoses (e.g. AD) and the future evolution of the DSM.

4.6.5 Bereavement

Beverley Raphael, Sally Wooding, and Julie Dunsmore

Bereavement is the complex set reactions that occurs with the death of a loved one: the emotions of grief with yearning, angry protest, and sadness; the cognitive processes of understanding and making meaning of the finality and nature of death; and the social, cultural, spiritual, and religious contexts of adaptation. Grief may also result from other losses such as health, home, country, and safe worlds. There have been investigations into potential neurobiological substrates, without, as yet consensus about the explanatory model.

In 'Mourning and Melancholia', Freud[(1)] described the psychological processes of mourning which involved the gradual relinquishment of bonds with the deceased, and how mourning differed from melancholia. Lindemann[(2)] described the 'Symptomatology and Management of Acute Grief' in his classic paper on his experiences assessing and treating the survivors of a nightclub fire. Engel[(3)] asked 'Is Grief a Disease?', and concluded in the negative.

Bowlby's work on attachment, separation, and loss[(4–6)] has been the most influential in informing research and clinical practice, with many studies of both adults and children utilizing such concepts. Early research focused chiefly on bereavement following the

death of a spouse, describing normal, high risk, and pathological patterns of grief.[7–9] There is also a number of excellent reviews of theory and research, including those of Stroebe's group.[10,11]

Phenomenology of 'normal grief'

Common phenomena of the grief experience of adults, identified through many research studies,[12–14] relate to similar domains influenced by developmental trajectories, through childhood and adolescence. Adult studies indicate consistent patterns: numbness, disbelief; yearning, angry protest, and 'searching' behaviours representing separation distress; and sadness with reviewing of memories of the lost relationship, with a range of associated emotions; progressive acceptance of the death and changed circumstances, sometimes referred to as resolution.

Bonanno[14] has shown that resilient trajectories, defined by low overall distress, are common. Other transient phenomena described by clinicians working with bereaved people[15] include: identificatory symptoms, reflecting the deceased's illness; a sense of the deceased's ongoing at presence, at times as though seeing the face, hearing the voice, or feeling the touch of the dead person. 'Yearning' is considered to be the most pathognomic of these grief phenomena, which usually settle over the first year, but may continue, triggered by anniversaries, or specific memories. Older people who have had a long relationship with a spouse may continue this relationship in their minds for the comfort of 'talking' with the person, and a need for the ongoing closeness.[16]

Recent research[17] has modelled sequential peaks of the reactive phenomena: disbelief, yearning, anger, and depression, which bereaved people more usually describe as sadness. Grief may be a precipitant of depression in those with pre-existing or bereavement-related vulnerabilities and the differentiation of normal and more pathological forms of grief from depression is important clinically.[15,18] Intense grief and the peaks of distress identified above do not usually continue beyond the first 4–6 months.[12,13] Continuing 'acute' grief beyond this time suggests the possibility of pathological response, as do other risk indicators, although some phenomena may continue intermittently for many years. Comparative studies have demonstrated that the intensity of adult grief is likely to be greatest for the death of a child, then spouse, or partner, then parent.[12,19]

Neurobiology of bereavement

Recent research has examined the neurobiology of grief through studies using functional magnetic resonance imaging of grief[20] and brain activity in womºen grieving the break-up of a romantic relationship.[21] Workers have attempted to develop a theoretical model based on a wide range of relevant data, encompassing a 'neurobiopsychosocial' framework for sadness and loss.[22] Stress hormones[23] and psychoimmune function is a further area of research. A comprehensive model integrating the relevant research findings is yet to be established.

Risk and protective factors influencing course and outcome

Pre-existing vulnerabilities that may influence the course and outcome have been reviewed alongside other risk factors.[24] These include personality vulnerabilities related to relationship styles such as avoidant and insecure attachments. Genetic factors do not appear to have been directly studied, but it is likely that the short allele of the serotonin gene promoter polymorphism of 5HTTLPR which influences response to adversity may contribute, through gene–environment interactions.[25] Prior loss and adverse experiences may add vulnerability, for instance multiple losses faced by indigenous peoples, with loss of culture, land, and loved ones, with multiple premature deaths and separations.[26] Separation anxiety in childhood, as well as pre-existing psychiatric disorder, family psychiatric disorder, and substance abuse may add to vulnerability. Successful negotiation of earlier losses, mature defence styles, and optimism may be protective.

The nature of the lost relationship has been identified in a number of studies as being a significant factor.[15,27] The special relationship between parent and child is associated with greater vulnerabilities, including increased risk of psychiatric hospitalization and even death by suicide. Patterns of distress differ by gender with stillbirth, neonatal deaths, and sudden infant death syndromes, perhaps suggesting different attachment patterns.[28] The death of an adolescent child is not infrequently by accident, suicide, or risk-taking with illicit drugs, bringing the extra complexities of adaptation for the grieving parents.

A great deal of research has explored the grief associated with the death of a partner or spouse both young and old. High levels of dependence and ambivalence have been shown to complicate grief and to be associated with more difficult bereavement,[15,27] and prolonged or complicated grief may be more likely.

Family members may have different relationships with the deceased, and thus varying patterns and trajectories of grief, which may cloud the recognition of children's and others needs.

Adults' loss of an older parent appears to be the least distressing, although there is still sadness plus the recognition of one's own mortality. Here, as at any age, intense fantasies of reunion with the deceased may indicate risk of suicide, especially for older widowed men.

Circumstances of the death may influence outcome. When dying is *prolonged*, as in the later stages of a terminal illness, the dying person may experience grief over his or her own life, and the loved ones who will be lost to him, alongside the anticipatory grieving of family members. While palliative care systems may provide bereavement programmes, families have complex dynamics, and may require family focused interventions.[29]

Sudden unexpected deaths bring an extra level of emotional shock,[30] especially if also untimely as with children's death. When violent death occurs, as with homicide or the mass violence of terrorism or war, those bereaved may experience a complex mixture of traumatic stress reactions and grief reactions, sometimes called traumatic grief.[31] The specific issues facing those bereaved by violent deaths of loved ones have been reported in a recent volume by Rynearson,[32] which deals with homicide, terrorism, and other violent deaths. The prolonged and difficult grief in such circumstances is highlighted by findings from September 11, Oklahoma, and Bali bombings.

When people are *missing*, believed dead, the uncertainty, other stressors including complex legal and evidentiary processes (e.g. Disaster Victim Identification requirements), may lead to alternating hope and dread. When there are no remains, it will be more difficult for those bereaved to accept the reality of the death.

Seeing and 'saying goodbye' to the dead person, have been shown to help those bereaved in disasters. If remains are much disfigured, as with burns, it is important that those bereaved are supported in their choice about this.

Social support, particularly the perceptions of the supportiveness of family and social network are likely to be protective and assist the bereaved psychologically,[33] while perceptions of unhelpfulness may be associated with more negative outcomes.[9] Cultural requirements for social support may differ, as may the delineation of the period of mourning, the roles of the bereaved, and associated spiritual and religious needs.[34]

Multiple other adversities may occur, either coincidentally or as a consequence of the circumstances and the loss of the person, for instance financial difficulties, loss of resources, changed status, loss of meaning and identity, or other profound stressors of illness, injury, or other bereavements. Such additional stressors may increase vulnerability.[15]

In terms of Prolonged Grief Disorder (previously known as complicated grief disorder, and initially traumatic grief) Prigerson *et al.*[35] have carried out extensive research to refine this syndrome. Bringing together the views of international researchers, they have developed consensus criteria for a distinct psychiatric disorder to be considered for inclusion in DSM-V. This definition requires that the reaction to loss encompasses one of three symptoms of separation distress (e.g. yearning) and a minimum of five from a total of nine other symptoms, experienced at least daily, to a distressing or disruptive level. These include: shock; emotional numbing; avoidance of the reality of the loss; difficulty accepting the loss; feelings of meaninglessness; difficulty moving on with life; bitterness over the loss; mistrust; and a diminished sense of self. Such symptoms would need to last at least 6 months, and be associated with significant levels of functional impairment. These findings fit well with earlier research identifying more chronic patterns of grief.[12,13]

Physical and mental health consequences of bereavement

A recent valuable review[36] outlines the evidence of increased *mortality* for bereaved spouses, particularly males which is most pronounced in the first 6 months, and includes a range of conditions such as heart disease, leading to death from 'a broken heart'. It is also more pronounced for those younger. Death of a child is associated with even greater mortality risk, particularly for mothers. Suicide is one of the heightened risks, especially for mothers and older males.

Physical health impairments are also found,[36] with a variety of physical symptoms as well as greater use of medical services, and medications. Further research is needed to clarify the nature of any increased rate of specific diseases. Changed health behaviours, the impact of loss of a health supporting partner, functional or social changes, or shared environments of risk may contribute.

With regard to *mental health* there may be an increased level of anxiety and depressive symptoms. There may be a heightened risk for some bereaved individuals for exacerbations of pre-existing conditions, or the precipitation of new illnesses, including Post-Traumatic Stress Disorder when there is a violent death.[32] Other anxiety disorders, major depression, substance use disorder, and bipolar disorder may be precipitated by bereavement. Complicated or prolonged grief disorder may also represent a psychiatric consequence.[35]

Assessment and management

Most bereaved people do not require counselling so assessment must be a basis for intervention. Assessment should be simple, synchronous with need, and do no harm, addressing the death and its circumstances, the relationship, and the bereaved's experience since, including social support.[31] A more structured format, potentially including grief measures,[37] can clarify the presence of PTSD, Depression or Prolonged Grief, or other health needs, including physical health changes or problems, establishing the basis for intervention.

Initial management of acutely bereaved persons requires empathic, compassionate support; and responding to any acute needs in ways that are protective of their mental health, recognizing the 'roller-coaster' of emotions that may occur, and facilitating natural resilience. Concepts of Psychological First Aid are also valuable in the immediate period after the death.[38] Dealing with concerns about the deceased's suffering, and support to view the dead person's remains should the bereaved choose to, are likely to be helpful.

Most evidence-based interventions focus on psychotherapeutic methods, ranging from preventive counselling of those with demonstrated heightened risk[39] to self-help guided interventions,[40] interpersonal psychotherapy modifications for traumatic grief,[41] integrated cognitive behaviour therapy models,[42] or psychodynamically informed models[43] and web-based treatments.[44] Counselling models[45] and psychoeducation have also focused on those bereaved through specific deaths such as those of infants.[46] Other models deal with grief work and tasks,[47] as well as specific treatment for morbidity of complicated grief[48] and depressive or anxiety disorders including the use of pharmacotherapy for such conditions when indicated.[49] Rynearson's[32] work with 'restorative retelling' following violent deaths emphasizes the narrative story which is central to much bereavement counselling and testimony.

A practical approach to assessment and counselling may be initiated with some gentle queries, such as 'Can you tell me a little about your loss?', 'What happened with 'John's' death?', 'Can you tell me about 'John' and your relationship?', 'What's been happening since?'

If there is: intense continuing distress; circumstances of death which are untimely or traumatic; a complex relationship with the deceased; disruption of family functioning which is impacting on the needs of children; inadequacies of social support; 'unresolved' earlier losses; multiple additional stressors, the bereaved may be at heightened risk of adverse outcomes. Preventive counselling, which facilitates grieving, is attuned to the bereaved person's readiness, vulnerabilities, and strengths, and helps them to tell the story of their experiences and the person they have lost, is likely to improve outcomes.[39]

If assessment indicates that psychiatric disorders have arisen, for instance depression, post-traumatic stress disorder, anxiety, or substance use disorders, these conditions should be managed appropriately alongside counselling for the bereavement should this be required. The use of antidepressants or other medication is not indicated for bereavement itself but may be appropriate for such complications.[49] Monitoring for suicide risk should accompany clinical management.

Prolonged or complicated grief may benefit from cognitive behaviour therapy interventions, as well as relevant rehabilitation. Those who are both traumatized and bereaved may need the traumatic stress issues, to be dealt with first, and facilitation of grieving following this.[43]

There is a need for more comprehensive research and evaluation of prevention, early intervention and treatment modalities, and their appropriate provision, to individuals, families, or groups.[50] Culturally appropriate models of support and intervention also need to be further developed. Many bereaved people present first within primary care settings, and to their general practitioners who will need the skills and knowledge to deal with their distress, assess their needs, counsel them as appropriate, and refer when necessary.

Much support also comes from community and non-government agencies including bereavement focused groups for specific losses or for grief generally, and from specialized services in public or private mental health sectors.

Telling the bereaved person how to grieve, that they should 'forget about the past', that 'time heals all', is usually perceived as unhelpful. Treating grief as a disease, for example antidepressant medication for normal sadness, is seen by many bereaved people as interfering with their capacity to grieve for their loved one.

Counselling bereaved people requires hopeful, compassionate psychotherapeutic intervention which recognizes the human suffering involved, validates the person's strengths, and respects their spiritual needs. Loss is a central issue for all of us, both our fears of it, and its reality. Counselling requires those involved to recognize their own sensitivities in this regard, and to assist the 'journey' of those affected in dealing with their loss. Most people grieve, remember with love those whom they have lost, and continue to love, and love anew.

Anxiety disorders

Contents

4.7.1 Generalized anxiety disorders

Stella Bitran, David H. Barlow, and David A. Spiegel

Anxious apprehension and overconcern are common to many anxiety and mood disorders. Prior to 1980 in the American DSM diagnostic system, and 1992 in the international ICD system, individuals who experienced those symptoms in the absence of a realistic focus of concern were classified as having an 'anxiety neurosis' (DSM-II) or 'anxiety state' (ICD-9). In DSM-III, panic disorder was split off from that classification, and the residual category was renamed generalized anxiety disorder (**GAD**). A similar nomenclature was adopted in ICD-10.

Since its inception, GAD as a nosological entity has been troubled by problems of poor reliability and high comorbidity.[1] Those concerns have prompted several revisions of the DSM criteria and also have raised more basic questions regarding the validity of GAD as a disorder distinct from other anxiety and mood states. The question of what is the nature of GAD is still being debated and it remains one of the least reliably diagnosed anxiety or mood disorders.[2] This diagnostic unreliability has led to various suggestions for revisions to the diagnostic criteria and criticisms of the current definition of GAD.

Clinical features

Individuals with GAD experience persistent anxiety and worry that is out of proportion to actual events or circumstances. Typically, the anxiety and worry involve minor or everyday matters, such as work, finances, relationships, the health or safety of loved ones, and routine tasks. Often, the focus of worry shifts from one concern to another. Although people with GAD do not always consider their worries to be unrealistic or excessive, they do find them difficult to control. Consequently, the worries often interfere with concentration and performance.

Associated with the anxiety and worry, individuals with GAD have a variety of cognitive and somatic symptoms, including trembling, feeling shaky, aching in the back and shoulders, tension headaches, chest tightness, restlessness, exaggerated startle, irritability, insomnia, fatigue, dry mouth, sweating, urinary frequency, trouble swallowing, nausea, and diarrhoea. In addition, GAD may be accompanied by other conditions typically associated with stress, such as irritable bowel syndrome or atypical chest pain.

Classification

Diagnosis

(a) DSM criteria

In DSM-III, GAD was essentially a residual category for individuals with somatic symptoms of anxiety who did not meet diagnostic criteria for another, more specific, anxiety disorder. Diagnosis required the presence, for at least a month, of symptoms from three of four symptom clusters: motor tension, autonomic hyperactivity, apprehensive expectation, and vigilance and scanning. Unfortunately, clinicians had difficulty applying those criteria. In addition, its diagnosis depended on the application of the criteria for other diagnoses since GAD was not diagnosed if another anxiety disorder was present.

In DSM-III-R, apprehensive expectation was removed from the diagnostic symptom clusters, was redefined as unrealistic or excessive anxiety and worry about two or more life circumstances, and was made the essential feature of GAD. In addition, the duration criterion was changed from 1 to 6 months, and the hierarchical exclusion rule was dropped, allowing GAD to be diagnosed in addition to other disorders.

Table 4.7.1.1 DSM-IV inclusion criteria for GAD

(a) Excessive anxiety and worry, occurring more days than not for at least 6 months, about a number of events or activities
(b) The person finds it difficult to control the worry
(c) The anxiety and worry are accompanied by at least three of the following six symptoms (one in children): restlessness or feeling keyed up or on edge; being easily fatigued; difficulty concentrating or mind going blank; irritability; muscle tension; sleep disturbance
(d) The anxiety, worry or physical symptoms cause significant distress or functional impairment

(American Psychiatric Association (2000), *Diagnostic and statistical manual of mental disorders* (4th edn, text revision). APA, Washington, DC)

Despite those changes, the diagnostic reliability of GAD remained essentially unchanged.[1] Investigations revealed that the new worry criterion was problematic. Interviewers commonly disagreed as to whether two distinct spheres of worry were present, whether the worry was unrealistic or excessive, or whether the focus of the worry could be construed to be part of the symptomatology of another disorder. Moreover, studies indicated that patients with GAD did not differ substantially from control subjects in the content of their worries.[3,4] The main difference between patients and controls was that the former experienced their worrying to be uncontrollable while the latter did not.

Based on those and other findings, the GAD criteria were revised again in DSM-IV. The 'unrealistic' descriptor and the requirement for anxiety or worry to involve at least two spheres of life circumstances were deleted, and a new criterion was added that the worry must be experienced as difficult to control. In addition, the associated symptom criterion was modified to require only three of six symptoms from the previous motor tension and vigilance and scanning clusters (Table 4.7.1.1). For additional information about the evolution of the DSM criteria for GAD, see Barlow or Wincze.[5]

(b) ICD-10 criteria

Like DSM-IV, ICD-10 requires a period of 6 months of generalized anxiety and worry accompanied by certain somatic symptoms (Table 4.7.1.2). The 6 months of 'prominent' tension and worry needs to be accompanied by at least 4 of 22 associated symptoms. The ICD-10 differs from DSM-IV in that it does not require that worry be 'uncontrollable', that the symptoms of GAD occur exclusively outside the context of a mood disorder, or that they meet a 'clinical significance' criterion.

(c) Differential diagnosis

Everyone experiences anxiety and worry sometimes, and some people describe themselves as born worriers. GAD differs from these non-pathological anxiety experiences in that it is both persistent and severe enough to cause significant distress or interference. Typically also, the worries are more pervasive and difficult to control than normal worries and are associated with physical symptoms of anxiety and tension.

A number of general medical conditions can present with signs and symptoms resembling GAD (Table 4.7.1.3). In addition, substances such as caffeine, alcohol, other drugs of abuse, toxins, and some medications (Table 4.7.1.4) can cause anxiety-like

Table 4.7.1.2 ICD-10 inclusion criteria for GAD

(a) At least 6 months of prominent tension, worry, and feelings of apprehension about everyday events and problems
(b) At least four of the following 22 symptoms must be present, at least one of which must be from the autonomic arousal cluster
Autonomic arousal symptoms: palpitations or pounding heart or accelerated heart rate; sweating; trembling or shaking; dry mouth (not due to medication or dehydration)
Symptoms involving the chest and abdomen: difficulty in breathing; feeling of choking; chest pain or discomfort; nausea or abdominal distress
Symptoms involving mental state: feeling dizzy, unsteady, faint or lightheaded; derealization or depersonalization; fear of losing control, 'going crazy', or passing out; fear of dying
General symptoms: hot flushes or cold chills; numbness or tingling sensations
Symptoms of tension: muscle tension or aches and pains; restlessness and inability to relax; feeling keyed up, or on edge, or mentally tense; a sensation of a lump in the throat, or difficulty in swallowing
Other non-specific symptoms: exaggerated response to minor surprises or being startled; difficulty in concentrating, or mind 'going blank' because of worrying or anxiety; persistent irritability; difficulty getting to sleep because of worrying

(World Health Organization (2004), *International statistical classification of diseases and health related problems* (2nd edn). WHO, Geneva, Switzerland)

Table 4.7.1.3 General medical conditions that can cause symptoms resembling anxiety

Cardiac conditions: arrhythmias, coronary insufficiency, mitral valve prolapse, heart failure
Endocrine conditions: hyperthyroidism, hypoparathyroidism, hypoglycaemia
Neurological conditions: temporal lobe epilepsy, vestibular nerve disease
Respiratory conditions: asthma, hypoxia, hyperventilation, obstructive lung disease, pulmonary embolism
Other conditions: porphyria, carcinoid tumour, systemic lupus erythemacosus, pellagra

Table 4.7.1.4 Medications that can cause symptoms resembling anxiety

Psychotropics: antidepressants, neuroleptics (akathisia), sedative hypnotics (withdrawal syndrome), disulfiram
Respiratory drugs: B-adrenergic stimulants, bronchodilators
Cardiovascular drugs: antiarrhythmics, antihypertensives
Neurological disorder medications: anticonvulsants, anticholinergic agents, L-dopa
Anaesthetic drugs: pre-anaesthetics, general anaesthetics (post-anaesthetic syndrome)
Other drugs: thyroid hormone, antibiotics, non-steroidal anti-inflammatory drugs, anticancer drugs

symptoms either as a direct effect or as part of a withdrawal syndrome. These causes may be established on the basis of a medical and substance use history, physical examination, or laboratory tests.

GAD is distinguished from other psychiatric disorders, in part, by the focus of the anxiety and worry, which is not limited to a feature of another disorder. For example, the worry is not only about the possible occurrence or implications of panic attacks (as in panic disorder), or about negative evaluations by others (social phobia), gaining weight (anorexia nervosa), or having a serious illness (hypochondriasis). In obsessive–compulsive disorder, the anxiety and worry are associated with intrusive thoughts, images, or impulses that are distressing.

Generalized anxiety commonly occurs in depression, and GAD and depression also share associated symptoms such as sleep disturbance, fatigue, restlessness, and poor concentration. When the associated symptoms could fit with either disorder, the distinction is made on the basis of the presence and time course of depressed mood relative to anxiety. In DSM-IV, GAD is not diagnosed if its features occur exclusively during a mood disorder.

(d) Epidemiology

Prevalence estimates of GAD vary considerably with the diagnostic criteria used. One large-scale study found a 12-month prevalence rate of 2.07 per cent and a lifetime prevalence rate to be 4.1 per cent.[6] Socio-demographic factors associated with increased risk for GAD included being female, middle-aged, and with low income. However, being African American, Asian, or Hispanic was associated with a decreased risk.[7]

The National Comorbidity Study Replication (NCS-R), which used DSM-IV criteria and included structured interviews of over 9000 individuals in the United States, found a 12-month prevalence of GAD of 3.1 per cent and a lifetime prevalence rate at 5.7 per cent.[8,9] Lifetime prevalence rates were lowest among 18- to 29-year-olds (4.1 per cent) and those 60 or older (3.65 per cent), with the highest rates found among 45- to 59-year-olds (7.7 per cent).

(e) Comorbidity

GAD usually coexists with other anxiety and mood disorders. One large-scale study found that 68 per cent of individuals with a principal diagnosis of GAD met criteria for another Axis I disorder (Table 4.7.1.5).[10] The most frequently comorbid disorders were MDD, social phobia, or panic disorder with or without agoraphobia. Ninety-two per cent of individuals from this study with a principal diagnosis of GAD met criteria for another lifetime disorder, with 64 per cent meeting criteria for MDD. Similarly, in the major epidemiological surveys, nearly two-thirds of individuals with GAD had additional DSM Axis I diagnoses.[11] Most common among these were specific (21–59 per cent) and social (16–59 per cent) phobias, followed by panic disorder (3–27 per cent) and depression (8–39 per cent). In addition, GAD was found to be approximately twice as common among women as men. There is less information about the prevalence of personality disorders among patients with GAD.

Table 4.7.1.5 Prevalence of comorbid disorders in 279 patients with GAD

Any additional lifetime disorder	96%
Any anxiety/mood	94%
Any anxiety disorder	85%
Any mood disorder	74%
Anxiety disorders	
Panic disorder with/or without agoraphobia	47%
Social phobia	46%
Specific phobia	22%
Mood disorders	
Major depressive disorder	67%
Dysthymia	11%

(f) Is GAD a valid disorder?

The findings of only fair diagnostic reliability and high comorbidity for GAD have been interpreted as indicating poor discriminant validity of the disorder, suggesting that differentiating GAD from other anxiety and mood disorders may be artifactual. In considering those arguments, it is important to distinguish the diagnostic criteria sets specified in the DSM and ICD classification systems from the clinical syndromes they are intended to identify. Low discriminant validity for a disorder may be due to problems with the former rather than the latter. To establish the construct validity of a syndrome, one must demonstrate that it has a consistent set of features, the pattern of which separates it from other related syndromes. One approach to doing that is to compare the profiles of patients with different diagnoses across various illness dimensions.

In one such study, data from patients who took part in the DSM-IV mixed anxiety-depression field trial were examined.[12] Using factor analyses of patients' scores on 73 items from the Hamilton anxiety and depression rating scales, four clusters were identified that corresponded to the dimensions of anxiety, depression, physiological arousal, and general negative affect (containing items that loaded on both the anxiety and depression factors). Patients with a principal diagnosis of GAD had a unique profile (high on negative affect and anxiety, low on physiological arousal and depression) that distinguished them from individuals with panic disorder, major depression, anxiety or depressive disorder not otherwise specified, or no mental disorder.

A subsequent study, using an anxiety clinic sample and an expanded array of measures, yielded similar results.[13] In this case, five primary factors (corresponding to panic, agoraphobia, social anxiety, obsessions/compulsions, and general anxiety) and a higher order factor (negative affect) were identified. Again, patients with GAD had a unique factor profile.

The findings from the preceding studies were replicated and extended in an independent sample of patients.[14] As in the earlier studies, GAD was found to be distinct from other anxiety syndromes and depression, although it had the highest degree of overlap with other syndromes, especially depression. In addition, GAD was strongly associated with the non-specific dimension of negative affect, which is common to anxiety and depression. The authors suggest that GAD may represent a 'basic emotional disorder', because it consists of features that are present to varying degrees in all anxiety and mood disorders.

Finally, all three of the preceding studies (and a variety of others, e.g. Barlow *et al.*[15] support the differentiation of symptoms of autonomic arousal, which are characteristic of panic attacks, from somatic symptoms related to central nervous system tension, which form the DSM-IV-associated symptom cluster of GAD.

(g) Aetiology

Findings from genetics, neurobiology, and psychology infer a multifactorial aetiology for GAD, which has been organized into a triple vulnerabilities model.[16,17] This model suggests that anxiety disorders result from the combination of a generalized biological vulnerability, a general psychological vulnerability, and a specific psychological vulnerability.

(i) Generalized biological vulnerability

Genetic contributions. Several studies investigating genetic vulnerabilities for mental disorders have supported the notion that a shared vulnerability underlies anxiety disorders.[18] It was shown through a meta-analysis of genetic epidemiological studies that many anxiety disorders (including GAD, panic disorder, phobias, and OCD) aggregate in families and that genetics has the most influence when examining familial risk.[19] In a family study that used DSM-III criteria, GAD (but not other anxiety disorders) was five times more prevalent (19.5 per cent versus 3.5 per cent) among first-degree relatives of patients with GAD than among relatives of controls.[20] However, two twin studies using the same criteria found concordance rates for GAD were no higher among monozygotic than dizygotic twins.[21] Two subsequent studies that used DSM-III-R criteria found a shared heritability for GAD and mood disorders.[22] At present, it appears that genetic factors play a modest role in the aetiology of GAD, and one that is more closely related to vulnerability for depression than for other anxiety disorders.

Neurobiological mechanisms. A variety of neuroanatomical, neurochemical, neuroendocrine, and neurophysiological systems have been implicated in the pathogenesis of anxiety states. Much of this information has come from animal models and research on the effects of stress. Studies of neurobiological functioning in humans with GAD are limited. Some of the physical systems that may be involved in the emotion of anxiety are summarized below. Additional information may be found in reviews by Davidson,[23] and Gray and McNaughton.[24]

The noradrenergic nervous system. Noradrenergic pathway (the **locus coeruleus-noradrenaline-sympathetic nervous system**) have long been associated with fear and arousal and play an important role in the body's response to threat. However, their role in persistent anxiety states is not clear. Resting catecholamine levels in patients with GAD appear to be normal. On the other hand, GAD patients exhibit subnormal responses to both stimulation[25] and blockade[26] of α_2-adrenergic receptors and a reduced density of α_2-receptors in platelets.[27] Those findings could reflect downregulation of the α_2-receptors due to initially high levels of noradrenaline (norepinephrine).

Consistent with those neurochemical findings, somatic measures of autonomic nervous system function (e.g. skin conductance, respiratory rate, heart-rate variability, blood pressure) in patients with GAD tend to show normal resting values with blunted and sometimes prolonged responses to stressful stimuli.[27] Psychophysiological studies have found that worry is associated with restricted sympathetic arousal and low vagal tone.[27] In contrast, it has been shown that compared to controls, individuals with GAD show greater muscle tension at baseline in response to psychological challenge.[28] In addition, structural analyses suggest that GAD, unlike other anxiety disorders, is not associated with autonomic hyperarousal when levels of negative affect are held constant.[14] These findings indicate diminished autonomic nervous system responsiveness in individuals with GAD.

The hypothalamic-pituitary-adrenal axis. The **hypothalamic-pituitary-adrenal axis** and its end-product, cortisol, are also involved in reactions to stress. Activity in the hypothalamic-pituitary-adrenal axis is subject to a variety of influences. Primary control is by means of hypothalamic secretion of corticotrophin-releasing factor, which stimulates pituitary secretion of ACTH, which in turn stimulates adrenal secretion of cortisol. Circulating cortisol, and analogues such as dexamethasone, exert inhibitory feedback at the level of the pituitary gland and apparently also by means of receptors on the hippocampus.

In rats, chronic exposure to stress or exogenous steroids results in a reduction of corticosteroid receptors in the hippocampus and a consequent decrease in feedback inhibition by cortisol.[29] These animals exhibit reduced dexamethasone suppression of cortisol secretion and greater or more prolonged adrenocortical responses to stress. Reduced dexamethasone suppression also has been observed in approximately one-third of patients with DSM-III-diagnosed GAD.[30] This reduction in the normal regulatory control of cortisol secretion may be one mechanism through which chronic or repeated stress can lead to persistent anxiety.

The amygdala and the bed nucleus of the stria terminalis. LeDoux[31] and others have demonstrated the central role played by the **amygdala** in the mediation of fear reactions. The amygdala is thought to be responsible for the detection of potential threats to the organism and the mobilization of a range of defensive responses (Fig. 4.7.1.1). Through connections with the hypothalamus, it can activate the sympathetic nervous system and hypothalamic-pituitary-adrenal axis. Through efferent fibres to the central grey area of the midbrain, it can mediate behavioural defence responses such as the fight-or-flight response and behavioural 'freezing'. Through connections to the nucleus reticularis pontis caudalis, it can enhance the defensive startle reflex.

A structural magnetic resonance imaging (MRI) study of children and adolescents found that those individuals with GAD had increased total and right amygdala volume compared to non-anxious controls.[32] In addition, abnormalities in fear circuitry, especially hyperactivation in the right amygdala, have been found in adolescents with GAD.[33]

The extent to which these pathways are involved in the neurobiology of anxiety (as opposed to fear) is unclear. However, a structure

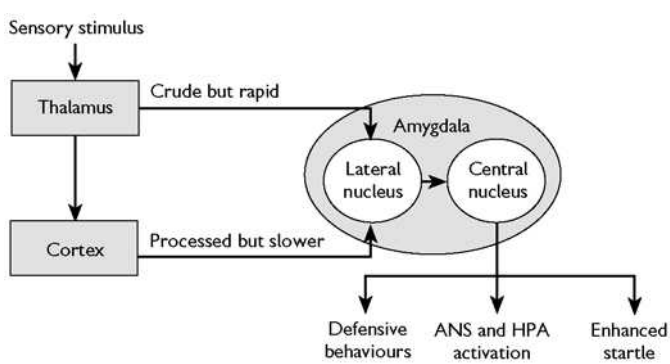

Fig 4.7.1.1 Fear pathways (based on descriptions by LeDoux[31] and Davis[34]). ANS, autonomic nervous system; HPA, hypothalamic-pituitary-adrenal axis.

closely related to the amygdala, the bed nucleus of the stria terminalis, may be involved in this emotion. The bed nucleus resembles the amygdala in its neurotransmitter content, cell morphology, and hypothalamic and brainstem connections and, like the amygdala, it exerts a modulating effect on the startle reflex.[34] Studies of this latter effect implicate it in the experience of anxiety.

Administration of corticotrophin-releasing factor into the cerebral ventricles of rats produces a state of generalized arousal resembling anxiety. Under those conditions, the startle reflex also is enhanced. Exposing rats to bright light for 5 to 20 min has similar effects. These effects are not blocked by damage to amygdala but are by lesions to the bed nucleus of the stria terminalis and by treatment with benzodiazepines or buspirone. Conversely, infusion of corticotrophin-releasing factor directly into the bed nucleus of the stria terminalis, but not the amygdala, produces a rapid increase in startle. Based on these observations, Davis[34] has suggested that the stria terminalis may play a role in anxiety analogous to that of the amygdala in fear reactions and, further, that prolonged or repeated stimulation of the stria terminalis by corticotrophin-releasing factor during periods of stress might lead to sustained activation and thus to persistent anxiety. A recent study has confirmed the differential association of these structures with fear and anxiety, respectively.[35]

The septohippocampal system (behavioural inhibition system). The bed nucleus of the stria terminalis is part of the larger septohippocampal system.[36] In 1982, based on data from several lines of research, Gray hypothesized that the septohippocampal system, together with the Papez circuit (a neural loop connecting the subicular area in the hippocampal formation to the mammillary bodies, anterior thalamus, cingulate cortex, and back to the subiculum), is responsible for mediating the emotion of anxiety as well as the major effects of anxiolytic drugs.[36] Gray called this network the **behavioural inhibition system**, because he believed that, when activated, it interrupts ongoing behaviour and redirects the organism's attention to signs of possible danger.

According to Gray's model,[24,36] the behavioural inhibition system receives information about the environment from the sensory cortex via the temporal lobe and hippocampal formation. The system checks the information for consistency with predictions, which are updated continuously by the Papez circuit based on preceding information and stored patterns, as well as for consistency with the immediate goals of the organism. When a mismatch is found, or if a predicted event is aversive, the outputs of the behavioural inhibition system are activated, resulting in a constellation of emotional and behavioural effects consistent with anxiety (Fig. 4.7.1.2).

The activation of the behavioural inhibition system appears to be moderated by ascending noradrenergic and serotonergic projections to the septohippocampal complex, providing a possible mechanism for the anxiolytic actions of some drugs. The amygdala also provides inputs to the behavioural inhibition system and may relay its outputs to the hypothalamus and autonomic nervous system, thereby mediating anxious arousal. Sustained activation of the behavioural inhibition system might therefore account for many of the features of GAD.

The benzodiazepine-γ-aminobutyric acid system. The powerful anxiolytic and sedative effects of benzodiazepines are believed to be mediated by benzodiazepine recognition sites located on γ-aminobutyric acid (**GABA**) type A receptor complexes in the central nervous system. When bound to those complexes,

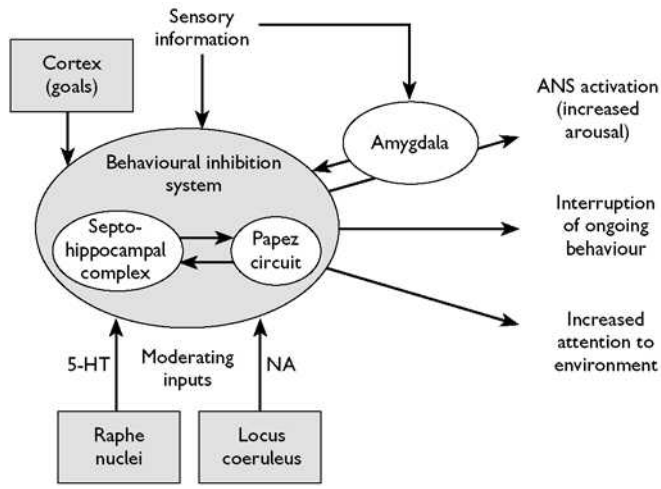

Fig 4.7.1.2 Behavioural inhibition system (based on descriptions by Gray and McNaughton[24]). ANS, autonomic nervous system; 5-HT, serotonin; NA, noradrenaline.

benzodiazepines allosterically modulate the GABA receptors to enhance the normal inhibitory effects of GABA on neurotransmission. Activation of **central benzodiazepine-GABA receptor complexes** also suppresses hypothalamic-pituitary-adrenal axis activity and, consequently, cortisol levels.

In addition to these central receptor complexes, benzodiazepine recognition sites of a different type are present widely in cells outside the central nervous system. These so-called **peripheral benzodiazepine receptors** are believed to be instrumental in controlling the synthesis of regulatory steroids. Their role in the anxiolytic actions of benzodiazepines is unknown; although they bind some drugs (e.g. diazepam), they have low affinity for others (e.g. clonazepam). Interestingly, peripheral benzodiazepine receptors are decreased in blood cells of individuals with untreated GAD but return to normal levels after successful treatment with benzodiazepines. Their numbers also vary in response to stress, being elevated following acute stressors and reduced during chronic stress.

A possible explanation for those changes has been suggested by Rocca *et al.*[37] The investigators note that peripheral benzodiazepine receptors in brain glial cells control the production of neurosteroids that act as modulators of $GABA_A$ receptor sensitivity. Their effect on GABA functioning appears to be opposite to that of clinically effective benzodiazepines, that is, they 'decrease' rather than increase the inhibitory effects of GABA. It is hypothesized that an endogenous ligand of these glial cell receptors (possibly diazepam-binding inhibitor) is released during stress, initiating the cycle of events depicted in Fig. 4.7.1.3.

The immediate effect of these events would be to enhance the stress-induced release of cortisol. However, prolonged cortisol excess is hypothesized to downregulate peripheral benzodiazepine receptors, resulting in the reduced receptor densities found in GAD. Administration of a clinically effective benzodiazepine drug would interrupt the proposed pathway at the point of the central GABA receptor, lowering cortisol levels and restoring synthesis of peripheral benzodiazepine receptors.

Other neurotransmitter systems. Individuals with GAD have been reported to have reduced serotonin levels in the cerebral spinal fluid[35] and decreased platelet binding of paroxetine, a selective serotonin reuptake inhibitor.[38] In addition, drugs that affect

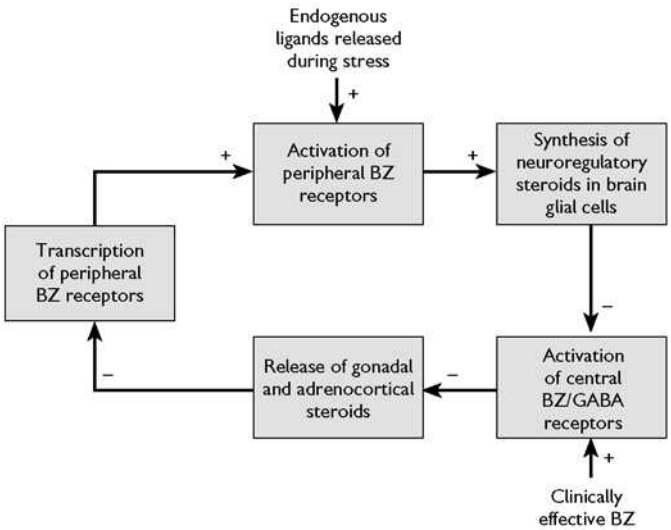

Fig 4.7.1.3 Possible involvement of peripheral benzodiazepine receptors in acute and chronic stress reactions (based on descriptions by Rocca *et al.*[37]). BZ, benzodiazepine.

serotonergic transmission (e.g. buspirone and venlafaxine) are effective in the treatment of GAD. These findings suggest that serotonin regulation may be abnormal in GAD.

Cholecystokinin neuropeptides (CCK-4 and CCK-8S) have been implicated in the genesis of arousal and fear responses.[40] It is unclear how those effects are mediated; however, cholecystokinin interacts with several neurotransmitters and systems believed to be involved in anxiety responses, including the noradrenergic nervous system, the hypothalamic-pituitary-adrenal axis, the benzodiazepine-GABA system, and serotonin.

(ii) Generalized psychological vulnerability

A diminished sense of control. Early experiences of uncontrollability may serve as a psychological vulnerability for emotional disorders.[16] Individuals in clinical populations, including people diagnosed with anxiety disorders, sexual dysfunctions, and depression, often perceive themselves as having little control over their experiences.[41,42] Patients with GAD are more likely than controls to perceive a lack of control over threatening events and to regard ambiguous information as threatening.[43] This perceived lack of control may result from a variety of events, including trauma and insecure attachment to primary caregivers.[44] In patients with GAD, worry may be an ineffective attempt to assert control on uncertain future events. Intolerance of uncertainty, a construct related to perceived lack of control, has emerged as an important variable in the study of anxiety disorders.[45] Defined as the inability to accept that future negative events may occur, intolerance of uncertainty has been associated with symptoms of several anxiety disorders, but is greater in individuals with GAD than in patients from a mixed anxiety disorder sample.[41]

Parenting. There is an extensive literature on the influences of early environmental factors on the development of anxiety and other negative emotions in children (for an integrative review, see Chorpita and Barlow[46]). Attachment theory holds that parents or other consistent caregivers serve an important function in a child's development by providing a protective and secure base from which the child can operate. Disruption of this base is hypothesized to lead initially to anxious apprehension and dependency and, if the disruption is severe, subsequently to withdrawal and depression.

An important aspect of a healthy parent–child relationship is its ability to foster in the child a sense of control over events. According to Chorpita and Barlow,[46] an individual who lacks sufficient early experiences of control may develop a general perception of personal inefficacy, which may predispose him or her to chronic negative emotional states such as GAD. Two aspects of parenting appear to be important in providing a child with opportunities to experience control: responsiveness to the child's efforts at engagement and encouragement of the child to explore and manipulate the environment. A parenting style characterized by excessive control of the child's environment (overprotection) coupled with a lack of warmth and responsiveness toward the child would deprive the child of such opportunities and thus, theoretically, could contribute to the development of anxiety.

Consistent with this theory, mothers of anxious preschool children were found to be more critical and intrusive and less responsive to their children than mothers of non-anxious children.[47] In addition, adults who rated their parenting as more protective and less caring had higher trait anxiety scores than other individuals surveyed. A similar pattern was found to distinguish patients meeting DSM-III-R criteria for GAD or panic disorder from controls.[48] One hypothesis is that the relationship of these early parenting experiences to the subsequent development of anxiety (or depression) is mediated by the early formation of cognitive vulnerability best described as a sense of uncontrollability regarding future events in one's life (Fig. 4.7.1.4).[46]

Specific psychological vulnerability. Data from twin studies suggest that environmental influences contribute more to the variance in aetiology of GAD than heredity.[19] In addition, the triple vulnerability model of the aetiology of anxiety disorders suggests that psychological and biological vulnerabilities interact with

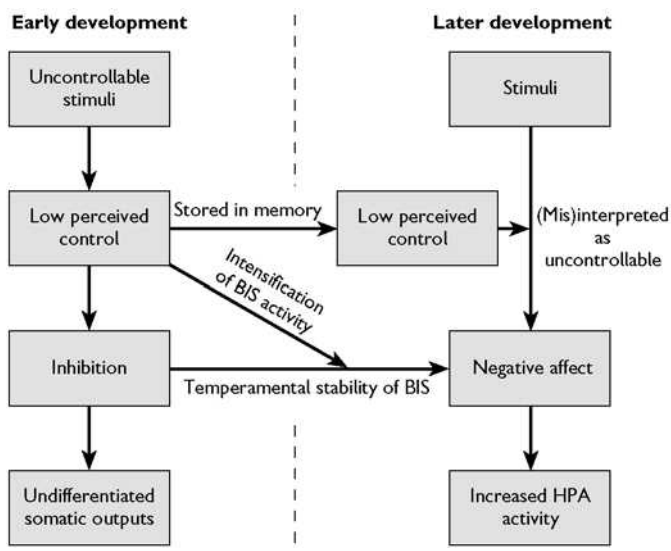

Fig 4.7.1.4 Model of the development of vulnerability for anxiety and depression. BIS, behavioural inhibition system[24]; HPA, hypothalamic-pituitary-adrenal axis (Copyright © 1998 by the American Psychological Association. Reproduced with permission. environmental factors (i.e. stressful life events), to produce anxiety symptoms that reach a clinical level.[16,17] Several environmental factors have been implicated.

Stressful life events. Several studies have found an association between stressful or traumatic life events and GAD. The natures of the stressors that precede the onset of GAD remain unclear. However, in one study, 52 per cent of individuals diagnosed with GAD reported experiencing at least one past traumatic event (i.e. an event that would meet for Criterion A of the DSM-IV definition of PTSD), compared to only 21 per cent of non-anxious controls. It was unclear in this study if the events occurred prior to the onset of the GAD.[49] In addition, a variety of stressors have been associated with increased risk of GAD, including early parental death,[50] rape or combat,[51] and chronically dysfunctional marital and family relationships.[52]

Course and prognosis. Although there is evidence to the contrary, GAD has often been considered a chronic and disabling condition. The Harvard/Brown Anxiety Research Program study provides information on the course and impact of GAD among patients treated naturalistically over a 3-year period.[53] The mean age at onset of GAD was 21 years (range 2–61 years), and the average duration of illness at initial evaluation was 20 years. Excluding patients with comorbid panic disorder, one-third of subjects had never married and another 17 per cent were separated, widowed, or divorced. Unemployment was higher than average, and 37 per cent of subjects had received public financial assistance. Despite the fact that more than 80 per cent of patients received treatment during the study period, remission from GAD was uncommon (15 per cent at 1 year, 27 per cent by 3 years). Among patients with comorbid psychiatric disorders, the proportions achieving remission from GAD and coexisting anxiety disorders were only 8 per cent and 17 per cent at 1 and 3 years, respectively.

However, there is evidence that the perception of GAD as a chronic, unremitting condition may not be completely correct. A longitudinal study of individuals with GAD found that many (46 per cent of women and 56 per cent of men) experienced episodes of full remission and that the periods with no symptoms last longer in women.[54]

Treatment

(a) Pharmacotherapy

Several pharmacological agents have been shown to be effective for the treatment of GAD (for a review, see Davidson[23]). Chief among these are the benzodiazepines, azapirones, and antidepressants. Evidence shows that several types of medications may be effective for at least short-term relief of anxiety, however, many are not effective in the long term unless taken indefinitely.[55]

(i) Benzodiazepines

Benzodiazepines have for decades been prescribed for short-term relief of anxiety.[55] Although, evidence demonstrates that these drugs can be effective in relieving anxiety for a short period, there is little or no evidence that they work over a long period. However, compared with other agents used to treat anxiety disorders, they are safe, fast-acting, and have relatively few side-effects. All currently available benzodiazepines probably are efficacious for GAD. Approximately two-thirds of patients experience moderate to marked improvement, with effects being evident within the first 1 or 2 weeks of treatment.[56]

Benzodiazepines appear to be more effective for the somatic symptoms of GAD than for psychic symptoms such as apprehensive worry and irritability, possibly because of their sedative and myorelaxant properties. In some studies, irritability actually has increased during treatment with benzodiazepines. Consequently, these drugs may be better for patients whose complaints are more somatic than psychic, whereas other agents may be better when the reverse is true.

(ii) Azapirones

In recent years, azapirone drugs have become a popular alternative to benzodiazepines for the treatment of GAD. These drugs lack the sedative and muscle relaxant properties of the benzodiazepines as well as their ability to potentiate the effects of alcohol. However, improvement is somewhat slower (2–4 weeks) than with benzodiazepines. The most widely used of these agents is buspirone, whose efficacy and safety have been demonstrated in several well-controlled trials (see Rickels[57] for a review) and became, in 1996, the only non-benzodiazepine approved by the U.S. Food and Drug Administration for the treatment of GAD.[58] It is as effective as benzodiazepines for general anxiety and may reduce some of the associated features of GAD as well, including depression and agitation. Buspirone also does not seem to be associated with as much dependence and withdrawal as found with the benzodiazepines.[55] Ipsapirone, an azapirone with somewhat greater affinity and selectivity for the 5-hydroxytryptamine-1A receptor and fewer side-effects than buspirone also appears to be effective.[59] Other drugs in this class include gepirone, tandospirone, and flesinoxan.

(iii) Antidepressants

Both imipramine and trazodone have been superior to placebo for the treatment of GAD in controlled trials. In one trial, the two drugs were comparable to each other and to diazepam in reducing anxiety after the first 2 weeks of treatment.[56] In another study, imipramine was as effective as chlordiazepoxide overall and produced greater reductions in associated depression. In addition, nefazodone, an agent related to trazodone but less sedating, was effective for GAD in a small open trial.[60]

Many studies have examined the use of newer antidepressants, including selective reuptake inhibitors (SSRIs) and serotonin and norepinephrine reuptake inhibitors (SRNIs), in the treatment of GAD and have had favourable results. One placebo-controlled study of the SSRI paroxetine found that 62 per cent and 68 per cent of patients receiving 20 and 40 mg of paroxetine had significant reduction in symptoms, compared to only 46 per cent in the placebo group.[61] In addition, due to results from several large, placebo-controlled trials, venlafaxine was the first antidepressant approved by the Federal Drug Administration for the treatment of GAD.[62,63]

(b) Psychosocial treatment

Early psychological treatments for GAD consisted mostly of non-specific interventions such as supportive psychotherapy, relaxation training, and biofeedback. In general, those treatments were not very effective. However, cognitive behavioural treatment (CBT) has been found in several randomized controlled trials to be associated with clinically significant improvement. Cognitive behavioural treatment consists of psychoeducation about the nature of anxiety,

symptom monitoring, relaxation training, exposure (imaginal and *in vivo*), and cognitive restructuring. Psychoeducation is a common CBT component in which the nature of anxiety is discussed in order to normalize the patient's experience. It also serves to teach patients to differentiate between adaptive and maladaptive anxiety. Symptom monitoring allows records of mood and anxiety to be recorded and allows patients to learn to observe their symptoms. Progressive muscle relaxation (PMR) is a common technique used to teach patients relaxation strategies to use in anxiety-provoking situations. Exposures are tailored to the nature of GAD and are either *in vivo* or imaginal and are often combined with rehearsal of coping skills (i.e. PMR) until anxiety subsides. Cognitive restructuring targets distorted cognitions and information-processing biases associated with GAD. Strategies to challenge catastrophizing or overestimating the probability of a negative event are often employed during this component of treatment. CBT is typically administered in a dozen or so sessions, and can be conducted in group or individual formats. In controlled trials, cognitive behavioural treatments have been more effective than no treatment or a psychological or drug placebo treatment and at least as effective as benzodiazepines (for a review, see Barlow *et al.*).[64] Attrition is low (10–15 per cent), and reductions in anxiety average about 50 per cent, with gains being maintained at follow-up. Currently, the most successful treatments combine relaxation training with cognitive interventions focused on making the worry process more controllable.

Consistent with the findings of individual studies, meta-analyses for GAD have found that CBT is more efficacious than control conditions, resulting in medium to large effect sizes when compared to pill or psychological placebo.[65] However, in studies directly comparing CBT with pharmacotherapy (most often benzodiazepines), there was no difference in effect sizes between the two treatments. Currently, neither mode of treatment has been shown to be consistently superior to the other.

Recent developments in psychosocial treatments for GAD have integrated acceptance and mindfulness approaches into traditional CBT.[66] These treatments are based on the notion that individuals' attempts to control their internal experience often backfire, resulting in increased anxiety. Components to these treatments may include experiential exercises, mindfulness training, identification of overriding values, and encouragement towards taking action in ways that are consistent with these values.[66] Further exploration with controlled trials needs to be conducted to examine the efficacy of these newer approaches with cognitive behavioural treatments.

(c) Combined pharmacotherapy and psychotherapy

Although common in clinical practice, little is known about the effects of combining pharmacotherapy and psychotherapy for GAD. In the only published study to date, Power *et al.*[67] compared cognitive behavioural therapy, diazepam, a pill placebo, cognitive behavioural therapy plus diazepam, and cognitive behavioural therapy plus a pill placebo in a sample of DSM-III-diagnosed GAD patients. At post-treatment and follow-up, patients in all three cognitive behavioural therapy conditions were more improved than those who received diazepam or placebo alone. Although the cognitive behavioural therapy groups did not differ significantly from each other on any measure, the cognitive behavioural therapy plus diazepam group improved earliest and had the largest percentage of patients achieving a criterion of clinically significant change on all measures. Unfortunately, the use of DSM-III criteria in this study makes its relevance to GAD as it is currently defined uncertain. In addition, the cognitive behavioural therapy used was briefer (seven sessions) and less specific than the currently recommended forms.

(d) Effect of comorbidity on treatment outcome and vice versa

Many treatment trials investigating GAD have excluded patients with comorbid Axis I disorders. A review of 48 GAD studies published between 1980 and 1991 found that only eight reported including patients with other psychiatric disorders.[68] When comorbid disorders have been permitted, their effect on treatment outcome generally has not been evaluated. In the Harvard-Brown Anxiety Research Program study, the presence of a comorbid psychiatric disorder reduced response rates at 1 and 3 years by nearly 50 per cent. In addition, it has been found that concurrent personality disorders impair outcome of treatment for GAD. In one study improvement was comparable among treatment completers with or without Axis II disorders, but attrition was greater in the former (44 per cent) than the latter (19 per cent) group.[69]

The high rates of comorbidity associated with GAD have important implications for treatment. Higher rates of comorbidity are associated with lower rates of remission and greater likelihood of relapse over 12-year follow-up.[70] On the other hand, successful treatment of GAD in patients with comorbid disorders often reduces the severity of the other disorders as well. Borkovec *et al.*[68] examined the effect of various psychosocial treatments for GAD on coexisting anxiety and mood disorders (except panic disorder or severe depression, which were excluded from the study). Across treatments, patients whose GAD improved exhibited reductions as well in other anxiety disorders (mostly social and simple phobia) and dysthymia. Only 4 of 13 successfully treated patients who had additional disorders at pre-treatment continued to have them at post-treatment.

Clinical management

Many anxious patients do not meet diagnostic criteria for GAD. These patients often respond to conservative measures. If the symptoms are minor or are related to a situational stressor, brief psychotherapy and support is the treatment of first choice. In one study, patients who initially reported physical or minor emotional complaints responded better to counselling than to diazepam, even when counselling was limited to only 3 h.[72] Often, an explanation of the relationship of physical symptoms to stress is reassuring to patients and can interrupt a spiral of symptoms leading to anxiety and worry about health, leading to increased symptoms, and so on. Simple behavioural interventions such as relaxation training for patients with prominent muscle tension or breathing exercises for those with dyspnoea or hyperventilation may be helpful as well.

For patients with marked adrenergic symptoms or insomnia, the temporary (a few days to a few weeks) use of a benzodiazepine may be helpful as an adjunct to psychotherapy. In some cases, a hypnotic drug alone is sufficient. In general, as-needed use of benzodiazepines should be discouraged, because it is more likely than scheduled use to foster reliance on drugs as the principal means of coping with anxiety. For the same reason, the drug dose should be kept as low as possible and should be tapered as therapy proceeds.

For patients meeting diagnostic criteria for GAD, treatment with an empirically validated form of psychosocial therapy for GAD is strongly recommended. Such treatments are available in manualized form with accompanying patient workbooks.[55]

When medication treatment is preferred, a trial of buspirone is a good initial choice. Exceptions are patients with comorbid panic disorder or marked adrenergic symptoms, for which benzodiazepines may be better if they are not contraindicated (see below). The typical starting dose of buspirone is 15 mg/day in divided doses (5 mg thrice daily or 7.5 mg twice a day), which is increased by 5 mg/day every few days to a target dose of 30 mg/day. If the response is insufficient after 2 to 4 weeks at that amount, or if the patient is experiencing significant depressive symptoms, the dose may be advanced gradually to a maximum of 60 mg/day. Improvement may continue for up to 3 months.

It is important to inform patients of the typical side-effects and response time of buspirone. Patients who have taken benzodiazepines previously may expect prompt relief and sedative side-effects from the medication and may become discouraged when these are absent. When switching from a benzodiazepine to buspirone, it may be helpful to continue the benzodiazepine during the first month of buspirone therapy before initiating a gradual taper. Remember that buspirone will not prevent benzodiazepine withdrawal symptoms.

Failing a course of buspirone, or in patients with comorbid major depression, trials of antidepressant medications (e.g. imipramine, venlafaxine, trazodone) would be a reasonable second choice. Venlafaxine may be effective at doses as low as 75 mg/day (the usual starting dose). Because of its short metabolic half-life, the extended release form is preferred, which allows once per day dosing and thus may improve compliance. The dose typically is advanced by 75 mg/day every 2 weeks to a maximum of 225 mg/day. Dosing for other antidepressants is the same as for the treatment of depression.

Because of the risk of dependence and (uncommonly) abuse, long-term use of benzodiazepines generally is reserved for patients who do not respond sufficiently to other options. Relative contraindications include a need to be alert (e.g. drivers and machinery operators), a personal or family history of alcoholism or drug abuse, and prominent aggressiveness or irritability. Generally, longer half-life benzodiazepines (e.g. diazepam, clonazepam), which can be taken once or twice daily, are preferred. A typical starting dose is 5 to 10 mg/day of diazepam or equivalent, which is advanced every few days to a maximum of 40 mg/day.

In instances where pharmacotherapy is the primary treatment, responders should be continued on medication for at least 6 months before a gradual drug taper is attempted. Even so, a substantial proportion will relapse after drug discontinuance and will require further treatment. Discontinuing pharmacotherapy in the context of effective psychosocial treatment may improve success rates.

Conclusions

Based on current knowledge, GAD seems to be the exaggerated expression of the human potential to apprehensively anticipate and prepare for future misfortune. As such, it may represent a 'basic' disorder, a better understanding of which may shed light on other anxiety and mood disorders. Although the definition of GAD has been revised considerably since being given status of a full disorder in DSM-III-R, much more information needs to be gathered regarding psychosocial treatments for GAD. In addition, due to its poor diagnostic reliability, many revisions to the diagnostic criteria of GAD have been suggested. Despite the progress in elucidating the nature of GAD, further research needs to be conducted to continue to enhance our understanding and development of effective and generalizable treatments.

4.7.2 Social anxiety disorder and specific phobias

Michelle A. Blackmore, Brigette A. Erwin, Richard G. Heimberg, Leanne Magee, and David M. Fresco

Introduction

As our classification systems have been refined, we have come to view social anxiety disorder (social phobia) and specific phobias as distinct disorders, with divergent patterns of prevalence, aetiology, and course. Moreover, treatments for these disorders have become increasingly sophisticated. This chapter presents an overview of the current state of the field with regard to social anxiety disorder and specific phobias.

Social anxiety disorder

In the first and second editions of the *Diagnostic and Statistical Manual of Mental Disorders* (**DSM**),[1,2] all phobias were grouped together. However, in 1966 Marks and Gelder[3] observed that various phobias had different ages of onset and symptom presentations, providing the initial impetus for the inclusion of *social phobia* as a distinct disorder in DSM-III.[4] At first, research into the nature and treatment of social phobia lagged behind that of other anxiety disorders, leading to its description in 1985 as the neglected anxiety disorder.[5] Over the past two decades, however, attention to the conceptualization, definition, and classification of social phobia has increased dramatically. To acknowledge the significant impairment now known to be associated with social phobia and its differentiation from specific phobia, the alternative (and increasingly utilized) label, *social anxiety disorder*, was added in DSM-IV.[6]

Clinical presentation

Anxiety in situations involving potential evaluation by others (e.g. job interviews, public speaking engagements, first dates) falls within the realm of 'normal' social anxiety. For individuals with social anxiety disorder, however, situations such as these are typically associated with incapacitating levels of anxiety and a desire for escape or avoidance. Socially anxious individuals are often self-critical and perfectionistic and go to great lengths to avoid the negative evaluation of others that they may perceive as epidemic. Commonly, persons with social anxiety disorder experience somatic symptoms such as blushing, trembling, dry mouth, or perspiring, which they believe will be noticed by others and provide further evidence of their incompetence. Children may manifest their anxiety differently than adults; they may cry, throw tantrums, freeze, shrink from interactions with strangers, and they may not acknowledge that their fears are irrational.[6] By leaving anxiety-provoking situations (escape) or foregoing them entirely (avoidance), individuals with social anxiety disorder may reduce or prevent the immediate experience of anxiety, but this behaviour reinforces beliefs in their inadequacies and serves to maintain anxiety in the absence of objective threat.[7,8]

Functional impairment

Individuals with social anxiety disorder experience significant impairment in social, educational, and occupational functioning.[5,9] They are less likely to marry and are more likely to divorce than those without the disorder.[10] They also have fewer friends and more trouble getting along with the friends they have than persons without the disorder.[11] Individuals with social anxiety disorder assessed in a primary care setting reported missing an average of 3 days of work and having an average of 6 days of reduced productivity in the last month because of their emotional problems.[12] Comparatively, mentally healthy individuals reported less than 1 day of lost work and reduced productivity combined. Unemployment, underemployment (working at a level below the individual's abilities), and financial dependency are also characteristic of individuals with social anxiety disorder.[10]

Classification

(a) DSM and ICD

Whereas the DSM is widely used in North America, the *International Classification of Mental and Behavioural Disorders* (**ICD**) is commonly used in other parts of the world. Social anxiety disorder, termed social phobia in ICD-10,[13] first appeared in ICD-10 12 years after its appearance in DSM-III. The ICD-10 criteria for social phobia are less detailed and more circumscribed than those in DSM-IV. Specifically, DSM-IV requires excessive fear of humiliation or embarrassment in social or performance situations, anxiety provoked by exposure to feared situations, recognition that the fear is excessive, avoidance of situations or endurance with distress, and significant distress or impairment. Further, the fear and avoidance cannot be better accounted for by another psychiatric disorder, a general medical condition, or the effects of a substance. The ICD-10, in contrast, requires only that the symptoms be representative of anxiety and not another psychiatric disorder, that the anxiety occurs in relation to social situations, and that avoidance of anxiety-provoking situations be present. Because most published research on social anxiety disorder relies on DSM rather than ICD criteria, this chapter will do so also.

(b) Diagnostic issues

Individuals presenting for treatment of social anxiety disorder endorse multiple fears and significant impairment. The *generalized* subtype is specified when 'most social situations' are feared, whereas the *non-generalized* subtype describes persons who fear a more limited set of social situations. Individuals with generalized and non-generalized social anxiety disorder differ on several dimensions, including symptom severity, functional impairment, and physiological symptoms when exposed to feared situations.[14] Conclusive differences between subtypes in course and response to treatment remain to be demonstrated.[15,16]

Like social anxiety disorder, avoidant personality disorder is regarded as an extreme fear of negative evaluation, leading researchers to view the two conditions on a continuum that is artificially divided at the boundary between Axes I and II. Many investigators conclude that the co-occurrence of generalized social anxiety disorder and avoidant personality disorder represent persons with the most severe social anxiety and the poorest global functioning.[17]

Social anxiety may also develop as a result of medical conditions, such as becoming excessively anxious or avoiding social situations because of obesity, acne, benign essential tremor, stuttering, or the disability associated with Parkinson's disease. These conditions are not considered exemplars of social anxiety disorder because anxiety developed secondary to the medical condition. Rather, they are assigned to the category 'anxiety disorder not otherwise specified'. However, persons who experience secondary social anxiety are often responsive to pharmacological or cognitive behavioural treatments with demonstrated efficacy for social anxiety disorder.[18]

(c) Comorbidity and differential diagnosis

Approximately 81 per cent of persons with primary social anxiety disorder meet criteria for at least one other lifetime psychiatric disorder.[19] Social anxiety disorder most commonly co-occurs with other anxiety disorders,[20] although comorbid diagnoses of depression and alcohol use disorders are also common. Differential diagnosis is complicated by the fact that certain Axis I disorders both resemble and co-occur with social anxiety disorder.

(d) Social anxiety disorder versus panic disorder with agoraphobia (PDA)

PDA can be differentiated from social anxiety disorder in several ways. Although many individuals with social anxiety disorder experience panic attacks, the attacks occur in anticipation of negative evaluation by others. For persons with panic disorder, panic attacks are often unexpected, may not be associated with specific cognitions, and can be nocturnal.[5] Persons with social anxiety disorder are more likely to experience blushing and muscle twitches, whereas individuals with PDA are more likely to experience symptoms such as blurred vision, headaches, chest pain, ringing in the ears, and fear that they will die or go crazy.[21] The age of onset for social anxiety disorder tends to be earlier than that for PDA.[22] Individuals presenting for social anxiety disorder treatment either show an equal gender distribution or are slightly more likely to be male,[23] whereas those presenting for PDA treatment are substantially more likely to be female.[21] Finally, persons with social

anxiety disorder report feeling more comfortable when alone, whereas persons with PDA may feel more at ease in the presence of others.[22]

(e) Social anxiety disorder versus generalized anxiety disorder (GAD)

Individuals with GAD endorse higher levels of social anxiety than other persons with non-social anxiety disorders.[23] Although individuals with either social anxiety disorder or GAD may devote excessive amounts of time to worrying and ruminating, the focus of worry in social anxiety disorder is on fear of evaluation in social or performance situations, whereas the hallmark feature of worry in GAD is heightened focus on possible catastrophic consequences across several domains of life. Persons with social anxiety disorder are more likely to experience sweating, flushing, and breathing problems; those with GAD more commonly experience headaches, insomnia, and fear of dying.[24]

(f) Social anxiety disorder versus depression

Social anxiety disorder and depression may have withdrawal from social situations in common.[21] In differentiating between the two disorders, one must consider the reason for this withdrawal. Persons with depression withdraw because they fail to experience pleasure or lack the energy for social engagement. Individuals with social anxiety disorder fear the negative evaluation they believe to be associated with such situations. Persons with depression may be indifferent about engaging in social situations, whereas individuals with social anxiety disorder often have a strong desire to affiliate with others that is hampered by anxiety.

Epidemiology

(a) Prevalence

The National Comorbidity Survey Replication (**NCS-R**) reported a lifetime prevalence rate of 12.1 per cent[25] and a 12-month prevalence rate of 6.8 per cent[20] for social anxiety disorder. NCS-R lifetime prevalence rates render social anxiety disorder the fourth most common psychiatric disorder behind major depression (16.6 per cent), alcohol abuse (13.2 per cent), and specific phobia (12.5 per cent).

(b) Age at onset/age of treatment seeking

Social anxiety disorder often begins early in life. Mean age of onset for the disorder ranges from 13 to 20 years old, although patients often report having experienced symptoms for as long as they can remember.[26] Despite early onset, persons with social anxiety disorder often do not seek treatment for approximately 16 years after onset,[27] and many never do.[28]

(c) Gender differences

Although men and women with social anxiety disorder who seek treatment do so in relatively equal numbers,[23] epidemiological studies suggest that women are more likely than men to have the disorder.[19,25] In a clinical sample, women reported fear of more social situations and scored higher on several social anxiety disorder assessment measures.[29] Thus, although women are more likely to experience social anxiety, men are more likely to seek treatment and may do so when troubled with less severe symptoms. It may be that social anxiety disorder impairs the expected role functioning of men to a greater extent that it does for women.[29]

Aetiology of social anxiety disorder

Genetic factors appear to contribute to the emergence of social anxiety disorder. Higher rates of social anxiety disorder have been found in relatives of individuals with the disorder compared to relatives of persons without the disorder.[30] Further, rates of social anxiety disorder in first-degree relatives of probands with the generalized subtype are higher than in relatives of probands with the non-generalized subtype or with no psychiatric history.[31] Kendler *et al.*[32] report concordance rates for social anxiety disorder among monozygotic twins (24.4 per cent) to be greater than the rates for dizygotic twins (15.3 per cent). A study conducted with the same cohort 8 years later found the heritability of social anxiety disorder to be approximately 50 per cent in female twins[33] and 25 per cent in male twins.[34]

Neurobiological factors may also be associated with social anxiety disorder. Imaging studies of individuals with social anxiety disorder have demonstrated increased activity in regions associated with fear and anxiety (i.e. prefrontal cortex, amygdala, hippocampus) during anxiety-provoking tasks.[35] Given the efficacy of serotonin reuptake inhibitors and monoamine oxidase inhibitors in treating social anxiety disorder,[36] dysregulation of the serotonin[37] and dopamine[38] systems have been investigated as potential correlates of the disorder.

Several studies also suggest the importance of parental influences and significant life events in the development of social anxiety disorder. Persons with social anxiety recall observing their mothers act more fearful and avoidant of social interactions[39] and describe their parents as overprotective.[40] Stressful social and performance situations early in life (e.g. public ridicule, being bullied, mind going blank during a presentation) are also commonly reported by persons with social anxiety disorder.[41]

Course of social anxiety disorder

Social anxiety disorder is chronic and unlikely to remit without treatment. The disorder persists throughout adulthood[42] and its course is unrelated to gender, age of onset, duration of illness, level of functioning at intake, lifetime history of anxiety disorders, or current comorbidity of anxiety or depressive disorders.[42,43] Two conditions related to social anxiety disorder emerge in childhood and are relatively stable into adulthood—shyness and behavioural inhibition. Individuals who had been shy as children exhibited overall lower levels of functioning when assessed 30 years later.[44] Similarly, children described as behaviourally inhibited, or having the tendency to withdraw from novel people, settings, or objects, have demonstrated increased risk for the development of social anxiety disorder in adolescence.[45] Behavioural inhibition was also more prevalent in children of individuals with anxiety disorders and remained relatively stable for over 7 years in children initially assessed between the ages of 21 to 31 months.[46] These findings suggest that extreme shyness and behavioural inhibition may be early manifestations of social anxiety disorder.

Empirically evaluated treatments

(a) Cognitive behavioural interventions

Cognitive behavioural treatments have been subjected to the most thorough evaluation in the empirical literature. Treatments that utilize exposure alone or combined with cognitive restructuring have received the greatest empirical support and are the focus of

our review. Because of space limitations, other cognitive behavioural treatments, such as social skills training and applied relaxation, will not be reviewed, and the reader is referred to other sources.[47]

(b) Exposure

Exposure requires individuals to imagine (imaginal exposure) or directly confront (*in vivo* exposure) feared stimuli. Research examining the efficacy of imaginal exposure for social anxiety disorder is limited; however, *in vivo* exposure has repeatedly demonstrated short- and long-term efficacy in therapist-directed and self-directed formats.[47] Exposure requires patients to progressively confront anxiety-provoking situations beginning with situations that elicit moderate fear. Patients turn to the next most feared situation after repeated and prolonged exposure to the previous situation no longer elicits a distressing level of fear. Individuals with social anxiety disorder treated with exposure alone experienced greater improvement than individuals receiving relaxation training,[48] pill placebo,[49] or delayed treatment.[50]

(c) Exposure combined with cognitive restructuring

Contemporary cognitive behavioural models of social anxiety disorder propose that anxiety is largely maintained by dysfunctional beliefs and information-processing biases, and that successful treatment will be associated with modification of cognition.[7,8] Accordingly, exposure is typically combined with techniques designed to modify dysfunctional thinking patterns.[51,52]

Cognitive restructuring is an intervention based on the theory that one's thoughts about a situation, not the situation itself, generate anxiety.[53] The intervention is designed to help patients challenge maladaptive beliefs by identifying irrational thoughts, evaluating the dysfunction inherent in these thoughts, and deriving rational alternatives to these thoughts. By engaging in this process and utilizing alternative thoughts during exposure to feared situations, patients acquire new, adaptive learning that competes with their previously-learned maladaptive views, and, in turn, lessens the anxiety they experience.[54]

Efficacy for the combination of cognitive restructuring and exposure has been demonstrated in comparison to wait-list control conditions,[55,56] pill placebo,[57] and psychological placebo conditions.[57,58] Several studies demonstrate equivalent outcomes for exposure alone and exposure plus cognitive restructuring, whereas others indicate the combination shows superior efficacy and additional gains at follow-up.[47] In one meta-analysis,[59] only the combination of exposure and cognitive restructuring was superior to placebo treatments, but this difference has not been reliably demonstrated.[60] Nevertheless, patients treated with exposure alone tend to show deterioration of gains after treatment, suggesting durability of gains may be enhanced with the addition of cognitive restructuring techniques.

(d) Cognitive behavioural group therapy (CBGT)

CBGT, originally developed by Heimberg and Becker,[51] is one of the most thoroughly examined cognitive behavioural treatments for social anxiety disorder. It integrates cognitive techniques and exposure and is typically conducted in 12 weekly, 2.5 h sessions, with approximately six patients and two therapists. In sessions 1–2, patients receive psychoeducation, rationale and instructions for exposure, training in cognitive restructuring, and homework assignments. Thereafter, therapists lead patients through individualized exposures preceded and followed by therapist-directed cognitive restructuring exercises. For homework, patients practice cognitive restructuring before and after exposure to real-life anxiety-provoking situations.

One study evaluating the efficacy of CBGT compared it to educational-supportive group therapy (ES), a credible placebo treatment consisting of lectures, discussions, and social support. Seventy-five per cent of CBGT patients made significant improvement compared to 40 per cent of ES patients.[58] At follow-up (4.5–6.25 years), CBGT produced durable treatment gains.[61] A comparison of CBGT to the monoamine oxidase inhibitor phenelzine, pill placebo, and ES demonstrated equivalent response and attrition rates after 12 weeks of treatment for CBGT and phenelzine, both of which were superior to placebo and ES.[57] Although the phenelzine group evidenced superior improvement on a subset of measures after 12 weeks, CBGT demonstrated more durable treatment gains, with only 17 per cent relapse compared to 50 per cent relapse in the phenelzine group after a 6-month maintenance phase and 6-month follow-up phase.[62] An intensive version of CBGT, based on a hybrid of the treatment approaches developed by Heimberg and by Clark, involving 2 weeks of daily treatment sessions separated by 1 week of homework assignments, also proved superior to a wait-list control.[63]

(e) Individual cognitive behavioural therapy

Group CBT may not always be feasible, particularly in clinical settings where it may be difficult to obtain an adequate number of patients to form a group. However, CBGT has been adapted to an individual format and proven superior to a wait-list control (Heimberg, unpublished observations). Clark[52] also developed a cognitively-focused individual treatment for social anxiety disorder that has demonstrated substantial efficacy. The treatment instructs patients on how to shift their attention externally (rather than on the self) and to reduce reliance on safety behaviours. Video feedback and exposure to feared situations aimed at restructuring distorted cognitions are also incorporated.

Individual cognitive therapy demonstrated superior efficacy to wait-list control, with clinically significant gains observed in 76 per cent of patients receiving cognitive therapy, compared to 38 per cent of patients receiving an applied relaxation treatment and 0 per cent of patients in the wait-list control group.[64] Cognitive therapy was also more efficacious than fluoxetine plus self-exposure instructions and placebo plus self-exposure instructions, with gains maintained at 1-year follow-up.[65] Although meta-analytic studies suggest that individual and group CBT are similar in efficacy,[60] individual cognitive therapy was superior to a group therapy based on Clark's model on several measures.[66] Similarly, individual cognitive therapy proved superior to a 3-week intensive group therapy based on Clark's model and treatment with psychiatrist-selected SSRIs.[67]

Pharmacotherapy

The efficacy of selective serotonin uptake inhibitors (**SSRI**s), serotonin–norepinephrine reuptake inhibitor venlafaxine (**SNRI**s), benzodiazepines, reversible and irreversible monoamine oxidase inhibitors (**MAOI**s), ß-adrenergic blockers, buspirone, gabapentin, and pregabalin have been evaluated in placebo-controlled studies. To date, most controlled trials have included patients with generalized social anxiety disorder, so it is unclear if similar efficacy would be observed among patients with the non-generalized subtype of the disorder.

(a) Selective serotonin reuptake inhibitors and venlafaxine

The SSRIs (e.g. paroxetine, sertraline, fluoxetine, fluvoxamine, and escitalopram) and the SNRI venlafaxine are regarded as first-line medication treatments for generalized social anxiety disorder, given demonstrated efficacy in placebo-controlled trials for the disorder as well as for other anxiety and affective disorders. Further, potential adverse side effects of SSRIs (e.g. sweating, sexual dysfunction) pose a lower risk than potential adverse side effects of the MAOIs (e.g. high blood pressure, seizure) or benzodiazepines (e.g. dependence, overdose).

The SSRIs have demonstrated superior efficacy to placebo as well as CBT in the short-term,[68] with the possible exception of fluoxetine.[65,69] There have been few direct comparisons of the various SSRIs or SNRIs. One study comparing escitalopram (5, 10, 20 mg), paroxetine (20 mg), and placebo, demonstrated superior efficacy for 5 mg and 20 mg of escitalopram and 20 mg of paroxetine compared to placebo at week 12.[70] At week 24, all doses of escitalopram proved superior to placebo and 20 mg of escitalopram proved superior to paroxetine on a subset of social anxiety measures. The SNRI venlafaxine produced results comparable to paroxetine, including superior efficacy relative to placebo.[71]

A fixed-dose trial of paroxetine showed 20 mg/day to be an efficacious and safe dose for the treatment of social anxiety disorder, with superior efficacy to placebo.[72] In a flexible-dose trial, paroxetine proved more efficacious than placebo after 8–12 weeks of treatment, with 55 per cent of paroxetine patients compared to 24 per cent of placebo patients identified as much or very much improved.[73] A double-blind discontinuation study demonstrated a 14 per cent relapse rate in the paroxetine group compared to a 39 per cent relapse rate in the placebo group at week 24.[74]

Van Ameringen and colleagues[75] found sertraline to be more efficacious than placebo, and a 20-week double-blind discontinuation trial demonstrated significantly lower relapse rates for patients continuing on sertraline than patients switched to placebo (4 per cent versus 36 per cent, respectively).[76] A study of fluvoxamine demonstrated superior outcome, beginning at week 8, for patients receiving fluoxamine (20 mg mean daily dose) than patients receiving placebo.[77]

Fluoxetine has yielded less promising results and is the only SSRI to date that has failed to separate from placebo in controlled trials.[65,69] However, in one study fluoxetine evidenced superior efficacy to placebo, although no differences were found between fluoxetine, CBGT, or their combination.[78]

(b) Benzodiazepines

Research suggests benzodiazapines have performed better than MAOIs and CBT in the short-term[68] and offer rapid onset of effect, good tolerability, and minimal side effects (e.g. sedation, withdrawal effects with abrupt discontinuation). However, benzodiazepines are contraindicated in the presence of substance abuse and lack efficacy for comorbid mood disorders. Clonazepam was shown to be efficacious for social anxiety disorder (2–4 mg/day), with patients showing improvement after 6 weeks of treatment and superior response rates compared to placebo patients at week 10.[79] Clonazepam also produced equivalent gains to CBGT after 12 weeks of treatment.[80] One study of alprazolam demonstrated that the medication was no more efficacious than placebo.[81]

(c) Monoamine oxidase inhibitors

MAOIs have demonstrated efficacy in the treatment of social anxiety disorder[36] similar to that of SSRIs. However, MAOI therapy requires strict dietary restrictions as ingesting foods rich in tyramine (e.g. most aged cheeses, red wine, beer) can increase the risk of rapidly escalating blood pressure. MAOIs are also associated with more adverse side effects (e.g. hypotension, sedation, weight gain, sexual dysfunction) than SSRIs. However, MAOI therapy (usually 45–90 mg/day) is justified when other treatments with more benign side effect profiles prove ineffective.

As discussed earlier, phenelzine proved superior to placebo and demonstrated equivalent response rates to CBGT after 12 weeks of treatment,[57], although CBGT evidenced more durable treatment gains.[62] Liebowitz and colleagues[82] found that after 8 weeks of acute treatment and 8 weeks of maintenance, phenelzine produced results superior to those of placebo and the ß-adreneregic blocker atenolol. Versiani and colleagues[83] found patients who received phenelzine endorsed significantly greater reductions in social anxiety than placebo patients at 8 weeks. In a comparison of phenelzine, alprazolam, CBGT, and placebo with instructions for self-exposure,[81] all groups produced relatively equivalent response. However, phenelzine demonstrated maintenance of gains at a 2-month follow-up, whereas alprazolam did not.

(d) Reversible inhibitors of monoamine oxidase

Moclobemide and brofaramine have been evaluated for the treatment of social anxiety disorder and offer fewer side effects and dietary restrictions than MAOIs. However, moclobemide has shown modest efficacy in controlled trials and is less |efficacious than the SSRIs and MAOIs.[36] Although brofaramine was found to be efficacious for social anxiety, it was never marketed.

(e) ß-adreneregic blockers

ß-adreneregic blockers (e.g. atenolol) have failed to surpass placebo in controlled trials.[49] Propranolol appears to be efficacious on an as-needed basis (10–40 mg) for anxiety related to performance situations.

(f) Buspirone

Buspirone appears no more efficacious than placebo at low dosages.[84] One study demonstrated greater efficacy of buspirone in doses greater than or equal to 45 mg/day or when used as an augmentation to an SSRI.[85]

(g) Gabapentin and pregabalin

A single study shows some efficacy of high doses of the anticonvulsant gabapentin (maximum of 3600 mg/day) in the treatment of social anxiety disorder relative to placebo.[86] Pregabalin was also superior to placebo in one study,[87] but a high dose was required as well.

(h) Other agents

D-cycloserine, a partial adrenergic agonist associated with the facilitation of learning and memory consolidation, appears to enhance the efficacy of exposure. Several animal trials demonstrated enhanced fear extinction when d-cycloserine was administered prior to and after exposure trials.[88] Similar results were shown when individuals receiving d-cycloserine 1 h prior to exposure demonstrated significantly less social anxiety posttreatment than those receiving placebo.[89]

Integrating pharmacotherapy and cognitive behavioural interventions

Several studies have examined the utility of combining pharmacotherapy with cognitive behavioural interventions. Blomhoff and colleagues[90] compared sertraline and pill placebo alone and in combination with physician-directed exposure or general medical care, which included non-directive encouragement. After 12 weeks, all active treatments surpassed pill placebo and non-directive encouragement, with sertraline and exposure proving equally efficacious. Only sertraline alone or in combination with exposure proved superior to placebo at 24 weeks. However, only patients who received exposure alone demonstrated further improvement at 1-year follow-up, whereas patients receiving sertraline with or without exposure showed some degree of deterioration.[91]

Preliminary data from a study comparing CBGT, phenelzine, their combination, and pill placebo, suggests phenelzine plus CBGT may be more likely to surpass placebo than either treatment alone.[92] A similar study by Davidson and colleagues[78] found no advantage in combining fluoxetine and CBGT. Preliminary data suggests the combination of d-cycloserine with exposure may enhance the efficacy of exposure treatment.[89]

Evidence for the utility of the combination of these treatments is mixed. To summarize, different studies suggest that combining some medication treatments with CBT is no more efficacious than either treatment alone;[78] combining medication with CBT may diminish the efficacy of CBT;[91] and combining treatments may show only modest benefits over the administration of either alone.[92] The hypothesis that sequential treatments might capitalize on rapid medication response for faster symptom relief and cognitive behavioural treatment for superior relapse protection needs evaluation. Cognitive behavioural treatments may be utilized to help patients discontinue medical regimens after initial drug response.

Management of social anxiety disorder

(a) Treatment selection

Given the chronic nature of social anxiety disorder, CBT offers more enduring treatment gains compared to medication and lacks the adverse side effects. When considering cognitive behavioural interventions, it is important to assess the patient's ability and willingness to endure exposure to anxiety-provoking situations, as exposure necessitates short-term increases in anxiety over and above what the individual may typically experience. Additionally, it is helpful to assess level of compliance with previous therapy experiences (e.g. homework compliance). Managing a patient's treatment expectancy may further improve outcome as individuals reporting higher expectancy regarding the efficacy of treatment have demonstrated greater improvement and maintenance of treatment gains.[93]

Medication may be a preferred choice for individuals requiring rapid response, CBT non-responders, those with a preference for medication, or those with severe social anxiety disorder and/or comorbid depression. When selecting medication treatment, it is important to consider possible side effects, the patient's physical health, and prior medication compliance. Benzodiazepines offer rapid onset of effect, particularly beneficial for short-term performance situations, but their use may be contraindicated among patients with a history of alcohol or substance abuse. Given these concerns and their more benign side effect profile, SSRIs and venlafaxine are best regarded as the first-line medications, with the benzodiazepines and MAOIs held in reserve for non-responding patients. To date, we know little of the appropriate duration of medication treatments in social anxiety disorder, although two studies evidenced significant relapse rates upon discontinuation of SSRIs after a total treatment period of 36–40 weeks.[74,76]

(b) Other issues in management

Comorbid conditions should also be considered when treating social anxiety disorder with cognitive behavioural or pharmacological treatments. Comorbid anxiety disorders do not appear to degrade a patient's response to CBT; however, patients with comorbid mood disorders may present with more severe social anxiety symptoms and, although they improve at a similar rate, require extended treatment.[94] In general, if any comorbid condition prevents the patient from engaging in exposure exercises, taking medications in the prescribed manner, or complying with any other therapeutic activities, it may be necessary to treat the comorbid condition before the social anxiety disorder. In other cases, a comorbid condition might become the focus after social anxiety disorder treatment. Patients who abuse substances to 'treat' their social anxieties are often reticent to give up their substances before other coping strategies are made available. Ultimately, the management of comorbid conditions in individuals with social anxiety disorder depends on the analysis of the relationships between the disorders and varies from case to case.

(c) Prevention

Few studies to date have specifically examined ways of preventing social anxiety disorder; however, evidence for familial aggregation and environmental influence is strong. Parents may reinforce anxious children for making avoidant choices.[95] Thus, it is important to consider including parents of socially anxious children in treatment to provide parents with strategies to help their child manage the social anxiety. Parents with social anxiety disorder may also benefit from treatment themselves.

Since social anxiety disorder has an early age of onset, treatment of children and adolescents should help prevent social anxiety from becoming a chronic condition. Prevention programmes have been integrated into school settings to teach children and parents coping skills (e.g. cognitive restructuring, relaxation) and instruct them on the proper conduct of exposures. Individuals in the intervention group have shown significant improvement compared to non-intervention controls.[96] Similar prevention programmes have targeted at-risk youth and resulted in decreased anxiety symptoms and lower rates of anxiety disorders compared to control groups.[97]

Specific phobia

Clinical features and functional impairment

The hallmark feature of specific phobia, prior to DSM-IV called simple phobia, is a 'marked and persistent fear that is excessive or

unreasonable, cued by the presence or anticipation of a specific object or situation' (6, p. 405). Commonly feared/avoided objects include animals, aspects of nature, or blood. Many individuals endorse some fear of these stimuli; however, in specific phobia, fear and avoidance cause significant interference with one's normal routine, career, academic pursuits, or social activities. Some individuals with specific phobias maintain a relatively normal routine by pursuing a lifestyle that minimizes exposure to the phobic stimulus. Often, specific phobias accompany a more impairing primary disorder that is the stimulus for seeking treatment.[98]

Classification

(a) DSM and ICD

Criteria for specific phobia are similar between DSM-IV and ICD-10. Both view fear as arising from exposure to a specific object or situation, which leads to acute autonomic and psychological symptoms of anxiety. However, ICD-10 does not stipulate that anxiety may be cued by the anticipation of the feared object or situation. Our review of specific phobia follows DSM conventions.

(b) Specific phobia subtypes

DSM-IV classifies specific phobias into five subtypes:

- animal
- natural environment
- blood-injection-injury
- situational
- other (e.g. dental/medical procedures, choking, etc.).

With the exception of blood-injection-injury phobias, exposure to the phobic stimulus evokes intense anxiety that may meet criteria for a situationally-bound panic attack. Additionally, there is extreme apprehension and desire to escape or avoid the phobic stimulus.[99] By contrast, individuals with blood-injection-injury phobias exhibit a biphasic anxiety reaction (vasovagal syncope) characterized by initial, short-lived sympathetic arousal, followed by parasympathetic arousal that may result in fainting.[100] The subjective experiences of these individuals tend to be characterized by disgust and repulsion rather than pure apprehension.[99]

(c) Comorbidity

The vast majority (83.4 per cent) of individuals with specific phobia experience at least one other lifetime psychiatric disorder.[19] In the original National Comorbidity Survey, individuals with specific phobia were 5 times more likely to have at least one additional disorder than individuals who had never met criteria for a phobic disorder. In most cases, the onset of the specific phobia preceded the onset of the other disorder.

Epidemiology

(a) Prevalence

The NCS-R reported a lifetime prevalence rate of 12.5 per cent[25] and a 12-month prevalence rate of 8.7 per cent for specific phobia.[20] One study found situational/environmental phobias to be the most common (13.2 per cent), followed by animal phobias (7.9 per cent) and blood-injection-injury phobias (3.0 per cent).[101]

(b) Age at onset/age of treatment seeking

Age at onset of specific phobia tends to be earlier than other anxiety disorders[19,102] and varies as a function of phobia subtype. For example, animal phobias onset earliest (age 7), followed by blood-injection-injury phobias (age 8), and most situational phobias (early 20s).[103] Individuals with phobic disorders often do not seek treatment for 20 years after onset.[27]

(c) Gender distribution

Women receive diagnoses of specific phobia more often than men. Lifetime rates for specific phobia in the NCS-R were 15.7 per cent for women but only 6.7 per cent for men.[25] In one study, women reported higher rates of animal and situational/environmental phobias, but rates of blood-injection-injury phobia did not differ.[101]

Aetiology of specific phobia

There is considerable evidence for familial/genetic transmission of specific phobia.[32,104] In one study, 31 per cent of first-degree relatives of persons with specific phobia also met criteria for specific phobia.[104] Rates of specific phobia were higher among first-degree relatives of persons with specific phobia and no other anxiety disorder than among first-degree relatives of persons who were never mentally ill.[105] In the Virginia Twin Study,[32] concordance rates for animal phobia were 25.9 and 11.0 per cent among monozygotic and dizygotic twins, respectively. Concordance rates for situational phobia were similar in monozygotic and dizygotic twins. Moreover, children classified as behaviourally inhibited have shown higher risk for the development of multiple specific phobias.[106]

Classical conditioning theory[107] holds that phobias are learned through the association of negative experience with an object or situation. However, individuals with more previous non-traumatic experiences with the object or situation are less likely to develop a phobia upon a negative encounter than those with less prior experience when traumatized. Two-factor learning theory[108] introduced avoidance as a critical component to the maintenance of anxiety. That is, responses of avoidance or escape are learned and serve to decrease the discomfort arising from exposure to conditioned stimuli. Repeated negative reinforcement of avoidance behaviour (i.e. reduction of arousal on removal of oneself from proximity to the phobic object or situation) maintains the fear and makes it resistant to extinction.

Some conditioning theorists assert that feared stimuli are not randomly determined; rather, humans have inherited a predisposition to fear specific stimuli through natural selection. Marks'[109] 'preparedness' theory maintains that commonly feared objects are those that historically threatened the survival of the individual or the species. In this model, phobias are viewed as instances of 'prepared learning', which is selective, easily acquired, difficult to extinguish, and non-cognitive.[110] However, a large number of studies also suggest that phobias may be acquired via observational and informational learning (e.g. hearing that the situation is dangerous).

Course of specific phobia

Individuals with specific phobias acquire their fear(s) early in life, and the disorder tends to be chronic or recurrent without treatment.[111] Often individuals with specific phobias adapt their lifestyle to avoid contact with the feared stimuli, such that only

persons with the most severe specific phobias seek treatment. Events that commonly precipitate treatment seeking include a change in lifestyle that increases exposure to the feared stimulus (e.g. change in occupation that requires frequent air travel) or the experience of a panic attack in anticipation or in the presence of the feared stimulus.

Empirically evaluated treatments

(a) Cognitive behavioural interventions

(i) Exposure

Prolonged and repeated *in vivo* exposure to feared stimuli is by far the most studied and efficacious intervention for specific phobia[112] and should be considered the first-line treatment. Although *in vivo* exposure is generally believed to be more efficacious than imaginal exposure for specific phobia, some studies found *in vivo* and imaginal exposure techniques to be similarly efficacious.[113] Modelling in the form of observing another patient receive treatment has been shown to enhance the effects of exposure and to increase the speed at which positive outcomes are attained.[114] Multiple exposures sessions are considered more efficacious than one session, although some studies report positive outcomes for one-session treatments.[115] Further, one-session group *in vivo* exposure treatment has produced gains similar to those of one-session individual *in vivo* exposure treatment.[115] Variations in spacing of exposure sessions (e.g. 10 daily versus 10 weekly) have shown equivalent outcomes.[116] Finally, therapist-directed treatments have generally been more efficacious than self-directed treatments,[117] with gains enduring up to 8 years.[114] When possible, exposures should be conducted in a variety of settings to enhance generalization outside the therapeutic setting.[54]

In vivo exposure situations can sometimes be difficult to arrange and imaginal exposure may not achieve the reality or intensity needed to elicit an anxiety response. In such instances, virtual reality exposure (**VRE**), in which feared situations are presented in three dimensional simulations, may greatly enhance the efficacy of exposures. The salience of virtual environments can be augmented by instructing patients to touch real objects (e.g. toy spiders) which correspond with the virtual environment. Recent case studies demonstrated the efficacy of VRE either alone[118,119] or in combination with anxiety management training.[120] In a controlled trial for fear of flying, VRE training showed equivalent gains to *in vivo* exposure at 6 and 12-month follow-up[121]. Another study indicated that VRE produced superior gains to an attention placebo therapy, although gains were not maintained at 6-month follow-up.[122] D-cycloserine in combination with VRE has also shown enhanced treatment efficacy over VRE with placebo.[123]

(b) Applied relaxation and applied tension

Applied relaxation combines focused attention on different muscle groups while tensing and relaxing muscles,[124] with instruction to practice these skills first in non-anxiety-provoking situations and then in anxiety-provoking situations.[125] Although research is limited, applied relaxation has demonstrated efficacy,[126] especially among patients with higher levels of physiological reactivity than behavioural avoidance. *Applied tension*, designed specifically for blood-injection-injury phobia to treat parasympathetic arousal, requires the patient to tense different muscle groups in the presence of phobic stimuli to elevate blood pressure. Persons with phobias for blood, wounds, and injuries responded equally well to applied tension, applied relaxation, or their combination[127] Individuals treated with applied tension also evidenced greater treatment gains posttreatment and at 1-year follow-up than those treated with *in vivo* exposure alone.[128] In one dismantling study, individuals treated with applied tension and tension only (without the exposure component) evidenced equivalent gains and maintained superior outcomes at posttreatment and 1-year follow-up compared to patients who received *in vivo* exposure.[129]

(c) Cognitive restructuring

Phobia-specific irrational thoughts may contribute to the development of the phobia, maintain avoidance behaviour, and contribute to physiological symptoms.[130] When combined with exposure to feared stimuli, cognitive restructuring has proven efficacious,[131] although there are relatively few studies of cognitively-oriented treatments for specific phobia.

Pharmacotherapy

Drug treatments for specific phobia have consistently been shown to be less efficacious than behavioural treatments and may hinder maintenance of treatment gains. ß-Adrenergic blockers reduce some symptoms of sympathetic arousal during exposure to feared stimuli but fail to decrease subjective fear.[132] Although benzodiazepines (e.g. diazepam) may facilitate approach to feared stimuli, they may also reduce the efficacy of behaviour therapies by inhibiting the experience of anxiety during exposure.[133] Recent studies suggest d-cycloserine may facilitate exposure and extinction to specific feared stimuli. In a study of acrophobia patients, d-cycloserine was administered prior to exposure sessions and proved superior to placebo in reducing anxiety symptoms.[123]

Management of specific phobia

(a) Treatment selection

Exposure is clearly the treatment of choice for specific phobia, although facing feared stimuli may be particularly challenging for some patients, and their willingness and ability to participate in exposures should be assessed prior to treatment. Tailoring treatment to individual response patterns may improve outcome. For instance, patients with heightened physiological reactivity may respond preferentially to applied relaxation, whereas patients showing avoidance behaviour may respond better to *in vivo* exposure.[126] Further, individuals who experience anxiety primarily in the form of anxious thoughts may respond better to cognitive techniques.[134]

For patients unwilling or unable to engage in cognitive behavioural interventions, medication may be an appropriate alternative. However, it is first important to educate patients about the possibility of dependence with regular use and the side effects of high doses (e.g. sedation). If the patient is participating in exposure therapy, it is also necessary to explain that medication may interfere with the efficacy of exposure treatment.

(b) Prevention

Children with specific phobia were included in the Queensland Early Intervention and Prevention of Anxiety Project, but no other preventive efforts have been mounted. It is tempting to speculate that children could be 'inoculated' against a variety of the more common specific phobias by systematic exposure to potentially feared objects or situations.

4.7.3 Panic disorder and agoraphobia

James C. Ballenger

Introduction

Panic disorder draws its name from the Greek god Pan, god of flocks. Pan was known for suddenly frightening animals and humans 'out of the blue'. The spontaneous 'out of the blue' character of panic attacks is the principal identifying characteristic of panic disorder and central to its recognition and diagnosis.

We know the syndrome that we currently call panic disorder with and without agoraphobia has probably existed since the beginning of recorded history. Hippocrates presented cases of obvious phobic avoidance around 400 BC.[1] One of the first modern descriptions was by Benedikt around 1870, describing individuals who developed sudden anxiety and dizziness in public places.[2]

Certainly, our current modern ideas of panic disorder evolved essentially simultaneously in the United States and Europe in the early to mid-1960s. Donald Klein in the United States described in 1964 the panic syndrome and reported that it was responsive to imipramine.[3] Isaac Marks in the United Kingdom also described panic attacks and agoraphobic avoidance, and treating the syndrome effectively with behaviour therapy.[4]

Until the last several decades, panic disorder and agoraphobia were actually thought to be rare syndromes. It is now clear that individuals with these difficulties are anything but rare. In fact, panic disorder is one of the most common presenting problems in individuals seeking mental health treatment and the fifth most common problem seen in primary care settings.[5] It was thought to be a mild problem, but we now know that it is associated with significant dysfunction. The disability in social, occupational, and family life is in fact comparable to major depression.

Although there are differences in the understandings of panic disorder and its treatments across the world, this chapter will review the current understanding about panic disorder, its characteristics, diagnosis, aetiology, and treatments.

Clinical features

One of the earliest and most accurate descriptions of panic attacks was provided by Charles Darwin in 1872 as he described his own episodes:

> The heartbeats quickly and violently so that it palpitates and knocks against the ribs . . . the skin instantly becomes pale as during incipient faintness . . . under a sense of great fear . . . in connection with the disturbed action of the heart, the breathing is hurried . . . one of the best marked symptoms is the trembling of all the muscles of the body.[6]

The most characteristic type of panic attack is the spontaneous 'out of the blue' episode of extreme anxiety. Other 'situational panic attacks' occur immediately upon exposure, or in anticipation of exposure to particular situations, usually where panic attacks have occurred previously. Some individuals have panic attacks in certain situations some of the time, but not always, and these are labelled 'situationally predisposed panic attacks'.

Panic attacks also occur in other anxiety syndromes and are more or less the same in whatever syndrome where they occur. However, spontaneous panic attacks in panic disorder tend to have more dizziness, paraesthesia, shaking, chest pain, and fears of going mad. Shortness of breath is more common in panic attacks in agoraphobia. Certainly blushing is particularly characteristic of panic attacks in social phobia.

The symptoms of panic attacks in order of their frequency include palpitations, pounding heart, tachycardia, sweating, trembling or shaking, shortness of breath or smothering, feeling of choking, chest pain or discomfort, nausea or abdominal distress, feeling dizzy, unsteady, lightheaded or faint, derealization or depersonalization, fear of losing control or going mad, fear of dying, paraesthesia, and chills or hot flushes.

Panic attacks by definition generally involve four or more of the above symptoms to meet diagnostic criteria for panic disorder in the DSM-IV. The anxiety is crescendo in nature, building to a peak in 10 min in most cases. Panic attacks usually last for several minutes, but in some patients they can last for hours. The frequency and severity of panic attacks varies greatly between individuals and, at times, in individuals. Some have only one to three panic attacks per year, whereas others may have multiple panic attacks each day. Some individuals have bursts of panic attacks and then an absence of all attacks for a period of time. Across a large panic disorder clinical trial, the typical patient described one to two panic attacks per week.[7]

Panic attacks with fewer than four symptoms have been labelled 'limited-symptom attacks' or 'little panic attacks', and most individuals with panic disorder have these, as well as panic attacks with four or more symptoms. The threshold of four symptoms was chosen for DSM-IV because individuals with panic attacks with four symptoms or more had more disability than patients with one- to three-symptom attacks. This threshold is clearly arbitrary, and patients having panic attacks with fewer symptoms do have significant morbidity.

Panic attacks are extremely frightening and patients develop an essentially logical fear of having more panic attacks. Patients develop worry and anxiety about the possibility of panic attacks recurring. This anxiety between attacks has been called 'anticipatory anxiety' and can be almost constant, and characteristically increases prior to exposure to situations previously associated with panic attacks (e.g. having to shop in the supermarket where a panic attack has occurred).

A significant number of people with panic attacks go on to develop fear and avoidance of situations associated with previous panic attacks. They also fear situations where escape would be difficult or embarrassing, or where help might not be available. Most patients mistakenly believe they become incapacitated and incapable of taking care of themselves during a panic attack and therefore, many go on to develop avoidance of a variety of situations where they could not easily get help. Factor analytical studies demonstrate that there are clusters of situations associated with avoidance. These typically include public transportation (e.g. buses, trains, planes), riding in or driving a car, especially on heavily travelled roads, crowds (e.g. the cinema, a football match, large shopping centres), shopping (especially in supermarkets), particularly where one must stand in queues, and bridges, tunnels, elevators, and other enclosed spaces.[8] In the event of a panic attack, people often have an overwhelming need to escape or return to a place of safety such as home. Therefore they fear situations where escape is difficult or impossible, e.g. airplanes, traffic jams on a bridge, dental appointments, etc. On closer examination, it is clear that patients do not actually fear the situation itself but rather reason 'what if' the panic feelings occur while in that situation. This has led to the syndrome being called the 'what if' syndrome, emphasizing that there is actually a 'fear of the fear'.[9]

Patients tend to avoid such situations or force themselves to endure them in distress or take a companion along 'to help'. Others limit their travel to short distances from home or take longer routes where they perceive help would be available (e.g. police, doctors' offices, fire stations, etc).

Some patients develop agoraphobic avoidance following their first attack, some only after frequent and severe attacks, and some never develop agoraphobic avoidance. In community samples, one-third to half of patients who meet criteria for panic disorder also has significant agoraphobic avoidance. The rate is higher (75 per cent) in most clinical samples. A minority (5 per cent) ultimately become unable to leave their homes and are housebound.

Many patients have panic attacks that awaken them from sleep (nocturnal panic attacks), as well as during the day. These are in fact quite common and the majority of panic disorder patients experience them. These occur during slow wave sleep early in sleep. These panic attacks are essentially identical to traditional panic attacks that occur during the day. There is a group of patients who have what are called non-fearful panic attacks. These involve the sudden onset of physiological symptoms without the cognitive components of fear or anxiety. These primarily are medical patients, usually cardiac, who might have episodes of sudden tachycardia and palpitations but no fear.[10]

Classification

The earliest modern accounts of what is almost certainly the panic disorder syndrome began appearing in the mid-1900s. There were accounts beginning in 1866 of paroxysmal anxiety episodes that did not use the term 'panic attack'. During the American Civil War, patients were diagnosed with 'irritable heart syndrome' or 'Da Costa syndrome' (1871) with clear descriptions of what we now know as panic disorder. Westphal in Germany in 1872 clearly described patients having panic attacks and agoraphobic avoidance of wide open spaces.[11] Again, in the First World War (1918) the syndrome 'neurocirculatory asthenia' was described which had most of the features of panic disorder.

It was, in fact, Freud in Case IV of Katharina, published in 1895, who set the background for the modern classification of panic disorder. However, it was the Feighner criteria published in the United States in 1972 that give the first formal diagnostic recognition to the syndrome.[12] The Research Diagnostic Criteria (RDC) which followed in 1978 first split panic disorder away from what we now call generalized anxiety disorder (GAD). In the RDC, panic disorder had panic attacks while GAD did not. These diagnoses were made part of the DSM-III diagnostic scheme in 1980.

It was the conceptualization of panic disorder by Donald Klein in 1964 in the United States that led to the predominant view of the syndrome, certainly in the United States.[13] Klein argued that panic attacks were the core of the syndrome, and the remaining clinical phenomena were consequences of the panic attacks. He conceptualized that anticipatory anxiety was the fear of the possible recurrence of panic attacks, and similarly that agoraphobia was the subsequent fear and avoidance of situations where panic attacks had occurred. The bringing together of these three phenomena into one concept was accepted in the DSM-IIIR, and more recently in the DSM-IV in the United States.[14]

The biological findings that typical panic attacks could be elicited in panic disorder patients with infusions of lactate, doses of caffeine, or breathing 35 per cent CO_2 supported this conceptualization of the syndrome as primarily centered around panic attacks. This hypothesis was further supported by epidemiological findings of essentially the same illness around the world.

However, this idea remains controversial across the different sides of the Atlantic. The American DSM-IIIR and DSM-IV diagnostic schema continue to utilize the idea that panic attacks are pre-eminent and created two diagnoses: panic disorder and panic disorder with agoraphobia. In Europe and in the ICD-10, agoraphobia is conceptualized as dominant over panic attacks. Therefore, when agoraphobia and panic attacks are both present, the diagnosis is conceptualized as a phobia and that condition is diagnosed as agoraphobia with panic attacks. Beyond this theoretical debate is the clinical question whether the treatment should be aimed first at panic attacks (in the United States concept) or at agoraphobic avoidance, for example with exposure therapy (in the European schema).

(a) Diagnosis

The most recently revised diagnostic schema for this syndrome is the DSM-IV. Changes from the DSM-IIIR were made based on two principles:

1 any new empirical data that required changes be made;

2 an attempt to make the DSM-IV and ICD-10 more compatible.

For the diagnoses of panic disorder and agoraphobia, an attempt was also made to more nearly describe the prototypic patient and to move away from the pseudoquantification of using number of panic attacks per week.[14]

The DSM-IV clarified that panic attacks occurred in multiple syndromes including social phobia, obsessive–compulsive disorder, depression, and others. However, DSM-IV utilized the distinction that only in panic disorder were there recurrent spontaneous panic attacks not bound to any particular situation. The diagnosis of panic disorder has several requirements including the following:

- Recurrent, unexpected panic attacks (situational panic attacks could also occur but there would need to be at least two unexpected panic attacks by history).
- Panic attacks needed to be followed by at least 1 month of persistent anxiety about potential recurrence of further panic attacks, implications of these attacks (e.g. going mad, something wrong medically), or a significant behavioural change because of these attacks. This was necessary because some patients had panic attacks and completely changed their lives but denied that they were worried about experiencing more panic attacks or the implications of the panic attacks.[14]

The agoraphobia criteria remained largely unchanged, but it was made more clear that the diagnosis was based on persistent fear and avoidance of certain clusters of situations and listed the most common.

The controversial diagnosis of agoraphobia without a history of panic disorder was retained until further clarification is obtained through research. Our current understanding is that these patients generally have never fully met criteria for panic disorder because their panic-like symptoms have not met the diagnostic criterion requiring four full symptoms for a panic attack. Available research suggests that these patients are otherwise very much like typical patients with panic disorder and agoraphobia. Some patients actually have only one or two symptoms (e.g. fear of loss of bladder or bowel control or only tachycardia).

Perhaps the most difficult diagnostic issue is the frequent comorbidity. The Epidemiologic Catchment Area study documented that approximately 50 per cent of panic disorder patients over their lifetime have another anxiety disorder.[15]

In actuality, depression is more commonly comorbid with panic disorder than even agoraphobia and suggests a close relationship between these syndromes. Comorbid depression ranged from 22.5 to 68.2 per cent in various samples. Lifetime rates vary from 35 to 91 per cent.[16] Although approximately half the patients developed panic disorder and depression at essentially the same time, one-quarter develop depression before panic disorder and one-quarter panic disorder before depression.[17] Surprisingly, bipolar illness has been reported to be as high as 20.8 per cent.

Easily one-third of panic disorder patients abuse alcohol. The percentage in clinical samples is much higher with 13 to 43 per cent of panic disorder patients also meeting criteria for alcoholism.[18]

(b) Differential diagnosis

It is particularly important to determine whether agoraphobic avoidance is present, because its treatment usually requires some sort of exposure therapy. Patients will often not volunteer that they are avoiding certain situations out of embarrassment. As mentioned earlier, depression and panic disorder often occur together and again patients often do not describe the other syndrome, but rather describe the syndrome which is most painful to them at that time. However, proper recognition of comorbid depression is especially important because of the marked increase (four-fold) in suicide attempts in patients with panic disorder and depression.

The difference between panic disorder and GAD depends on whether patients have panic attacks and whether they have multiple, unrealistic, and excessive worries about most aspects of life, not just panic attacks. These worries in GAD often concern money, health, children, work problems, etc. The differential with social phobia centres on whether the anxiety is confined entirely towards social situations where the individual fears embarrassment and humiliation. Specific phobias involve panic attacks, but they occur in very specific situations (e.g. high places, thunderstorms) or in the presence of specific objects (e.g. animals, snakes). The post-traumatic stress disorder patient may have many panic-like symptoms, but their illness begins quite specifically after a traumatic experience and anxiety is associated with reminders of that trauma. Finally, obsessive–compulsive disorder can involve panic attacks but only in the specific context of obsessional concerns (e.g. contamination, etc.). In these patients, panic attacks are also dwarfed in importance by typical obsessions and compulsions/rituals concerning contamination, symmetry, bad events, etc.

(c) Medical conditions

Panic-like symptoms do occur in various medical conditions (hyperthyroidism, phaeochromocytoma, hyperparathyroidism, seizures, cardiac arrhythmias, especially supraventricular tachycardia, inner ear difficulties, chronic obstructive pulmonary disease, use of marijuana, withdrawal from drugs of abuse, and over the counter drugs containing caffeine or pseudoephedrine) (Table 4.7.3.1). Also, the typical panic disorder patient does report a large number of physical symptoms and usually to a non-psychiatric physician.

As mentioned, there are medical conditions that can mimic panic disorder (Table 4.7.3.1). There is also evidence that there are slightly increased rates of certain illnesses, for example hyperthyroidism (11–13 per cent) and perhaps mitral valve prolapse. However, these are uncommon in panic disorder patients. Most experts recommend a relatively conservative diagnostic medical work-up. Generally, the most valuable part of a medical examination is a careful history with follow-up of any strongly suggested possibilities, supplemented by a few laboratory tests (complete blood count, thyroid function tests, metabolic screen, and ECG, especially if the patient is over 40 years of age).

(d) Panic disorder in the general medical setting

Conservative estimates of panic disorder in primary care have ranged from 3 to 8 per cent with at least 50 per cent going unrecognized.[19] The average panic disorder patient in general medicine

Table 4.7.3.1 Medical conditions that produce panic-like symptoms

Endocrine	*Respiratory*
Hyperthyroidism	Chronic obstructive
Hypoparathyroidism	pulmonary disease
Hypoglycaemia	Asthma
Phaeochromacytoma	*Substance-induced*
Carcinoid syndrome	Caffeine
Cushing's disease	Cocaine
Cardiovascular	Marijuana
Arrhythmias (supraventricular)	Theophylline
Atypical chest pain	Amphetamines
Mitral valve prolapse	Steroids
Neurological	Alcohol/sedative
Seizures	withdrawal
Vestibular disease	*Haematological*
	Anaemia

takes 10 years or more for a correct diagnosis to be made with an escalation of the use of health care services over this period. In general, the presence of panic disorder leads to a three-fold increase in utilization of general medical services.

The percentage of panic disorder patients is also markedly higher in certain medical groups. These include the very prevalent but most difficult to diagnose patients with vague symptoms such as fatigue, back pain, headache, dizziness, chest pain, etc.[20] or multiple symptoms (more than five).[21]

In a classic study of unrecognized panic disorder patients who were referred for a psychiatric consultation from primary care, 39 per cent had cardiovascular symptoms, 33 per cent gastrointestinal symptoms, and 44 per cent neurological.[22] It is now clear that 16 to 25 per cent of patients presenting to the emergency room with chest pain have panic disorder. Fully 25 per cent of cardiology practice involves panic disorder, usually unrecognized with 80 per cent of patients with chest pain and normal angiograms ultimately diagnosed with panic disorder. We could also increase our yield of recognizing panic disorder patients in certain procedure-oriented situations. For instance, 28 per cent of patients referred for Holter monitoring for palpitations have panic disorder, as do 66 per cent of patients undergoing a work-up to rule out phaeochromocytoma.[23] Also, 44 per cent of irritable bowel syndrome and 15 per cent of patients with headache symptoms seeing a physician have panic disorder, and these are both very prevalent disorders.

Recent studies document that treatment of panic disorder in the medical setting when diagnosed there is most cost-effective.

(e) Comment

A recent large study sponsored by the World Health Organization (WHO) studied primary care patients in 14 different countries.[19] Of patients in that study who had a single panic attack in the previous month, 99 per cent had an anxiety disorder or depression, or a subthreshold anxiety disorder or depressive disorder. The occurrence of a single panic attack also predicted the onset of panic disorder in two-thirds of the patients studied in the next year, a four-fold increase in depression (51 per cent) in the next year, and marked increases in alcoholism, social phobia, and obsessive–compulsive disorder. It would appear that the occurrence of even a single panic attack may well represent the 'tip of the iceberg' and should serve as a signal for increased scrutiny for anxiety and depressive syndromes. This has been recently replicated in a large ($N = 3021$) European sample.[24]

Epidemiology

Surveys largely utilizing DSM diagnoses have found wide agreement and generally equal prevalence's of panic disorder across many countries.[16,25] Utilizing specific criteria for panic attacks, prevalence for panic attacks has generally averaged 7 to 9 per cent of the population (range 1.8–22.7 per cent). However, if criteria for panic attacks are liberalized somewhat ('fearful spells') in terms of the number of times and severity, the prevalence doubles.

There is a striking uniformity worldwide for the observed prevalence of panic disorder. In 10 community studies involving over 40 000 subjects, the majority of studies found lifetime prevalence rates for panic disorder averaging 1.5 to 3.7 per cent, with a yearly prevalence of around 1 and 1.1 per cent of panic disorder with agoraphobia (lifetime).[25] In clinical samples there is greater variability. In the previously mentioned WHO survey of 14 countries, the prevalence for panic disorder in primary care ranged from a low of 1.4 per cent to a high of 16.5 per cent for panic attacks and 0 to 3.5 per cent for panic disorder itself.[19] The average was 1.1 per cent (currently) and 3.5 per cent (lifetime), which is surprisingly similar to the community samples. As mentioned, rates are much higher in specialized medical clinics and range from 15 per cent in dizziness clinics, to 16 to 65 per cent in cardiology practices, to 35 per cent in hyperventilation clinics, etc.

Risk factors

Panic disorder has been uniformly observed to be at least two times more prevalent in females than males.[25] The Epidemiologic Catchment Area study demonstrated a prevalence of 3:2. In clinical samples it is generally 3:1. The onset of panic disorder appears to fall into two peaks. The first occurs in the early to mid-twenties (15–24 years old) with a second peak at 45–54 years of age. The onset of panic disorder after the age of 65 is rare (0.1 per cent).

The highest rates of panic disorder and agoraphobia occur in widowed, divorced, or separated individuals living in cities. Limited education, early parental loss, and physical or sexual abuse are also risk factors. Agoraphobia is clearly more prevalent in females, and females make up three-quarters of the sample with extensive avoidance. Males tend to have longer duration of illness but less agoraphobia and depression, and less frequent help seeking. Perhaps the greater necessity to perform in the workplace retards avoidance in males.

Aetiology

Genetic predisposition

Certainly the preponderance of evidence suggests there is a genetic contribution to the predisposition to develop panic attacks and agoraphobia. There are increased rates of panic disorder in first-degree relatives ranging from 2- to 20-fold with the median

seven- to eight-fold. Overall, studies suggest that another affected relative can be found 25 to 50 per cent of the time, two times as often in female relatives. The increased familial aggregation is specific for panic disorder. These findings are certainly consistent with a modest genetic transmission with relatively high specificity.

Although twin studies are limited, Torgersen[26] did find increased concordance in monozygotic twins (31 versus 0 per cent). In the largest sample of interviewed female twins, a several-fold increase was again found (23.9 versus 10.9 per cent).[27] Skre *et al.*[28] found a two-fold increase of panic disorder in monozygotic twins, while other studies fail to find an increased incidence.

Overall, evidence from family and twin studies suggests that panic disorder involves modest inheritability of around 30 to 40 per cent. The best model suggests 50 per cent genetic and 50 per cent environmental influences. Recent linkage studies to confirm these hypotheses have been contradictory (e.g. with angiotensin, brain-derived neurotropic factor) but do suggest that single-gene transmission is unlikely. However, research is active in this area with positive replicated linkages with chromosomes 13q, 22q, 7p, and 9q31. Identified candidate genes include the ADOR2A, 10832/T, CCK genes, and genes coding for the 5HT1A, 5HT2A, and COMT genes and there is evidence of a link to the corticotrophin releasing hormone gene.[29] This leaves the possibilities of either heterogeneity across families and/or a polygenic inheritance.[30]

Several converging lines do link childhood anxiety with adult anxiety, consistent with a genetic predisposition. This is particularly true for separation anxiety in children. Kagan *et al.*[31] have prescribed that 10 per cent of Caucasian children are born with heightened anxiety which they call behavioural inhibition. Behavioural inhibition is higher in children of anxiety-disordered parents, and there are high rates of anxiety disorders in children of adults with panic disorder. As behaviourally inhibited children have matured, they have been found to show higher rates of anxiety and phobic disorders.[32] Currently, this is probably the best model of an inherited anxiety predisposition. A variant of this type model proposes that there is an aethological factor involving an evolutionarily determined vulnerability to unfamiliar territory. This might explain why the seemingly inherited anxiety is to specific situations. This is also consistent with the high rate of precipitating events prior to the onset of clinical difficulties. In this model an evolutionarily/genetically determined vulnerability would be clinically 'activated' by critical stressors.

Precipitating events have been reported in 60 to 96 per cent of cases. These have often centred on separation or loss, relationship difficulties, taking on new responsibility, and physiological stressors (e.g. childbirth, surgery, hyperthyroidism).[33] This is certainly consistent with a diathesis/vulnerability model with the illness being precipitated in a predisposed individual in adulthood.

There are also many studies suggesting that traumatic early events may figure in the vulnerability leading to panic disorder. The majority of children in some studies have experienced early parental separation. A traumatic event in childhood has been retrospectively reported in at least two-thirds of individuals, a three-fold increase.[34] The most common adult disorder following sexual abuse before the age of five is in fact a 44 per cent incidence of agoraphobia.[35]

There is some evidence in a prospective study involving over 3000 individuals that dependent personality traits were later associated with the development of anxiety disorders. There are also retrospective data that adult panic disorder patients describe their parents as being overly protective and less caring. It is difficult to separate the effects on individuals of the anxiety disorders themselves which create dependent behaviour, or overprotectiveness in the parents producing dependent personality traits.

Biological models

(a) Noradrenaline

There is considerable evidence implicating the brain noradrenaline (norepinephrine) brain systems and panic disorder. The noradrenergic agents yohimbine and isoproterenol stimulate panic attacks in panic disorder patients, suggesting a possible subsensitivity of pre-synaptic alpha 2 inhibitory adrenoreceptors. Both these drugs increase the firing rate of the locus ceruleus, generally thought to be part of the brain anxiety circuit. It is also true that most effective medications in the treatment of panic disorder in fact decrease locus ceruleus firing rate and most panicogenic stimuli increase the locus ceruleus firing rate.

(b) Serotonin (5HT)

Findings with 5HT brain systems in panic disorder are contradictory, probably because of the different 5HT circuits and receptors in different areas of the brain. Most investigators believe, however, that an increase in 5HT transmission decreases panic disorder perhaps because 5HT neurones in ventrolateral periaqueductal grey appear to inhibit sympathoexcitation and the fight or flight response in the rat.[36] The principal human evidence for 5HT being central in panic is that the selective serotonin reuptake inhibitors are effective and that they increase 5HT transmission after long-term use. Also, rapid depletion of 5HT has been shown to result in an increase in panic responses to flumazenil. Whether this increased neurotramsmission in fact leads to downregulation of a supersensitive post-synaptic receptor is one logical possibility, but is as yet unproven. These theories received recent support from PET scan studies demonstrating reductions in brain 5HT1A receptors[37] and 5HT transporter binding.[38]

(c) γ-Aminobutyric acid

The γ-aminobutyric acid (GABA) system is almost certainly involved in panic disorder with perhaps the strongest evidence being that benzodiazepine agonists such as alprazolam and clonazepam are clearly effective treatments for panic disorder. Also GABA antagonists such as flumezanil have panicogenic effects in panic disorder patients, and reverse benzodiazepine agonists such as β-carbolines can cause panic attacks. There is an impaired GABA neuronal response to benzodiazepines (BZs) on brain magnetic spectroscopy and decreased GABA levels in the cingulate and basal ganglia, also on magnetic spectroscopy. Also, positron emission tomography data have demonstrated decreased benzodiazepine binding in the inferior brain areas, including the inferior parieto-temporo-occipital areas.

(d) Cholecystokinin–pentagastrin

Cholecystokinin is clearly involved in anxiety in animals. Also, panic disorder patients develop panic attacks in a dose-dependent fashion with administration of pentagastrin. However, cholecystokinin antagonists have not yet been shown to be effective in humans.

Recent genetic studies implicate CCK gene polymorphisms in panic disorder.

(e) Brain imaging

The explosion of brain imaging data demonstrating a brain circuit for fear and anxiety involving the extended amygdala circuit (amygdala, hippocampus, periaqueductal grey, locus coeruleus, thalamus, cingulate, and orbitofrontal areas) has lead to the hypotheses that it is this circuit which is abnormally active in panic disorder.[39]

(f) Psychological factors

Many critics disagree with the importance of biological findings in panic disorder, principally, various European workers and the cognitive theorists. They argue that panic attacks are not 'biological' and that a phobic attitude is required, and/or certain temperamental factors. Others attempt an integrated model utilizing both findings of biological differences and psychological factors of temperament and child-rearing practices.

Course and prognosis

There is limited evidence with appropriate population-based samples to clearly delineate the course of panic disorder. Available evidence suggests that panic disorder is a stable but chronic condition once criteria for the disorder are met. Most patients seeking treatment have experienced chronic, frequently chronically worsening, illness generally for 10 to 15 years prior to diagnosis.[7] However, other evidence does suggest that there is heterogeneity in terms of course.

As previously mentioned, the Klein model suggests that spontaneous panic attacks are the first manifestation of the illness, followed by anticipatory anxiety, and agoraphobia in some individuals. However, for most panic disorder patients examined closely, a panic attack is rarely the first symptom. In some studies, over 90 per cent of patients have had mild phobic or hypochondriacal, milder symptoms prior to the onset of their first panic attack.

The first panic attack is usually in a 'phobogenic' situation such as a public place, street, store, public transportation, crowd, elevator, tunnel, bridge, or open space. As mentioned, these are often preceded by stressful life events.

The earliest studies indicated low-recovery rates with chronic waxing and waning in most patients. Some individuals have outbreaks of symptomatology with less difficulty in between, but the majority of untreated individuals seem to have a more or less continuous symptom picture which ranges from mild to severe.

Recovery rates vary from 25 to 75 per cent for 1 to 2 years follow-up. Over a 5-year follow-up, only 10 to 12 per cent had fully recovered in one study and 30 per cent in another. The most common picture is about 50 per cent of patients are neither well nor very sick with mild symptoms most of the time.[40] After diagnosis and some sort of treatment, functional recovery occurs in the majority of patients.[41]

In acute pharmacological trials, 50 to 70 per cent of patients have excellent acute responses with another 20 per cent having a moderate response. With behavioural therapy, again the majority of patients recover and in some trials over 75 per cent of patients are much improved 1 to 9 years following therapy, with an average decrease in symptoms of 50 per cent.[42]

Poor responses were most consistently associated with initial high symptom severity and high agoraphobic avoidance at baseline. Poor response is also associated with low socio-economic status, less education, longer duration, limited social networks, death of a parent, divorce or unmarried status, and personality disorders.

Treatment

Introduction

Multiple effective treatments have been developed since the early 1960s and include both psychological and pharmacological treatments. Both exposure-based treatments and imipramine were shown to be effective in treating panic disorder and agoraphobia in the early 1960s.[3,4,43] Psychological-based treatments have moved increasingly towards cognitive behavioural therapy with efficacy roughly comparable to pharmacological treatments.

Imipramine and monoamine oxidase inhibitors (MAOIs) were the first medications shown to effectively treat panic disorder in the 1960s.[3,44] The high-potency benzodiazepines (alprazolam and clonazepam) were also shown to be effective in the 1980s.[7] Most now agree that the selective serotonin reuptake inhibitors (SSRIs) are the medication of first choice.[45–47]

Factors that influence the choice of initial treatment include patient preference and past history of treatment response, costs, and often availability. Medication treatment is usually easier to obtain but does involve significant costs and side effects. Although many patients prefer psychological treatments, as many as 10–30 per cent refuse treatments that involve exposure to frightening situations or resist the time and effort required. Where available, CBT can be more cost-effective than medications.

CBT has been modified in various ways to try to make it more easily available. This has included delivery in groups by computer or telephone or in shorter amounts or in a high intensity strategy with multiple hours of therapy over just a few days. All of these approaches show promise. There is clear evidence that bibliotherapy with and without phone contacts is also effective.

Eye movement desensitization and reprocessing (EMDR) was developed for treatment of post-traumatic stress disorder. The evidence available suggests that it is not effective in panic disorder.

Panic disorder can have an onset prior to adolescence, and it does occur frequently during adolescence. Although empirical data are very limited, it is generally assumed that treatments effective in adults are also effective in children. (see American Academy of Child and Adolescent Psychiatry's *Practice Parameters for the Assessment and Treatment of Children and Adolescents with Anxiety Disorders*.[48]

Medication treatments

(a) Selection of initial pharmacotherapy

Evidence indicates that medication from five classes—the SSRIs, SNRIs, benzodiazepines, tricyclics (TCAs), and monoamine oxidase inhibitors (MAOIs) are all roughly equal in their efficacy and therefore the choice of initial therapy should be made on other factors such as tolerability, cost, prior treatments, etc. (see Table 4.7.3.2). For patients with a history or concurrent depression (usually 25 per cent), the antidepressants would be preferable to the benzodiazepines. The antidepressants generally take 4 to 6 weeks to become effective, whereas the benzodiazepines begin working within the first week. There is evidence that adding benzodiazepines to the antidepressants speeds the therapeutic response.

Table 4.7.3.2 Advantages and disadvantages of various antipanic agents

	Advantages	Disadvantages
SSRIs	Well-tolerated antidepressant Safe in overdose Little weight gain Once-daily dosing	Initial activation Nausea, headache, asthenia, insomnia initially Sexual side effects
SNRIs	Very similar to SSRIs	*Hypertension*
Benzodiazepines	Rapid efficacy Reduce anticipatory anxiety Well tolerated No initial activation Safe in overdose	Sedation Some memory problems Withdrawal Abuse potential Rare sexual dysfunction
Tricyclic antidepressants	Single daily dose Less expensive Long experience Antidepressant	Initial activation Anticholinergic side effects Weight gain Orthostatic hypotension Dangerous in overdose Sexual dysfunction
MAOIs	More effective (against comorbid depression)? Antidepressant	Dietary restrictions Hypertensive crises (rare) Initial activation, insomnia Onset delayed Anticholinergic side effects Orthostatic hypotension Dangerous in overdose

A hyperstimulation reaction has been observed to all of the antidepressants and has lead to the widespread use of very low doses initially with gradual escalation. Benzodiazepines do not appear to produce the initial hyperstimulation response and are therefore preferred by many patients. However, difficulties with tapering and discontinuing benzodiazepines are the principal negative consideration for their use.

(b) Selective serotonin reuptake inhibitors (SSRIs)

In the United States, there are now six SSRIs available and three have FDA approval for panic disorder (fluoxetine, sertraline, and paroxetine—IR and CR formulations). There is no scientific or even clinical evidence to suggest significant differences in efficacy between the SSRIs in this indication. However, there are differences in side effects, principally, weight gain and discontinuation symptoms, different potential drug interactions, and availability of generic formulations.[49]

Initial jitteriness or increased anxiety are observed with the SSRIs. Therefore, treatment is often begun with the lowest doses available (see Table 4.7.3.3). Some patients do respond at lower doses, although most require higher doses (again see Table 4.7.3.3). The reason the SSRIs are generally regarded as the first choice for pharmacotherapy include their better tolerability and absence of anticholinnergic effects, compared to the TCAs. Patients often have mild difficulties with nausea, insomnia, headache. Certainly, the most problematic side effect is sexual dysfunction in both men and women, most frequently delay in orgasm. There are rare reports of extrapyramidal side effects and gastrointestinal bleeding. Discontinued too rapidly, withdrawal symptoms of headache, irritability, dizziness, can appear in the first 1 to 5 days after withdrawal, and generally clear within 1 to 2 weeks. These can generally be avoided by taper over 1 to 3 weeks.

(c) SNRIs

The SNRI venlafaxine has recently been demonstrated in large multicenter trials to be effective in the range of 75 to 225 mg/day. The side effect profile was similar in severity and symptomatology to the SSRIs, although a small number may develop sustained hypertension. There is some evidence that venlafaxine can result in higher rates of death from overdose than the SSRIs.

(d) Tricyclics (TCAs)

The first trial demonstrating that imipramine was significantly better than placebo was published in 1964[3] and was followed by multiple controlled trials demonstrating its effectiveness. There is also a significant number demonstrating effectiveness of clomipramine and some even demonstrating greater efficacy than imipramine.[50,51] Some data are supportive of desipramine and nortriptyline. Consistent problems with poorer tolerability compared to the SSRIs has lead to the TCAs being used only infrequently.

(e) Benzodiazepines (BZs)

The most widely studied and utilized benzodiazepine has been alprazolam. The largest trial was the Cross National Collaborative

Table 4.7.3.3 Medication doses in treatment of panic disorder

	Starting dose mg/day	Therapeutic range mg/day
SSRIs		
Paroxetine	10–12.5 CR	10–40*
Fluoxetine	2.5–10	10–20
Sertraline	25	50–200**
Fluovoxamine	50	100–300
Citalopram	10	20–30***
Escitalopram	5	5–10
SNRIs		
Venlafaxine	37.5	75–225
TCAs		
Imipramine	10	50–200
Clomipramine	25	25–150
BZs	TID or QID	Acute total daily dose
Alprazolam	0.25–0.5	2–10†
Clonazepam	0.25–0.5	1–4
Lorazepam	0.5	1–7
Diazepam	5	5–40
MAOIs	BID	
Phenelzine	15	15–45 (or 90)
Tranylcypromine	10	10–40 (or 70)

*40 mg demonstrated as target dose in RCT.

**All doses equivalent in one trial 50, 100, 200.

***In one trial, 20–30 was more effective than 40–60 mg/day.

†Mean dose 5.4 mg/day in largest trial.

Panic study involving more than 1000 patients and 11 trials, the majority of which were double-blind.[7] Alprazolam was effective against all of the symptoms of panic disorder, was comparable to imipramine and better tolerated. A sustained release form of alprazolam which can be taken once-daily is currently available. This formulation's long half-life appears to have solved the inter-dose rebound symptoms and 'clock watching' which was problematic with the immediate release form.

Clonazepam has also been demonstrated to be effective and is FDA approved for panic disorder in the United States.[52] Diazepam and lorazepam have also been shown to be clinically effective. Although generally well tolerated, the benzodiazepines principal side effects include sedation, occasional ataxia, slurred speech, and small increases in memory complaints. The largest concern and controversy has been with the possibility of dependency and the possibility of recreational abuse. However, the *American Psychiatric Association Task Force on Benzodiazepine Dependence, Toxicity and Abuse*, based on multiple large trials stated 'there are no data to suggest that long-term therapeutic use of benzodiazepines by patients commonly leads to dose escalation or to recreational use'.[53] Doses in long-term treatment are either similar to short-term or lower. Discontinuation symptomatology is perhaps the largest problem with the benzodiazepines. Panic patients have more difficulty discontinuing benzodiazepines than patients with generalized anxiety disorder. Symptoms are often seen during taper and are greatest during the last part of taper and the first week after taper. It is inconclusive whether these symptoms represent withdrawal, rebound or relapse, or the combination. However, it is clear that abrupt discontinuation results in greater symptomatology than a gradual taper. Most experts suggest a taper over several months (2–4 months).[54] Gradual taper and personality issues (more symptoms with a higher anxiety sensitivity and avoidance) are more critical than half-life of the medication.

Daily doses of alprazolam have varied from 2 to 10 mg. Greater efficacy is generally seen with higher doses, and the largest trial averaged 5.4 mg/day[7] (see Table 4.7.3.3).

Doses of clonazepam are often 50 per cent or less than doses with alprazolam.[52] Some clinicians prefer clonazepam over alprazolam because its longer half-life allows it to be used less frequently each day.[52] However the recent availability of an extended release once daily alprazolam (alprazolam ER) has perhaps reversed that issue. Although the BZs are generally safe in overdose, there is recent evidence that alprazolam is associated with more morbidity than the other BZs. There are studies demonstrating that lorazepam is effective averaging 7 mg/day and 5 to 40 mg/day is effective in diazepam trials (Table 4.7.3.3). The most important aspects of benzodiazepine treatments are the rapid response and increased tolerability and perhaps the greater reduction in everyday anticipatory anxiety (Table 4.7.3.2). Certainly, the largest drawbacks are in general the lack of efficacy against depression and difficulties with the tapering and discontinuation of treatment.

(f) Monoamine oxidase inhibitors (MAOIs)

Many experienced clinicians feel the MAO inhibitors may be the most effective medication class in treatment of panic disorder. However, there is only one scientifically rigorous trial supporting its use.[44] Further, concerns about its safety and the requirement of a tyramine diet limit their use. Modern studies aimed at developing reversible inhibitors of the MAOI enzyme that could eliminate the dietary restrictions have unfortunately been disappointing. The MAOI-B inhibitor selegiline has recently been made available in the United States but there are no known studies of its use in panic disorder.

Patients must also avoid sympathomimetic agents frequently found in decongestants, the antibiotic linezolid, meperidine, fentanyl, and tramadol, serotonergic agents like fenfluramine and the migraine triptan medications. Other significant side effects include weight gain, sexual dysfunctions, postual hypotension, anticholinergic side effects, and sleepiness.

(g) Other antidepressants

There are two uncontrolled trials of buproprion and buproprion SR in panic disorder, one positive and one negative. Mirtazepine has limited evidence supporting its use, as does inositol. Reboxetine has positive and negative evidence, as does with buspirone.

(h) Other agents

Although there is no evidence that conventional antipsychotic medications are effective, there is growing clinical use of the atypical antipsychotics, particularly in treatment resistant patients. There are single trials suggesting the anticonvulsants valproate and levetiracetam may be effective.

(i) Antihypertensives

Although widely used by non-psychiatric physicians in panic patients, the evidence suggests that propranolol, although it does reduce heart rate, is ineffective in treating panic disorder.

(j) Second-line medication treatments

There is limited scientific evidence to guide the clinician in the choice of the second course of treatment if the first is ineffective. Clinically, if the patient has experienced some benefit from the first medication, most clinicians would either add a benzodiazepine or CBT (which has been shown to work in SSRI failures). If the first treatment is completely ineffective, certainly switching treatment to a different SSRI or a different class of medications would be reasonable. If the second-line treatment is also ineffective, there is preliminary evidence that use of the atypical antipsychotics, olanzapine, or resperidone might be appropriate in severe non-responsive patients, and the other atypicals are also likely to work.

(k) Length of treatment

If patients do respond to an antidepressant, continuing treatment for 6 months or longer generally results in continued improvement and a decreased risk for relapse and recurrence, especially if symptoms remit.[55] Response is generally retained as long as medications are maintained. Most studies, clinical experience, and consensus opinion suggests continuation of effective medications for 12 to 18 months or longer.

(l) Discontinuing treatment after an effective response

Although antidepressants can be tapered over 10 days, clinical evidence recommends a much slower taper involving weeks to months. With benzodiazepines, it appears critical to taper even more slowly. Discontinuation symptoms are common but are significantly minimized if taper is accomplished over 2 to 4 months.[56] CBT has been demonstrated to be helpful in decreasing discontinuation difficulties when focused on the sensations, bodily symptoms, and catastrophic misinterpretations that are often seen.

Psychological treatments

(a) Psychodynamic psychotherapy

Although psychodynamic psychotherapy remains a popular treatment for all psychiatric disorders including panic disorder, there has been very little research demonstrating its efficacy in panic disorder. There is one large case-report study of patients with panic disorder reporting that most patients did respond well. One trial compared clomipramine with clomipramine plus 15 weekly sessions of brief dynamic psychotherapy. Patients in both groups responded well with 75 per cent of the patients in the clomipramine group being panic free and all of the patients in the combination group.

In an extension of this work, an emotion-focused treatment for panic disorder has been developed which explores typical fears of being abandoned or trapped as stimuli for panic attacks. This often involves a 12-session acute treatment with six sessions of monthly maintenance in which patients are encouraged to identify, reflect upon, and attempt to change problematic feelings and their responses. A specific form of dynamic psychotherapy 'panic-focused psychodynamic psychotherapy' which is generally applied in 3-month increments, was recently shown to be effective in a RCT.[57]†

Behavioural treatments

(a) Exposure treatments

Behavioural treatments which utilize *in vivo* exposure to phobic situations have been the mainstay of the behavioural treatments of panic disorder. They are based on the theory and evidence that patients who enter a feared situation experience habituation of their anxiety whether they are exposed slowly or suddenly and extensively (flooding). The critical nature of exposure for improvement was made clear in one study in which patients being treated with imipramine received no improvement from imipramine when given anti-exposure instruments.[58] However, they significantly improved if it were simply suggested that they re-expose themselves to their previously phobic situations when ready. Exposure treatment is consistently associated with long-lasting continuation of acute improvements even without formal follow-up treatment.[59]

Studies have compared use of exposure therapy to cognitive behavioural therapy, and have found them to be essentially equal in efficacy.[60] At this point, exposure has become an integral part of most CBT protocols.

(b) Cognitive behavioural therapy (see Chapter 6.3.2.1)

Cognitive behavioural therapy of panic disorder evolved from early work of Aaron Beck, but has been applied to panic disorder primarily by Barlow and colleagues working in the United States[42,61] and by Clark in the United Kingdom (see Chapter 6.3.2.1).

CBT for panic disorder usually begins with education (e.g. symptoms are part of body's fear response and aren't dangerous) about panic and the cognitive model of panic attacks, use of diaries for self-monitoring of symptoms, cognitive restructuring, habituation to fearful cues including internal cues (e.g. dizziness, tachycardia, etc.) and external situations (e.g. public places, elevators, etc.), anxiety management techniques (e.g. diaphragmatic breathing), and education to prevent relapse. Although evidence suggests that breathing retraining is not an essential component of effective CBT, it is widely utilized as an anxiety management technique.

The most informative trial to date was a multicentre (N 312) 11-week acute trial with a 6-month follow-up for responders and a 6-month follow-up after discontinuation of treatment.[62] This trial compared imipramine to cognitive behavioural therapy, their combination, and placebo. Improvement in all the active treatment cells was approximately equal at the end of the acute trial and significantly greater than placebo on most measures. This was also true at the 6-month follow-up. Interestingly, responders to imipramine had a more robust response than responders to cognitive behavioural therapy alone. The combination of imipramine plus cognitive behavioural therapy was significantly better than CBT or imipramine treatment alone at the 6-month point where all treatments were still present. However, at follow-up 6 months after treatment, none of the treatment cells were statistically different from placebo. There are many well-controlled trials demonstrating that CBT delivered in various forms and formats is effective. Its effects are robust, and at least comparable to medications.[62–64] Benefits are generally long-lasting, with or without booster sessions in follow-ups to 5 years.[63,65] CBT delivered in a group format is also effective.

Continuation/maintenance treatments

There are now a series of studies utilizing antidepressants or benzodiazepines as maintenance treatment for 6 and 12 months for panic disorder and agoraphobia. In most trials, treatment gains from acute treatment are almost always maintained, and generally are extended while the medication is continued. In a 12-month trial comparing clomipramine and placebo, the clomipramine group continued to improve and tolerated the medication well. Placebo patients who were switched to active medication matched the good responses of the clomipramine group.

In a 6-month continuation study of alprazolam patients following an 8-week initial trial, the group maintained their efficacy with a dose at the end of the 8-week trial of 5.1 ± 2.3 mg/day. This decreased to 4.7 ± 2.1 mg/day at week 32 and subsequent follow-up 1 to 2 years later found most patients' doses had drifted down to 1 to 2 mg/day.

In the large follow-up to the Phase II Cross-National Panic Trial, there was a 32-week double-blind comparison of alprazolam, imipramine, and placebo in 181 patients. Again, efficacy was maintained with both medications with no escalation of dose. Patients on both active treatments generally extended their improvement, although the placebo patients tended to lose some efficacy and certainly had a higher drop-out rate. A long-term extension continued paroxetine, clomipramine, and placebo in 176 patients following an acute trial. During the 1-year extension, both the paroxetine and clomipramine patients continued to improve and again, placebo patients tended to lose some of their initial response.

As evidence has accumulated of the high relapse rate with discontinuation of effective medication treatments for panic disorder, longer-term treatment, generally 6 to 18 months, has become routine. Although not well documented, perhaps one of the more important issues is that it appears that patients not only continue to improve for the first 6 months but that improvements continue to be extended the longer patients are on treatment, perhaps even throughout the first 2 years of treatment.

Prevention of recurrence

Available evidence remains inconclusive about the percentage of patients who will relapse if effective pharmacotherapy of panic disorder is discontinued. Early estimates suggested that most patients relapse. It remained the prevailing opinion that 35 to 85 per cent of patients relapse after antidepressants or benzodiazepines were discontinued. However, one trial reported almost no relapse after discontinuation of clomipramine patients, perhaps because they used a gradual taper.

The early trial by Zitrin *et al*. reported only 26 per cent relapse.[65] In a modern trial comparing imipramine and cognitive behavioural therapy, the imipramine relapse rate was 40 per cent. One of the most carefully performed relapse prevention trials followed a fixed-dose study of paroxetine. After acute treatment, patients were re-randomized in double-blind fashion to receive either paroxetine at their prior dose, or to placebo for an additional 3 months of treatment. Interestingly, only 30 per cent of the patients randomized to placebo relapsed, compared with 5 per cent relapse if paroxetine was continued.[47] The relapse rate after medication discontinuation in a recent trial was only 14 per cent. Although these studies certainly need replication, it suggests that the relapse rate may be lower than previously estimated if patients are slowly tapered and carefully followed.

There is one small study that suggests that the relapse rate is lower if treatment is longer. Mavissikalian followed a small group of patients who responded to imipramine, discontinuing some after 6 months of treatment and the other group after 18 months of treatment.[66] In these patients, there was an 80 per cent relapse rate in the 6-month treatment group, but only 20 per cent in the 18-month treatment group. This suggestive finding is consistent with clinical experience but certainly needs replication; however, it is certainly supportive of the general recommendation of continued treatment for 12 to 18 months if effective.

There is certainly a strong suggestion that rapid taper of benzodiazepines produces significant withdrawal symptoms which probably stimulates relapse.

Management

The suggestions for management in this section are based on evidence of the empirically based treatments in panic disorder and agoraphobia, much of which has been reviewed above. However, as in treatment of all patients, there are suggestions that also involve the 'art' of treating these patients which have evolved, but have not been empirically studied or confirmed.

Management of the uncomplicated patient

As reviewed above, it appears clear that the average patient with panic disorder can be treated with a variety of medications or exposure-based and/or cognitive behavioural treatments designed for panic disorder with approximately equal efficacy. There are some patients who have strong feelings or prejudices for or against both medication and cognitive behavioural treatments. Given that situation, as well as the lack of any clear reason to choose one treatment over the other, ethical practice would dictate offering patients a choice of treatment. There is also some evidence that patients will respond better to the treatment they 'believe in'. Unfortunately, the types of treatments are not equally available in all settings or all countries. Psychiatrists tend to use medication treatment with education, exposure, and cognitive based work of a less systematic nature than psychologists and other non-physician caregivers. Although many behaviourally and cognitively oriented psychologists do affiliate with psychiatrists and other physicians to provide medications, for many this ease of combination treatment is not readily available.

As mentioned, most psychiatrists utilize one of the medications mentioned above, supplemented by clear educational efforts with the patient and pertinent family members. This generally includes use of some written material which the patient and spouse read and discuss with the psychiatrist. (see Appendix for suggestions) Education is also a critical part of the initial treatment of patients in exposure-based treatments and cognitive behavioural therapy. These educational efforts are almost always very helpful and in the more mildly symptomatic patients may suffice. Certainly a central issue to increase the therapeutic alliance is to make clear that the therapist does understand that panic attacks involve marked 'real' physical symptoms which are extremely frightening, even though they are not dangerous and are short-lived generally.

For the patient who will be prescribed medication, it is most reasonable to offer a discussion of which medications might be appropriate, and the pros and cons of each. As outlined in Table 4.7.3.2, each medication is different, and depending upon the individual patient's needs and previous experience, any of the classes of medications might be appropriate. As mentioned, current opinion would suggest that the medication of first choice, would probably be an SSRI. In a recent meta-analysis of all the effective medications utilized in the treatment of panic disorder, the SSRIs were shown to be more effective than the other classes.[67] Coupled with their greater tolerability, lack of weight gain, and safety in overdose, they would appear to be the logical first choice.

For clinical and other practical issues, all patients should be told initially that whatever medication is the initial treatment, there are multiple other effective medications. It is important to emphasize that there is little way of knowing which specific medication is most appropriate for which patient and that the initial choice may not be effective, but subsequent choices are likely to be effective.

There are few data to direct the choice of the medications beyond those favouring the SSRIs mentioned above (see Table 4.7.3.2). There is only one trial documenting a difference in patient type leading to a choice of medication. In the large cross-national comparison of imipramine, alprazolam, and placebo, patients with predominantly respiratory symptoms responded better to imipramine.[68] Similarly, patients with a predominantly cardiovascular symptom picture responded better to alprazolam than imipramine. Otherwise, there are no data suggesting a particular medication for a specific patient beyond the various advantages and disadvantages listed in Table 4.7.3.2.

Once medication is chosen, it is prudent to begin at the lowest dose possible (see Table 4.7.3.3). This beginning low dose also extends to the benzodiazepines but is less critical since they are not associated with an initial hyperstimulation reaction. This is one of the reasons why benzodiazepines are easier to utilize and usually more popular with patients who somehow realize that from previous experience or feedback from other patients that they are not associated with an initial worsening of symptoms and are better tolerated overall. At a practical level, management of the worries about the initial hyperstimulation reaction is one of the most important issues in the psychopharmacological management of

panic disorder patients. If handled incorrectly, this issue can lead to a drop-out rate that reaches 25 to 50 per cent. With proper reassurance and close follow-up of patients, this drop-out rate can be reduced to almost zero. Patients need to be told that hyperstimulation can occur in one-third of patients but is transient and not dangerous. Because of the inherent anxiety and even phobia about taking medications, this reassurance is not usually sufficient and patients need to be invited to contact the treating physician with any anxiety or questions they might have about taking medications coupled with a quick response to their concerns.

After initial tolerance of medication is established, the dose can be raised over several weeks to a target level. Obviously, if a patient does not show a response at lower doses, the medication should be raised to maximum doses (Table 4.7.3.3).

It is important for the patient and physician alike to keep in mind that effectiveness of medications often requires a significant amount of time. The antidepressants as a class routinely take 2 to 6 weeks and with certain medications and patients as much as 6 to 12 weeks before significant effectiveness is established. This is less an issue with benzodiazepines, where initial effectiveness is generally seen in the first week or two, but there too the appropriate doses must be obtained, which often takes several weeks. Higher doses of all medicines are needed to reduce agoraphobic avoidance.

As mentioned, if agoraphobic patients do not gradually re-expose themselves to situations they fear, their avoidance fears will not be decreased. This exposure to their actual phobic situations can be accomplished in many ways. Some patients are capable of gradually re-exposing themselves after they understand the principles of exposure and the need to remain in the situation until their fears diminish. They may need help in establishing a hierarchy of their fears, although it is not actually necessary that they in fact do work-up the hierarchy in a gradually increasing fashion from 'least feared' to 'most feared'. However, it is often easier for most patients to conceptualize and accomplish it in this fashion.

Many therapists develop a hierarchical list and then monitor the patient's progress on a regular basis. Use of a standard scale which monitors the various symptom domains can be very helpful, such as *The Panic Disorder Severity scale* (PDSS).[69] There is evidence that the exposure must be regular, and extensive, often on a daily basis. Also, encouragement from the therapist and partner have both been shown to be important. Some patients can re-enter their phobic situations better if supported by their partner, or other phobics from a support group. If they are particularly afraid, an *in vivo* therapist (often recovered phobics) can be very helpful. The critical issues appear to be approaching their fears in a consistent and systematic basis in the real phobic situations accompanied by encouragement and support.

In a similar fashion, many psychiatrists combine principles of cognitive behavioural therapy without embarking on a formal cognitive behavioural therapy programme. Certainly, this should always involve education about the illness and its treatments. Other elements of identification and challenge of catastrophic thinking are widely applied by psychiatrists, but in a less systematic fashion than in formal cognitive behavioural therapy protocols.

It is important that from the beginning most patients be told that if medication treatment is effective, the expectation is to continue the medication for 12 to 18 months. An important issue to negotiate with the patient is how, when, and if effective pharmacotherapy should be tapered and discontinued.[70] Most evidence and experience suggests that patients be continued long enough to receive maximum benefit from medication treatment. In that context, patients should have experienced symptomatic and functional recovery to a maximum extent possible before discontinuation is considered. Patients should have regained a sense of confidence and control of their symptoms and lives. This might be conceptualized as a 'period of normal living' after attainment of symptomatic control before consideration is given to discontinuing an effective treatment. Relapse rates after such a remission are lower. Because the principal danger of discontinuation is relapse, the time should be carefully chosen. This should be a time when potential disruption from discontinuation symptoms and/or relapse would be least problematic.

There are strong suggestions in the literature, some of which is reviewed above, that all medications, and certainly the benzodiazepines, should be tapered very slowly, probably over 2 to 6 months, if possible.[54] This is both to minimize withdrawal symptoms which are especially frightening to panic patients and to observe for relapse symptoms as medications are slowly tapered.

The strongest reasons for discontinuing effective pharmacotherapy are the problematic side effects and expense.[70] Because this is a syndrome frequently seen in young women, the most important reason may be the wish to conceive a child or the onset of pregnancy. Certainly, routine practice is to try to taper and discontinue all medications before or during pregnancy, but sometimes this is not possible. There are now a series of women who have delivered normal children after having tried unsuccessfully to discontinue medication during pregnancy.

Many patients want to manage their own symptoms without the use of medications, and this is also a reasonable reason to taper and discontinue medications, if strongly felt by the patient.[70] The therapist should explore, however, unreasonable prejudices against the use of medications stimulated by reading, television shows, relatives, or even well-meaning physicians. Most in the field now believe that panic disorder and agoraphobia are conditions similar to hypertension and diabetes in the sense that most patients do not like the thought that they are ill and resist compliance with medication treatment. However, treatment is beneficial and not harmful, and patients often need encouragement and education in order to agree to a programme where they continue medications rather than press to discontinue them.

If medications are discontinued, the patient should be followed closely, at least by telephone, for difficulties that could include withdrawal symptoms, especially with benzodiazepines, or incipient relapse. If relapse does occur, evidence suggests that patients will respond to reinstitution of the same medication treatment regimen. If symptoms and/or functional disability associated with relapse are problematic, patients should be offered retreatment with the same medication or offered other effective non-medication treatments.

Psychological treatments

Management of patients with predominantly psychological treatments also begins with the use of educational materials, as is frequently the case with medication treatment of panic disorder. Almost all psychological treatments involve some sort of exposure-based treatment. In some, this is the predominant modality with considerable variation on how exposure to feared situations is

accomplished. Although some initial exposure therapy in particularly frightened patients may be accomplished in imagination prior to *in vivo* exposure, most exposure treatments are usually attempted *in vivo* from the outset. Most treatments have been shown to be effective if they involve *in vivo* exposure. Gradual exposure is the norm, although some programmes use very rapid exposures often called 'flooding', which involves exposure to multiple phobic situations rapidly over several days. Most programmes involve therapist-assisted exposure, sometimes utilizing professional *in vivo* therapists or volunteers who accompany phobics into their feared situations. Partners of patients are often enlisted as assistants, and there is some evidence that this more effective than non-partner exposure aides.

Most exposure-based treatments involve frequent, often daily practices involving several hours. Often the critical issue is adequate support of the patient to accomplish this much exposure 'homework', as well as encouragement and praise.

Almost anything that can help the patient accomplish the actual exposure appears to be useful and helpful. For instance, manuals and computer programs, as well as telephone-based supervision and encouragement have been shown to be effective. Although many therapists utilize relaxation techniques, applied relaxation has been the most widely utilized and effective. Many therapists also employ breathing retraining, encouraging people who hyperventilate to slow their breathing by utilizing their diaphragm. Although both have been shown to be effective and are widely utilized, other studies suggest they are not essential components of treatment, and their use does vary. Although use of benzodiazepines do decrease patient anxiety about exposure, evidence suggests that the benzodiazepines interfere with the cognitive benefits and habituation effects of exposure.

Cognitive restructuring involves the patient and therapist identifying the so-called 'automatic thoughts' they have with and after each panic attack. These are the misinterpretations that patients make about what these symptoms mean. For instance, the patient and therapist together identify that these symptoms often trigger thoughts that they are very ill, having a heart attack, or perhaps even dying. Over several sessions, these are identified and it is made clear to the patient the power these thoughts have to frighten them. At that point a number of strategies can be tried to try to correct these cognitions. Some involve attempts to compute the actual probability of the catastrophic consequences that patients fear. Others involve 'decatastrophizing' in which the ultimate consequences that patients fear are exposed, and generally can then be disavowed by the patient as extremely unrealistic. Patients can be taught to correct these thoughts or substitute more positive self-statements in their place. These skills are then worked on as 'homework', including actual exposure in which negative thoughts are identified and challenged *in vivo*.

The other usual aspect of cognitive behavioural therapy for panic disorder is interoceptive exposure, in which physical symptoms that frighten patients are identified and then they are taught to habituate to those symptoms and challenge the negative cognitions that arise with them. This can easily be accomplished in an office setting. For instance, if the patients are afraid of dizzy feelings, they can be spun in a chair. If they have fears of fast heartbeat, they can run up the stairs and challenge the negative cognitions that arise.

Both exposure-based treatments and cognitive behavioural therapy often are delivered in an 8- to 16-week treatment format, with varying frequencies of follow-up and attempts are underway to shorten these treatments. There is evidence that patients failing to respond to CBT often respond to subsequent medication treatment.

Treatment of comorbid patients

Treatment of the panic disorder patient comorbid with substance abuse is probably the most difficult challenge. In general, the substance abuse problem tends to be predominant even if it were temporally secondary to panic disorder symptoms. Therefore, treatment of substance abuse generally has to be initiated and completed first, although as soon as possible treatment of panic disorder needs be initiated.

Treatment of comorbid social phobia, obsessive–compulsive disorder, or GAD has recently been made somewhat simpler with the demonstration that the SSRIs are effective in these other conditions as well. Although not yet empirically demonstrated, it is reasonable to expect that an SSRI would effectively treat the panic disorder as well as the other comorbid anxiety disorders. This is an important area for future research. Behavioural treatments specific to obsessive–compulsive disorder and to social phobia may well be needed in addition to medication treatment.

The most common comorbidity is with depression and again one of the advantages of antidepressants is probable dual treatment of panic disorder and depression.[71] Perhaps the most important management issue is recognition that comorbid depression carries with it a marked increase in suicide risk. As mentioned, there is some evidence that depressed panic disorder patients respond better to MAOIs.

Resistance to treatment

There are relatively few systematic data about treatment options for patients resistant to initial medication or to exposure- or cognitive behavioural-based treatments. Generally, however, most patients can be tried on another medication, often with success. If they are on medicine and have not tried exposure or cognitive behavioural therapy that should definitely be added. The converse is also true. Non-response can often be traced to inadequate doses or blood levels of the medication or an inadequate length of trial. Comorbid psychiatric and particularly comorbid medical conditions need to be ruled out. Apparent resistance is often related to concomitant personality disorders or failure of agoraphobics to actually attempt exposure treatments. True resistance to one medication is sometimes overcome by a switch to another medication or to two medications at a time. If the combination of an antidepressant and benzodiazepine has not been tried, that is often the first attempted combination. In highly resistant patients, sometimes a combination of tricyclic and SSRI antidepressants or an atypical antipsychotic can be utilized.

Pregnancy

Panic disorder occurs disproportionately in young women making the issue of pregnancy a critical one. The course of panic disorder through pregnancy is highly variable. Use of SSRIs may be associated with low birth weight and a higher rate of spontaneous abortions, cardiac abnormalities, pulmonary hypertension, and withdrawal symptoms in the newborn if used late in pregnancy.

In general however, increases in congenital abnormalities have not been observed with the SSRIs. Whether benzodiazepines are associated with major malformations like cleft palate is unclear. Use of benzodiazepines near delivery is associated with sedation in the newborn. Also, both antidepressants and benzodiazepines are secreted in breast milk. For all these concerns, CBT is strongly recommended for pregnant women and should be considered in women planning pregnancy.

Ethical issues

The principal ethical issues concern the availability of treatment. Because the two types of effective treatments (medications and exposure or cognitive behavioural therapy) are not widely or equally distributed in all practices or locations, sometimes caregivers face a difficult ethical choice of having only one type of treatment available. In these instances, patients should be informed of the limitations and participate in the choices made.

Most of the treatment experience and certainly the empirical evidence has been in Caucasian patients. We do know that symptoms are different across ethnic groups and that response is often less positive in non-Caucasian groups. Treatments need to be tested and developed for all ethnic and national groups as part of the ethical development of the field.

Possibilities for prevention

The best evidence now suggests that panic disorder is often preceded by an anxiety pattern in childhood. In Kagan's model of behaviourally inhibited children, there is certainly a tendency for the pattern to persist throughout life, but some children appear to lose this trait during their development. This may well be related to parental child-rearing practices in which children are encouraged to face issues they fear rather than be withdrawn and fearful. Research is needed to explore whether different parental rearing practices or educational efforts or early treatment with these children can reduce later development of anxiety disorders. If so, these efforts at the public health and school level need to developed.

The other major preventable aetiological consideration for panic disorder and agoraphobia has been the evidence of negative traumatic events occurring in the childhood of adults with panic disorder. Preventative efforts need to be aimed at these issues through public education and education of caregivers of children. Also, one of the intervention goals in helping a traumatized child should be to prevent future development of anxiety disorders and other problems.

Obsessive–compulsive disorder

Joseph Zohar, Leah Fostick, and Elizabeth Juven-Wetzler

Introduction

Obsessive–compulsive disorder (OCD) is a common, chronic, and disabling disorder marked by obsessions and/or compulsions that are egodystonic and cause significant distress to the patients and their families. During the last 25 years, there has been a resurgence of studies into various aspects of OCD, including epidemiological, pathophysiological, and pharmacological investigations. With the progress in finding effective treatments for OCD, different algorithms for the management of these patients have been developed. The progress in OCD includes advanced methodologies of imaging studies (both before and after treatment), along with insight into the neurological aspects of OCD and OCD-related conditions, leading to selective treatments.

Up to the early 1980s, OCD was considered a rather rare, treatment-refractory, and chronic condition of psychological origin. Dynamic psychotherapy was of little benefit and several pharmacological treatments were attempted without much success.[1] Since then, several researchers have reported that the prevalence of OCD is around 2 per cent in the general population.[2,3] In addition, numerous studies have reported on the efficacy of various serotonin reuptake inhibitors, and consequently an understanding of the biological basis of OCD has begun to unfold.

The observation that clomipramine, a tricyclic antidepressant with a serotonergic profile, is effective in treating symptoms of OCD[4,5] has increased interest in OCD in general and in the relationship between serotonin and OCD in particular. Substantial evidence currently suggests that OCD is almost unique among psychiatric disorders, as only serotonergic medications appear to be effective in this disorder.[6] For example, non-serotonergic drugs, such as desipramine, a potent antidepressant and antipanic agent, are entirely ineffective in OCD.[7–9] This specific response to serotonergic drugs has paved the way for further research on the role of serotonin in the pathogenesis of OCD in particular, and in OCD-related disorders in general.

Epidemiology

The lifetime prevalence of OCD in the general population is between 2 and 3 per cent (i.e. it is more prevalent than schizophrenia).[2,10] This rate has been confirmed across different cultures.[3] The prevalence of OCD among children and adolescents appears to be as high as among adults.[11] However, Nelson and Rice[12] and Stein *et al.*[13] have suggested that the diagnosis of OCD by the Diagnostic Interview Schedule administered by lay people leads to overdiagnosis, and so have proposed lower prevalence rates of 1 to 2 per cent.

Men and women are equally likely to be affected, although some reports have suggested a slight female predominance.[3] During adolescence, boys are more commonly affected than girls. The mean age of onset is about 20 years of age. Single people are more commonly affected, probably representing the difficulty for people with OCD to maintain a relationship.

Patients with OCD are commonly afflicted by other mental disorders; for instance, the lifetime prevalence for a major depressive episode in these patients is around 67 per cent.[3,14] Other common comorbid psychiatric diagnoses include alcohol-use disorders, social phobia, specific phobia, panic disorder, eating disorders, and post-traumatic stress disorder (PTSD).[15] The comorbidity with schizophrenia and with tic disorders raises interesting pathophysiological and therapeutic implications. The rate of tic disorders approaches 40 per cent in juvenile OCD, and there is an increase in the prevalence of Tourette's syndrome among the relatives of OCD patients.[16]

The relationship between OCD and obsessive–compulsive personality disorder (OCPD) has been a focus of debate. Although prospective research is lacking, it appears that OCPD is not a prominent risk factor for developing OCD, as the prevalence of OCPD among patients with OCD is not far from its prevalence in other psychiatric disorders.

Clinical features and diagnosis

The diagnosis of OCD according to DSM-IV criteria is based on the presence of either obsessions or compulsions, which cause marked distress, are time-consuming (more than an hour per day), or significantly interfere with the person's normal routine and social and occupational activities. It stipulates that, at some point during the course of the disorder, but not necessarily during the current episode, the person has recognized that the obsessions or compulsions are excessive or unreasonable. However, if the patient does not recognize for most of the time during the current episode that the obsessions and compulsions are excessive or unreasonable, the diagnosis is OCD with poor insight.

If another Axis I disorder is present, it is mandatory that the content of the obsessions or compulsions is not restricted to it (e.g. a preoccupation with food or weight in eating disorders, or guilt feelings in the presence of a major depressive episode). The disturbance should not be due to the direct effects of a substance (e.g. of a drug abuse or a medication) or a general medical condition.

The obsessions are recurrent, intrusive, and distressing thoughts, images, or impulses, whereas the compulsions are repetitive, seemingly purposeful, behaviours that a person feels driven to perform. Obsessions are usually unpleasant and increase a person's anxiety, whereas carrying out compulsions reduces anxiety. Resistance to carrying out a compulsion results in increased anxiety. The patient usually realizes that the obsessions are irrational and experiences both the obsession and the compulsion as egodystonic.

Patients with both obsessions and compulsions constitute at least 75 per cent of the affected patients, with most patients presenting with multiple obsessions and compulsions. The symptoms may shift, for example a patient who had washing rituals during childhood may present with checking rituals as an adult.

OCD can express itself in many different symptoms, but the classical presentations include washing, checking, aggressive, religious, or sexual obsessions, and ordering, counting, hoarding, and symmetry compulsions. Dimensional approaches have been used to analyze these characteristic subtypes, and present the different symptoms in an innovative way.[17]

The most common pattern is an obsession with dirt or germs, followed by washing or avoiding presumably contaminated objects (doorknobs, electrical switches, newspapers, people's hands, telephones). Because it is hard to avoid the feared object is (e.g. faeces, urine, dust, or germs), patients wash their hands excessively and sometimes avoid leaving home because of their fear of germs. A second common pattern is an obsession of doubt, followed by a compulsion of checking. The person checks whether the oven is turned off or the front and back doors are closed—the checking may involve many trips back home to recheck what had already been checked. In OCD, the checking, instead of resolving uncertainty, often contributes to even greater doubt, which leads to further checking. The patients exhibit obsessional self-doubt, and feel guilty for having committed some damage (for instance, a fear of hurting someone while driving, leading to driving back over the same spot again and again). Other patterns include hoarding and religious obsessions. More recently, a dimensional approach to OCD has been launched by Leckman and colleagues, stating four symptom dimension of OCD: obsessions/checking, symmetry/ordering, contamination/cleaning, and hoarding.[17,18] Another pattern of OCD involves intrusive obsessional thoughts without a compulsion. Such obsessions are usually repetitious thoughts of some sexual or aggressive act that is reprehensible to the patient. Still another pattern is the need for symmetry or precision, which leads to a compulsion of slowness. Patients can take hours to eat a meal or shave, in an attempt to do things 'just right'. Unlike other patients with OCD, these patients usually do not resist their symptoms.

The gap between the knowledge that the symptoms are irrational on one hand and the overwhelming urge to perform them on the other hand contributes to the immense suffering associated with OCD.

OCD and schizophrenia

About 25 per cent of patients with chronic schizophrenia may also present with OCD symptoms (range 5 to 45 per cent)[19]; and 15 per cent of the patients with schizophrenia may fully qualify for the diagnosis of OCD. As in OCD, the OC symptoms in these patients will not necessarily surface unless specific questions are asked. Many patients with schizophrenia can distinguish the egodystonic, obsessive–compulsive symptoms, perceived as coming from within, from the egosyntonic delusions perceived as introduced from the outside. Follow-up studies demonstrate a diagnostic stability over the years, and it seems that the presence of OCD in schizophrenia predicts a poor prognosis.[19] Several studies among patients with schizophrenia and OCD reported an improvement in OCD symptomatology after the addition of serotonin reuptake inhibitors.[19]

The poor prognosis of patients with schizophrenia and OCD, preliminary data regarding their response to the unique combination of antipsychotic and anti-obsessive medications, along with the high prevalence of this presentation has led several researchers to suggest that a 'schizo-obsessive' category may be of value.[20]

Differential diagnosis

Personal distress and functional impairment, which are required for the diagnosis, differentiate OCD from ordinary or mildly excessive worries, thoughts, and habits. The medical differential diagnosis includes tic disorders (especially Tourette's syndrome), temporal-lobe epilepsy, trauma, and postencephalitic complications.

Psychiatric diagnoses that should be ruled out include depressive disorder, schizophrenia, OCPD, PTSD, phobias, delusions, hypochondriasis, and paraphilias. OCD can usually be differentiated from schizophrenia by the absence of other schizophrenic symptoms and by the patients' insight into their disorder. Moreover, patients with OCD usually attempt to resist the obsessions. OCPD does not have the degree of functional impairment characteristic of OCD and it is egosyntonic.

Phobias are distinguished by the absence of a relationship between the obsessive thoughts and the compulsions. The fears in OCD usually involve harm to others rather than harm to oneself. In addition, in OCD, when patients are 'phobic' they are usually afraid of an unavoidable stimulus (for instance, viruses, germs, or dirt) as opposed to the classic phobic objects like tunnels, bridges, or crowds.

Major depressive disorder (MDD) can sometimes be associated with obsessive ideas, but patients with OCD usually fail to meet all the criteria of MDD. Other psychiatric diagnoses closely related to OCD are hypochondriasis, body dysmorphic disorder, and trichotillomania. As these patients have repetitive worries or behaviours, although they are focal, they are still related to the 'OCD Spectrum'.

Course and prognosis

Many patients with OCD may have an onset of symptoms after a stressful event (e.g. pregnancy, a loss, or a sexual problem). Owing to the secretive nature of the disorder, there is often a delay of 5 to 10 years before patients come to psychiatric attention. However, the delay may shorten due to increased public awareness to the disorder through articles, books, and movies. The course of OCD is

usually long, but variable; some patients experience a fluctuating course, while others experience a chronic course.[21]

About 20 to 30 per cent of the patients show a significant improvement in their symptoms, and 40 to 50 per cent a moderate improvement. The remaining 20 to 40 per cent become chronic or their symptoms worsen.

OCD patients are prone to depression and sometimes even to suicide. A poor prognosis is indicated by yielding (rather than resisting) to compulsions, a early onset, male gender, tic related forms of OCD with associated to hoarding/symmetry compulsions, the need for hospitalization, psychotic features, a coexisting major depressive disorder, delusional beliefs, the presence of overvalued ideas (i.e. some acceptance of the obsessions and compulsions), and the presence of personality disorder (especially schizotypal personality disorder).[22–24] A good prognosis is indicated by good social and occupational adjustment and less avoidance.[21] The obsessional content does not seem to be related to the prognosis, except for hoarding, which is usually considered to have a less favourable outcome.

Aetiology

Neurotransmitters

Many clinical trials of various serotonergic drugs lend support to the hypothesis that a dysregulation of serotonin is involved in the beneficial therapeutic effect in OCD. However, this does not necessarily reflect on pathogenesis. Abnormality of the serotonergic system, and particularly the hypersensitivity of postsynaptic 5-HT receptors, constitutes the leading hypothesis for the underlying pathophysiology of OCD.[7,25–38] However, a potential role for dopamine has been emerging as well.[39]

Clinical studies have assayed cerebrospinal levels of serotonin metabolites (e.g. 5-hydroxyindoleacetic acid [5-HIAA] a 5-HT metabolite that serves as an index of 5-HT turnover)[25,26] and affinities of imipramine and paroxetine[40] binding sites on platelets show that it binds to serotonin reuptake sites,[27–30] in some studies of OCD patients. A study supporting the relationship between a decreased function of the serotonergic system and a positive response to selective serotonin reuptake inhibitors (SSRIs), demonstrated normalization of the number of platelet 5-HT transporters following treatment with different SSRIs.[31] In an earlier study, patients who responded to clomipramine had higher pretreatment levels of 5-HIAA than the non-responders.[25] Moreover, the clinical improvement was positively correlated with a decrease in the concentration of 5-HIAA in cerebrospinal fluid.[25]

Another approach is to examine peripheral measures of serotonergic and noradrenergic function in patients with OCD. In one study, clinical improvement during clomipramine therapy closely correlated with pretreatment platelet serotonin concentration and monoamine oxidase activity, as well as with the decrease in both measures during clomipramine administration.[32] Moreover, only the plasma levels of clomipramine (a potent 5-HT reuptake inhibitor), but not the plasma levels of its primary metabolite, desmethyl clomipramine (which has noradrenergic properties), correlated significantly with an improvement in OCD symptoms. These findings suggest that the effects of anti-obsessive medications, clomipramine in this study, on serotonin function are pertinent to the anti-obsessional action observed.

Additional support for the importance of serotonin in the therapeutic response to serotonin reuptake inhibitors (SRIs) in OCD came from a study by Benkelfat *et al.*[38] in which the investigators administered the serotonin receptor antagonist metergoline and placebo to 10 patients with OCD in a double-blind crossover study. Patients receiving clomipramine on a long-term basis responded with greater anxiety to a 4-day administration of metergoline when compared with the placebo phase of the study.

Additional evidence for disturbances of the serotonergic system in OCD was provided by challenge studies. Challenges with L-tryptophan,[33] *m*-chlorophenylpiperazine (mCPP),[7,34] sumatriptan (a 5-HT1D agonist[6]), ipsapirone (a 5-HT1A receptor ligand[35]), and MK-212 (a 5-HT1A and 5-HT2C agonist[36]), among others, were used to evaluate whether they worsen obsessive–compulsive symptoms or whether they elicit different physiological responses (thermal or neuroendocrine) in patients with OCD compared with controls. Only two compounds (*m*-chlorophenylpiperazine and sumatriptan) have shown behavioural hypersensitivity and neuroendocrine hyposensitivity to be characteristic of serotonergic challenges in patients with OCD. These studies may have the potential to pinpoint the receptor subtype involved in OCD, raising the possibility that 5-HT_{1B} (but not 5-HT_{1A}) could be involved in OCD.[37]

Dopamine

The most compelling evidence for dopaminergic involvement in OCD comes from the abundance of OCD symptoms in basal ganglia disorders, such as Tourette's syndrome, Sydenham's chorea, and postencephalitic parkinsonism. The therapeutic benefits obtained with the coadministration of dopamine blockers and SRIs in a subset of patients with both OCD and tic disorder[41] has also suggested a role for dopamine dysfunction. A study evaluating levels of platelet sulphotransferase, an enzyme involved in the catabolism of catecholamines (providing a marker of presynaptic dopamine function), reported a decreased level of platelet [^{3}H]imipramine binding and a parallel increase in the level of sulphotransferase activity in OCD compared with controls. This provides further support for the hypothesis of reduced 5-HT activity and increased dopamine transmission in OCD.[28,39]

Immune factors

Study of autoimmune factors has been prompted by the association of OCD and the autoimmune disease of the basal ganglia, Sydenham's chorea. This complication of rheumatic fever is accompanied by obsessive–compulsive symptoms in over 70 per cent of cases[42]: 10 out of 11 children had antibodies directed against the caudate.[42] These children had a history of obsessive–compulsive symptoms, which started prior to the onset of the chorea, reached a peak in line with the motor symptoms, and declined with their resolution. This is consistent with the hypothesis of basal ganglia dysfunction in OCD.

Antibodies against two peptides of the basal ganglia have also been found.[43] A strong connection was reported between OCD/Tourette's syndrome and the B-cell antibody D8/17, which is another antibrain antibody.[44] The specificity of these antibodies to OCD, as well as the generalizability of these rare cases, is as yet unclear.

Brain imaging studies

The use of positron emission tomography has demonstrated the presence of increased activity (i.e. metabolism and blood flow) in the frontal lobes, the basal ganglia (especially the caudate nucleus), and the cingulum of patients with OCD.[45] Pharmacological and behavioural treatments reportedly reverse those abnormalities.[46] The data from functional imaging studies are consistent with the data from structural brain imaging studies. Both CT and magnetic resonance imaging studies have found decreased sizes of caudate bilaterally. Both functional and structural imaging procedures are also consistent with the observation that neurological procedures involving the cingulum are sometimes effective in the treatment of patients with OCD.

Overall, the brain imaging research suggests a role for the prefrontal cortex-basal ganglia thalamic circuitry. Dysfunction of these circuits can be explored by neuropsychological testing and recording evoked potentials. Indeed, a study of patients with OCD demonstrated that they are slower in performing tasks involving frontocortical systems, suggesting alterations at this level.[47] An evoked potential study showed enhanced processing negativity in the frontal cortex consistent with the prefrontal hyperactivity shown in brain imaging studies.[48] Moreover, the reflection of behavioural challenge on brain activity (brain responsivity) may be a potential tool for predicting a response to successful intervention with SSRI.[49]

Genetics

A significantly higher concordance rate was found for monozygotic twins than for dizygotic twins.[50] Of the first-degree relatives of patients with childhood-onset OCD, 35 per cent are also afflicted with the disorder.[51] Although this high rate is possibly related to the early-onset subtype, it nevertheless suggests a genetic component in OCD. Genetic research has yet to find abnormalities at the 5-HT transporter gene level. A study exploring the polymorphism of the promoter region of the gene for the 5-HT transporter failed to identify any differences between patients with OCD and controls.[52] However, several studies found polymorphism of $5HT_{1B\beta}$ in OCD,[53,54] hence providing further support for the $5HT_{1B}$ involvement in OCD.

Other biological data

Sleep electroencephalography and neuroendocrine studies have found abnormalities similar to those seen in depression, such as decreased rapid eye movement latency, non-suppression on the dexamethasone suppression test, and decreased growth hormone secretion with clonidine infusions.[55,56]

Behavioural factors

According to the learning theory, obsessions can be considered conditioned stimuli. When a relatively neutral stimulus is coupled with an anxiety-provoking stimulus, through conditioning, it will produce anxiety even when presented alone. In this regards, even the thought of the anxiety-provoking stimulus can cause anxiety, similarly to Pavlov's dog, which salivated even before he actually had food. Consequently, avoidant behaviour is being adopted in order to avoid the anxiety-provoking stimulus and any other stimuli, which remind it. The compulsions are learnt as a way to reduce anxiety. Once producing a relief of the anxiety, the relief serves as reinforce to the compulsion, which are then being repeated by the patient. Through the process of conditioning, reward and reinforcement, rituals, and avoidant strategies are become fixed.

Psychological factors

The dynamic aspects of OCD were first described by Sigmund Freud, who coined the term 'obsessional neurosis'. The disorder was thought to result from a regression from the Oedipal phase to the anal phase, with its characteristic ambivalence. The coexistence of hatred and love towards the same person leaves the patient paralyzed with doubt and indecision. Freud originally suggested that obsessive symptoms result from unconscious impulses of an aggressive or sexual nature. These impulses cause extreme anxiety, which is avoided by the defence mechanisms. One of the striking features of patients with OCD is the degree to which they are preoccupied with aggression or cleanliness (anal phase), either overtly in the content of their symptoms or in the underlying associations.

Freud described three major psychological defence mechanisms that are important in OCD: isolation, undoing, and reaction formation. According to the psychoanalytical formulation, OCD develops when these defences fail to contain the anxiety. Isolation is the separation of the idea and the affect that it arouses. Undoing is a secondary defence to combat the impulse and quit the anxiety that its imminent eruption into consciousness arouses. Undoing is a compulsive act, performed to prevent or undo the results that the patient irrationally anticipates from a frightening obsessional thought or impulse. Reaction formation is related to the production of character traits rather than symptom formation (characteristic of the above defences). The trait seems highly exaggerated and inappropriate (i.e. the switch of anger and hate into exaggerated love and dedication).

Summary

The efficacy of the SRIs for OCD, together with the lack of efficacy of adrenergic antidepressants, has suggested that serotonin is involved in the pathophysiology of OCD. This relationship was validated by research on serotonergic markers in OCD and by the challenge paradigm.[6] Which type of serotonergic receptor is involved in the pathogenesis and/or the mechanism of action of anti-obsessional drugs, is still unclear. However, the possible role of $5HT_{1B}$ has emerged. Further studies are crucial for elucidating the role of serotonin and other neurotransmitters (i.e. dopamine) in the pathophysiology and management of OCD.

The pharmacological treatment of OCD

Since the early 1980s, several potent SRIs have been studied extensively in OCD. Aggregate statistics for all SRIs suggest that 70 per cent of treatment-naive patients will improve at least moderately.[57]

Efficacy of serotonergic versus adrenergic antidepressants

Whilst anecdotal reports have suggested that clinical benefit can be obtained with a range of reuptake blockers, effectiveness has only been demonstrated consistently for the SRIs. Several studies have directly compared clomipramine with other antidepressants with a consistent finding: antidepressant drugs that are less potent SRIs than clomipramine are generally ineffective in OCD.[7–9,25]

In the late 1960s, clomipramine was the first reported effective medication for OCD.[4,5] Since then, numerous placebo-controlled studies have clearly shown clomipramine's effectiveness, and this has been confirmed in a United States multicentre controlled trial ($n = 520$).[58] In this study, after 10 weeks of treatment, 58 per cent of patients treated with clomipramine rated themselves much or very much improved versus 3 per cent of placebo-treated patients.

Besides the SRI clomipramine, the newer non-tricyclic SSRIs, such as fluoxetine, fluvoxamine, paroxetine, sertraline, citalopram, and escitalopram are gaining acceptance as effective alternatives for the treatment of OCD in controlled studies. Actually, they were found to be as effective as clomipramine.[59–62] Since SSRIs are less toxic in case of overdose, and as they have less cholinergic side-effects, they are considered as a first-line treatment for OCD.

(a) Onset of treatment response

It has been suggested that a relatively long period, up to 8 or even 12 weeks, is needed before one can consider a serotonin reuptake inhibitor to be ineffective. Several months' treatment is often needed to achieve a maximum response.

(b) Long-term treatment

Most patients relapse after prematurely discontinuing treatment, but, as stated above, it may take many months for a maximum response to be seen. Pato *et al.*[63] reported that 16 out of 18 patients with OCD relapsed within 7 weeks after stopping clomipramine, although some had been treated for more than a year (mean, 10.7 months). All patients regained the therapeutic effects when clomipramine was reintroduced. Leonard *et al.*[9] examined the effect of clomipramine substitution during a long-term clomipramine treatment in 26 children and adolescents with OCD (mean duration of treatment was 17 months). Half the patients were blindly assigned to 2 months of desipramine treatment, and then clomipramine was reintroduced. Almost 90 per cent relapsed during the 2 months' substitution period compared with only 18 per cent of those kept on clomipramine throughout the study. Therefore, it seems advisable that patients with OCD should be maintained on anti-obsessive medications for a long period, and certainly for more than a year before a very gradual attempt is made to discontinue the treatment.

The maintenance dose needed in OCD is also unclear. In a study that examined this issue, Mundo *et al.*[64] investigated the effect of dose reduction in patients previously treated successfully with fluoxetine. Patients were randomized to receive the same drug dosage or to receive a reduced dose. It appears that 'the dose that makes you well keeps you well'; i.e. that medium to high doses of SRIs are required.

(c) Drug dosage

Higher doses of SSRIs have been used in the treatment of OCD as compared to treatment of depression. Two fixed-dose studies using fluoxetine and one pan-European study with paroxetine have found some advantage with using higher doses, and those effects were found with citalopram and escitalopram studies.[6,37,62,65–67] A theoretical basis for this clinical finding, which is related to the 'stickiness' of the $5HT_{1B}$ receptor has been reported.[67,68]

Comparative studies of clomipramine versus SSRIs

The introduction of SSRIs has raised the question regarding the comparative efficacy of clomipramine versus that of the SSRIs. SSRIs are important alternatives to clomipramine, since their range of side-effects is different (absence of anticholinergic side-effects, sedation, safety with overdose, etc.). Although SSRIs may be associated with sexual side-effects, headaches, and appetite disturbances, these side-effects are usually less troublesome as compared to clomipramine's side-effects.

Fluoxetine was compared with clomipramine in 11 patients with OCD in a 10-week crossover study.[69] Although no significant differences were noted regarding clinical efficacy, the proportion of fluoxetine non-responders who later responded to clomipramine tended to be higher compared with the clomipramine non-responders who were switched to fluoxetine. However, patients reported significantly fewer side-effects while on fluoxetine. Freeman *et al.*[70] compared the efficacy of fluvoxamine and clomipramine in a multicentre randomized double-blind parallel-group comparison in 66 patients. Both drugs were equally effective and well tolerated, but fluvoxamine produced fewer anticholinergic side-effects and caused less sexual dysfunction than clomipramine, but more reports of headache and insomnia.

Paroxetine was of comparable efficacy to clomipramine and both were significantly more effective than placebo in a multinational double-blind placebo-controlled parallel group study of 399 patients with OCD.[71] Bisserbe *et al.*[72] reported that sertraline (50–200 mg/day) was significantly more effective than clomipramine (50–200 mg/day) in a double-blind study ($n = 160$).

Other pharmacological approaches and neurosurgery

Considered as one of the anxiety disorders according to DSM-IV (but not according to the ICD-10), it is not surprising that anxiolytics have been suggested for the treatment of patients with OCD. Thus, clonazepam has been reported as efficient in several uncontrolled studies and case series, and even in a small double-blind randomized multiple crossover study. However, since OCD is a chronic disorder, the long-term use of anxiolytics raises questions of dependency.

Despite reports in open studies regarding the efficacy of trazodone, buspirone, and lithium, results from double-blind studies proved negative. Adding drugs that affect dopamine function, especially the atypical antipsychotics (i.e. risperidone or quetiapine), to SRI therapy in patients with treatment-resistant OCD, may result in improvement for patients with a personal or family history of tics.[53] A combination of SSRI and small doses of high potent dopamine blocker (haloperidol or pimozide) was found to be useful for both the tics and the OC symptoms.[73]

Neurosurgery and Deep Brain Stimulation (DBS) have been reported to be effective in some patients with OCD. Neurosurgery involves procedures that disconnect the outflow pathways originating from the orbitofrontal cortex. Cingulotomy can help some intractable patients, but although the immediate results may be striking, the long-term prognosis is more reserved.[74] As for DBS, initial reports are optimistic[75] but as the total number of patients who underwent this procedure is very small, its efficacy needs to be further elucidated.

Summary of drug treatment for OCD

The first-line treatment consists of either an SSRI or clomipramine. Any one of the six SSRIs (fluoxetine, fluvoxamine, paroxetine, sertraline, citalopram, escitalopram) in current use constitutes an effective and safe choice, but choosing which SSRI depends on the

drug's pharmacokinetic profile, as well as the physician's familiarity with the drug. The dose should be higher than that used for treating depression (e.g. 40–60 mg of fluoxetine) and the trial should last at least 12 weeks. If clomipramine is chosen, cardiovascular problems and closed-angle glaucoma should first be ruled out. Doses of 200 to 300 mg of clomipramine are needed, but titration should last for 1 to 3 weeks and the optimal dose should be continued for at least 12 weeks before determining a lack of response.

If the patient cannot tolerate the first drug (an SSRI) or did not respond, a trial of another SSRI or CMI is advised or augmentation (i.e. risperidone) is recommended.

The third stage in non-responders, and in cases of only a partial response, includes small doses of antipsychotics (especially in Tourette's syndrome), or the addition of lithium or trazodone, buspirone, or tryptophan. The fourth stage consists of atypical neuroleptics, thyroid supplementation, clonidine, a monoamine oxidase inhibitor, and intravenous clomipramine. In truly severe and resistant cases, neurosurgery or DBS could be tried.

Psychological approaches

The effect of a psychodynamic approach in OCD is limited, whereas modern interventions like cognitive and behavioural therapy show promising results.[76] Behavioural therapy was found to be effective in OCD,[76,77] and some data indicate that the beneficial effects of behavioural therapy may be longer lasting.[78] About two-thirds of patients with moderately severe rituals can be expected to improve substantially, but not completely. A combination of behavioural therapy and pharmacotherapy may constitute the optimal treatment for OCD. Recently, two neuroimaging studies found that patients with OCD who are successfully treated with behavioural therapy show changes in cerebral metabolism similar to those produced by successful treatment with SRIs.[47,79]

Behavioural therapy can be conducted in in- and outpatient settings. The principal behavioural approaches in OCD are exposure for obsessions and response prevention for rituals (see Chapter 6.3.2.1). Desensitization, thought stopping, flooding, implosion therapy, and aversion conditioning have also been used in patients with OCD. In behavioural therapy the patient must collaborate and perform assignments. In a study of 18 patients with OCD, those who received exposure and response prevention therapy showed significant improvement, whereas patients on a general anxiety management intervention (control) showed no improvement from baseline.[80] Direct comparisons of behavioural therapy and pharmacotherapy are few and are limited by methodological issues.

In thought stopping, the patient (or initially the therapist) shouts 'stop' or applies an aversive stimulus to counteract the obsessional preoccupation. The patient may also imagine a stop sign with a police officer nearby or another image that evokes inhibition at the same time that he or she recognizes the presence of the obsession. Another technique is to 'postpone' the thought until a specified time (e.g. an hour later) and not to think about it until then.

Psychological factors might be of considerable benefit in understanding what precipitates exacerbations of the disorder and in treating various forms of resistances to treatment, such as non-compliance to medications or to homework assignments. It is important to remember that the symptoms may have important psychological meanings that make patients reluctant to give them up.

In the absence of controlled studies of insight-oriented psychotherapy for OCD, the anecdotal reports reporting lasting change do not allow generalizations to be made regarding efficacy. Also, the efficacy of medications in producing quick improvement has rendered slow and long-term psychotherapy out of favour.

Supportive psychotherapy has a non-specific place in managing patients with OCD, and may help patients improve their functioning and adjustment. The management plan should also include attention to the family members through the provision of emotional support, reassurance, explanation, and advice on how to manage and respond to the patient. Family therapy may reduce marital discord and build a treatment alliance, as well as helping in the resistance to compulsions. Group therapy is useful as a support system for some patients.

Summary

The treatment of OCD was characterized by pessimism until 25 years ago when effective treatments including behavioural therapy and the serotonin reuptake inhibitors were developed. Although introduced for OCD in 1967, it was only in the 1980s that double-blind studies confirmed the efficacy of clomipramine, an SRI. This was followed by the introduction of the selective serotonin reuptake inhibitors, which also proved effective for OCD. The anti-obsessive activity of these drugs was found to be independent from the drugs' antidepressant effect, as established by their efficacy both in depressed and non-depressed patients. Overall, serotonergic therapies have provided a better outlook for these patients and have contributed to our understanding of the pathophysiology of OCD.[6,7] Previously thought to be a rare and untreatable disorder, OCD is now recognized as common, and there is good reason to expect that patients with OCD will benefit substantially from potent SRIs and behaviour therapy.

Many patients with OCD do not seek treatment and the disease tends to be chronic. There is about a 10-year lag between the onset of symptoms and the seeking of professional help due to feelings of embarrassment. Further delay ensues until the diagnosis and correct treatment are given.[81] Census data suggest that over $8 billion are spent in the United States each year on the management of OCD, one-fifth of that spent on cardiac disease.[82] Because patients with OCD often attempt to conceal their symptoms, it is incumbent on clinicians to screen for OCD in every mental status examination, since appropriate treatment can result in improved quality of life, reduced OCD chronicity, and a decrease in cost to the individual and society.

Depersonalization disorder

Nick Medford, Mauricio Sierra,
and Anthony S. David

Introduction

Depersonalization, a term coined by Dugas in 1898,[1] is defined in DSM-IV as 'an alteration in the experience of self so that one feels detached from and as if one is an outside observer of one's outside mental processes or body'. Brief, self-limiting experiences of depersonalization commonly occur in healthy people in the context of fatigue, intense stress, or during/after intoxication with alcohol or illicit drugs. However, some people experience chronic depersonalization of a disturbing intensity, causing significant distress and impacting on quality-of-life and daily functioning. This may occur as a **primary depersonalization disorder (DPD)**, or in the context of other psychiatric or neurological conditions. In this chapter, we consider the primary disorder, although some sections are also relevant to secondary depersonalization.

The depersonalization experience is one of feeling strangely altered and unreal, in a way that sufferers often find very hard to convey. It is often accompanied by the related phenomenon of **derealization**, in which the person's surroundings are experienced as somehow remote and lacking immediacy and vibrancy, as if the world itself has become oddly unreal. Patients with persistent depersonalization and derealization often use the analogy of feeling as if they are on the set of a play or film, where nothing is real and they are acting out a role rather than living a real life.

Clinical features

The diagnosis requires the presence of persistent, distressing depersonalization and/or derealization, occurring in clear consciousness, and not due to another disorder or substance. Some patients find it impossible to divide their symptoms into depersonalization and derealization, seeing them as essentially two ways of describing the same experience. Nevertheless, one may encounter patients who describe one without the other. 'Pure' derealization is, however, uncommon.

In addition, there are a number of other symptoms that occur with sufficient frequency to be considered as part of the depersonalization syndrome, although their presence is not essential for making the diagnosis. These are as follows:

Desomatization—a loss or diminution of bodily sensation, sometimes accompanied by a feeling of disembodiment.

De-affectualization—a loss or diminution of emotional reactivity-the feeling that life has somehow been drained of emotional content, or that the sufferer feels little emotion in response to people or events that would normally be expected to elicit an emotional response. This may have significance for intimate relationships. It should be noted that de-affectualization is not usually accompanied by blunted affect of the type commonly seen in schizophrenia.

De-ideation—a feeling of mental emptiness which may cause difficulty in concentrating, a distorted experience of time, and a sense of detachment from memories. Often accompanied by a feeling of 'stuffiness in the head' or 'as if my brain has turned to cotton wool'.

While 'depersonalization' and 'derealization' are well-established in the psychiatric lexicon, the three terms listed above are not widely used or discussed. However, a recent analysis of symptoms reported by patients with DPD gave strong support to the idea that the condition should be considered as a syndrome, with symptoms occurring in domains corresponding to the terms used above.[2]

Classification

In DSM-IV, DPD is classified as a dissociative disorder, while in ICD-10 it falls under the vague heading of 'other neurotic disorders', and is not linked to any other category of disorder.

It has been argued that DPD is not truly a dissociative disorder, as dissociation is generally characterized by a lack of subjective awareness of change, whereas in DPD the experience of feeling changed is central. However, this apparent contradiction can be resolved if dissociation is conceptualized as a category incorporating both types of phenomenon.[3]

Diagnosis and differential diagnosis

The diagnosis should be established by a careful clinical assessment. Because DPD remains a somewhat obscure disorder, patients with this condition may have had unproductive consultations with other professionals and formed the impression that their symptoms are baffling, perhaps even unique. Being given the correct diagnosis and the opportunity to discuss it in depth with an informed psychiatrist may come as a great relief. The reassurance derived from this may in itself have a powerful therapeutic effect.

Where there are other psychiatric symptoms (e.g. anxiety, panic attacks, depressive features), the distinction between primary and secondary depersonalization may be difficult. The best way to approach this is simply to establish what the dominant symptoms are at the time of presentation. In a patient with a history of panic disorder who has developed severe unremitting depersonalization, and now has very infrequent panic attacks, the most pragmatic approach is to diagnose DPD. The fact that the panic symptoms preceded the onset of DPD is less important than the fact that it is now the DPD symptoms that dominate the clinical picture.

This issue aside, the main psychiatric differential hinges on the possibility that when patients describe feeling altered or unreal, they are articulating delusional beliefs. It is important to establish that patients have no psychotic symptoms; in particular, that they do not literally believe themselves to be unreal or dead, as this is suggestive of psychotic depression and the Cotard delusion, rather than DPD.

Depersonalization can also occur in neurological disorders, principally temporal lobe epilepsy and migraine.[4] Here the history is usually of brief, stereotyped episodes, with associated features that should provide sufficient clues to the underlying diagnosis.

Epidemiology

Until recently, DPD was considered rare, but contemporary epidemiological work suggests that it affects 1–2 per cent of the general adult population,[5] with a gender ratio of 1:1.

Symptom surveys suggest that depersonalization is perhaps the third commonest symptom (after anxiety and low mood) in psychiatric populations. It should be noted that these studies do not distinguish between primary and secondary depersonalization.

Aetiology

Various factors have been implicated in the genesis and maintenance of the condition. Biological and psychological issues are considered separately here, but should not be seen as mutually exclusive.

Psychological factors: Many patients with primary DPD have concurrent anxiety or mood symptoms, or a previous history of anxiety and/or panic attacks. The clinical impression is often that feelings of detachment and unreality have arisen as a defence against feeling anxious and threatened—a way of keeping a stressful world at a safer psychological distance. There is sometimes a history of DPD symptoms first occurring in the context of some particularly stressful event or period. Often, however, specific precipitants are not identifiable.

Once DPD develops, further anxiety may follow—patients may worry that, for example, the peculiar feeling of unreality is a sign that they are on the verge of mental breakdown. These concerns often manifest as obsessional rumination and self-monitoring, characterized by a compulsive checking of the inner state and a comparison of this state with some idealized standard of normality. This further anxiety can lead to reinforcement and perpetuation of depersonalization and derealization, so that symptoms feed each other in a 'vicious circle'.

Biological factors: There is objective biological evidence relating to the loss of emotional reactivity that patients with DPD commonly report. Patients with DPD show attenuated skin conductance responses to emotional stimuli,[6] while fMRI work suggests that the brain's emotional response circuitry is inhibited in DPD.[7,8]

Some 10–20 per cent of patients with DPD describe symptoms beginning during or after an episode of illicit drug use, cannabis being the drug most commonly implicated. Many illicit drugs are known to cause depersonalization phenomena acutely, but it is unclear how any drug might produce chronic symptoms persisting long after the drug is cleared from the system. It seems likely that the initial symptoms are due to the drug, but become chronic and unremitting through the kind of "vicious circle" outlined above.[9]

Course and prognosis

Two large case series[10,11] suggest that age of onset is usually in late adolescence or early adulthood, although up to a third of patients describe symptoms originating in childhood. Onset may be sudden or gradual, and symptoms thereafter may be episodic or continuous. Patients often report little or no fluctuation in symptom nature or severity, although with close questioning it is often possible to establish that certain factors (e.g. stress, fatigue) worsen the symptoms.

Symptoms are often unremitting for many years. In the largest case series to date,[10] patients had been symptomatic for a mean of 13.9 years at the time of initial presentation to a specialist DPD clinic. This striking statistic may, in part, reflect the widespread lack of familiarity with the condition and consequent delays in diagnosis.

While there is little available data on which to base predictions about prognosis, symptoms that have been continuous for many years tend to be more refractory than those of more recent origin.

Evaluation of treatments

Until recently, the treatment literature consisted of small case series or single case reports, but a few larger studies have now been performed. Key findings are:

Pharmacological treatments

Lamotrigine: Despite encouraging results from a pilot study, a placebo-controlled crossover trial did not show evidence of efficacy. However, in a larger, more recent open-label study of lamotrigine-antidepressant combination therapy, significant improvements were seen in a majority of patients.[12]

Opioid antagonists: Transient reductions in symptoms have been reported in response to naloxone infusion, and a recent open-label study of oral naltrexone showed some evidence of efficacy.[13]

Clomipramine: One small open-label study, results inconclusive.[14]

There remains a paucity of data from rigorous controlled trials. To date, the only large double-blind randomised controlled trial is a study of *fluoxetine*, which found no evidence of efficacy.[15]

Psychological treatments

Despite a number of reports of successful treatment with a range of psychotherapeutic techniques, the only treatment trial is an open study of cognitive behavioural therapy (CBT), which showed significant clinical benefits.[16]

Management

It will be appreciated from the above that there is insufficient evidence on which to base definitive treatment guidelines, and as yet

no drugs are licensed for the treatment of DPD in the UK. Current treatment strategies are based on encouraging results from exploratory studies, rather than on any overwhelming weight of evidence, and this limitation should not be concealed from patients.

The combination of lamotrigine (up to 500 mg per day) and an SSRI (usually citalopram or escitalopram) is often used as first-line treatment (see Medford *et al.* in Further Reading below). An alternative is clonazepam (0.5–4 mg per day).There have been no clinical trials of clonazepam in DPD, but many patients find it helpful, particularly when there is co-morbid anxiety. The risk of dependency must be carefully weighed against possible clinical benefits.

Naltrexone (see above) may also have a role, while clomipramine may be helpful when obsessional ruminations are prominent. There is anecdotal evidence to support the use of bupropion in treatment-refractory cases.

CBT may be beneficial, either alone or in combination with pharmacotherapy. Depersonalization experiences do not readily lend themselves to a cognitive behavioural analysis, but CBT techniques may be helpful in addressing associated anxieties, ruminations, and avoidance behaviours, and use of CBT should be considered whenever any of these features are prominent.

The use of standardized rating scales can assist in diagnosis and monitoring response to treatment. The Cambridge Depersonalization Scale[17] is particularly recommended.

In secondary depersonalization, it is usually appropriate to simply pursue conventional treatment of the primary condition, but if depersonalization becomes severe and disabling it may be necessary to treat it more specifically. Treatment of depersonalization in the context of substance misuse is particularly difficult: since most drugs of abuse can cause or exacerbate the symptoms, there is generally little point in attempting specific treatment unless abstinence has been established.

4.10.1 Anorexia nervosa

Gerald Russell

Introduction: history of ideas

Two different approaches may be discerned in the conceptualization of anorexia nervosa.

1 The medicoclinical approach defines the illness in terms of its clinical manifestations; the main landmarks were the descriptions by William Gull in 1874[1] and Charles Lasègue in 1873.[2]

2 The sociocultural approach is unlike the more empirical clinical approach and takes causation into account by viewing the illness as a response to prevailing social and cultural systems. This was well argued by the social historian Joan Jacobs Brumberg who considers anorexia nervosa simply as a control of appetite in women responding to widely differing forces which may change during historical times.[3]

There is a strong argument for accepting the original descriptions by Gull and Lasègue as containing the essence of anorexia nervosa. They both recognized a disorder associated with severe emaciation and loss of menstrual periods, inexplicable in terms of recognized physical causes of wasting. They were both extremely cautious about the nature of the mental disorder. Gull spoke of a morbid mental state or 'mental perversity', and adopted the more general term anorexia 'nervosa' which has persisted until today. Lasègue also referred to 'mental perversity' but was bold enough to call the condition 'anorexie hystérique, faute de mieux'.

It is probably best to seek a balance between the diagnostic rectitude of the medicoclinical approach and the malleability of anorexia nervosa in different sociocultural settings. Looking back in historical times, it may well be that the self-starvation and asceticism of St Catherine of Siena corresponded to modern anorexia nervosa.[4] In more recent times the preoccupations of the patients have altered so that their disturbed experience with their own body[5] or their 'morbid fear of fatness'[6] has become one of the diagnostic criteria. Yet this concern with body size was not remarked upon by Gull or Lasègue. This is an argument for concluding that at least the psychological content, and perhaps also the form, of anorexia nervosa are changeable in response to historical times and sociocultural influences.

Epidemiology

Screening instruments

The most commonly used screening test in the detection of anorexia nervosa is the Eating Attitudes Test (**EAT**).[7] Doubt has, however, been expressed about the predictive value of the EAT in the very populations where its use was introduced, as only a small percentage of the EAT-screened positive scores will have an actual eating disorder. Thus, the EAT has limited usefulness in surveys for detecting anorexia nervosa unless it is supplemented by detailed clinical assessments. There is also a risk of failing to detect cases of anorexia nervosa as it was found that patients currently receiving active treatment were among the non-respondents, presumably because they wished to conceal their disorder.[8]

Populations surveyed

(a) General population surveys

These are often impracticable when the aim is to detect anorexia nervosa, a relatively uncommon disorder.

(b) Surveys of primary care populations

A useful compromise is that of surveying populations of patients who consult their general practitioners. A Netherlands study was successful because a large population was surveyed (over 150 000) and the general practitioners themselves, after suitable training, were responsible for making the diagnoses.[9,10]

(c) Populations thought to be more at risk

Surveys of ballet and modelling students were conducted because it was thought likely that there would be a high prevalence of anorexia nervosa among them as a result of pressures exerted to sustain a slim figure in keeping with their professional image.[11,12]

Populations of adolescent schoolgirls have also been surveyed as their susceptibility might be raised by virtue of their age, sex, and the frequency of dieting among the school population.[13] The most thorough survey of 15-year-old schoolchildren was that conducted in Göteborg, Sweden.[14]

(d) Surveys based on case registers and hospital records

Data have been obtained on patients referred to inpatient and outpatient psychiatric services, or with the addition of patients who had consulted paediatricians, general medical services, or gynaecologists.[15,16]

Results of epidemiological surveys

(a) Incidence of anorexia nervosa

The studies which counted only hospitalized patients tended to yield low estimates of the annual incidence of anorexia nervosa expressed per 100 000 population (e.g. 0.45 in Sweden[15]). Estimates based on case registers of psychiatric patients similarly yielded fairly low incidence rates (e.g. 0.64 in Monroe County, New York[15]). The incidence found in community-based studies was by far the highest (7.7 in The Netherlands[10] and 8.2 in Rochester, Minnesota[17]), presumably because they included the less severe cases.

(b) Prevalence of anorexia nervosa in vulnerable populations

A high prevalence rate was found among Canadian ballet students (6.5 per cent) and modelling students (7 per cent).[11] A similar survey in an English ballet school also showed a high prevalence of 'possible' cases of anorexia nervosa (7.0 per cent).[12]

Surveys among schoolgirls have shown a fairly wide variation in prevalence rates, ranging from 0 per cent to 1.1 per cent. In the English studies a consistent difference in prevalence rate was found between private schools (1 per cent) and state schools (0–0.2 per cent).[13] This social class distinction was not so definite in the Swedish study where the overall prevalence of 0.84 per cent of schoolgirls, up to and including 15 years of age, represents a high rate for anorexia nervosa.[14]

(c) Age and sex

Epidemiological surveys have confirmed clinical opinion that anorexia nervosa commences most frequently in the young, especially within a few years of puberty. The peak age of onset is 18 years.[13] The illness is less common before puberty, but in a series of patients admitted to a children's hospital the age of onset ranged from 7.75 to 14.33 years.[18] A prevalence of 2.0 per cent in females aged 18 to 25 was found in a community survey in Padua, Italy.[19]

A marked predominance of females over males is usually reported in surveys, for example 92 per cent in North-east Scotland[15] and 90 per cent among the children in Göteborg.[14] On the other hand a community survey in the province of Ontario gave rise to a more balanced female to male ratio (2:1) when cases of partial anorexia nervosa were included.[20]

(d) Social class and socio-economic status

The view has been widely held that anorexia nervosa occurs predominantly in patients with middle-class backgrounds, since Fenwick's classical observation that anorexia nervosa 'is much more common in wealthier classes of society than amongst those who have to procure their bread by daily labour'.[15]

Epidemiological surveys aimed at wider populations leave the question of social class distribution somewhat equivocal. Whereas a high percentage of combined social classes 1 and 2 (Registrar General's categories) were found in clinical studies,[21] a high social class predominance was not found in studies utilizing case registers.[15] On the other hand, the schoolgirl studies mentioned above tended to confirm a high social class predominance.

Has the incidence of anorexia nervosa increased since the 1950s?

From the 1970s experienced clinicians have expressed their view that anorexia nervosa had increased in frequency. This view gained support from surveys repeated on the same population after intervals of 10 years or more in Sweden, Scotland, Switzerland, and Monroe County, New York.[15] Most investigations found a clear trend for an increased incidence over time although it appears that a plateau was reached in the 1980s.[16] In the most thorough study, from Rochester, Minnesota[17] the increase was confined to female patients aged 15 to 24 years. There were similar findings from the Netherlands with a rise from 56.4 to 109.2 per 100 000 among 15- to 19-year-old females from 1985–1989 to 1995–1999.[10] Although there is support for an increased incidence of anorexia nervosa, there remain dissenting voices.

It is better to pose a different question which renders any controversy unnecessary. We should ask instead whether there has been an increase in the incidence of eating disorders including anorexia nervosa. This is especially relevant in view of the fact that bulimia nervosa is a variant of anorexia nervosa.[22] There is strong evidence that bulimia nervosa is a new disorder and has not simply appeared because of improved medical recognition.[23] Moreover, the incidence of bulimia nervosa has risen sharply at least until the mid 1990s, so that it is now about double that of anorexia nervosa[24] (see also Chapter 4.10.2). In conclusion, it is clear that since the 1960s there has been a significant increase in eating disorders, of which the two clearest syndromes are anorexia nervosa and bulimia nervosa.

Aetiology

Aetiological concepts

According to one robust opinion, it is essential to pursue the search for a specific and necessary cause of anorexia nervosa because the currently popular 'multifactorial' approach has little explanatory power. Accordingly the failure to identify a necessary causal element is regrettable. Many of the factors within a wide range of psychological, social, and physical causes so far studied may therefore only be relevant in predisposing to anorexia nervosa, whose causes still elude clarification'.[25]

The multidimensional approach to anorexia nervosa

It is precisely because we do not know the fundamental (necessary) cause of anorexia nervosa that recourse has to be had to a multi-

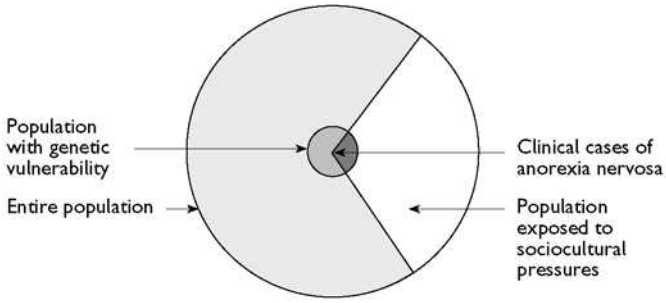

Fig. 4.10.1.1 Diagrammatic illustration of the way that genetic predisposition interacts with sociocultural pressures to cause anorexia nervosa.

dimensional approach, faute de mieux. Although it has its limitations, a multidimensional approach permits one to consider a range of possible causal factors which not only act in an additive manner but may combine in a specific way to bring about the illness: 'It is the interaction and timing of these phenomena in a given individual which are necessary for the person to become ill'.[26]

It is useful to provide a simple model of the way that two broad sets of factors may interact and augment each other (Fig. 4.10.1.1). The outer circle represents the entire population in a developed 'westernized' country. Within the circle there is a large sector representing females within an age range of 10 to 50 years who experience prevailing social pressures to acquire a slender body shape through dieting. Evidently only a small proportion of these women develop the illness. It is likely that for anorexia nervosa to develop it is also necessary to possess a genetic predisposition, represented by the small inner circle. The intersection of the inner circle and the large sector produces a small sector of females who have the genetic predisposition and also experience sociocultural pressures to lose weight, interacting to cause clinical anorexia nervosa.

Causal factors may not only interact as explained above, but they can also influence the content of the illness, its 'colouring', and its form. This modelling function is described by the term 'pathoplastic' which was introduced by Birnbaum.[27] Pathoplastic features are to be distinguished from the more fundamental causes of psychiatric illness, but they do exert a predisposing tendency as well as a modelling role.

Sociocultural causes

(a) The cult of thinness

The pathoplastic sociocultural causes of eating disorders have been subsumed under the term 'the modern cult of thinness' prevalent in westernized societies.[15] Vulnerable patients are likely to respond to this pressure by experimenting with weight-reducing diets which carry a degree of risk, and anorexia nervosa is arguably but an extension of determined dieting.[28]

It is proposed that the cult of thinness is responsible for the increase in the incidence of eating disorders since the 1950s. The social pressures which lead to dietary restraint include the publication of books and magazines advising weight-reducing diets, the fashion industry which caters mainly for the slimmer figure, television attaching sexual allure and professional success to the possession of a svelte figure, and the emphasis on physical fitness and athleticism.[3]

(b) Changes in the psychopathology of anorexia nervosa

At the beginning of this chapter it was pointed out that the psychological content and the form of anorexia nervosa have changed over historical time and in response to sociocultural influences. Whereas Gull and Lasègue spoke only of 'anorexia nervosa' and 'anorexie hystérique' respectively, more recent descriptions of the psychopathology of anorexia nervosa have stressed a disturbed experience of one's own body,[5] a weight 'phobia',[29] or a morbid dread of fatness.[6] It is precisely the modern anorectic's dread of fatness that is most in keeping with today's cult of thinness. It is arguable therefore that modern societal pressures have determined the patients' preoccupations and contributed to their food avoidance. These beliefs are held obstinately and amount to overvalued ideas.

(c) Anorexia nervosa as a culture-bound syndrome

The proposition that anorexia nervosa is a culture-bound syndrome has much support.[30,31] An intense fear of becoming obese is as culture bound as the disorder koro (a fear of shrinkage of the genitals) in Malaysia and South China.

A culture-bound syndrome may be defined as a collection of signs and symptoms which is not to be found universally in human populations, but is restricted to a particular culture or group of cultures. Implicit is the view that culture factors play an important role in the genesis of the symptom cluster . . . [30]

Anorexia nervosa meets these criteria, first because it is limited to westernized or industrialized nations, and secondly because it is clear that the psychosocial pressures on women to become thin constitute a powerful cultural force leading to anorexia nervosa.

In order to allow for exceptions to the rule, when anorexia nervosa occurs in non-westernized countries, the illness may be understood as arising from cultures undergoing rapid cultural change.[31] Anorexia nervosa is thus a 'culture-change syndrome', explaining its increased incidence in Japan and Israel. Anorexia nervosa remains rare in Asia (particularly India), the Middle East (with the exception of Israel), and generally in poorly developed countries.

Young female immigrants who move to a new culture may suffer from an increased prevalence of eating disorders. For example, children with anorexia nervosa were found among Asian families living in Britain. This was linked with an exposure to a conflicting set of sociocultural norms in comparison with their parents and grandparents.[32]

Adverse life events

Anorexia nervosa may be precipitated by adverse life events. Early clinical studies depended solely on the patient's reports of an adverse life event preceding the onset of the illness. These varied widely in severity and included the death of grandparents, a father's remarriage, a severe physical illness, stress or failure of school examinations, or being teased about being overweight.[21]

Recent studies have relied on more objective measurements of adverse life events and comparisons with control groups. In one such study,[33] life events rated included the death of a close relative, a poor relationship with parents, or an unhappy marriage. Fairly severe life events and lasting difficulties were found in the majority of patients with a late onset (after 25 years), whereas they were only found in a minority of patients with an early onset.

Anorexia nervosa can also be precipitated by sexual experiences and conflicts. In a series of 31 adolescent and young women it was

observed that in 14 first sexual intercourse had occurred before the illness.[34] Sexual problems were seen by 13 patients as major precipitants of their illness; 10 of them had experienced intercourse. The authors concluded that a specific aetiological role of sexual factors seemed unlikely, but there might be a direct relationship between the onset of eating difficulties and concurrent sexual problems.

In a series of 15 patients, anorexia nervosa developed during pregnancy or, more often, during the post-natal period when it was accompanied by depression.[35] Risk factors included ambivalence about motherhood, a large weight gain during the pregnancy, physical complications during pregnancy, post-natal depression, and past psychiatric illness.

Childhood sexual abuse

Since it was reported that a high proportion of patients in a treatment programme for anorexia nervosa gave histories of sexual abuse in childhood, it has been supposed that this trauma would be a contributory causal factor.[36] It would be better if this history could be corroborated, but for obvious reasons it is often difficult to do so. Hence this subject raises unusual difficulties in judging the reliability of the data. Child sexual abuse is also discussed in the chapter on bulimia nervosa (Chapter 4.10.2).

In a careful study of childhood sexual experiences reported by women with anorexia nervosa, the authors classified the events according to the seriousness of the sexual act in childhood and concentrated on sexual experiences with someone at least 5 years older.[37] They found surprisingly high rates (about one-third) of adverse sexual experiences in women with eating disorders, and, unlike other investigators, they did not find that the frequency of these reports was less in anorexia nervosa than bulimia nervosa. They concluded that it was plausible that childhood sexual contact with an adult may in some cases contribute to a later eating disorder.

The complexity of this subject has been increased by a study on the relationship between sexual abuse, disordered personality, and eating disorders.[38] The authors found that 30 per cent of patients referred to an eating disorders clinic gave a history of childhood sexual abuse. In addition, they found that 52 per cent of their patients had a personality disorder. A significantly higher proportion of women with a personality disorder had a history of childhood sexual abuse, compared with those without a personality disorder. Surprisingly they still concluded that in patients with eating disorders it was not possible to show a clear causal link between child sexual abuse and personality disorder.

In a review of the subject a number of hypotheses were examined on the relationship between childhood sexual abuse and eating disorders.[39] One hypothesis is that child sexual abuse is more common in bulimia nervosa than in anorexia nervosa. The authors had to concede that the findings remain inconclusive. They also examined the question of whether child sexual abuse is a specific risk factor for eating disorders. They concluded that this was not the case, as the rates of child sexual abuse in eating disorder patients were similar to or less than those in various other psychiatric comparison groups. Finally, they found strong evidence that patients with eating disorders reporting child sexual abuse were more likely to show general psychiatric symptoms including depression, alcohol problems, or suicidal gestures, as well as an association with personality disorders.

Family factors

Two influential groups of family therapists (Minuchin at the Philadelphia Child Guidance Clinic and Selvini Palazzoli in Milan) have devised family models to explain the genesis of anorexia nervosa.

Minuchin *et al.* identified faulty patterns of interaction between members of the anorexic patient's family; they in turn were thought to lead to the child's attempt to solve the family problems by starving herself:[40] 'The sick child plays an important role in the family's pattern of conflict avoidance, and this role is an important source of reinforcement for his symptoms'. Five main characteristics of family interaction were identified as detrimental to the function of the family: enmeshment (a tight web of family relationships with the members appearing to read each other's minds), overprotectiveness, rigidity, involvement of the sick child in parental conflicts, lack of resolution of conflicts.

Selvini Palazzoli[41] also identified abnormal patterns of communication within these families and in addition described abnormal relationships between the family members. She assumed that anorexia nervosa amounted to a logical adjustment to an illogical interpersonal system.

Bruch[42] described girls who developed anorexia nervosa as 'good girls', who previously had a profound desire to please their families to the point of becoming unaware of their own needs. The frequency of broken families in anorexia nervosa is thought to be fairly low. Anorexic families have been found to be closer: the patients more often perceived themselves as having happy relationships within the family.

It remains uncertain whether these abnormal interactions are to blame for the illness or develop as a response by parents faced with a starving child. Careful therapists take pains to reassure parents at the commencement of family therapy: ' . . . we always find it useful to spend some time discussing the nature of the illness, stressing in particular that we do not see the family as the origin of the problem'.[43]

Personality disorders

A sizeable proportion of patients (30 per cent[15] and 32 per cent[21]) were said to have had a 'normal' personality during childhood before their illness. Nevertheless there is general agreement of a close relationship between obsessional personalities and the later development of anorexia nervosa. In fact Janet, who carefully described obsessions and psychasthenia, was dubious about the validity of the diagnostic concept of anorexia nervosa. He thought that the patient's fear of fatness was an elaborate obsessional idea.[44]

In a study of patients admitted for treatment they were classified into anorexia nervosa, bulimia nervosa, or a combination of the two disorders.[45] Personality disorders were identified through the Structured Clinical Interview for DSM-IIIR personality disorders (SCID-II). Seventy-two per cent of the patients met the criteria for at least one personality disorder. Anorectics were found to have a high rate of obsessive–compulsive personality disorder.

There have been attempts to disentangle the features of premorbid personality and illness in order to clarify the personality characteristics predisposing to anorexia nervosa. Women who had recovered from restricting anorexia nervosa were tested at an 8- to 10-year follow-up, using a number of self-report instruments.[46] They were compared with two control groups: normal women and the sisters of the recovered anorexic patients. The women who had

recovered rated higher on risk avoidance and conforming to authority. They also showed a greater degree of self-control and impulse control, and less enterprise and spontaneity.

Biomedical factors and pathogenesis

(a) Historical notes

Since the early part of the twentieth century a recurring theme has been the possibility that anorexia nervosa is primarily caused by an endocrine or cerebral disturbance. From 1916 there was much preoccupation with the concept of Simmonds' cachexia,[47] the assumed result of latent disease of the pituitary gland. There was diagnostic confusion between anorexia nervosa and hypopituitarism, which was only clarified much later when it became known that in true hypopituitarism weight loss and emaciation are uncommon. Hormonal deficits indicative of impaired pituitary function are indeed common in anorexia nervosa, but are merely a secondary manifestation of prolonged malnutrition.

Interest in the neuroendocrinology of anorexia nervosa led to the formulation of the hypothalamic model.[6,48] From the beginning the model was aimed at explaining pathogenesis rather than aetiology; it was not considered an alternative to the psychological origin for anorexia nervosa, but a means of explaining a constellation of disturbed neural mechanisms, as follows:

1 a disordered regulation of food intake;

2 a neuroendocrine disorder affecting mainly the hypothalamic-anterior pituitary-gonadal axis;

3 a disturbance in the regulation of body temperature.

It was known that these functions all reside within the complex of hypothalamic physiology. A 'feeding centre' had been described in the lateral hypothalamus because bilateral lesions there induced self-starvation and death in rats.[49] Over the years it has become clearer that many of the disturbances could be attributed to the patients' malnutrition, as demonstrated by experimental studies in healthy young women who were asked to follow a weight-reducing diet. It was found that ovarian function is extremely sensitive to even small restrictions of caloric intake which often lead to impaired menstrual function.[50]

(b) Cerebral lesions and disturbances

Interest in the hypothalamic model was fuelled early on by clinical reports of patients diagnosed as suffering from anorexia nervosa who were later found to have cerebral lesions, especially tumours of the hypothalamus. More recently, occult intracranial tumours have been detected, masquerading as anorexia nervosa in young children.[51]

Neuroimaging studies in anorexia nervosa have led to findings suggestive of an atrophy of the brain. CT has disclosed a widening of the cerebral sulci and less frequently an enlargement of the ventricles.[52] The outer cerebrospinal fluid spaces were enlarged markedly in 36 per cent of the patients. When the CT examination was repeated after weight gain 3 months later, the widening of the sulci had disappeared in 42 per cent of the patients who had previously shown this finding. In other patients, however, the widening remained unaltered for 1 year after body weight had returned to normal.

Functional neuroimaging techniques have also been applied to research in anorexia nervosa. Regional cerebral blood flow was measured in three series of children.[53] In the majority of the children there was an above-critical difference in the regional cerebral blood flow most often between the temporal lobes but sometimes affecting other brain regions. Hypoperfusion was found on the left side in about two-thirds of the children. Follow-up scans were undertaken in children after they had returned to normal weight; the reduced regional cerebral blood flow in the temporal lobe persisted on the same side as the initial scan. The authors found that there was a significant association between reduced blood flow and impaired visuospatial ability, impaired complex visual memory, and enhanced information processing.

(c) Genetic causes

As with general psychiatric disorders, genetic and environmental factors are no longer viewed as opposing causes of anorexia nervosa, but rather as interacting with one another. Thus there may be groups of genes that determine risk of the illness and specific environmental situations that elicit or prevent the expression of these genes. There is evidence for a family aggregation of anorexia nervosa. This does not necessarily mean that the origin of the disorder is genetic because environmental factors common to the family must also be considered. In a series of 387 first-degree relatives of 97 probands with anorexia nervosa, it was found that the illness occurred in 4.1 per cent of the first-degree relatives of the anorexic probands, whereas no case was found among relatives of the controls who were probands with a primary major affective disorder, or with various non-affective disorders.[54] The authors concluded that anorexia nervosa was familial with intergenerational transmission. It was roughly eight times more common in female first-degree relatives of anorexic probands than in the general population. The absence in the relatives of probands with major affective disorder indicated the specificity in the risk of transmission of anorexia nervosa and the absence of shared familial liability with affective disorders.

The strongest argument favouring a part-genetic causation of anorexia nervosa is derived from the classical method of comparing the concordance rate of the illness in monozygotic and dyzygotic twins. Underlying the method of twin studies is the supposition that the environment for MZ twins and DZ twins is the same, or at least it does not differ in such a way as to cause greater concordance for MZ twins. Although it is known that the environments shared by MZ twins are more often similar than those shared by DZ twins, these similarities are thought not to be of aetiological relevance to anorexia nervosa.[55] The first sizeable series of twins came from the Maudsley Hospital and St George's Hospital in London and showed higher concordance rate for MZ than for DZ twins.[56] Since then the findings have been replicated and the analysis of the twin data has suggested that the liability can be broken down into three sources of variability:

a^2 Additive genetic effects	88 per cent
c^2 Common environmental effects, found to be	0
e^2 Individual-specific environmental effects.[55]	12 per cent

The individual-specific environmental effects are those which contribute to differences between the members of the twin pair. This would happen if only one member of the twin pair had suffered from an adverse effect. It is perhaps surprising that the unique environmental effects contribute to the disorder but not the twins' common environment.

Bulik has found the concept of heritability and its estimation prone to misinterpretation. There is not just one heritability estimate because this statistic varies across the population sampled and the time of the study. One estimate of heritability of anorexia nervosa gave it as 0.74 in 17-year-old female twins.[55]

It remains uncertain how the genetic vulnerability to anorexia nervosa expresses itself in terms of the pathogenesis of this disorder. One view is that this vulnerability confers instability of the homeostatic mechanisms, which normally ensure the restoration of weight after a period of weight loss. This hypothesis would explain why in western societies, where dieting behaviour is common, those who are genetically vulnerable would be more likely to develop anorexia nervosa.[57] It has also been found that MZ twins have a higher correlation for the trait of 'body dissatisfaction' than DZ twins.[55]

(d) Neurotransmitters

Since the early 1970s, the hypothalamic model of anorexia nervosa has been transformed from a consideration of anatomical 'centres' to 'systems' involving neurotransmitters. Much evidence has been presented to show that a wide range of neurotransmitters modulate feeding behaviour, and it was only a small conceptual step to suggest that some were involved in the pathophysiology of eating disorders. At first the neurotransmitters considered were mainly the monoamine systems-noradrenaline (norepinephrine), dopamine, and serotonin. In addition, opioids, the peptide cholecystokinin, and the hormones corticotrophin-releasing factor and vasopressin have also been thought to play a part in the pathogenesis of eating disorders. During recent years the main interest has been focused on the role of serotonin (5-hydroxytryptamine, 5-HT) in the control of natural appetite, especially those aspects concerning the phenomenon of satiety, mediated through a range of processes called the 'satiety cascade'.[58] There is now strong evidence that pharmacological activation of serotonin leads to an inhibition of food consumption. It was also postulated that a defect in serotonin metabolism confers a vulnerability to the development of an eating disorder.[59]

A boost to the concept of altered serotonin activity in anorexia nervosa has come from research showing that these patients while still underweight had significant reductions in cerebrospinal fluid 5-hydroxyindoleacetic acid (**5-HIAA**). The levels became normal when the patients were retested 2 months after they reached their target weight.[60] In order to test whether these findings were secondary to malnutrition, the researchers resorted to the ingenious step of studying patients after 'recovery' when they had reached normal weight. They found elevated levels of cerebrospinal fluid 5-HIAA, possibly indicating increased serotonin activity contributing to the abnormal eating behaviour which often persists in patients who have otherwise recovered.[61] The arguments against this simple model of enhanced serotonin activity as a vulnerability trait in anorexia nervosa should be briefly presented. Serotonin function was again assessed in long-term weight-restored anorectics.[62] The investigators used a dynamic neuroendocrine challenge with d-fenfluramine as a specific probe of serotonin function, which mediates the release of prolactin. If there were any persistent abnormality in serotonin function, the response to this challenge test should differ from that in normal controls. In fact, the rise in prolactin levels was very similar in former patients and normal controls. Accordingly, this study failed to support the notion of increased central serotonin function as a vulnerability trait in anorexia nervosa.[62]

Clinical features: classical anorexia nervosa (postpubertal)

The illness usually occurs in girls within a few years of the menarche so that the most common age of onset is between 14 and 18. Sometimes the onset is later in a woman who has married and had children.

By the time the patient has been referred for psychiatric treatment she is likely to have reduced her food intake and lost weight over the course of several months, and her menstrual periods will have ceased. A regular feature of the illness is its concealment and the avoidance of treatment. Even after having lost 5 to 10 kg in weight and missed several periods, the patient's opening remark is often 'there is nothing wrong with me, my parents are unduly worried'. It is only when the clinician asks direct questions that she will admit to insomnia, irritability, sensitivity to cold, and a withdrawal from contacts with her friends, including her boyfriend if she has one.

Because of this denial, it is important to enquire from a close relative, as well as the patient, about the most relevant behavioural changes.

History

History of food intake. A **food intake history** is obtained by asking the patient to recall what she has eaten on the previous day, commencing with breakfast, which is often missed. An avoidance of carbohydrate and fat-containing foods is the rule. What remains is an often stereotyped selection of vegetables and fruit. 'Diet' drinks and unsweetened fruit juice are preferred, although some patients are partial to black coffee. It is the mother who will indicate that her daughter finds ways of avoiding meals, preferring to prepare her own food and withdrawing into her bedroom to eat it.

Weight history. The patient is usually willing to provide an accurate **weight history**. She may try to conceal her optimum weight before her decision to 'diet', but she is likely to be objective about her current weight, if only to express pride in the degree of 'self-control' she has exerted. The clinician then has an opportunity to enquire into her 'desired' weight by simply asking what weight she would be willing to return to. Her answer will betray a determination to maintain a suboptimal weight.

History of exercising. A **history of exercising** should be taken. Again, the patient is likely to conceal the fact that she walks long distances to school or to work rather than use public transport. She may also cycle vigorously or attend aerobic classes. A parent may report that his or her daughter is running on the spot or performing press-ups in the privacy of her bedroom, judging from the noise that can be heard. The amount of exercising may be grossly excessive, with the patient indulging in brisk walks or jogging even in the presence of painful knees or ankles due to soft tissue injuries.

Additional harmful behaviours, which should be enquired into include self-induced vomiting, purgative abuse, and self-injury. Vomiting and purgative abuse are similar to the behaviours that occur in bulimia nervosa (see Chapter 4.10.2). In anorexia

nervosa they may occur without the prelude of overeating and the patient's motive is simply to accelerate weight loss. The laxative abuse is often at the end of the day. The favourite laxatives in the United Kingdom are Senokot and Dulcolax, and the patient is likely to take them in increasing quantities to achieve the wanted effect as tolerance develops. Self-injury should also be enquired into, and the skin of the wrists and forearms inspected for scratches or cuts with sharp instruments.

Menstrual history. The patient may not volunteer that her periods ceased soon after commencing the weight-reducing diet. On the other hand she may admit that she is relieved that her periods have stopped as she found them to be a nuisance or unpleasant.

(a) The patient's mental state

(i) Specific psychopathology

Several near-synonyms have been used to describe the specific attitude detectable in the patient who systematically avoids fatness: a 'disturbance of body image',[5] a 'weight phobia',[29] or a 'fear of fatness'.[6] Magersucht, or seeking after thinness, was a term applied in the older German literature. The patient will express a sensitivity about certain parts of her body, especially her stomach, thighs, and hips. Not only is she likely to assert that fatness makes her unattractive, but she may add that it is a shameful condition betraying greed and social failure. These distorted attitudes generally amount to overvalued ideas rather than delusions. Occasionally, however, a patient may be frankly deluded, such as one young woman who believed that her low weight was due to thin bones and that fatness was still evident on the surface of her body.

Studies have demonstrated that wasted patients, when asked to estimate their body size, see themselves as wider and fatter than they actually are.[63] Since these early observations, numerous perceptual studies have been undertaken and the conclusion drawn that anorexic patients overestimate their body width more often than normal controls. These distorted attitudes are often associated with a negative affect, so that the disturbance might be viewed as one of 'body disparagement'.[64]

The patient's dread of fatness is so common that it is pathognomonic of anorexia nervosa. There are, however, exceptions. Sometimes a patient may simply deny these faulty attitudes. Another exception is the occurrence of anorexia nervosa in eastern countries where thinness is not generally admired (e.g. Hong Kong and India). The imposition of fear of fatness as a diagnostic criterion on patients from a different culture, where slimness is not valued, amounts to a failure to understand the illness in the context of its culture.[65] An appropriate solution, proposed by Blake Woodside[66] is to accept diagnostic criteria where the psychopathology includes culture-specific symptoms which will differ for western, Chinese, and Indian ethnic groups.

(ii) Denial

Denial in anorexia nervosa is sometimes included within diagnostic criteria of the disorder, for example DSM-IV. Vandereycken[67] has written a scholarly treatize on the subject. He has pointed out that the term 'denial' is used with apparently simplicity in clinical practice, but this stands in contrast to its intriguing complexity. It is a multi-layered concept, which is difficult to measure. Denial is not a static condition but fluctuates over time. A crucial element in its assessment is the inherent conflict of perception between the patient and the clinician. The patient carries out distortions by omissions, concealments, or misrepresentations. She often denies hunger and fatigue and appears not to accept that she is thin. She shows a lack of concern for the physical and psychosocial sequelae of being underweight and may even deny the danger of her condition.

Vandereycken has proposed two categories of denial:

1 Unintentional denial (e.g. the patient's way to improve her self-esteem and preserve her sense of identity).

2 A deliberate denial including the pretence of being healthy and avoiding the treatment others want her to accept. Strong denial is often accompanied by the avoidance of treatment, but the refusal of help is not entirely due to the patient's lack of recognition of her problems.

(iii) Depression

Depression of varying severity, including a major depressive disorder, is common. The patients express guilt after eating, adding that they do not deserve food. A high rate of depression (42 per cent) was found at presentation in one study[21] and the lifetime history of depression in follow-up studies may be as high as 68 per cent.

(iv) Obsessive–compulsive features

The patients frequently eat in a ritualistic way, for example restricting their food intake to a narrow range of foods which experience tells them are 'safe' because they will not lead to weight gain. There is often a compulsive need to count the daily caloric intake. One patient rejected prescribed vitamin tablets in case they contained 'calories'. The frequency of obsessive–compulsive disorder in anorexia nervosa was found to be 22 per cent in a clinical series.[21] In studies using structured clinical interviews the frequency ranged from 25 to 70 per cent.

(v) Neuropsychological deficits

These deficits are seldom detected clinically, and an emaciated patient may pursue studies and obtain surprisingly good examination marks. On the other hand, neuropsychological testing has revealed deficits in attention, and impairment of memory and visuospatial function.[59]

(b) The endocrine disorder

(i) The impairment of hypothalamic-pituitary-gonadal function

Amenorrhoea is an early symptom of anorexia nervosa and in a minority of patients may even precede the onset of weight loss. Amenorrhoea is an almost necessary criterion for the diagnosis of anorexia nervosa. An exception is when a patient takes a contraceptive pill, which replaces the hormonal deficit and may lead her to say she still has her periods.

Generally, when the patient is undernourished, levels of gonadotrophins and oestrogens in the blood are found to be low or undetectable. Not only do malnourished patients show low blood levels of luteinizing hormone and follicle-stimulating hormone, but the secretion patterns of these pituitary hormones regress to a phase of earlier development. For example, severely wasted patients display an infantile luteinizing hormone secretory pattern with a lack of major fluctuations over the course of 24 h. With some degree of weight gain a pubertal secretory pattern appears, consisting first of a sleep-dependent increase of luteinizing hormone at night, and later displaying more frequent fluctuations.[68]

When a patient is still malnourished the ultrasound pelvic examination will reveal that ovarian volume is much smaller than in normal women.[69] Three stages can be discerned in the appearance of the ovaries as the patient gains weight:

1 small amorphous ovaries;

2 multifollicular ovaries (with cysts 3–9 mm in diameter);

3 dominant follicle (10 mm or more in diameter).

At the same time there is a corresponding return of hormonal secretion; follicle-stimulating hormone appears first, followed by luteinizing hormone and finally oestradiol which leads to enlargement of the uterus.[70]

These abnormalities signify that the patient is infertile and remains so until endocrine function recovers. Pregnancy occasionally occurs as the patient is still underweight and improving but before the appearance of the first menstrual period.[71] The pregnancy carries a risk of poor foetal growth during the first trimester, albeit with some 'catch-up' growth during the neonatal period.[72] Occasionally an underweight anorexic patient may seek treatment at an infertility clinic. Treatment with gonadotrophin-releasing hormone may restore fertility, but this practice has been severely criticized.[73]

(ii) Hypothalamic-pituitary-adrenal and hypothalamic-pituitary-thyroid axes

The emaciated anorexic patient shows an increased 24-h plasma cortisol level which returns to normal with a minimal increase in weight, as it is the nutritional intake that is critical.[74]

Reduced tri-iodothyronine (T_3) levels are linked to a reduction in energy expenditure during starvation and are adaptive in nature, so that treatment with L-thyroxin is not appropriate in anorexia nervosa.[68]

(c) Weight loss and malnutrition

(i) Body weight

The severity of weight loss may be recorded as follows:

1 As a percentage of an 'average' body weight to be found in tables for normal populations according to age and height (e.g. the *Metropolitan Life Insurance Tables*).

2 As a percentage drop from the patient's 'healthy' weight before the onset of her illness.

3 Using the Quetelet body mass index

$$\text{BMI} = \frac{\text{weight (kg)}}{(\text{height (m)})^2}$$

A BMI between 20 and 25 is regarded as healthy. A BMI of 14 or less indicates a need for hospitalization. A BMI between 10 and 12 represents the lower limit of human survival.

(ii) Physical examination

Wasting is variable but may be extremely severe, resulting in a skull-like appearance of the head, stick-like limbs, and flat breasts, buttocks, and abdomen. The hands and feet feel cold and readily turn blue in winter. The skin is dry with an excess of downy hair (lanugo) covering the cheeks, the nape of the neck, the forearms, and the legs. Heartbeat is slow (50–60 beats/min) and the blood pressure is low (e.g. 90/60 mmHg) with orthostatic lability. During the routine physical examination muscle power should be tested to detect proximal myopathy, as explained below.

Differential diagnosis of classical anorexia nervosa

The diagnosis of anorexia nervosa is usually straightforward, especially as the modern diagnostic criteria are objective. Wasting diseases such as inflammatory bowel disease (Crohn's disease or ulcerative colitis), thyrotoxicosis, and diabetes mellitus may sometimes be mistaken for anorexia nervosa, but they can be identified through specific investigations. Occasionally there is an interaction between such a medical illness and anorexia nervosa, when a patient wishes to perpetuate the weight loss caused by the former. Rarely, anorexia nervosa may be mimicked by a cerebral tumour altering the function of the hypothalamus.

In older patients there may be diagnostic difficulty with a major depressive or schizophrenic illness. The weight loss in a severe depressive illness results from loss of appetite and the patient's belief that she does not deserve food. A schizophrenic patient may avoid food because of paranoid delusions of being poisoned.

Complications of malnutrition

The complications, which are part of the illness, such as amenorrhoea due to failure of the hypothalamic-pituitary-gonadal axis, have already been discussed. The range of medical complications has been extensively reviewed,[74] with recommendations for the investigations needed on presentation of the patient.

(a) Fluid and electrolyte disturbances and cardiovascular complications

Patients who induce vomiting, abuse laxatives, or take diuretics are likely to experience dehydration and various electrolyte disturbances.

(i) Self-induced vomiting

Loss of gastric acid leads to a metabolic alkalosis and hypokalaemia. A low serum level of potassium may lead to cardiac conduction defects and arrhythmias, skeletal muscle weakness, and renal tubular dysfunction.

(ii) Laxative abuse

The abuse of laxatives is likely to cause dehydration, metabolic acidosis, hyponatraemia, and hypokalaemia.

(iii) The use of diuretics

The use of diuretics such as the thiazide group gives rise to low serum sodium levels which in turn cause fatigue and general weakness. A level below 120 mmol/l may lead to coma. The patient often justifies the use of a diuretic as a treatment for swollen ankles or even 'bloating' of the stomach, which she misinterprets as being due to fluid retention.

(iv) Impaired renal function

This may be caused by different mechanisms: pre-renal failure due to dehydration or hypokalaemic nephropathy.

(b) Peripheral oedema

Fluid retention leading to oedema occurs frequently in patients with anorexia nervosa. It is important to distinguish between 'benign' oedema, which often occurs during the course of effective refeeding, and oedema from other causes, which may have serious consequences.

(i) 'Benign' oedema

'Benign' oedema may occur during inpatient treatment. If the patient accepts a high-caloric intake, fluid retention is the rule as shown by a steep upward rise in the weight curve.

(ii) Famine oedema

If oedema is detected when the patient first presents clinically, or if it develops without a preceding improvement in food intake, the underlying mechanisms should be carefully investigated in order to avoid the risks of congestive cardiac failure and pulmonary oedema. By the time peripheral oedema is detectable, the amount of fluid retained in the body contributes several kilograms to the patient's weight, thereby concealing the true loss of weight. It is a misconception that peripheral oedema is usually due to a lowering of plasma albumen, as this is not necessarily so in anorexia nervosa. Therefore the clinician must look for other reasons.

1 A fall in interstitial fluid pressure has been proposed whereby water seeps from the blood into the interstitial spaces[75] whereas the total exchangeable sodium is likely to remain within the normal range.

2 'Rebound' oedema following hyponatraemia due to abuse of laxatives or diuretics.

3 Wet beri–beri: vitamin deficiency in anorexia nervosa is uncommon because many patients continue to eat vegetables and fruit. Nevertheless a lack of vitamin B_1 (thiamine) may occur in patients who eat a stereotyped diet, and Wernicke's encephalopathy may follow.[76] It may also lead to congestive cardiac failure with severe oedema from a nutritional cardiomyopathy, precipitated by refeeding without thiamine.

4 Congestive heart failure and pulmonary oedema may occur as a result of general undernutrition leading to a decreased cardiac mass, cardiac output, and volume. **Death may be caused by an injudicious intravenous infusion of fluids**.

(c) Metabolic disturbances

(i) Hypoglycaemia

Severe hypoglycaemia with plasma glucose levels as low as 1.0 mmol/l is recognized as a cause of death. Hypoglycaemia may go unrecognized, as a lack of sympathetic nervous response may mask the classical symptoms and signs.

(ii) Hypercarotenaemia

This is a benign condition causing an orange–yellow colouration of the skin of the palms, soles, forearms, and the region of the nose. It is partly due to the consumption of large amounts of foods rich in carotenoids, especially carrots, tomatoes, and the green outer leaves of vegetables.

(d) Myopathy

Weakness of specific muscle groups is common and is due to severe protein-energy malnutrition. There is a 'proximal' myopathy, affecting the musculature of the pelvic girdle and the shoulder girdle. The patient first notices an increasing difficulty in climbing stairs. Weakness may also affect the muscles of the head and neck and the face. When the patient is asked to rise from a sitting position, she will tend to push herself up using her hands and arms. She also has difficulty in rising unaided from a squatting position.[78]

There are no characteristic abnormalities in blood chemistry, although creatine kinase and liver enzymes may be elevated and the activity of the enzyme carnosinase may be reduced. Myopathic changes are consistently present in muscle biopsy specimens. Histology reveals the 'chequerboard' distribution of muscle fibres with a selective type 2 fibre atrophy. Electron microscopy reveals the presence of strikingly abundant glycogen granules between the myofibrils and under the sarcolemma.[78]

The detection of myopathy is a clear indication for the patient's admission to hospital and a refeeding programme. After a weight gain of a few kilograms her muscle strength will begin to return and a complete recovery is the rule.

(e) Osteoporosis

A high proportion of patients with anorexia nervosa risk developing osteoporosis and consequent pathological fractures. Significant reduction in bone mineral density of the femoral neck was found in all 20 patients with anorexia nervosa of 6 years or more duration.[79] The favourite method of measuring bone density in the lumbar spine and hip is by dual-energy X-ray absorptiometry. A measurement for all patients with anorexia nervosa of 2 years duration or more is recommended.[74, 79] It is difficult to disentangle the harmful effect of the nutritional deficiency itself from the associated oestrogen deficiency. The pathogenesis of osteoporosis in anorexia nervosa differs from that in postmenopausal women. In anorexia nervosa the nutritional deficiency (including a lack of calcium and vitamin D) leads to a low rate of the recycling of bone through bone formation and resorption, but the balance is disturbed with a relative increase in bone resorption.

The evidence favours the likelihood of improvement of bone density with nutritional recovery and resumption of menstruation.[79] There is much uncertainty about the best treatment. Although patients are often automatically prescribed oestrogen replacement, the only controlled trial undertaken so far indicated that oestrogen was only effective in severely underweight anorexic patients.[81] Indeed, it has been argued that oestrogen replacement could be harmful in some patients (children with premenarchal onset) and unnecessary in others with an illness of less than 3 years duration.[82] Instead the emphasis should be on encouraging weight gain, with the possible addition of calcium and vitamin D. Older patients with a poor prognosis (e.g. who have been ill over 10 years) might benefit from oestrogen replacement. There is little evidence for the use of other medication such as biphosphonates.

(f) Disturbed temperature regulation

Disturbances in the control of temperature are evident from clinical observations; the patients frequently complain of feeling cold, and in the winter they have cold and blue extremities and suffer from chilblains. In the severely malnourished patient hypothermia may be a cause of death. Severe malnutrition is accompanied by a low central body temperature, presumably because of a low metabolic rate. Ingestion of a high-calorie meal can cause a significant increase in the central body temperature[83] with complaints of heat in the periphery and sweating after food.

(g) Haematological changes

Anorexic patients may develop a significantly lowered haemoglobin level and a reduced haematocrit and white cell count, with a relative decrease in neutrophil leucocytes and an increase in lymphocytes.[84] The anaemia is usually moderate and is normocytic normochromic in type. The mechanism is that of starvation-induced bone marrow hypoplasia. Only occasionally is there an iron deficiency. The anaemia gradually becomes corrected with weight gain. A low platelet count in the blood has also been observed and there may be an associated thrombocytopenic purpura.

(h) Complications arising during rapid refeeding

(i) Acute dilatation of the stomach

This complication has been described in anorexia nervosa during the course of refeeding.[85] The patient develops copious vomiting, upper abdominal pain, distension of the upper abdomen, and rapid dehydration. Treatment is by continuous gastric aspiration, and this complication is one of the rare indications for intravenous infusions of glucose and saline. Gastric dilation is best prevented by avoiding a food intake above 1500 cal daily during the first week of refeeding.

(ii) Hypophosphataemia

When the illness has been protracted and has led to severe emaciation, the body stores of phosphate become depleted. The fall in serum phosphate is aggravated during refeeding, especially parenteral feeding.[86] Levels of phosphate may fall as low as 0.2 mmol/l. Clinical features are cardiac irregularities with a prolonged QT interval, impairment of consciousness, and delirium. Treatment is with oral phosphates rather than by intravenous administration.

Anorexic mothers as parents

A patient who is improving may conceive despite having a suboptimal weight and still not menstruating.[71] A mother may also develop the illness after having borne children. In a series of eight mothers, 9 out of 13 of their children suffered from food deprivation, identified by reductions in weight for age and in height for age as shown on Tanner–Whitehouse charts.[87] The anorexic mothers had no intention of abusing the children and indeed were affectionate towards them. **They simply extended their abnormal concern with body size to their own children**. They adopted different ways to ration their children's food intake according to their age. They might prolong breast feeding, dilute the bottle feeds, reduce the amount of food available in the home, confine eating to meal times, forbid the consumption of sweets, and prevent others giving them food. An important part of the management is to anticipate the risk to any children and conduct tactful enquiries. A whole-family approach should be adopted, focusing on the children's needs for food. The children should be followed up to ensure that they gain weight and catch-up growth is established.[87]

Clinical features: anorexia nervosa of early onset (premenarchal)

It would be too arbitrary to define an early onset by age limits such as an onset from 8 to 16 years. A more meaningful frame of reference is the onset in relation to the stage of puberty reached by the child.[88] Because puberty is a complex developmental process spanning 2 to 3 years, it is best to name as 'premenarchal' the illness which commences some time after the first signs of puberty and before its completion as shown by the first menstrual period. In true prepubertal anorexia nervosa the illness begins even earlier, before the very first signs of puberty. Postpubertal anorexia nervosa is when the illness commences after menstruation has been established.

There is much similarity between the clinical features of an illness of early onset and one which is postpubertal. However, there are two important differences. The first is the potential for the illness to interfere with the child's pubertal development. The second is the heart-rendering impact on the child's family. It follows that the management of the family is of supreme importance, and the clinician should be prepared for parental reactions, which may detract from a rational plan of treatment.

The clinical presentation is variable. Often there are precipitating events such as a family bereavement or a physical illness leading to weight loss. The onset is likely to be insidious,[18] with the parents noticing nothing amiss except for non-specific features. Symptoms of depression and irritability are common.[14,77] Some children cannot describe feelings of depression, but tearfulness may be obvious. They withdraw from friends and may refuse to go to school. Others express ideas of being underserving of love or food. Increasingly these youngsters have been found to injure themselves, especially by scratching with their nails or cutting the skin of the wrists and forearms with sharp objects, and occasionally by knocking and bruising the head. In a severe depression the child may say she hears voices calling her 'bad', but further questioning indicates that these are not true hallucinations but vivid expressions of her own thoughts. Another common presentation is with bodily symptoms, especially headaches, abdominal discomfort, and a wide range of gastrointestinal symptoms, which inevitably elicit physical investigations.

At some stage, however, the parents observe that their child is avoiding food and is reluctant to eat at normal meal times. She resorts to deviousness and secrecy. The omission of school meals often goes undetected. Eventually it is noticed that she has become thinner and may have lost a great deal of weight. Resistance is met when attempts are made to reverse the loss of weight. Even a young child may become preoccupied with the caloric values of foods and adopt additional methods of inducing weight loss. The child is likely to exercise excessively—jogging, walking, or cycling long distances. An attempt to reduce the excess activity may lead to solitary exercising in the bedroom, including press-ups or running on the spot. Other patients may induce vomiting or take laxatives even after small meals, but overeating typical of bulimia nervosa is rare in young children.[77]

(a) Weight loss

Because of the early onset while the child should still be growing in stature, there is a failure to gain the weight, which normally accompanies the growth spurt. Later there occurs an actual loss of weight and, because the child has not yet reached her optimum weight, a very low weight indeed may result—25 kg or even less. Symptoms of malnutrition ensue including tiredness, constipation, and sensitivity to cold with cold extremities.

(b) The psychological disorder

Even younger children are likely to disclose that they are fearful of becoming fat, a disturbance similar to the overvalued idea held by older patients. A minority of patients will disclose their reluctance to develop personal, sexual, or social maturity, in a manner, which fits into Crisp's model (see p. 796 of this chapter). A few may express reluctance to have menstrual periods. A girl may say she is indifferent whether she menstruates or not, but would like to develop breasts like other girls in her class. The reluctance to 'grow up' may be expressed in social terms, with the patient saying that she could not imagine herself ever leaving home or her mother. On the other hand most girls are keen to reach a normal stature.

Severe depression was found in 69 per cent of youngsters in the Göteborg study.[14] In the same series one-third of the patients had an obsessive–compulsive personality disorder, and 8 per cent developed hand-washing and other compulsions.

(c) Physical examination

Physical examination will reveal a varying degree of wasting, affecting the limbs, the abdomen, the buttocks, and the facial appearance. The extremities are blue and cold, and ischaemic changes may lead to gangrene affecting the toes. Other physical changes are similar to those in the adult, with the addition of a delay in puberty.

(d) Delay or arrest of puberty

The illness may adversely affect pubertal development depending on its time of onset. If the onset is truly prepubertal the child will not yet have shown the first signs of puberty, such as the appearance of pubic hair and breast buds. When the illness begins during the course of puberty these early signs may have appeared, but the breasts will show early growth only (Tanner stages 1 or 2), and the child will not yet have menstruated. The effects on pubertal development can be divided into those affecting growth in stature, breast development, and menstrual function.[88]

(i) Growth in stature

Growth in stature may have become arrested. In a series of 20 patients with a premenarchal onset, only two of them had reached the 50th centile in height. With successful treatment and weight gain, catch-up growth of 2 to 5 cm may be achieved, but only in patients aged 17 or less.[88]

(ii) Breast development

Breast development: in the same series only six patients had normal breasts and as many as 10 had infantile breasts. After prolonged weight gain, eight of the 14 patients showed a considerable response in breast growth.[88]

(iii) Menstrual function

Menstrual function: Primary amenorrhoea is the rule. In the series already referred to only four of the 20 patients had menstruated by the age of 16 years. A further three began their periods between 16 and 18 years of age, and four at ages ranging from 18 to 25. The remaining patients had prolonged amenorrhoea.

The above series consisted of selected patients in whom pubertal delay was severe, whereas marked pubertal delay has seldom been reported in other series in which only delayed menstruation has been remarked upon.

A young boy who develops anorexia nervosa is also likely to become preoccupied with fatness and accordingly avoids food in order to lose weight. The endocrine disorder in the male similarly consists of a disturbance of the hypothalamic-pituitary-gonadal axis. With a prepubertal onset, the penis and scrotum remain infantile, there is only a scanty growth of pubic and facial hair, and the voice may not break.

Special investigations

Pelvic ultrasound monitoring of the ovaries and uterus is a useful method of ascertaining regression and recovery in children with anorexia nervosa.[89] On first testing, and in the presence of low weight and amenorrhoea, ovarian volume and uterine volume were found to be reduced in comparison with normal pubertal girls. In the latter the normal range of ovarian volume is 3.95 ± 1.7 cm^3 and uterine volume is 14.8 ± 7.6 cm^3. On retesting the patients 18 months after the first scan those who were menstruating showed significantly larger ovarian and uterine volumes than those with amenorrhoea. The authors concluded that for ovarian and uterine maturity to occur it is necessary to achieve a mean weight of 48 kg and a mean weight-to-height ratio of 96.5 per cent. They found that pelvic ultrasound scanning helped to motivate the children to accept a higher body weight.

Differential diagnosis of early-onset anorexia nervosa

Frequent bodily complaints, loss of weight, and abnormalities of growth lead these children to be referred to paediatricians for special investigations. It has been proposed that young anorexic boys should be investigated by means of neuroimaging, so as not to miss occult intracranial tumours.[32] The diagnosis of anorexia nervosa should be distinguished from atypical eating disorders in childhood.[77]

Pervasive refusal syndrome is characterized by a child refusing to eat, drink, walk, talk, or take care of herself. Anxiety, phobic responses, and depression are also present.

Selective eating is the term applied to a child who restricts food intake to two or three different foods, such as biscuits, crisps, or potatoes, but usually remains in good health.

Food avoidance emotional disorder. this condition is one in which food avoidance is attributable to an emotional disturbance in the absence of a dread of fatness, a necessary criterion for the diagnosis of anorexia nervosa.

Food fads and food refusal. they are usually intermittent and physical health is not compromised.

Classification

ICD-10[80] (including patients with premenarchal onset[88])

1 Body weight is maintained at least 15 per cent below that expected for health. Prepubertal children may fail to gain the weight expected during the growth spurt. Weight loss is caused by avoidance of 'fattening' foods, possibly with the addition of self-induced vomiting, purgative abuse, excessive exercise, or the use of appetite suppressants.

2 The patient holds the overvalued idea of a dread of fatness and keeps her weight below a self-imposed threshold.

3 There is an endocrine failure manifest in women as amenorrhoea and in men as a loss of sexual interest and potency.

4 If the onset is premenarchal, the sequence of pubertal events is delayed: growth is arrested; in girls the breasts do not develop and there is a primary amenorrhoea; in boys the genitals remain juvenile.

DSM-IV[90]

1 Refusal to maintain body weight above the minimally normal weight for age and height (e.g. weight less than 85 per cent of that expected).

2 Intense fear of gaining weight or becoming fat, even though underweight.

3 Disturbance in the way in which one's body weight or shape is experienced.

4 In postmenarchal females, there is amenorrhoea of at least three menstrual cycles.

DSM-IV subdivides anorexia nervosa as follows.

1 Restricting type, without regular binge-eating or 'purging' behaviour (in the United States this term includes self-induced vomiting and the misuse of diuretics as well as laxatives).

2 Binge-eating/purging type.

Anorexia nervosa in males

The reduced frequency of anorexia nervosa in the male might lead one to surmise that the disorder is likely to differ between the sexes in its aetiology, clinical manifestations, and prognosis. Yet, there are remarkable similarities between the sexes as regards the age of onset and the specific features of the psychopathology.[91–93] For example, the male patients tended to select a diet which was low in fattening foods and resorted to subterfuges to dispose of food, such as self-induced vomiting and purging, and strenuous exercising. They expressed a fear of fatness and considered themselves overweight, even when they were thin.

Of course there are fundamental biological differences which inevitably alter the manifestations of the endocrine disorder in the male and, to a lesser extent, the nutritional disorder. Testicular function, as gauged by the urinary output of testosterone, is disturbed in male patients when they are emaciated. Refeeding leads to a partial correction of this abnormality.[91] The body composition of the mature male differs from that in the female; he has a lower reserve of adipose tissue so that protein depletion occurs more rapidly when he loses weight.

The relative resistance of the male against developing anorexia nervosa remains a mystery. It is even unclear whether the sex difference is likely to be due to biomedical factors or psychosocial differences. It has been suggested that young females often become preoccupied with 'fatness' because of its reproductive, biological, and social significance, whereas young males are more concerned with their musculature and its significance for strength, dominance, and masculinity.[92] These differences are linked with the frequency of dieting among adolescent girls and its rarity in boys.[94]

In a series of male patients with 'primary' anorexia nervosa most of the patients reported problems with sexuality.[95] Sexual anxieties had been present with respect to heterosexual as well as homosexual behaviour. One quarter admitted homosexual tendencies. Almost all were relieved by the loss of libido following weight loss. The authors concluded that males with atypical gender role behaviour had an increased risk of developing anorexia nervosa in adolescence.

There are only a few follow-up studies of anorexia nervosa in males. In one impressive study, 27 patients were followed up for a minimum of 2 years and a mean of 8 years.[96] Expressed in terms of the Morgan–Russell categories of general outcome, a good outcome was found in 44 per cent, an intermediate outcome in 26 per cent, a poor outcome in 30 per cent, and no deaths. Only a few predictors of outcome were identified: disturbed relationships with a parent in childhood led to a poor outcome, and the occurrence of previous sexual activity was associated with a good outcome. The outcome in males was remarkably similar to that in females.[94]

Course and prognosis

The natural outcome is defined as the long-term results of the illness or disease process. The clinical prognosis is the difficult task of forecasting the future course and final outcome of the illness in an individual patient.

Outcomes from follow-up studies in anorexia nervosa

There have been comprehensive appraisals of follow-up studies in anorexia nervosa[97] which have put forward criteria for the near-perfect follow-up study, which in practice are seldom fully met. Among these criteria are precision in the diagnostic features, the use of standardized interviews, 100 per cent success in tracing the patients, and a sufficiently long follow-up to determine eventual outcome. An arbitrary interval of at least 4 years was previously set[21] and most recent studies have adhered to this recommendation. Several groups of investigators have adopted measures of outcome based on the Morgan–Russell scales.[98] Their use gives rise to three possible categories of general outcome based on body weight and menstrual function: 'good', 'medium', and 'poor'.

In a review comparing three British studies and one Swedish study,[99] each with a mean follow-up of 5 to 6 years, it was found that the patients treated in Bristol had a better outcome than those treated at the Maudsley Hospital in London. The explanation is one of selection bias already mentioned: the Maudsley patients had all required inpatient treatment, whereas in the Bristol series the majority were outpatients. The third British study, from St George's Hospital, London, showed a quality of outcome intermediate between the other two.

The Swedish study was extended by two later follow-ups at 15 and 33 years. On the one hand, the percentage of good outcomes gradually increased and the percentage of poor outcomes diminished. On the other hand, the death rates increased with time; after 33 years the total mortality from anorexia nervosa or suicide was 18 per cent. Slow recovery was the rule: only 29 per cent of patients recovered in less than 3 years of illness, another 35 per cent within 3 to 6 years, and the remainder took much longer with recovery after 12 years being rare.[99] The Maudsley series of patients was also extended to a mean follow-up of 20 years. There was a reduction in the percentage of patients with a poor outcome, but an increase in the mortality rate close to that of the Swedish study.[100]

Prognostic predictors of outcome

In the long-term Maudsley study a poorer outcome was predicted by an older age of onset, a longer duration of illness, the presence of neurotic traits in childhood, personality problems, and the occurrence of relationship difficulties within the family.[100]

Comparison of mortality rates

In a review of 42 studies the aggregate annual mortality rate from anorexia nervosa was found to reach 0.56 per cent on average.[101] Complications of anorexia nervosa accounted for 54 per cent of deaths, suicide for 27 per cent, and other causes for 19 per cent.

A fair measure of consistency has been found in different parts of the world, especially when allowance is made for selection biases: in Denmark 0.5 per cent per annum (younger patients), in Sweden 0.75 per cent per annum, in the United States 0.66 per cent per annum, and in the United Kingdom 0.75 per cent per annum.[100]

Follow-up studies in early-onset anorexia nervosa

In a series of 60 patients in Berlin with a mean age of onset of 14.7, followed up for at least 4 years, recovery occurred in 68 per cent of patients but there was a 6.6 per cent mortality over a mean of 4.8 years,[102] a higher rate than was found in the Danish study already mentioned. A study of teenage-onset anorexia nervosa had the advantage of community screening and the use of a comparison group. At a 10-year follow-up the outcome was good in 43 per cent, intermediate in 29 per cent and poor in 20 per cent. There were no deaths. Strikingly there was a poor psychosocial outcome in half the anorexic patients with high dependence on state benefits.[103]

Conclusions

Theander[104] has provided good advice and useful definitions:

> Clinical experience has repeatedly shown that patients with anorexia nervosa can recover after a period of illness amounting to more than 10 years.

A distinction should be made between a 'chronic' illness and a long-standing illness. The word 'chronic' should be restricted to a continuous illness of more than 15 years' duration because up to then the patient is still capable of a full recovery. The term 'protracted' is preferable for an illness of prolonged duration but not as long as 15 years.

Treatment: review of evidence

In this review the evidence underpinning treatments for anorexia nervosa will be presented. Whenever possible the clinician should use a treatment whose efficacy has been established, but he will seldom be able to confine himself to such treatments. For example, in the case of the severely malnourished patient who presents as an emergency an admission to the specialized eating disorder unit may be the first necessary step, even though it has sometimes been argued that the evidence underpinning inpatient treatment is limited. In the majority of patients presenting with only moderate weight loss it is possible to select a treatment with a higher level of evidence for its efficacy. Such a treatment is family therapy, the treatment of choice in an adolescent patient.

Some cautionary words are called for on the subject of evidence-based psychiatry. For anorexia nervosa, there is no truly specific treatment in the sense of effecting a long-term 'cure'. The choice of treatment should be determined by the needs of the patient at the time when she presents for treatment and will vary according to the severity of the illness and the stage it has reached. It is wise to take into account the patient's age, her maturity, and her personality. A given treatment may be indicated for a short period only at the end of which the therapeutic aims need to be reviewed. Such a selective approach has sometimes been called the 'stepped care' approach but this concept can be misleading. The steps may not be in the same direction. They may go down as well as up. For example, a patient may be in urgent need of refeeding and if she makes good progress the next stage would consist of consolidating her improvement. If she is unfortunate, however, earlier priorities will reassert themselves.

A tendency to decry the benefits of treatment in anorexia nervosa first appeared in the early 1990s, and in more recent years cries of despair have become ever shriller. To some extent this is a side effect of the treatment evaluation industry which has unintentionally caused confusion between the usefulness of treatments on the one hand and the solid scientific evidence for their efficacy on the other. In an ideal world the two would be the same. In an illness such as anorexia nervosa they often are not, as will be illustrated further on.

A key member of the treatment evaluation industry in the United Kingdom is **the National Institute for Clinical Excellence** (NICE).[105] NICE has developed a hierarchy for the strength of the evidence underpinning various treatments, as described in Chapter 1.10. I is the strongest level of evidence, followed by Ia, IIa, IIb, III, and IV, the last being the lowest level. Anorexia nervosa is an area of care, which particularly requires Clinical Practice guidelines because of substantial dangers to life and physical health and some clinical uncertainties. So far NICE has failed to provide the required 'statements to assist practitioner decisions about appropriate health care for specific clinical circumstances'. NICE has not recognized the solid evidence favouring family therapy in adolescents (according it only Grade B in an ill-defined set of Grades A, B, and C for clinical guidelines). Family therapy should be regraded as A. NICE has also failed to identify the specific value of a specialized eating disorder service in patients with a risk to physical health and life. This should have been graded at least as B, or as (I) using the system of clinical recommendations described in Chapter 1.10. The correction of severe malnutrition requires a specialized eating disorder service rather than the involvement of a physician and medical unit (proposed by NICE) whose treatment is usually restricted to tube-feeding. NICE has also failed to recognize the value of other treatments, according them only a Grade C, implying there have been no good clinical studies.

The randomized controlled trial (RCT) has been idealized as the 'gold standard' for the level of evidence. The absence of such evidence for a given treatment does *not* signify that this treatment lacks efficacy. Some colleagues write and speak as if treatments other than those confirmed by RCT are not worthy of consideration. In truth they may well be effective, but the evidence for this is hard to come by. An effect of concentrating on RCTs and ignoring sound clinical evidence, is the conclusion reached by one authority that evidence-based treatment of anorexia nervosa is 'barely' possible. This is to ignore the fact that there are essential treatments for which evaluation by RCT has not yet been possible, because of insuperable ethical obstacles or limited patient compliance.

RCTs are particularly problematic in the assessment of treatments for patients with anorexia nervosa. For example, the NICE guidelines do not mention the role of a specialized eating disorder service, although there are oblique references to 'professionals with specialist experience of eating disorders' and 'a place for inpatient management'. Specialized eating disorder units (EDUs) long ago graduated to providing a broad service not confined to inpatient treatment but including daycare and outpatient treatment. It is important to evaluate the benefits of a specialist eating disorder service, and this is not mentioned in the NICE Guidelines. There has been only one study randomizing low weight patients to inpatient or outpatient treatments,[96] as the difficulties are obvious.

A balanced view needs to be taken towards the role of RCTs in the evaluation of treatments in anorexia nervosa. There has recently been a swing of the pendulum in the reverse direction. Some researchers have reached the surprising conclusion that RCTs in anorexia nervosa are so difficult that they should be considered as 'premature' in view of their cost and the failure of some of hem.[106]

An important reason why researchers may fail to complete a satisfactory RCT is the patient's behaviour in the course of the trial. The anorexic patient's resistance to treatment may extend to sabotaging the basic requirements of the treatment trial itself, e.g. compliance with the treatment and the follow-up assessments. These problems are difficult to eliminate entirely. Nevertheless RCTs are still possible if the researchers are assiduous in following-up their patients. Evaluators of research trials should see that the perfect trial in anorexia nervosa is a contradiction in terms. The pessimists favouring the abandonment of RCTs should remember that new ideas can emerge unexpectedly during the course of a trial, thus pointing the researcher towards fresh treatment approaches capable of being retested at a later date.

In the remainder of this section levels of evidence for the efficacy of treatments will be discussed, even when they are not considered by NICE.

Family therapy

Family therapy is the main treatment to have been carefully evaluated in anorexia nervosa, having now been tested in a number of randomized controlled trials. Any one of these trials has its imperfections, but taken as a body of evolving evidence, family therapy should be seen as the method of choice for treating anorexic patients with an early age of onset. Some of these trials will be summarized in order to illustrate ethical and technical difficulties, as well as the strength of the evidence.

(a) The first controlled trial of family therapy

The ***first controlled trial of family therapy*** was begun at the Maudsley Hospital in the early 1980s on a series of 57 patients.[107] The principles of the family therapy have been incorporated in the Maudsley model, which has been adopted by researchers in the United States who have reached broadly similar conclusions.[108] One assumption of the Maudsley model of family therapy is that the family is ineffective in helping the patient eliminate her symptoms and might indeed contribute to their maintenance, because family life has become so organized around a potentially life-threatening problem. It is considered essential to correct the patient's starvation by assisting the parents to take control of their child's eating until her weight has returned to normal.

The first Maudsley trial had to overcome ethical objections to a randomized allocation bearing in mind the severity of the illness. Risks were minimized by first ensuring that the patients' weight loss had been corrected during an admission to an eating disorders unit. Family therapy itself commenced on discharge and aimed at the prevention of relapse. The outpatient family therapy was administered for 1 year and the patients were assessed on the completion of 1 year's treatment and 5 years later.

The 57 anorexic patients were subdivided into three groups according to recognized prognostic criteria. This showed that the benefits of family therapy were confined to one of the three subgroups, namely patients with the age of onset less than 19 years and a duration of illness less than 3 years.

Patients in each subgroup were randomly allocated to family therapy or the control treatment which consisted of a supportive and problem-centred individual therapy. Most important in assessing progress was body weight. The Morgan-Russell scales were utilized to obtain categories of general outcome and measures of adjustment along five dimensions: nutritional status, menstrual function, mental state, psychosexual adjustment and socio-economic status, as well as their mean, the 'average outcome score'.

(i) Group 1: early age of onset (short history)

A tendency for the patients to lose weight on discharge from hospital was reversed more readily in patients in receipt of family therapy. The superiority of family therapy was demonstrated by a higher weight at the end of 1 year's treatment (Fig. 4.10.1.2). Family therapy was also demonstrated to be more beneficial on the Morgan-Russell scales in terms of more good outcome categories and a higher average outcome score.

(ii) Group 2: patients with late age of onset

In this group the effect of the two therapies was reversed (Fig. 4.10.1.3). Individual therapy appeared to result in a greater weight gain than family therapy but significant only at a 6-months follow-up.

It was concluded that family therapy was more effective than individual therapy in patients whose illness began before the age of 19 years and had lasted less than 3 years.

(b) Beneficial components of family therapy in adolescents: the second Maudsley RCT[109]

The finding that family therapy is effective in younger patients with anorexia nervosa has led to a search for the effective components of this therapy. Many family therapists consider that it is important to understand the way the family functions. Others, however, prefer a symptom oriented approach with an emphasis on helping the parents to manage their child's problem.[43] The relative importance of these two components of family therapy has been investigated by comparing conjoint family therapy with separated family therapy.[109] In conjoint family therapy (CFT) the whole family is seen together in the treatment sessions. In separated family therapy (SFT) the parents are seen together and the same therapist also sees

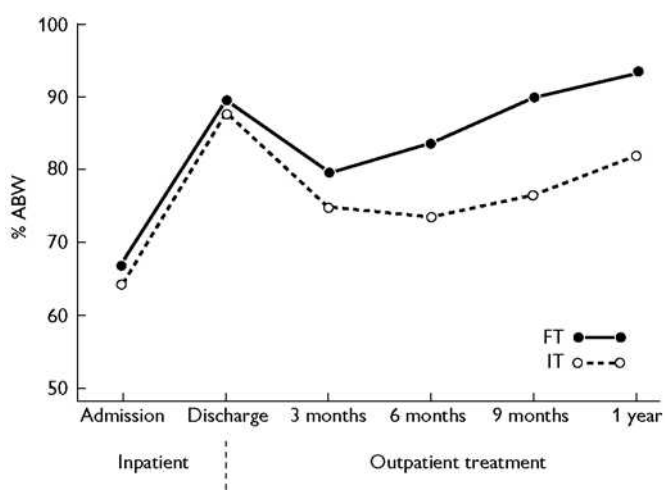

Fig. 4.10.1.2 Group of patients whose illness had an early onset and was of short duration. FT, family therapy; IT, individual therapy; ABW, average body weight.

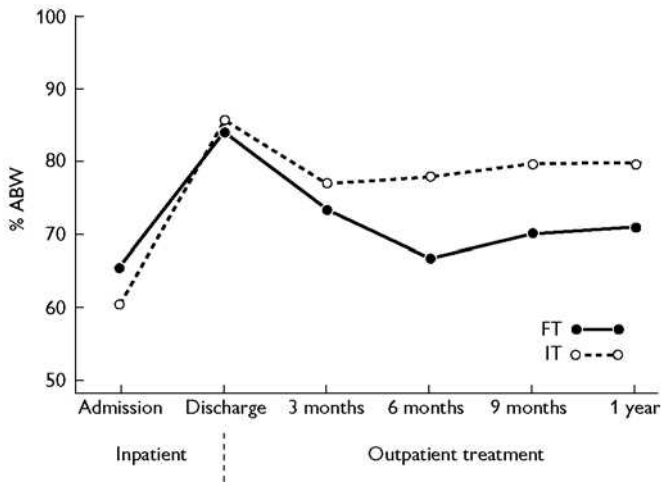

Fig. 4.10.1.3 Group of patients with relatively late onset of anorexia nervosa. FT, family therapy; IT, individual therapy; ABW, average body weight.

the patient separately for therapy and support. In CFT it is possible to observe and interpret family transactions, whereas this is not possible in SFT. The two treatments share the therapeutic advice for the parents to sustain a united approach aimed at improving their child's eating pattern.

The RCT was between CFT and SFT, given for 1 year on an outpatient basis. Forty adolescent patients were enrolled, most of them severely underweight (mean BMI 15.4).

In the course of the year the benefits of CFT and SFT were similar with considerable gains in weight (mean 8.2 kg) and marked improvements in the Morgan/Russell average outcome scores. Significant differences in the patients' responses to CFT and SFT were only obtained when treatment outcome was analysed separately in patients of high and low expressed emotion (EE) families. The patients within the high EE group allocated to SFT reached a significantly higher weight at follow-up (99.9 per cent ABW) than those in the CFT group (85.8 per cent ABW).

(c) RCT undertaken in Stanford, USA[108]

This trial was also on adolescent patients, this time comparing two courses of family therapy: one lasting for 6 months (10 sessions) and the other for 1 year (20 sessions). The aim of the study was to ascertain whether the duration of the family therapy exerted a critical effect on outcome.

The therapy was given according to the Maudsley Model, but the US study had a number of advantages, including a larger patient population (86 adolescents) and hence a greater statistical power. The therapy was given by therapists trained on a manual-based form of family therapy.

In comparison with the 2000 Maudsley Study[109] the patients were not so ill, (mean BMI 17.1). The principal measures of outcome were body weight and the eating disorder examination (EDE). There were no statistically significant differences between the two treatments.

The authors concluded that the short-term course of family was as effective as the long-term one for adolescents with a short duration anorexia nervosa. However, patients with more severe obsessive compulsive thinking, or coming from non-intact families, benefited from the longer treatment.

Strictly speaking, this RCT as such did not provide evidence of benefit from family therapy as there was no alternative form of treatment as a control. Nevertheless the outcomes at the end of 1 year's treatment were highly satisfactory with improvements not reported previously in natural outcome follow-up studies.

(d) Enduring benefits of family therapy

(i) 5-year follow-up with the first Maudsley RCT[110]

Patients who took part in the original Maudsley RCT of family therapy were followed up 5 years after the end of treatment in order to look for evidence of long-term benefit. Follow-up information was obtained on all 57 patients.[110] Apart from three deaths, there was a further overall improvement mainly attributable to the natural outcome of anorexia nervosa.

Within the subgroup of patients with early onset/short history, the mean weight achieved was 103 per cent ABW in patients who had received family therapy. On the Morgan/Russell scale, significantly greater improvement after family therapy was still discernable with a higher proportion of patients achieving a 'good' outcome and a higher average outcome score.

(ii) 5-year follow-up with the Maudsley adolescent RCT[112]

Of the original 40 patients 38 agreed to be reassessed. Compared with the end of treatment there were more patients in the good outcome category and fewer in the poor outcome category, and a further increase in weight. There were no deaths. The main purpose of this study had been to compare CFT and SFT. There was a significant difference between the two groups in the number of patients who resumed normal menstruation, higher in the SFT than in the CFT group. The findings at 1 year in patients from families with raised levels of maternal criticism (high EE) were still evident at 5 years. This group had done less well at the end of treatment in terms of weight and resumption of menstruation if they had been offered CFT.

(iii) 4-year follow-up with the US (Stanford) adolescent RCT[113]

Of the original 86 adolescent patients 71 were followed up. The long-term clinical outcome was good. Again there was little difference between patients treated with short-term or long-term family therapy. The BMI at follow-up for the short-term was 20.6, and the group as a whole showed good psychosocial functioning.

(e) Family therapy conclusions

There is now a strong body of evidence from RCTs that family therapy benefits younger patients with anorexia nervosa. The strength of the evidence in favour of family therapy has grown because of the increasing size of the patient populations tested: 21 in the 1987 Maudsley study, 40 in the 2000 Maudsley study, and 86 in the 2005 Stanford study.

1 From the search for specific components of the family therapy in the Maudsley studies, it can be concluded that the therapy should not be aimed at 'changing the family' but rather at helping them manage a sick family member.

2 Differences in the patients' responses to CFT and SFT were detected when there was a separate analysis for treatment outcome in patients in high and low expressed emotion (EE) families. From this it was concluded that SFT is the more appropriate treatment in families with high expressed emotion.

3 The Stanford study points towards the family therapy of shorter duration (6 months) being acceptable, except in the case of patients with obsessive compulsive thinking or in split families.

4 Finally, it is impressive that the quality of the clinical outcome increases in the long-term follow-ups. The patients in the 1987 Maudsley study showed the best outcome at the end of 5 years. This is not simply due to an expected good natural outcome, as the benefits of family therapy were still evident after 5 years.

Cognitive behavioural therapy

A theory for faulty cognitions maintaining the illness has been put forward by Fairburn *et al.*[114] The argument for examining the role of faulty cognitions in anorexia nervosa is inescapable. The original description of perceptual and conceptual disturbances in anorexia nervosa was put forward by Bruch in 1962.[5] It was appreciated that faulty attitudes to body size contributed in part to the patient's determination to reduce her food intake and lose weight. These observations led to the development of cognitive behavioural therapy (CBT) for anorexia nervosa. At first the evidence of its benefit relied on clinical impressions and case reports.[115] In recent years there have been valiant attempts to assess CBT in adult anorexic patients. It must be said, however, that these studies have met with limited success.

(a) CBT as a post-hospitalization treatment

The most fruitful RCT was conducted at the New York State Psychiatric Institute.[116] The design depended on the random allocation to CBT or the control treatment nutritional counselling (NC) of outpatients after discharge from an inpatient programme. Patients were eligible to enter the outpatient trial when they reached at least 90 per cent of ideal body weight. 33 who were eligible were randomly assigned to one or other treatment. The value of each treatment was assessed by its ability to prevent a relapse, defined as a fall in weight below a BMI of 17.5, or the development of medical or psychiatric complications.

Overall treatment failure was counted as the number of patients who had relapsed plus those who had dropped out from the treatment. The main finding is that the CBT group had a lower relapse and dropout rate and a better clinical outcome than the NC group.

(b) Comparison of CBT with a non-specific supportive clinical management (NSCM)

This study was conducted in Christchurch, New Zealand.[117] In this randomized controlled trial three therapies were compared:

1 CBT

2 Interpersonal psychotherapy

3 Non-specific supportive clinical management (NSCM).

The hypothesis was that the two specialized psychotherapies would be more effective than NSCM.

56 women were enrolled in the study. In fact the mean weights at baseline were not all that low (mean BMI 17.3). Twenty sessions were provided over a course of 20 weeks. The main assessments were a Global Assessment of Functioning (GAF) scale designed by the authors, body weight and the EDE.

The improvement in the group as a whole was perhaps disappointing with mean weight gains of 2.2 kg for CBT to 4.0 kg for NSCM. The hypothesis was not upheld and the specific therapies were less good than the non-specific supportive clinical management. The main lesson from this study is that good general clinical care combined with supportive psychotherapy can be at least as good as CBT.

(c) Multi-centred US study of CBT on its own or combined with medication[106]

An RCT was conducted in three well-established centres in the United States (White Plains New York, Minneapolis, and Stanford). In the original design there were three treatment groups:

1 Medication only

2 CBT only

3 Combined CBT and medication

Altogether 122 patients were randomized to one or other of these treatments. The patients were mainly adult. Their mean BMI (17.7–17.9) suggested the patients were not extremely thin. Intensive treatment was offered for up to 1 year. The patients were withdrawn from the study if they were 'treatment failures'. There were only low rates of completion: 27 per cent of the patients allocated medication, 43 per cent in the CBT group and 41 per cent in the combination group.

The methodological problems prevented an evaluation of the relative effectiveness of the treatments. The overall conclusions were somewhat pessimistic:

> 'It appears premature to conduct randomized controlled trials for *adults with anorexia nervosa* until the reasons for poor acceptance and high dropout rates . . . have been identified, and methods to remedy these serious problems have been devised'.

In fact the investigators were unlucky with the high rate of non-compliance; other studies offering psychotherapy to adult anorexic patients did not encounter such high dropout rates.[118]

The specialist eating disorder service

There is evidence that the treatment of anorexia nervosa is superior in specialized eating disorder units (EDUs) to that of general psychiatric units (adult or adolescent) or general medical units. The EDU comprises a team of professionals with training in the treatment of patients with anorexia nervosa and in maintaining the particular therapeutic ethos that is required. An EDU used to provide mainly inpatient care, but in recent years this has been extended to day and outpatient care. The clinical staff consist of a wide range of personnel including a psychiatric leadership and a trained nursing staff. The psychotherapeutic skills may vary but should include family therapy. The ethos of the EDU needs to combine a mix of therapeutic empathy for the patient with the ability to persuade her to return to a normal weight and eating habits. It is essential that the EDU nurse should be able to combine these skills.

This ethos was established in EDUs set-up in London in the 1970s and 1980s, particularly at St George's Hospital, the Royal Free Hospital and the Maudsley Hospital. It is from there that evidence has arisen for the effectiveness of a specialized eating disorder service.

An ambitious study from St George's Hospital, London, initially aimed at evaluating the advantages of three treatment settings.[96] Fortunately the study incorporated a control group and the

comparison with the active treatment groups yielded the most important results. The four groups were as follows:

1 Inpatient treatment: 4 months on average followed by outpatient psychotherapy.

2 Outpatient treatment combining individual and family therapy.

3 Outpatient group therapy.

4 The control group provided no treatment at the EDU after a 'one-off' evaluation.

90 patients were randomly allocated to one or other of the four options. The study began in the mid-1980s when uncertainty in the subject still warranted from an ethical point of view a random allocation to four groups, including one in which no treatment was provided but the patients returned to the care of their general practitioners. There were methodological difficulties. The patients sometimes dropped out of the treatment when it was not what they wished: out of 30 patients offered inpatient treatment, only 18 accepted it.

At 1 year follow-up there were few clear-cut differences between the patients in the three treatment groups: the inpatients' weights were similar to the outpatients. The clearest finding was that patients allocated to any one of the three treatment groups fared much better than those allocated to the one-off evaluation session only.

The main lesson from this valiant study is that care within an ED service, whether inpatient or outpatient, and irrespective of the specific treatment modality, is superior to treatment received outside an ED service.

(a) Day care and community treatment

There is a paucity of controlled trials of day programmes. An exception is the comparison of inpatient and day treatment carried out in Edinburgh.[119] A traditional inpatient programme, aimed strictly at weight gain, was compared with a more permissive day programme stressing open communication and patient autonomy. The day programme consisted of intensive psychological treatments and was available on 4 days each week. 32 patients who would have merited admission to hospital were randomly allocated to the day programme or the inpatient programme. Although statistically significant differences were not found between the two methods of treatment, the author reported interesting trends in improved outcome using the Morgan/Russell scales. The only advantage conferred by inpatient treatment was a slightly greater weight gain. In contrast, the day programme was more popular with patients who preferred to have a greater say in their rate of weight gain. There was also a greater return of personal autonomy.

(b) Inpatient treatment

Inpatient treatment in recent years has attracted a bad press. It has been argued that there are few RCTs, which have thrown any light on the benefits of inpatient treatments. This is a blinkered approach because RCTs addressed to some of the questions, are either inappropriate or ethically impossible to carry-out. An example of a largely inappropriate question from a clinical point of view is the comparison of inpatient and outpatient treatment in anorexia nervosa because the indications and the patient's suitability for each are very different. It is justified to state this categorically because there now exists solid clinical experience to show what can be achieved by inpatient treatment. The limitations of inpatient treatment are that the benefits may last only a number of months when there is a variable likelihood of relapse. A useful research question would be to identify patients who are most likely to relapse after inpatient treatment. The firm statement made above is warranted because of the valiant study by Crisp and his colleagues[120] previously discussed. Today this study would probably not be possible from an ethical point of view.

The most obvious benefit from inpatient treatment in an EDU is that this is the surest and safest method of improving the patient's nutrition and correcting her weight loss, thereby reversing physical complications, and sometimes saving her life. In various cohort studies the weight gain has varied around 12 kg in 12 weeks.[120–122] There are no comparable rapid improvements with outpatient treatments, not even family therapy in adolescents.

There have been a small number of RCTs in anorexia nervosa in addition to the Crisp *et al* study, and they have addressed narrower questions. For example, a comparison of two different inpatient treatment programmes has yielded the helpful finding that a strict operant conditioning programme offers no advantages over a 'lenient' programme.[123] The value of a specialized eating disorder unit in inducing weight gain was also demonstrated in a cohort of patients admitted to the Maudsley Hospital in 1990. They had previously been admitted to a general psychiatric or medical unit, and information on their previous weights was obtained. In the case of the Maudsley admissions the mean weight rose from 65.8 per cent average body weight (abw) to 90.4 per cent abw; in comparison the admissions elsewhere only led to a mean weight gain from 64.4 to 75 per cent abw.[122]

(c) Compulsory treatments

A study of the use of compulsory treatment in patients admitted to the Eating Disorders Unit at the Maudsley Hospital, comprised 81 patients or16 per cent of admissions. Section 3 of the Mental Health Act, valid for up to 6 months, was the most frequently applied section.[121] The compulsorily admitted patients were compared with a group of voluntary patients. The need for a compulsory admission was found to have two dimensions—the presence of a severe illness and a rejection of treatment. The compulsory patients gained at least as much weight as the voluntary patients but required a longer admission for them to return to a near-normal weight. The compulsory patients represented a selected group by virtue of a more entrenched reluctance to accept treatment. Accordingly it was predicted that in the long term they would fare less well than voluntary patients. The mortality rate of these patients was determined by the National Register, which provided the data at a mean of 5.7 years after the index admission. Ten out of 79 detained patients had died in comparison with two out of 78 voluntary patients, a statistically significant difference. The deaths among the compulsory patients were all due to anorexia nervosa or one of its nutritional complications. Thus the mortality rate among compulsory patients was extremely high at 2.17 per cent per annum, presumably skewed because of the selection factors. Compulsory treatment is an obvious example of the inappropriateness of an RCT.

Treatment: advice on management

It is not possible for the clinician to confine his treatment of anorexia nervosa to those methods that have been subjected to

randomized control trials. This does not mean that his treatment is ineffective or unsupported by evidence. The evidence has to be derived from other kinds of studies. They should not be dismissed as mere clinical experience if they can be supported by evidence-based clinical or experimental observations.

The main obstacle to treatment

The avoidance of treatment by the patient is part and parcel of anorexia nervosa and accentuated by her capacity for denial (see p. 783 of this chapter). There have been attempts to predict the likely level of the patient's compliance with treatment. For example, a 'transtheoretical model of change' is aimed at improving the patient's motivation by overcoming ambivalence while at the same time avoiding confrontation.[124] Different stages in the patient's approach to treatment have been recognized: precontemplation, contemplation, preparation, action, maintenance, and relapse prevention. Motivational enhancement therapy is at an early stage of development with only preliminary information on its impact on treatment outcome.

At our present level of knowledge it is simplest to ascertain the patient's attitude to treatment through the mental state examination. At the initial interview she should be asked what weight she would be willing to reach. At this stage it is best to refrain from challenging the patient's weight threshold, even though it will be well below a reasonable therapeutic goal. Having ascertained the limited degree of compliance, the clinician needs to develop a strategy to improve it gradually as treatment proceeds. It is poor clinical practice to place all the onus on the patient herself for accepting or rejecting a package of treatment at the first interview, or even at a later stage. 'Engaging' the patient in treatment is an essential part of most psychotherapeutic methods including CBT.[115] Another tactic for improving the patient's co-operation is to enlist the help of close members of the family. Young patients are likely in any case to require a family treatment.

Inpatient treatment

Although inpatient treatment is less often employed nowadays it will be described first because it is most important in patients who present as emergencies with an urgent need to preserve life and correct serious physical and psychiatric complications.

(a) Indications for admission

- It is tempting to specify a BMI threshold for admission, but it should be remembered that the BMI can only provide a very rough guide with many exceptions. If the BMI is below 14 admission should always be considered, all the more if there has been rapid weight loss during recent weeks. Indeed a BMI of 16 may cause anxiety if it represents a drop in weight from a BMI of 21 in the course of 2 or 3 months. Close attention should be given to the physical manifestations of malnutrition, especially hypoglycaemia and electrolyte disturbances.
- **The BMI may be totally unreliable in patients who have developed oedema as the result of malnutrition, causing a vicarious weight gain, which may deceive the patient and even the clinician into a false sense of security.**
- The BMI is also less reliable in children and adolescents, especially if their growth in height has been retarded thus distorting the calculation for the BMI towards a falsely reassuring value.
- Dangerous or disabling physical complications:
- Emergencies may result from low blood glucose levels, hypokalaemia or hyponatraemia. The electrolyte disturbances are most likely to occur in the presence of self-induced vomiting or laxative abuse. Hyponatraemia may be induced by polydipsia. Signs of proximal myopathy also indicate a need for admission, as do the occurrence of anaemia, low platelet counts (sometimes accompanied by purpura) and impaired liver function tests.
- Severe depression or obsessional behaviour may also arise in part as complications of malnutrition. Suicidal ideas may require admission, but persistent depression of lesser severity may also be an indication, because it renders the patient less amenable to outpatient psychological treatments, as does severe obsessional behaviour affecting the patient's eating pattern.
- Intractable self-induced vomiting or laxative abuse or determined fasting may require a greater supervision than is possible in an outpatient setting. These behaviours are less disconcerting in patients with bulimia and at a reasonable weight, but a severe weight loss makes it probable that vomiting will result in electrolyte disturbances or other physical complications.
- The decision to admit is often determined by the patient not engaging in the recommended outpatient psychological treatment when the malnutrition persists several months to 1 year.
- Young patients with a retarded puberty (premenarchal anorexia nervosa) should elicit an urgent correction of malnutrition, especially if there is evidence of retarded growth and short stature. There is a narrow window of opportunity for regaining stature, which may depend partly on bone age but it is safest to assume that after the age of 16 the probability of resuming growth becomes increasingly limited, especially in girls.

The great advantage of treating a patient in a specialized eating unit is the certainty that considerable benefit will accrue, including a substantial gain in weight, so long as the patient can be persuaded to remain in hospital.[120]

(b) Nursing and dietary care

Inpatient treatment will include a wide range of psychotherapeutic interventions (individual, group, and family) as well as occupational therapy and an educational programme. But the sheet anchor of successful treatment is a well-trained nursing staff working as a team. The role of the medical staff is one of maintaining a high level of expectation that the patient's weight will be restored to a normal (or healthy) level. It is necessary to give the nursing staff moral support so that they can develop their confidence and skills.

There are two main components to the nurses' treatment: their psychotherapeutic input and their supervisory role. The latter should never be draconian. The nursing team establish a relationship of trust with the patient and get to know her personal needs and concerns. The nurses should also be acutely aware of the anorexic patient's tendency to avoid food and exercise excessively. The treatment programme should stress the supportive aspects of the nurse's relationship with her patient rather than the undoubted need for careful supervision. The nurse will come to rely on the daily weight record to monitor the success of her treatment as the weight chart should show a smoothly rising curve. All meals are taken in the ward: thus the anorexic patients constitute a group in which peer interactions take place. The meal is taken in the presence

of one or more nurses also seated at the table. The patient learns that she is expected to consume all the food placed before her.

A detailed protocol for the refeeding programme has been produced by Andersen and his group.[120] It is not only the patient who tends to underestimate the food requirements to restore her weight to normal. Metabolic studies have demonstrated that for each kilogram of weight gain a surplus calorie balance of 7500 cal is needed.[111] It is prudent to begin with a modest calorie intake of 1200 to 1500 cal daily during the first 7 days in order to avoid the complications of hypophosphataemia and acute gastric dilation. Thereafter the caloric intake is gradually increased and may rise to 4000 cal. daily. The best diet is that consisting of a wide range of foods including carbohydrate and fat-containing foods. Concentrated foods (e.g. Build-up, Complan, Scandishake, Fortisip, Ensure Plus) may be used to achieve a high caloric intake. The aim is to achieve a positive energy balance of at least 1500 cal daily, leading to a weekly weight gain of 1 to 1.5 kg.

(c) Assessment of progress

Weighing should be a standardized daily procedure before breakfast after the patient has emptied her bladder and while wearing light night clothes. A paradoxical psychological improvement, with a diminution in concern with body size and shape, occurs with weight gain. The improvement is partly through the correction of malnutrition and partly the result of the 'exposure treatment' whereby the patient gradually accepts a higher body weight.

(d) Medication

Exceptionally the patient's tension and depression do not improve and there is a continued resistance to food. It may then be helpful to prescribe moderate doses of olanzapine (not more than 10 mg daily), carefully avoiding a fall in blood pressure, which is a risk in the emaciated patient. In the case of persistent depression, treatment with an antidepressant may be indicated. However, antidepressants are often ineffective in the presence of malnutrition, and by themselves do not assist the patient to gain weight.

(e) General measures

Inevitably the patient will find it irksome to forego home visits during the early period of weight gain. Therefore interesting and therapeutic activities should be provided through group meetings, occupational therapy, and social interactions. Visiting is generally encouraged unless the visiting parents are subjected to emotional appeals to take her home. They may then be asked to postpone their visits or reduce their duration. The monotony can be relieved when the patient's weight gain is on course by providing accompanied outings avoiding mealtimes.

The aim is to restore body weight to a healthy level within 8 to 10 weeks; a further period (usually 2 weeks) in hospital is needed to allow the patient to test her ability to maintain her weight by eating in a general dining room or going on home leave for two or more days at a time. The aim is to effect a smooth transition to day care or outpatient treatment.

Compulsory treatment in anorexia nervosa

The management of patients reluctant to accept essential therapeutic goals requires that they should be gradually engaged in a genuine alliance. However, there remain a minority of patients with whom this strategy fails and whose health and life become endangered. For them, compulsory treatment should be considered.[121] A compulsory admission to hospital is indicated not only when patients threaten suicide or suffer from a life-threatening malnutrition, but also when they fail to respond to simpler measures such as outpatient treatment or day care, or in the event of avoiding treatment altogether. Ill health persisting over the course of several months or the development of serious physical complications (e.g. water and electrolyte imbalance, hypoglycaemia, or myopathy) should also elicit compulsory admission if the patient cannot be persuaded to accept inpatient treatment voluntarily.

The evidence points to the usefulness of a compulsory admission in appropriate circumstances in so far as the patients respond well in the short term. Nevertheless, a patient who has required a compulsory admission carries a higher risk, so that it is essential to safeguard her through a long follow-up.

Day and community treatment

The Edinburgh trial of a day patient programme has already been discussed. At the Toronto Hospital a day hospital programme for eating disorders has been established since 1985.[125] and is now offered on 4 days a week.

The goals are as follows:

1 A normalization of disturbed eating behaviour and weight gain.

2 The identification of psychological and familial processes that serve to perpetuate the eating disorder.

Two meals and a snack are provided during the treatment hours. The staff take turns to supervise the patients during meal times. The psychological treatment consists of intensive group therapy addressing disturbed behaviours around eating and weight, and more general conflicts.

The clinical advantages of day treatment are a reduction in the dependence of patients who need to be able to function outside the hospital. The group treatment provides an atmosphere of mutual support while permitting interventions through group pressures. A wide range of patients can be admitted but those with medical or suicidal risks will elicit inpatient care instead. When patients succeed in reducing their disturbed eating behaviours they may 'act out' by self-harm. The clinical staff may find their skills severely taxed by the continuous staff/patient interaction.

A home oriented service extended to outpatient and day care, has been devised by Robinson (2006) for an area of North London (1.2 million). A wide range of treatments were devised including family interventions and carer support. The educational needs of members of the multi-disciplinary team are well described as are administrative and financial issues. Robinson's book includes an audit on the use of hospital and hostel beds requiring only 4–5 total beds per million population per year.

Outpatient psychotherapies

In the event of a patient's weight loss being less than 20 per cent of her healthy weight, it may be possible to obtain a therapeutic response by outpatient treatment, including attendance at non-specialist general psychiatric clinics or child/adolescent psychiatric services. The feasibility of this approach will depend on the availability of appropriate psychotherapeutic resources. The clinician should guard himself against imaginary conflicts between a psychotherapeutic approach and recording the weight of the patient. It is never justified to accept apparent compliance with psychotherapy if the patient's weight continues to decline.

(a) Family treatments

(i) Conjoint family therapy

The frequency of the sessions is determined by clinical need: it averaged 10.5 over the course of 1 year in the Maudsley trial. There are three stages to the therapy:

1 In the first phase the parents are urged to identify their future joint attitude to the feeding pattern that should be adopted by their daughter. With a younger patient the therapist assumes that the parents would initially need to take control of their child's eating.

2 During the second phase the parents are urged to be present together at each meal so that they can reinforce each other's efforts in the practical task of ensuring an improved food intake and a steady weight gain.

3 When the patient's weight is under control, responsibility for continued weight gain is handed back to her. Discussions can then commence on more normal family concerns. With an adolescent patient the main focus is on achieving increased autonomy. The eventual aim is to establish healthy relationships with her parents without the eating disorder as a medium for communication.

(ii) Separated family therapy

As in conjoint family therapy the parents are given direct advice on how to manage their daughter's eating problem. The patient herself is provided with individual psychotherapy. The therapist provides counselling about abnormal attitudes to weight and emphasizes the weight issue until steady progress has been made. This method is often preferred by the patient and her parents, largely because it avoids confrontation. It is also easier to gain access to the patient's fears and conflicts.

(b) CBT

CBT has much in common with other methods of treatment including the refeeding programme described under inpatient treatments. It relies on building a positive therapeutic alliance between therapist and patient.

The patient's weight and food intake is monitored at each session and she is told her weight. She is encouraged to think of food as medication and to follow a meal plan. The patient is educated in the disturbances of bodily and psychological function consequent on the state of starvation. The content of the therapy may be divided into two 'tracks'. The first track includes an examination of the behaviours adopted by the patient in order to reduce her weight. The second track is more concerned with psychological themes such as self-esteem, perfectionism, interpersonal functioning, and family conflicts. By asking the patient to give her reasons for specific behaviours, the therapist discovers faulty beliefs and assumptions on her part. For example, the 'anorexic wish' is the patient's wish to recover from her disorder without gaining weight. She is gently persuaded that this is an impossible aim because her real psychological difficulties will remain inaccessible so long as her experiences are clouded by starvation and dieting. The patient also expresses a fear of 'losing control' meaning that she will run the risk of overeating and become fat. It is explained to the patient that her rigid 'control' overeating deprives her completely of choice, and that far from being in control the reality is the converse. It is also useful for the therapist to analyse the pros and cons of maintaining the disorder of anorexia nervosa. The patient often feels more uncomfortable at confronting the hidden rewards of remaining thin.

Having ascertained the particular meanings of attitudes and behaviours for the patient, she is helped to find more adaptive ways of achieving healthier goals, including more relaxed normal eating and weight gain.

(c) Dynamic psychotherapy: therapeutic model

(i) Crisp's model of anorexia nervosa as a flight from growth

Crisp has explained how his programme of treatment is based on his model of anorexia nervosa as a refuge from puberty, which the patient has found overwhelming. The youngster reverses her pubertal development by limiting her intake of food.[126] His treatment initially involves an intensive inpatient programme lasting 10 to 12 weeks followed by outpatient treatment for up to 6 years. The advantage of this extensive programme is that it enables the patient to accept gradually an increase in weight while facing up to the feelings of panic and helplessness that originally led her to arrest her puberty through self-starvation. This interpretation is presented to the patient and to her family so that they come to see the psychotherapy as a way of solving the problems.

The model is a useful one even within a more limited outpatient psychotherapeutic setting. Some patients will readily identify their distress when overwhelmed by powerful sexual feelings or when confronted with personal and social responsibilities perceived as the result of growing up. The aims of the psychotherapy are to support the patient while she is beginning to abandon the psychobiological regression of anorexia nervosa. In addition she is encouraged to broaden her perception of herself in ways that are no longer wholly dependent on her physical appearance but include an improved sense of competence and self-esteem. She is helped to tackle personal and social problems from which she had previously escaped so that she can address her own and her parents' concerns about sexuality.

Ethical and medico-legal issues

In the United Kingdom the Mental Health Act Commission[127] has clarified many of the doubts in the minds of clinicians and social workers called upon to consider a compulsory admission under the Mental Health Act 1983. It recognized that anorexia nervosa is a mental disorder within the meaning of the Act and that in some patients their ability to consent may be compromised by fears of obesity or denial of the consequences of their actions. The Mental Health Act Commission concluded that when the patient's health is seriously threatened by food refusal she may be detained in hospital so as to treat the self-imposed starvation. The Commission went as far as to state that nasogastric feeding can be a medical process forming an integral part of the treatment for anorexia nervosa, notwithstanding that nasogastric feeding is seldom required.

Prevention

Preventive measures have been aimed at eating disorders generally rather than just anorexia nervosa. The main approach has been school-based intervention programmes educating adolescent girls into the risks of dieting and other methods of weight control. The commonest outcome has been an increased knowledge about

eating disorders without a change in the behaviours, such as dieting, likely to cause them. One controlled study, six weekly sessions were provided by teachers on a wide range of topics covering attitudes and behaviours relevant to eating disorders including a 'non-dieting approach'. Positive changes were detected at a 6-month follow-up but they were modest in size and poorly sustained.[128]

Currently there are active campaigns by the Academy of Eating Disorders and Beat Eating Disorders (UK) to encourage the fashion industry not to employ thin models. Unilever has adopted a policy not to employ models with a BMI less than 18.5. John Lewis requires models to be not less than size 12.

4.10.2 Bulimia nervosa

Christopher G. Fairburn,
Zafra Cooper, and Rebecca Murphy

Introduction

Origins of the concept

The history of the diagnosis bulimia nervosa begins as recently as 1979. It was in this year that Russell published his now seminal paper 'Bulimia nervosa: An ominous variant of anorexia nervosa'[1] in which he described 30 patients (28 women and 2 men), seen between 1972 and 1978, who had three major features in common. First, they had recurrent episodes of uncontrolled overeating; second, they regularly used self-induced vomiting or laxatives as means of weight control; and third, they had a morbid fear of becoming fat. Russell described many other features shared by these patients, including a history of anorexia nervosa (present in 80 per cent), the presence of severe depressive symptoms, and the fact that in most cases their body weight was in the healthy range. He noted that the disorder tended to run a chronic course and that it was 'extremely difficult to treat'. Finally, he suggested that this clinical picture should be viewed as a syndrome, distinct from anorexia nervosa, and he proposed the term 'bulimia nervosa'.

It is difficult to exaggerate the importance of Russell's paper. Its greatest contribution was perhaps its prescience in that it crystallized out from among the range of eating disorders seen in clinical practice a subgroup of patients that was just starting to become more common; it identified its central features; and it gave it an appropriate name.

Events since 1980

Events gathered pace in the 1980s. In 1980 a syndrome termed 'bulimia' was included in DSM-III.[2] This was intended to denote the type of patient that Russell had described, although its diagnostic criteria proved to be overly inclusive. In 1987, the criteria were refined and brought more in line with Russell's original concept. The syndrome was also renamed bulimia nervosa.[3] Also in the early 1980s evidence mounted that bulimia nervosa might be common and this led to a spate of studies of its prevalence. At the same time reports were published describing the successful treatment of these patients, the two most promising approaches being a specific form of cognitive behaviour therapy and the use of antidepressant drugs. By the mid-1980s, both treatments had been tested in the first of what has become a large series of controlled trials.

Now, three decades later, the diagnosis bulimia nervosa is included in both DSM-IV[4] and ICD-10,[5] its prevalence is established, aspects of its aetiology are beginning to be understood, and much has been learned about its treatment.

Classification and diagnosis

The classification of the eating disorders and their principal diagnostic criteria are shown in Table 4.10.2.1. Bulimia nervosa is one of the two main eating disorders recognized in DSM-IV and ICD-10, the other being anorexia nervosa (discussed in Chapter 4.10.1). In addition, in DSM-IV there is a residual category termed 'eating disorder not otherwise specified'. This is reserved for eating disorders of clinical severity that do not meet the diagnostic criteria for anorexia nervosa or bulimia nervosa.[6] In ICD-10, various eating disorder categories other than anorexia nervosa and bulimia nervosa are recognized (for example, atypical anorexia nervosa, atypical bulimia nervosa, overeating associated with other psychological disturbances), although these concepts have never been adequately defined or differentiated.

The relationship between the three DSM-IV diagnoses is represented diagrammatically in Fig. 4.10.2.1. The two overlapping inner circles represent anorexia nervosa (the smaller circle) and bulimia nervosa (the larger circle) respectively, the area of potential overlap being that occupied by those people who would meet the diagnostic criteria for both disorders but for the rule that the diagnosis of anorexia nervosa trumps that of bulimia nervosa (see Table 4.10.2.1). Surrounding these two circles is an outer circle which defines the boundary between having an eating disorder, a state of clinical significance, and having a lesser, non-clinical, eating problem. It is this boundary that demarcates what is, and is not, an eating disorder. Within the outer circle, but outside the two inner circles, lies eating disorder not otherwise specified (eating disorder NOS).

In DSM-IV a new eating disorder diagnosis was proposed termed 'binge eating disorder'. It is designed to denote an eating problem characterized by recurrent binge eating in the absence of the extreme weight-control behaviour seen in bulimia nervosa. Since binge eating disorder is a provisional diagnostic concept, it is currently an example of eating disorder NOS.

The two schemes for classifying eating disorders encourage the view that anorexia nervosa and bulimia nervosa are distinct clinical states. Consideration of their clinical features and course over time does not support this.[7] Binge eating disorder aside, patients with anorexia nervosa, bulimia nervosa, and eating disorder NOS have

Table 4.10.2.1 Classification of eating disorders and their principal diagnostic criteria.

Classification of eating disorders
◆ Anorexia nervosa
◆ Bulimia nervosa
◆ Eating disorder not otherwise specified (eating disorder NOS)
Binge eating disorder (a provisional new diagnosis, currently subsumed under eating disorder NOS)
Principal diagnostic criteria
Anorexia nervosa
1 Over-evaluation of shape and weight (i.e. judging self-worth largely, or exclusively, in terms of shape and weight)
2 Active maintenance of an unduly low body weight (e.g. body mass index < 17.5)
3 Amenorrhoea (in post-menarcheal females who are not taking an oral contraceptive). This criterion is often omitted.
Bulimia nervosa
1 Over-evaluation of shape and weight (i.e. judging self-worth largely, or exclusively, in terms of shape and weight)
2 Recurrent binge eating (i.e. recurrent episodes of uncontrolled overeating)
3 Extreme weight-control behaviour (e.g. strict dieting, frequent self- induced vomiting, or laxative misuse)
4 Diagnostic criteria for anorexia nervosa are not met
Eating disorder not otherwise specified
Eating disorders of clinical severity that do not conform to the diagnostic criteria for anorexia nervosa or bulimia nervosa
Binge eating disorder
Recurrent binge eating in the absence of the extreme weight-control behaviour seen in bulimia nervosa

(Reproduced from Fairburn, C.G. Cognitive Behaviour Therapy and Eating Disorders, copyright 2008, Guildford Press, NY.)

many features in common, most of which are not seen in other psychiatric disorders, and studies of their course indicate that patients migrate between these diagnoses over time: indeed, temporal migration is the norm rather than the exception. This temporal movement, together with the fact that the disorders share the same distinctive psychopathology, has led to the suggestion that the current diagnostic scheme is a poor reflection of clinical reality and that common 'transdiagnostic' mechanisms may be involved in the maintenance of eating disorder psychopathology.[8]

Clinical features

The great majority of patients with bulimia nervosa are female and most are in their 20s (although the age range is between 10 and 60 years). In considering the psychopathology of the disorder, a distinction may be drawn between its 'specific' and 'general' features. The former comprises features that are largely peculiar to eating disorders (for example, self-induced vomiting, the over-evaluation of shape and weight), whereas the latter consists of features seen in other psychiatric conditions (for example, depressive symptoms). The clinical features of bulimia nervosa are similar in men and women and in those with and without a history of anorexia nervosa.

Specific psychopathology

(a) Dieting and binge eating

The eating habits of patients with bulimia nervosa are characterized by strict dieting punctuated by repeated episodes of binge eating (see Fig. 4.10.2.2). The dieting is extreme and it is governed by multiple self-imposed dietary rules. These rules tend to be applied to all aspects of eating, including when to eat, what to eat, and how much to eat. As a result, the food eaten (when not binge eating) is restricted in quantity and range.

Recurrent episodes of 'binge eating' interrupt this dieting. (The term binge eating denotes discrete episodes of eating that have two characteristics: first, an unusually large amount of food is eaten,

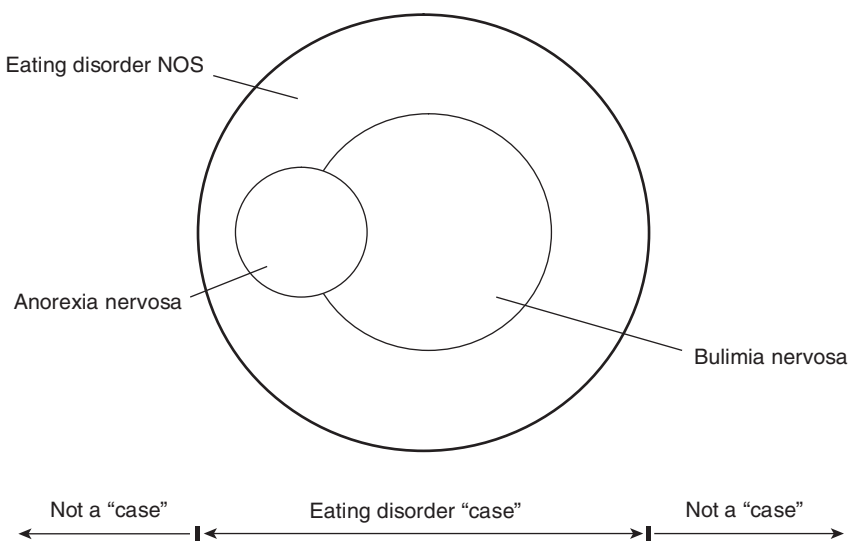

Fig. 4.10.2.1 A schematic representation of the relationship between anorexia nervosa, bulimia nervosa, and eating disorder NOS (Reprinted from Fairburn, C.G. and Bohn, K. Eating disorder NOS (EDNOS): an example of the troublesome "not otherwise specified" (NOS) category in DSM-IV, *Behaviour Research and Therapy*, **43**, 691–701, copyright (2005), with permission from Elsevier).

Day.....Thursday..... Date .....March 21 .....

Time	Food and drink consumed	Place	*	V/L	Context and comments
7.30	Glass water	Kitchen			[8stone 9lbs - really gross] Thirsty after yesterday
8:10	1 bowl muesli with skimmed milk Black coffee	Kitchen	*		Should have had less muesli. Must not binge today.
10:35	Half banana Black coffee	Work - at desk			Better - on track
11:45	Ham and lettuce slimline sandwich Diet coke	In canteen			Usual lunch
6.40 to 7.30	Slice of chocolate cake 1/2 tub ice cream 4 slices of toast with jam Diet coke Another slide of cake 2 slices of toast with jam Diet coke Jam from jar Two kit kats Mars bar Diet coke - large	Kitchen	*	V	Help - I can't stop eating. I'm completely out of control. I hate myself. I am disgusting. Why do I do this? I started as soon as I got in. I've ruined another day.
9:30	Rice cake with fat-free cheese Diet coke	Kitchen			Really lonely. Feel fat and unattractive. Feel like giving up.

Fig. 4.10.2.2 A monitoring record illustrating the eating habits of a patient with bulimia nervosa. Asterisks are used to signify episodes of eating that were viewed by the patient as excessive. The column headed 'V/L' is for recording episodes of self-induced vomiting or laxative misuse.

given the circumstances; and second, there is a sense of loss of control at the time. Some patients with eating disorders have similar episodes of uncontrolled overeating that do not involve the consumption of objectively large amounts of food. These episodes are sometimes referred to as 'subjective binges' although technically speaking they do not meet the definition of a 'binge'.) The frequency and regularity of the binge eating varies. Some patients have episodes almost every day, whereas in others the episodes are intermittent. In DSM-IV, it is specified that the binges should occur on average at least twice a week, but this is an arbitrary figure that has little discriminatory value. Among those patients in whom the binge eating is frequent, the binges have few, if any, obvious triggers, although there may be circumstances under which binge eating is more likely (for example, when alone at home). Among patients in whom the binge eating is less frequent, the binges often have clear precipitants. These tend to be of three overlapping types: first, there is breaking a personal dietary rule (for example, exceeding a daily calorie-limit or eating a banned food); second, there are situations which intensify concerns about shape and weight (for example, receiving an adverse comment about appearance); and third, there is the occurrence of negative moods (often as a result of interpersonal events). All three undermine the maintenance of strict dietary control.

The amount of food eaten during binges varies, both from patient to patient and from episode to episode. Typical episodes involve the consumption of 1000 to 2000 kcal.[9] The food eaten generally comprises items that are otherwise being avoided. Thus binges tend to be composed of energy-dense, high-fat items such as chocolate, ice cream, and pastries. Binges come to an end as a result of the combined influence of exhaustion, extreme fullness, a diminution of the drive to eat, and the running out of food supplies. In about three-quarters of patients they are immediately followed by measures designed to counteract the effects of the overeating, the most common being self-induced vomiting and the taking of laxatives or diuretics.

The binges are a source of considerable distress. They magnify these patients' fears of weight gain and fatness, and they may result in shame and self-disgust. For this reason most binges occur in private and are kept secret from others. It is the binge eating that eventually drives these people to seek help.

(b) Purging and other forms of weight control

In DSM-IV bulimia nervosa is subdivided into two types, a purging and non-purging type. In the purging type there is regular self-induced vomiting or the misuse of laxatives or diuretics, or both, whereas in the non-purging type such behaviour ('purging') is either not present or it is infrequent. The majority of patients seen in clinical practice have the purging form of the disorder and it has been the focus of most research.

Self-induced vomiting is the most common form of purging. In most patients it only takes place after binge eating. It is generally achieved by stimulating the gag reflex, using the fingers or some

other long object, although in more established cases it can be accomplished with no mechanical aid. The vomiting is repeated until patients think that they have retrieved all the food that they can. Patients get extremely distressed if they are unable to vomit after binge eating: indeed, if they foresee that they may not have the opportunity to vomit, they tend not to binge. A minority of patients also induce vomiting at other times, for example, following smaller episodes of overeating (subjective binges) or ordinary meals or snacks.

The misuse of laxatives or diuretics is somewhat less common than self-induced vomiting. It takes two forms: one is to compensate for specific episodes of binge eating, like self-induced vomiting; and the other is as a general method of weight control (like dieting), in which case it is not tied to particular episodes of overeating. The number of laxatives or diuretics taken varies considerably, sometimes far exceeding the recommended dose.

None of these methods of purging is an effective method of weight control. Self-induced vomiting results in the retrieval of only about half to two-thirds of what has been eaten, the taking of laxatives has a minimal effect on food absorption, and diuretic-taking has none. As a result, a significant proportion of each binge is absorbed.

The weight of most of these patients is in the healthy range (BMI between 20 and 25) due to the effects of the under-eating and over-eating cancelling each other out. As a result they do not experience the secondary psychosocial and physical effects associated with maintaining a very low weight seen in anorexia nervosa.

Other forms of weight-control behaviour are practised by some patients, including over-exercising, the spitting out of food, and the taking of repeated enemas or saunas. Over-exercising is the most common of these, but it is not nearly as prominent or as obviously pathological as in anorexia nervosa. A minority of patients ruminate, that is, repeatedly regurgitate and re-chew food that has been eaten. They may then either re-swallow the food or spit it out. This behaviour is not well-understood.

In the non-purging type of bulimia nervosa there is no vomiting or misuse of laxatives or diuretics, or they occur infrequently. Instead, there is sustained and marked dietary restriction outside the binges. This is both a response to the binge eating and contributor to it, in that this type of eating increases the risk of further episodes. In all other respects the two subtypes of the disorder are similar.

(c) Attitudes to shape and weight

A characteristic set of attitudes to shape and weight is the other distinctive element of the specific psychopathology of bulimia nervosa. Equivalent attitudes are found in anorexia nervosa and most cases of eating disorder NOS. These attitudes are often described as the 'core psychopathology' of eating disorders. They are characterized by an overconcern with shape and weight in which there is a fear of weight gain and fatness that is generally accompanied by a pursuit of weight loss and thinness. Underlying this psychopathology is the tendency to judge self-worth largely, or even exclusively, in terms of shape and weight. Whereas it is usual to evaluate self-worth on the basis of perceived performance in a variety of domains of life (such as interpersonal relationships, work, sport, artistic ability, etc.), people with anorexia nervosa or bulimia nervosa evaluate themselves primarily in terms of their shape and weight. These attitudes and values constitute a good example of an overvalued idea.

Most features of bulimia nervosa can be understood as being secondary to these attitudes to shape and weight. The dieting, purging, and over-exercising are obvious secondary features. In addition, there are direct behavioural expressions of these concerns. For example, many patients repeatedly weigh themselves and scrutinize their appearance in mirrors. Others avoid any knowledge of their weight while being acutely sensitive about their appearance. Some avoid others seeing their body and some even avoid seeing it themselves. This can have a major impact on social and sexual relationships.

The concerns about shape and weight, and eating, have a major effect on others in the patient's immediate environment. Meals are often times of tension and social events which involve eating may be avoided. The feeding of children may be affected[10] and their growth may be impaired[11] (see Chapter 9.3.6).

General psychopathology

General psychiatric symptoms are prominent in bulimia nervosa; more so than in anorexia nervosa. The nature of the comorbid symptoms also differs. Depressive features are particularly striking: indeed, the level of depressive symptoms in bulimia nervosa is equivalent to that seen in major depressive disorder. Anxiety symptoms are also encountered, many of which are directly related to the eating disorder; for example, there is often pronounced anxiety about eating in public. Obsessive-compulsive features are sometimes present, although they are less common than in anorexia nervosa. Similarly, social functioning is less impaired.

The depressive features of bulimia nervosa deserve special mention. In most patients the depressive features can be attributed to the presence of the eating disorder but in a subgroup there appears to be an independent coexisting, but interacting, clinical depression. Features suggestive of such coexisting clinical depressions include the following: recent intensification of depressive features (in the absence of any change in the eating disorder or the patient's circumstances); pervasive and extreme negative thinking (i.e. broader in content than concerns about eating, shape, and weight); hopelessness in general (i.e. seeing the future as totally bleak, seeing no future, resignation); recurrent thoughts about death and dying; suicidal thoughts; guilt over events in the far past; a decrease in involvement with others over and above any impairment that already accompanied the eating disorder (e.g. ceasing to see friends); loss of interest in activities that had been pursued despite the eating disorder (e.g. ceasing to listen to music; ceasing to read newspapers or follow the news); and a decrease in drive and initiative.

These coexisting clinical depressions often go undetected since they are viewed as characteristic of bulimia nervosa. This is unfortunate for two reasons: first, they interfere with the treatment of the eating disorder; and second, they are readily treated with antidepressant drugs (unlike the secondary depressive features).

A minority of patients with bulimia nervosa have 'impulse-control' problems, such as the overconsumption of alcohol or drugs, or repeated self-harm (e.g. cutting). Some of these patients also meet diagnostic criteria for borderline personality disorder (see Chapter 4.12.2). The prevalence of such features varies according to treatment setting: they are unusual in community samples, whereas they are more frequent among patients seen in specialist treatment centres.

Much more common than frank personality disorders are two traits which are also seen in anorexia nervosa. The first is low self-esteem. This generally antedates the eating disorder, although it is often exaggerated by it. Many patients with bulimia nervosa describe longstanding doubts about their worth and ability, irrespective of their accomplishments. The second is perfectionism, that is, imposing on oneself inordinately high personal standards in a range of domains (for example, work, sport, personal conduct). Since many of these standards are unachievable, it is common for these patients to give long histories of viewing themselves as perpetually failing.

Physical features

There are few physical abnormalities in bulimia nervosa. Body weight is unremarkable in the majority of patients and thus the physical effects of starvation are rarely seen. Nevertheless, menstrual abnormalities or amenorrhoea are present in about a quarter of patients. These are likely to be secondary to the disturbed eating since they generally respond to the successful correction of the eating disorder. On laboratory testing endocrine abnormalities are sometimes encountered and these tend to be mild versions of those found in anorexia nervosa. Fertility appears not to be affected.

Frequent purging, and especially the combination of vomiting and laxative misuse, results in fluid and electrolyte abnormalities in some patients. These abnormalities are varied in nature but most often consist of some combination of hypokalemia, hyponatremia, and hypochloremia. The patients appear to accommodate to these abnormalities since medically serious complications (for example, cardiac arrhythmias) are much less common than might otherwise be expected given the laboratory findings. Some patients experience intermittent oedema particularly if there is a sudden decrease in the extent of their purging.

Localized physical abnormalities include erosion of the dental enamel (especially from the lingual surfaces of the front teeth) among those who have vomited for many years; traumatic calluses on the knuckles of the hand of those who use their fingers to induce the gag reflex (Russell's sign); and enlargement of the salivary glands, especially the parotids, probably as a result of chronic inflammation. A small proportion of patients have raised serum amylase levels usually due to an increase in the salivary isoenzyme.

Relationship to other disorders

Anorexia nervosa and eating disorder NOS

Bulimia nervosa has many features in common with anorexia nervosa and eating disorder NOS, particularly the characteristic attitudes to shape and weight and the behaviour that arises directly as a result.[12] In most cases, bulimia nervosa is preceded either by frank anorexia nervosa (in about a quarter of cases) or an anorexia nervosa-like form of eating disorder NOS. While movement from bulimia nervosa to anorexia nervosa is unusual, progression on to some form of eating disorder NOS is common. Whether it is appropriate to view such patients as having recovered from one psychiatric disorder and developed another is a moot point: rather, it would seem more appropriate to view them as having a single evolving eating disorder.

There is some evidence of co-aggregation between bulimia nervosa, anorexia nervosa, and eating disorder NOS with there being increased rates of all three diagnoses among the relatives of probands with either condition.[13]

Obesity

Few patients with bulimia nervosa are overweight or have obesity. On the other hand there is evidence of raised rates of parental and premorbid obesity.[14] Obesity is an unusual sequel of the disorder although this may be because those at most risk of obesity are less likely to recover and so continue to suppress their weight.

Other psychiatric disorders

As noted above, depressive features are common in bulimia nervosa and they may antedate the eating disorder. The same is true of anxiety and anxiety disorders. Most family studies have found a raised rate of affective disorder among these patients' relatives whereas little is known about the familial relationship between bulimia nervosa and the anxiety disorders.[15] There is a raised rate of alcohol and drug abuse among patients with bulimia nervosa and a raised rate among these patients' relatives.[15] Substance abuse rarely antedates the eating disorder but this is to be expected given the age of onset of substance abuse disorders.

It is hazardous making personality disorder diagnoses among those with eating disorders. This is because eating disorders have their onset in adolescence and they directly affect many of the characteristics upon which personality is judged. Thus there is a risk of overestimating the presence of personality disturbance. Nevertheless, some patients with bulimia nervosa do seem to have a coexisting personality disorder, the most common form being borderline personality disorder. Little is known about the rate of personality disturbance among these patients' relatives although there is evidence of familial co-aggregation of anorexia nervosa and obsessional and perfectionist traits.[15]

Diabetes mellitus

It was thought that eating disorders were over-represented among those with Type I diabetes mellitus. This is now not clear. Controlled studies in which eating disorder features have been assessed by interview rather than self-report questionnaire (the preferred method and one which minimizes the risk of false positive diagnoses) have found little evidence of an elevated rate of anorexia nervosa although the rate of bulimia nervosa may be increased.[16]

Distribution

The fact that it took Russell more than 6 years (1972–1978) to collect 30 cases of bulimia nervosa suggested that the disorder was not common. It is therefore remarkable that within a few years of the publication of Russell's paper it was evident that bulimia nervosa was an important source of psychiatric morbidity among young women.

In the early 1980s large numbers of previously undetected cases were identified using the media.[17,18] These cases were remarkably similar to Russell's, except that almost all were female and a small proportion had a history of anorexia nervosa. Most had kept their eating disorder secret for many years, and because of shame and hopelessness few had sought help. Many thought that they were the only person with this type of eating disorder. Simultaneously however, and doubtless partly as a result of the media attention,

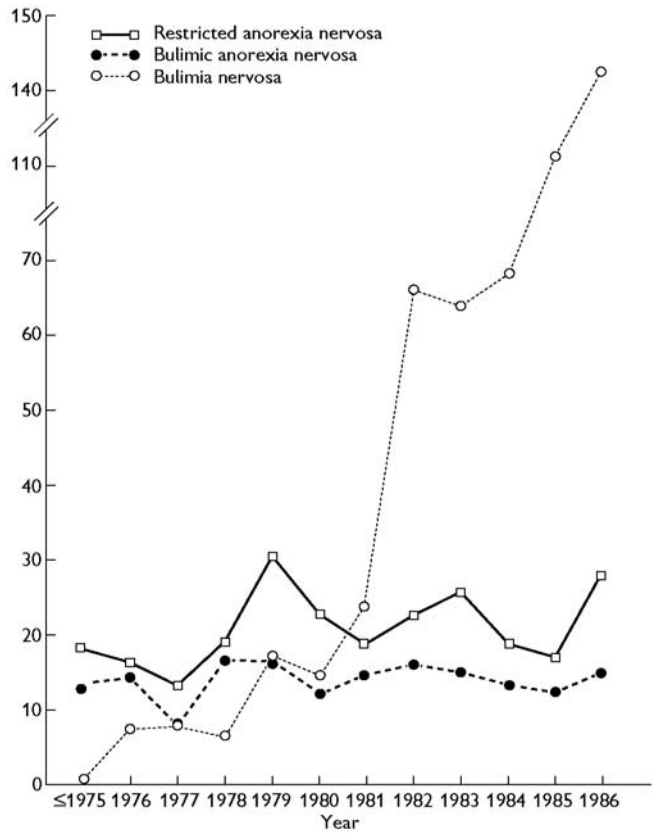

Fig. 4.10.2.3 Rates of referral to a major eating disorder centre in Toronto (1975–1986) (Reproduced from Garner, D.M. and Fairburn, C.G Relationship between anorexia nervosa and bulimia nervosa: diagnostic implications. In *Diagnostic issues in anorexia nervosa and bulimia nervosa* (eds. D.M. Garner and P.E. Garfinkel), copyright 1998, Brunner/Mazel, New York).

there was also a sharp increase in the number of people requesting treatment for bulimia nervosa (see Fig. 4.10.2.3).

The marked increase in the number of patients with bulimia nervosa stimulated interest in the prevalence of the disorder. By 1989 over 50 prevalence studies had been conducted, many of which yielded unrealistically high prevalence figures as a result of using weak assessment and sampling procedures. Gradually methods improved with the result that estimates of the prevalence of bulimia nervosa decreased to more modest and consistent levels with the point prevalence among young adult women (aged 16 to 35 years) being in the region of 1 per cent,[19,20] a similar figure being obtained for lifetime prevalence.[20] The prevalence of bulimia nervosa among men is not known. Among patient samples, male cases are unusual. Bulimia nervosa is thought to be uncommon in non-Western societies although few prevalence studies have been conducted and most have had significant methodological shortcomings.[21]

There have been few estimates of the incidence of bulimia nervosa, and since these have been based upon clinic rather than community samples, they are likely to underestimate the true figures. Even today, many people with bulimia nervosa do not seek help. The lack of reliable community-based incidence figures also makes it impossible to know whether the disorder has become more common since the 1970s or whether the upsurge in cases in the early 1980s was as a result of undetected cases being more likely to seek treatment. Data from the assessment of women in different birth cohorts suggest that the disorder has become much more common[22] although other explanations for the apparent increase cannot be ruled out.

Aetiology

Development of the disorder

As noted in Chapter 4.10.1, anorexia nervosa generally starts in mid-adolescence with a period of voluntary dietary restriction which proceeds to get out of control. As a result body weight falls and a state of starvation develops. Shape and weight concerns may pre-date the onset of the dieting or develop as weight is lost.

Bulimia nervosa starts in a similar way although the age of onset is typically some years later and shape and weight concerns usually antedate the dieting. The dietary restriction resembles that seen in anorexia nervosa and it leads to weight loss sufficient to result in anorexia nervosa in about a quarter of cases. (As a result of referral bias, this proportion is higher in cases seen in specialist centres.) In the remaining cases there is also weight loss but it is less extreme. After a variable length of time (generally within 3 years) dietary control breaks down with the patient's dieting becoming punctuated by episodes of overeating. At first, the episodes of overeating may be modest in size and intermittent, but gradually they become larger and more frequent. As a result, the lost weight is regained and body weight returns to near its original level. By this point the disorder tends to be self-perpetuating. At some stage in this sequence of events, self-induced vomiting and laxative misuse may be adopted to compensate for the overeating. In practice, however, both forms of behaviour have the opposite effect since belief in their effectiveness encourages a relaxation of control over eating. In those who vomit this phenomenon is exaggerated by the discovery that the process is easier after eating large amounts of food.

Predisposing factors and processes

There are many risk factors for the development of bulimia nervosa[14] and these overlap with those for anorexia nervosa[23] (see Table 4.10.2.2).

The risk factors may be usefully divided into a number of categories.

- Demographic factors—these are being female, adolescent and living in a Western society.
- Exposure to an immediate social environment that encourages dieting—this includes being brought up in a family in which there is intense interest in shape, weight, and eating as a result of one or more members either having some degree of eating disorder or having a medical condition that affects eating or weight (such as diabetes mellitus). Extreme occupational or recreational pressures to diet also appear to be associated with increased risk (for example, ballet dancing), although there may also be an element of self-selection. Another important influence is parental and childhood obesity, the rates of which are substa ntially increased in bulimia nervosa. Both are likely to sensitize individuals to their appearance and weight, and thereby make them prone to diet. There is also some evidence that puberty occurs comparatively early which may also magnify concerns about shape.

Table 4.10.2.2 Principal risk factors for anorexia nervosa and bulimia nervosa

General factors
Female
Adolescence and early adulthood
Living in a Western society
Individual-specific factors
Family history
Eating disorder of any type
Depression
Substance abuse, especially alcoholism (bulimia nervosa)
Obesity (bulimia nervosa)
Premorbid experiences
Obstetric complications
Adverse parenting (especially low contact, high expectations, parental discord)
Sexual abuse
Family dieting
Critical comments about eating, shape, or weight from family and others
Occupational and recreational pressure to be slim
Premorbid characteristics
Low self-esteem
Perfectionism (anorexia nervosa and to a lesser extent bulimia nervosa)
Neuroticism
Anxiety and anxiety disorders
Obesity (bulimia nervosa)
Early menarche (bulimia nervosa)
Type I diabetes (bulimia nervosa)

- Exposure to factors that increase the risk of psychiatric disturbance in general and depression in particular—these include a family history of psychiatric disorder, especially depression, and a range of adverse childhood experiences including parenting deficits and sexual and physical abuse. It was thought that sexual abuse was especially common among those who develop bulimia nervosa, but the balance of evidence suggests that the rate is no higher than that among those who develop other psychiatric disorders.
- Perfectionism and low self-esteem—both traits are common antecedents of anorexia nervosa and bulimia nervosa. Typically they interact resulting in feelings of incompetence and ineffectiveness.
- Family history of substance abuse—there is a raised rate of substance abuse in the families of patients with bulimia nervosa. It is not clear how this increases the risk of bulimia nervosa. Clinical observations suggest that some of those who develop bulimia nervosa learn to modulate their mood by engaging in self-harm (e.g. by cutting themselves) or by consuming large quantities of food, alcohol, or psychoactive drugs.

An important question is how those with anorexia nervosa are able to maintain strict control over their eating whereas this is not true of those with bulimia nervosa. The explanation is unclear but several processes may be of relevance. First, perfectionism is even more pronounced in anorexia nervosa and it may enhance self-control. Second, the vulnerability to obesity found in bulimia nervosa may somehow undermine dietary restraint. Third, the mood lability of bulimia nervosa may also disrupt restraint.

Contribution of genetic factors

The fact that eating disorders run in families suggests that there may be a genetic contribution. In the absence of adoption studies, twin designs have been used to establish its extent.[24] Clinic samples show concordance for anorexia nervosa of around 55 per cent in monozygotic twins and 5 per cent in dizygotic twins, with the corresponding figures for bulimia nervosa being 35 and 30 per cent, respectively.[7,25] These findings suggest a significant heritability to anorexia nervosa but not to bulimia nervosa. Despite this, there is uncertainty as to the size of the genetic contribution to both disorders with there being differing point estimates and wide confidence intervals. The same applies to the contributions of individual-specific and shared (common) environmental factors. A number of issues affect the interpretation of the data. For example, there has been insufficient power to detect shared environmental effects, and established diagnostic criteria have been broadened considerably to increase the number of 'affected' twins available for analysis.

Given the clear and possibly substantial genetic contribution to both disorders, molecular genetic studies have been conducted to identify the underlying loci and genes. Genetic association studies have focussed in particular on polymorphisms in 5-HT (serotonin)-related genes because this neurotransmitter system is important in regulation of eating and mood, but a range of other polymorphisms have also been investigated. Despite this, no associations with eating disorders have been clearly replicated or confirmed in a family study or by meta-analysis. There has been one multi-centre genome-wide linkage study. It found linkage peaks for anorexia nervosa and bulimia nervosa on chromosomes 1, 4, 10, and 14. A further analysis, which covaried for related behavioural traits, identified a different locus on chromosome 1, as well as loci on chromosomes 2 and 13. All these findings await replication.

Neurobiological findings

There has been extensive research into the neurobiology of eating disorders. This has focussed on neuropeptide and monoamine (especially 5-HT) systems thought to be central to the physiology of eating and weight regulation.[26] Of the various central and peripheral abnormalities reported, many are likely to be secondary to the disturbed eating and associated weight loss. However, some aspects of 5-HT function and its receptors remain abnormal after recovery, leading to speculation that there is a trait monoamine abnormality which may predispose to the development of eating disorders or to associated characteristics such as perfectionism. Furthermore, normal dieting in healthy women has been shown to alter central 5-HT function, providing a potential mechanism by which eating disorders might be precipitated in women vulnerable for other reasons.

Brain functional imaging studies have identified altered activity in the frontal, cingulate, temporal, and parietal cortical regions in both anorexia nervosa and bulimia nervosa, and there is some evidence that these alterations persist after recovery.[27] Whether they are a consequence of the eating disorder or have somehow contributed to it is not known.

Maintaining factors and processes

Once established, bulimia nervosa tends to run a chronic course although it commonly evolves into eating disorder NOS. There are a number of processes which account for its self-perpetuating character. These are discussed in Chapter 6.3.2.2 (CBT for eating disorders). They include the ongoing influence of the extreme concerns about shape and weight; the form of these patients' dieting, which encourages binge eating; the mood-modulating effect of binge eating; and the fact that the loss of control overeating perpetuates fears of weight gain.

Assessment

The identification of patients with bulimia nervosa is not difficult so long as the diagnosis is considered. This is important because the shame that characterizes the disorder leads many people to delay seeking help—the average delay between onset and presentation is about 5 years—and when they do present for treatment, some do so indirectly. Thus they may complain of depression, substance abuse, menstrual disturbance, or gastrointestinal symptoms, rather than the eating disorder itself. The best policy is for psychiatrists to always keep in mind the possibility of bulimia nervosa when assessing female patients aged between 16 and 35 years. Negative responses to the following questions should suffice to exclude the disorder:

- 'Do you have any problems with your eating?'
- 'Do you have any problems controlling your eating; that is, problems with binge eating?'
- 'Do you ever make yourself sick or take laxatives to control your weight or shape?'

Patients who present directly complain of having lost control over eating and their assessment is generally straightforward. It should always include an assessment of the extent to which the disorder is interfering with everyday functioning and an evaluation of general psychiatric features and especially those of depression.

The best established measure of eating disorder features is the Eating Disorder Examination.[28] This interview is widely regarded as the 'gold standard' measure of eating disorders, but it is possibly too exhaustive to use on a routine clinical basis. Various self-report questionnaires are available but they provide a more basic level of assessment and they cannot be used to make a clinical diagnosis. The leading self-report measures are the Eating Disorder Inventory[29] and the self-report version of the Eating Disorder Examination.[30]

No assessment is complete without weighing the patient and checking their height. Weighing needs to be done with considerable sensitivity because of these patients' concerns about their weight. A physical examination is not essential unless the patient is underweight (or there are other medical indications), nor are laboratory tests required except in those cases in which there is reason to suspect that there might be fluid or electrolyte disturbance.

Treatment

Given that bulimia nervosa has only recently been described, there has been a remarkable amount of research on its treatment. Over 70 randomized controlled trials have been completed. An authoritative meta-analysis has been conducted by the United Kingdom National Institute for Health and Clinical Excellence or 'NICE'.[31] The majority of the trials have focussed on adults with bulimia nervosa, the treatment of adolescents having received little attention, and almost all these studies have been 'efficacy' rather than 'effectiveness' studies. However, there are reasons to think that their findings are of direct relevance to routine patient care not least because the patients studied have been similar to those seen in clinical practice. Nevertheless, there is a definite need for effectiveness studies particularly now that the main treatment options are clear.

Studies of pharmacological treatment

A variety of drugs have been tested as possible treatments for bulimia nervosa including antidepressants, appetite suppressants, anticonvulsants, and lithium. Only antidepressants have shown promise.

(a) Antidepressant medication

All the major classes of antidepressant drug have been evaluated, including tricyclic antidepressants, monoamine oxidase inhibitors, selective serotonin uptake inhibitors, and atypical antidepressants. The findings have been relatively consistent and may be summarized as follows (adapted from Wilson and Fairburn[32]):

- Antidepressant drugs are more effective than placebo at reducing the frequency of binge eating and purging. On average, among treatment completers there is about a 50 per cent reduction in the frequency of binge eating and a cessation rate of about 20 per cent. The therapeutic effect is more rapid than that seen in depression. There is generally little change in the placebo group. The dropout rate varies but averages about 30 per cent.
- The longer-term effects of antidepressant drugs remain largely untested. Almost all the studies to date have been of their short-term use (16 weeks or less). The findings of the few longer-term studies suggest that outcome is poor and compliance low.[33]
- Few studies have evaluated the effects of antidepressant drugs on features other than binge eating and purging. Mood improves as the frequency of binge eating declines but this effect is common to all treatments for bulimia nervosa. Antidepressant drugs do not appear to modify these patients' extreme dieting which may account for the poor maintenance of change.
- Different antidepressant drugs seem to be equally effective, although there have been no direct comparisons of different drugs.
- With one exception, there have been no systematic dose-response studies. The exception showed that fluoxetine at a dose of 60 mg/day, but not 20 mg/day, was more effective than placebo.[34]
- Patients who fail to respond to one antidepressant drug may respond to another. There have been no drug augmentation studies.
- No consistent predictors of response have been identified. Pretreatment levels of depression appear not to be related to outcome.

- The mechanism(s) whereby antidepressant drugs exert their 'antibulimic' effects is not known. The apparent comparability of different classes of drug implicates a common mechanism but this is unlikely to be their antidepressant action since the response is too rapid and the level of depression does not predict outcome.

Studies of psychological treatment

(a) Cognitive behaviour therapy (CBT)

The most intensively studied psychological treatment is a specific form of CBT.[35,36] This was the first promising treatment described and it remains the leading treatment for the disorder. The treatment and its rationale are described in Chapter 6.3.2.2.

CBT is conducted on an outpatient basis and involves 15 to 20 sessions over about 5 months. It is suitable for all patients bar the small minority (less than 5 per cent) who require hospitalization.

The findings of the studies of CBT (over 20 controlled trials) are summarized below (adapted from Wilson and Fairburn[32]):

- The drop-out rate with CBT (about 20 per cent) is less than that seen with antidepressant drugs. The treatment is also more acceptable to these patients than treatment with medication.
- CBT has a substantial effect on the frequency of binge eating and purging. On average, among treatment completers there is about an 80 per cent reduction in the frequency of binge eating, and a cessation rate of about 60 per cent.
- The effects of CBT appear to be well-maintained. Most of the recent studies have included a 6 to 12-month follow-up period. The relapse rates are low.
- CBT affects most aspects of the psychopathology of bulimia nervosa including the binge eating, purging, dietary restraint, and the over-evaluation of shape and weight. In common with other treatments, the level of depression decreases as the frequency of binge eating declines. Social functioning and self-esteem also improve.
- CBT is more effective than delayed treatment (i.e. a waiting list control group), other psychological treatments (other than possibly interpersonal psychotherapy—see below) and antidepressant drugs at reducing the frequency of binge eating and purging. Among the other psychological treatments studied have been supportive psychotherapy, focal psychotherapy, supportive-expressive psychotherapy, interpersonal psychotherapy, hypnobehavioural treatment, stress management, nutritional counselling, behavioural versions of cognitive behaviour therapy, and exposure with response prevention.
- No consistent predictors of response to CBT have been identified. Severity of symptoms at presentation, a history of anorexia nervosa, low self-esteem, and the presence of borderline personality disorder have been associated with worse outcome in some studies but not others. However, the extent of initial response (over the first 4 weeks of treatment) is a potent and potentially valuable predictor of outcome.[37,38]
- The mechanism(s) of action of CBT have yet to be established although they appear to be mediated at least in part by a reduction in dietary restraint.[39] It also seems that the cognitive procedures are required for progress to be maintained since behavioural versions of the treatment are associated with a greater risk of relapse.[40]
- There is some evidence that the combination of CBT and antidepressant drugs may be more effective than CBT alone in reducing accompanying anxiety and depressive symptoms.
- Simpler forms of CBT may help a small subset of patients although the findings are not consistent. These include brief versions of the treatment and cognitive behavioural self-help in which patients follow a cognitive behavioural self-help programme either on their own (pure self-help) or with the guidance of a therapist (guided self-help). The programme may be delivered via a book, CD-ROM or the internet. This type of treatment is still in its infancy and it has yet to be rigorously evaluated.

(b) Interpersonal psychotherapy (IPT)

IPT is the leading alternative to CBT. This treatment was originally devised by Klerman and colleagues as a treatment for depression (see Chapter 6.3.3).[41] It is a focal psychotherapy, the main emphasis of which is to help patients identify and modify current interpersonal problems. The treatment is both non-directive and non-interpretative and, as adapted for bulimia nervosa,[42] it pays little attention to the patient's eating disorder. It is therefore very different to CBT. There have been two comparisons of CBT and IPT in the treatment of bulimia nervosa and both have found that they are about comparably effective but that IPT takes 4 to 8 months longer to achieve its effects.[40,43] The second of these studies was also designed to identify variables that might allow patients to be matched to CBT or IPT but none emerged.

Management of bulimia nervosa

Given that the leading treatment for bulimia nervosa is CBT, the ideal form of management is the provision of CBT by a therapist trained in its implementation. Unfortunately there is a shortage of the necessary expertise with the consequence that a 'stepped care' approach has been advocated on pragmatic grounds. With such an approach a simple treatment is used first and only if this proves insufficient a more complex and specialized intervention is provided. Three steps may be distinguished.

Step 1—Having established the diagnosis, the first decision is whether the patient may be managed on an outpatient basis. The great majority (over 95 per cent of referrals to non-specialist centres) may be managed this way. Exceptions are patients at significant risk of suicide and the presence of physical complications necessitating inpatient or day patient care. Severe substance abuse requires treatment in its own right, although this can sometimes be integrated with the treatment of the eating disorder. For example, it is possible to adapt CBT for bulimia nervosa so that it addresses the patient's substance abuse at the same time.

Step 2—If the patient is suitable for outpatient-based treatment, guided cognitive behavioural self-help, and/or antidepressant medication is the next step. The former involves following a cognitive behavioural self-help programme under the guidance of a 'facilitator' (a non-specialist therapist). Three cognitive behavioural self-help books are available,[44–46] two of which are direct translations of CBT for bulimia nervosa. There is evidence to support the use of all three and it is a matter of preference which is chosen. Each provides information about bulimia nervosa together with a self-help programme. The role of the facilitator is not to provide

treatment as such, as in a conventional 'therapist-led' treatment, but rather to support and encourage the patient to follow the programme. Thus, this is a 'programme-led' form of treatment, and it is this characteristic that makes it suitable for widespread dissemination. Treatment generally takes about 4 months and involves eight to ten meetings with the facilitator, each lasting up to 30 min. It is best if the first few appointments are weekly.

Guided self-help may take place in a variety of settings including primary care. Unfortunately only a small proportion of patients show substantial change and there are no reliable predictors of outcome. Patients who have obtained little benefit after 4 to 6-weeks are unlikely to do so and should be moved on to Step 3.

Antidepressant medication is an alternative to guided self-help. It is important to note that the medication is being used for its antibulimic effect not its antidepressant action. This affects the choice of drug and the dose chosen. The drug of choice is fluoxetine at a dose of 60 mg in the morning. It is usually well tolerated. As with guided self-help, if there has been little benefit after 4 to 6-weeks it is best to move on to Step 3.

A third alternative would be to combine antidepressant medication and guided self-help to see if the two augment each other. This would be a reasonable strategy although there are few data to support it.

Step 3—Patients who do not benefit from cognitive behavioural self-help or antidepressant medication should receive full CBT on a one-to-one basis (see Chapter 6.3.2.2). Ideally this should be delivered by a well-trained therapist who is used to following the protocol.[36]

Step 4—The fourth step is for those who are still symptomatic after having received well-delivered CBT. This step is pragmatic since there are few research findings of relevance. To guide the choice of treatment, the reasons for the poor response need to be carefully considered. Explanations include the presence of an undetected clinical depression; failure of CBT (which itself needs to be explained); poorly delivered CBT; poor patient compliance (which also needs to be explained); and disruption by outside events.

There are a number of different treatment options under these circumstances, the choice depending upon the outcome of the reassessment and the resources available. They include the following:

- Stop treatment and arrange to re-evaluate the patient after an interval of some months. Some patients and therapists 'burn out' after a sustained period of therapeutic work. A break can often be helpful. Deciding to stop treatment should be a joint decision and it is not appropriate with patients who are distressed or with those whose physical or psychological well-being is a cause for concern.
- Embark upon a new psychological treatment. While the obvious choice is IPT, there are no grounds for supposing that patients who fail to respond to CBT will respond to IPT. Indeed, there is evidence that this is not the case.[47] An alternative strategy would be to change the form of the CBT. The re-evaluation of the patient may have resulted in the identification of problems that might be amenable to cognitive behavioural procedures outside the realm of mainstream CBT for bulimia nervosa. Indeed, the fact that this occurs has led to the development of a new 'enhanced' form of CBT for eating disorders that is not only designed to be more potent that the earlier treatment but it also addresses common obstacles to change external to the eating disorder psychopathology (i.e. mood intolerance, clinical perfectionism, low self-esteem, and interpersonal problems).[8,48] It is also of note that this treatment is designed to be suitable for all forms of eating disorder not just bulimia nervosa.
- Arrange for day patient or inpatient treatment. In a small minority of cases outpatient treatment proves not to be sufficient, either because the disorder is resistant to outpatient-based forms of treatment or because the patient's life circumstances are interfering with progress. In such cases day patient or inpatient treatment can be useful. Generally this involves a combination of therapeutic approaches including elements of CBT. It is essential that both day patient treatment and inpatient treatment are followed by outpatient treatment designed to ensure that progress is maintained.

Course and outcome

Much remains to be learned about the course and outcome of bulimia nervosa. It is clear from epidemiological studies that many people do not present for treatment. The course of their disorder is completely unknown. Those who do present tend to do so after a considerable period of time indicating that among this subgroup the disorder has a tendency to run a protracted course. On the other hand, the findings of the treatment studies indicate that the outcome is considerably better than Russell originally suggested, although it must be stressed that even with CBT, the most effective treatment, only about half the patients make a full and lasting recovery.

There have been few studies of long-term course or outcome. A 5-year prospective study of a community sample found that at each assessment point between a half and two-thirds of the cases had an eating disorder of clinical severity, the majority being cases of eating disorder NOS.[49] A 10-year follow-up study found that about 10 per cent met diagnostic criteria for bulimia nervosa and a further 20 per cent had a form of eating disorder NOS.[50] There is no evidence that bulimia nervosa evolves into any other psychiatric disorder, and anorexia nervosa is a very unusual outcome. Body weight changes little over time and, in contrast with anorexia nervosa, the mortality rate appears not to be raised. Robust predictors of long-term course or outcome have been identified.

4.11.1 Normal sexual function

Roy J. Levin

Introduction

Normal sexual function means different things to different people. It is studied by a variety of disciplines: biology, physiology, psychology, medicine (in the domains of endocrinology, gynaecology, neurology, psychiatry, urology, and venereology), sociology, ethology, culture, philosophy, psychoanalysis, and history. There is often little liaison or cross-fertilization between these disciplines and each has its own literature and terminology. Some are regarded as 'hard science', suggesting hypotheses that can be supported or rejected by experiment, observation, or measurement (evidence-based). Others are looked on as 'soft science', where individual and anecdotal evidence are the norm and are encouraged.

As space is limited, this chapter will characterize 'normal sexual activity' in the Western world mainly from biological, physiological, and psychological aspects but will occasionally utilize other disciplines when they yield insights not available from the 'harder sciences'.

Biological determinants of normal sexual function

Humans are the highest evolved primates. A number of our anatomical/biological features unrelated to reproduction have been described as strongly enhancing our sexual behaviour when compared with other primates,[1] although recent studies have shown that the bonobos (pygmy chimpanzees) also use sex for reasons unconnected with reproduction.[2]

In brief, these features are as follows:

1 The relative hairlessness of our bodies allows well-defined visual displays (see point 6 below) and enhanced tactile skin sensitivity.

2 The clitoris, which is an organ whose sole function is for inducing female sexual arousal/pleasure.

3 Orgasms, in both male and female, provide intense euphoric rewards for undertaking sexual arousal to completion. The female is able to have multiple serial orgasms.

4 The largest penis among primates, whether flaccid or erect, the latter acting as a good sexual stimulator of the female genitalia.

5 Concealed (cryptic) ovulation which could influence males to undertake coitus more frequently to create pregnancy and prevent cuckolding.

6 Well-defined visual sexual displays in the female that are not linked to season or fertility (i.e. breasts, pubic hair, buttocks, and lips). The everted mucous membranes of the lips serve both as a surface display (red, moist, and shiny), and for haptic stimulation during kissing and sucking.

7 Ability of the female to undertake sexual arousal and coitus independent of season, hormonal status, or ovulation. Human females (unlike other primates) can and often do willingly partake of sexual activity and coitus when they are menstruating, pregnant, or menopausal.

8 Development of large mammary glands during puberty which act as visual sexual signals in most cultures.

These biological determinants are augmented by socio-cultural factors:

1 Language, art, and music for erotic stimulation.

2 Facial adornment with make-up to heighten appearance and sex displays (viz., lipstick).

3 Clothing, especially of the female, such as brassières to redefine the shape of breasts, corsets to redefine the shape of the body, and high-heeled shoes to elongate the legs and thrust out the

buttocks. Young adult males use tight trousers to create a genital 'bulge' and to emphasize firm rounded buttocks, the latter being a highly sexually attractive feature to young women.

4 Perfumes and scents to enhance body aroma.

The last three features (2, 3, and 4) use artificial means to enhance normal sexual signals.[1] These biological and socio-cultural factors give human sexual activity an increased appetitiveness and make it more rewarding.

Sexuality as a social construct and the concept of sexual scripting

Laqueur[3] suggests that while the sexual biology remained unchanged, its expression has been influenced over the centuries by culture, social class, ethnic group, and religion. This concept, that human sexuality is a social construct, has been strongly argued by Foucault[4] and promoted by other social constructionist authors.[5] Gagnon and Simon[6] introduced the concept of 'sexual scripting'. Scripts organize and determine the circumstances under which sexual activity occurs, they are involved in 'learning the meaning of internal states, organizing the sequences of specific sexual acts, decoding novel situations, setting limits on sexual responses and linking meanings from non-sexual aspects of life to specifically sexual experience'. Money[7] employed a similar construction in his development of 'love maps' for the individual. While patterns of behaviour are influenced by society and social forces, there is a dearth of evidence to show that sexual identity, orientation, or sexual mechanisms are also influenced.

Modelling normal sexual function—(i) the sex survey

One obvious way of describing normal sexual function is to ask people what they do. Two classic sex surveys were conducted by Kinsey and his coworkers who reported the results of interviews with 12 000 males in 1948[8] and 8000 females in 1953.[9] Their technique of sampling was to interview everyone in specific cooperating groups (clubs, hospital staff, universities, police force, school teachers, etc.). This gave samples of convenience but not a valid statistical sampling of the population. Despite their age and faulty sampling, however, there are still useful data in these surveys. In the sexual climate of the 1950s many of the findings were regarded as highly controversial. Clement[10] has reviewed the subsequent studies of human heterosexual behaviour up to 1990.

Surveys give a selective picture of sexual function. Results depend on the formulation of the questions, they rely on self-reports, and they represent only those prepared to describe their sexual behaviour. It is known, for example, that females tend to under-report their premarital sexual experiences[11] while males tend to over-report their lifetime partners.[11] Berk *et al.*[12] studied the recall by 217 university students of their sexual activity over a 2-week period assessed by questionnaires answered 2 weeks after the recording period, and by daily diaries kept over the same 2 weeks. Subjects reported more sexual activity in the questionnaires than in their diaries. Women reported giving and having more oral sex than the men. Clearly, data from questionnaire surveys should be treated cautiously.

A survey tells only what is frequent and not necessarily what is normal, but the most frequent practices often become identified with normal sexual behaviour. Surveys also vary in the range of behaviours that are asked about, for example coitus without condoms is important in the age of AIDS. Surveys have one great disadvantage, the facts that they produce are often 'perishable'; many aspects of the sex surveys of the pre-pill era, or more recently the pre-AIDS era, are now of use only in a historical or comparative basis.

Two recent well-organized surveys based on samples of the whole population have been undertaken, one in the United States and the other in the United Kingdom. Interestingly, in both surveys, questions about masturbation were disliked by the respondents. In the American survey these questions were asked in a separate self-administered questionnaire, while in the British survey they were abandoned.

The American survey[13] was conducted face to face with 3159 selected individuals who spoke English in representative households by 220 trained interviewers (mainly women). Nearly 80 per cent of the individuals chosen agreed to be interviewed. Men thought about sex often, more than 50 per cent having erotic thoughts several times a day, while females thought about sex from a few times a week to a few times a month. The frequency of partnered sex had little to do with race, religion, or education. Only three factors mattered: age, whether married or cohabiting, and how long the couple had been together. Fourteen per cent of males reported having no sex in the previous year, 16 per cent had sex a few times in the year, 40 per cent a few times a month, 26 per cent two to three times a week, and 8 per cent four times a week. The percentages were similar for women. The youngest and the oldest people had the least sex with a partner; those in their 20s had the most. Of the women aged 18 to 59 years, approximately one in three said they were uninterested in sex, and one woman in five said sex gave her no pleasure. Unlike frequency, reported sexual practices do depend on race and social class. Most practices other than vaginal coitus were not very attractive to the vast majority. In women aged 18 to 44 years of age, 80 per cent rated vaginal coitus as 'very appealing' and an additional 18 per cent rated it as 'somewhat appealing'. Among men 85 per cent regarded vaginal coitus as 'very appealing'. The most appealing activity second after coitus was watching the partner undress, and this was appealing to more men (50 per cent) than women (30 per cent). This reflects the greater voyeuristic nature of men and their willingness to pay to look at women undressing or undressed.

In regard to oral sex, both men and women liked receiving more than giving. This practice varied markedly with race and education, with higher reported rates among better educated white people than among less educated and black people. Some 68 per cent of all women had given oral sex to their partner and 19 per cent experienced active oral sex the last time they had intercourse. Seventy-three per cent of all women had received oral sex from the partner, and 20 per cent had received it the last time they had had intercourse. Corresponding experiences were reported by men.

This survey, unlike many earlier ones, asked about anal sex. Of females aged 18 to 44, 87 per cent thought it not at all appealing, and only 1 to 4 per cent thought it very or somewhat appealing. In males of the same age 73 per cent thought it not at all appealing and rather more than women thought it very or somewhat appealing. Similar reports were obtained from women and men aged 44 to 59.

Regarding masturbation, older people (over 54 years old) had lower rates than at any other age, indicating that they do not use masturbation to compensate for an overall decrease in sexual activity with their partners.

In the United Kingdom survey,[14] 18 876 people were interviewed by 488 interviewers (of whom 421 were women). The sampling used one person per address and the acceptance rate was 71.5 per cent. Questions were asked about the frequency of vaginal coitus, oral sex, and anal sex, but not masturbation. The median number of occasions of sex with a man or woman was five times a month for females aged 20 to 29 and males aged 25 to 34, but declined to a median of two per month for males aged 55 to 59. More than 50 per cent of the females in the 55 to 59 age group reported no sex in the last month, but in this age group females are more likely than men to have no regular partner because they are widowed, separated, or divorced.

Vaginal coitus was reported by nearly all females and males by the age of 25. Fifty-six per cent of males and 57 per cent of females reported vaginal coitus in the previous week, and non-penetrative sex was practiced by 75 per cent men and 82 per cent of women. Twenty-five per cent of males had genital stimulation in the previous 7 days. Cunnilingus and fellatio were common but less practiced than vaginal coitus. Of men and women aged 18 to 44, 60 per cent had oral sex in the previous year but in the 45- to 59-year-old group this fell to 30 per cent for women and 42 per cent for men. This and other sex surveys suggest that the practice of oral sex has increased since the 1950s and 1960s. Anal coitus was infrequent; approximately 14 per cent of the males and 13 per cent of the females had ever undertaken it, and only 7 per cent of males or females had practiced it in the previous year.

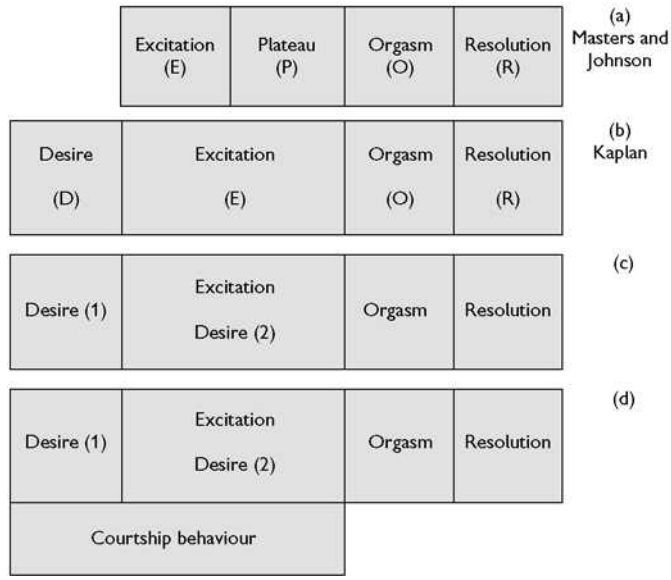

Fig. 4.11.1.1 The development of the human sexual response model from (a) the original **EPOR** model of Masters and Johnson[15] through (b) the desire, excitation, orgasmic, and resolution (**DEOR**) model of Kaplan[17] to (c) the proposed modification with desire phase 1 (before initiation of the excitation phase and desire phase 2 during excitation phase) and finally (d) with added courtship behaviour.

Modelling normal sexual function—(ii) the sexual response cycle

A direct way of investigating normal sexual function is to observe and measure the body changes that take place when men and women become sexually aroused. From these data, models have been constructed of the normal sequence of changes during sexual arousal, coitus, and orgasm. The first models described a simple sequence of increasing arousal and excitement culminating in rapid discharge by orgasm, displayed graphically as an ascent, peak, and then descent. As the investigations became more sophisticated, understanding of the body responses grew and the models became more detailed and complex.[5,15,16]

The EPOR model—a sexual response cycle model

A most successful human sexual response model was that formulated by Masters and Johnson.[15] In the laboratory, they observed the changes that took place in the male and female body and especially the genitals during sexual arousal to orgasm either by masturbation or by natural or artificial coitus with a plastic penis that allowed internal filming of the female genitalia. After studying approximately 7500 female and 2500 male arousals to orgasm in some 382 female and 312 male volunteers over 11 years, they proposed a four-phase, sequential, and incremental model of the human sexual response cycle (Fig. 4.11.1.1). The phases were described as the excitation (**E**) phase (stimuli from somatogenic or psychogenic sources raise sexual tensions), the plateau (**P**) phase (sexual tensions intensified), the orgasmic (**O**) phase (involuntary pleasurable climax), and finally the resolution (**R**) phase (dissipation of sexual tensions). The great success of this **EPOR** model was its wide compass; it could characterize the sexual responses of women and men, both heterosexual and homosexual, ranging from simple petting to vaginal or anal coitus with or without orgasm. However, it had several weaknesses.

Modifying the EPOR model into the DEOR model

The first weakness of the EPOR model is that it was derived from the study of a highly selected group of American men and women volunteers who could arouse themselves to orgasm in a laboratory, on demand, and allow themselves to be watched/filmed or measured for scientific and altruistic (or perhaps exhibitionistic) purposes. The second weakness was the lack of interobserver agreement about the changes observed and of confirmation of their sequential reliability. Robinson[16] examined the **E** phase and **P** phase, and concluded convincingly that the **P** phase was simply the final stage of the **E** phase. Helen Kaplan,[17] a New York sex therapist, proposed that before the **E** phase there should be a 'desire phase' (**D** phase). This proposal came from her work with women who professed to have no desire to be sexually aroused, even by their usual partners. She suggested that the desire must occur before sexual arousal can begin. Kaplan's subjects were attending a clinic and remarkably no studies were ever conducted with a control normal population (either women or men) to investigate whether this 'self-evident' fact was true. Despite this, the **EPOR** model gradually became replaced by the desire, excitation, orgasmic, and resolution phase (**DEOR**) modification. While this is the currently accepted model, the centrality of the desire phase in women remains uncertain (Fig. 4.11.1.1). In a survey of non-clinic sexually experienced women in Denmark, about a third reported that they never experienced spontaneous sexual desire[18] and in an American survey women reported periods of several months when they lacked interest in sex.[13] The other problem with the desire phase is its location in the sequential **DEOR** model.

Sexual desire (D1-proceptive desire) that appears to be spontaneous (but presumably must still be activated by a trigger) should obviously be placed at the beginning of the model (Fig. 4.11.1.1b), while sexual desire (D2-receptive desire) created when the person is sexually aroused by another occurs during the E-phase (Fig. 4.11.1.1c).

It has been proposed[19] that while the DEOR model fits for females in younger couples' relationships for longer maintained ones sexual activity is undertaken often for factors such as intimacy, security, and acceptance and becomes more influenced by cognitive and emotional processes and the possible outcomes of the experience (e.g. mutual pleasure, confirming commitment and trust, enhancing emotional intimacy) rather than proceptive/receptive desires.

Courtship (mating) behaviour—activity initiating normal sexual behaviour

With the possible exception of rape, the pre-initiation of sexual activity normally starts with flirting/courtship behaviours. Sometimes this activity can precede the desire phases; sometimes it occurs during the desire phases, and sometimes in the excitation phase (Fig. 4.11.1.1d).

Evolutionary psychology attempts to explain the strategies of mating.[20] Its message is not always palatable to modern sensitivities about sexual equality. It is argued that women invest more in their offspring than men,[21] that this investment is a scarce resource that men compete for, and that men can enhance their reproductive strategy by mating frequently. Most men are first visually attracted to a possible female sexual partner. They look for youthfulness and physical attractiveness in the form of regular features (symmetry), smooth complexion, optimum stature, and good physique, and they value virginity and chastity. Partner variety is highly desired. Women, however, need to obtain high-quality mates with abundant resources and look for emotional and financial status and security. Clearly the strategies conflict giving rise to different preferences in mate choice and casual sex, and different levels of investment or commitment to relationships.[22]

Once the chosen female (or male) accepts the initiation of flirting/courtship behaviour, the subsequent stages form a stereotyped sequence which is found in many different cultures. The stages are look, approach, talk, touch, synchronize, kiss (caress), sex play, coitus. It is a sequence that the poet Ovid knew in the first century BCE. Morris[1] characterized human courtship behaviour further into 12 basic stages: eye to body, eye to eye, voice to voice, hand to hand, arm to shoulder, arm to waist, mouth to mouth, hand to head, hand to body, mouth to breast, hand to genitals, genitals to genitals. Similar hierarchies have been constructed extending the behaviour to oral-genital contacts.

Although kissing has been described as 'an inhibited rehearsal for intercourse and other sexual practices'[23] and is usually undertaken in the courtship behaviour well before genital activity occurs, it is sometimes thought of as more intimate than coitus. Prostitutes, for example, traditionally do not kiss their clients on the mouth, reserving the activity for their private sexual behaviour. Nicholson[24] has speculated that kissing may be a mechanism by which semiochemicals (similar to pheromones) are exchanged between humans to induce bonding.

Common extragenital changes during sexual arousal

In both males and females, effective sexually arousing stimuli cause a number of physiological changes.[15,25] There is increased respiration, heart rate, and blood pressure, nipple erection, often sweating, and a sex flush (maculopapular skin rash). Muscle tension increases (myotonia) and the pupils dilate. All these changes become more intense as arousal increases. Following orgasm the changes dissipate rapidly (R phase); without orgasm they dissipate more slowly.

The endocrinology of normal sexual function

(a) Peptide hormones and neuropeptides

Prolactin, a peptide hormone, is secreted by cells of the anterior pituitary in both males and females. In females it is a key lactogenic hormone involved in stimulating the manufacture of breast milk but it has no proven physiological reproductive function in males. Pathologically high plasma levels of prolactin (hyperprolactinaemia) are accompanied by disturbances of sexual/reproductive function especially erectile dysfunction in males and inhibition of ovulation in females. The exact causes are unknown. As it is secreted in higher amounts at orgasm in both sexes it has been claimed to be a major factor responsible for 'switching off' sexual arousal but this ignores the fact that women are multiorgasmic while the evidence for this function even in males is unconvincing.[26]

Two neuropeptides, oxytocin and vasopressin (Antidiuretic Hormone, ADH) are hormones and also act as neuropeptide transmitters with distribution in parts of the brain and spinal cord. They are secreted as hormones by the hypothalamus/posterior pituitary with increases at orgasm in both males and females. Oxytocin is often claimed to be responsible for facilitating smooth muscle contractions during ejaculation and uterine contractions during orgasm but the possible role of vasopressin has been ignored. In some animals, oxytocin is involved in pair bonding but the evidence for this in humans is poor.

Males

(a) Androgens

The major steroids influencing normal sexual function in males are the androgens secreted by the testes mainly as testosterone with much smaller quantities of androstenedione and dihydrotestoterone. The adrenal cortex also manufactures and secretes androgens but this amounts only to 2 per cent of the total. Of the total testosterone (260–1000 ng/dl), 95 per cent is bound to plasma proteins; only the unbound fraction (34–194 pg/ml) is an active virilizing hormone.

The development and maintenance of the masculine musculature, bone growth, genitals, and pubic and axillary hair is androgen dependent. The mechanism of the hormonal masculinization of the brain in rodents involves the aromatization of testosterone, but in humans the role of aromatization is still uncertain.

(b) Androgens and male sexual behaviour

The involvement of androgens in adult human male sexual behaviour has been reviewed many times (see Levin[27] for references). Removal of testosterone by castration usually leads to a decrease in sexual activity and drive (libido) in the majority of subjects within

12 months. There is, however, large individual variations, and some castrates retain sexual activity and interest for years.[28] Factors such as adrenal androgens, the availability of sexual partners, and attitude to the operation influence the response. In castrates and in hypogonadal males, replacement of testosterone restores sexual interest and activity.

Females

(a) Oestrogen, progesterone, and androgens

In the female, oestrogen, progesterone, and androgens are involved in differentiating and maintaining genital and breast tissues and in influencing normal sexual function. Female genital development, unlike that of the male, does not appear to need hormonal stimulation as the development of female genital structures are the foetal prototype or default programme.[29] During puberty, ovarian oestrogen and progesterone together with androgens from the adrenal cortex induce growth and functional changes in the internal and external genitalia, breast, and nipples. Oestrogens induce growth in the fallopian tubes, uterus, vagina, and breasts and lay down subcutaneous fat largely in the breast, hip, and thigh regions to create the rounded contours of the female body that are highly attractive to the male. The fat laid down is enough to supply the energy for a pregnancy and the subsequent lactation. Females have a plasma androgen concentration some 10 times less (15–70 ng/dl) than those in the male. Androgens are produced by the ovaries (25 per cent), adrenals (25 per cent) and in peripheral tissues from adrenal-secreted androgen precursors. They are responsible for the development and maintenance of the clitoris, nipples, pubic and axillary hair, and probably the labia, periurethral glans and pelvic-striated musculature. The variation of the androgen levels in the plasma during the menstrual cycle is small and it is the free androgen level (1–21 pg/ml) not the bound that is the active principle.

(b) Role of hormones in female sexuality

While over 60 studies have been undertaken to examine whether the changing hormonal levels of the menstrual cycle influence the sexual arousal of the female,[30] neither oestrogen or progesterone have been found convincingly to play a direct role in influencing the sexual activity of the human female apart from their indirect functions in the maintenance of the structures and functions of the female genitals, especially the vagina.

The role of androgens in female sexuality is not clear-cut.[31] Some propose that, as in the male, it is the major hormonal influence on the female libido. Removal of the adrenals has been shown to reduce desire and ability to reach orgasm. Excess androgens stimulates libido but in pharmacological not physiological doses. Such doses affect the structure and sensitivity of the clitoris (an androgen-sensitive tissue), so the effects on sexuality might not be only brain mediated.

(c) Sexual behaviour during the menstrual cycle

Despite numerous studies it is still uncertain whether female sexual behaviour is influenced by the hormonal changes in the menstrual cycle. Meuwissen and Over[30] surveyed 64 published studies. A significant number showed a premenstrual peak in sexual desire and activity, others a postmenstrual peak, either at menstruation or ovulation but the latter studies often used poor methodology to determine the time of ovulation.

Male genital functions during normal sexual arousal

While the **DEOR** model characterizes the general sexual arousal of humans, a more specific detailed physiological model in males is that of excitation, erection, emission, and ejaculation with orgasm. Each of these is served by separate mechanisms. Although ejaculation and orgasm usually occur temporally together, they also have separate mechanisms.

(a) Excitation

Sexual excitation can occur through any of the five senses by psychogenic or somatogenic stimuli. In special circumstances arousal can become linked to or greatly enhanced by fetishitic association with non-sexual objects such as feminine garments of underwear, rubberware, shoes, furs, etc.

The sexual excitation is manifested in the brain by activation of numerous areas (see section on brain activation during human sexual arousal). Centres in the spinal cord for erection and ejaculation are known from animal studies and it is likely that they also exist in the human cord. They are activated by neural efferent activity from the aroused areas of the brain and initiate erection and ejaculation.

(b) Erection: the conversion of the flaccid urinary penis to the rigid sexual penis

The three longitudinal erectile chambers of the penis are arranged with a side-by-side dorsal pair of corpora cavernosa above the single ventral corpus spongiosum. The corpora cavernosa are covered by the tunica albuginea, a 2-mm thick fibrous membrane which is resistant to stretch. The corpus spongiosum surrounds the length of the penile urethra and is enlarged at its base to form the urethral bulb and distally to create the glans penis. While it becomes engorged with blood during arousal it is not involved in the rigidity of the erection but protects the urethra from closure. The unaroused penis is flaccid because the pudendal arterial blood flow into the erectile tissues is limited by the high sympathetic (adrenergic-mediated) constrictive tone in the smooth muscle of the vessels of corpus cavernosum. On sexual arousal, the sympathetic tone is reduced; the neural innervation of the arteries and cavernosal chambers is activated to release vasoactive intestinal peptide (VIP), a peptidergic vasodilator neurotransmitter that directly relaxes smooth muscle and nitric oxide (NO), the nitrergic neurotransmitter. NO activates the enzyme cyclic guanylase in the smooth muscle cells of the cavernous tissue and blood-vessel endothelium to produce cyclic guanosine monophosphate (cGMP), the second messenger that creates intracellular conditions to relax the muscle. The enzyme phosphodiesterase 5 breaks down the cGMP and inhibitors of this enzyme, which can be taken by mouth, facilitate the attainment of erection even with reduced neural inputs.

The vasodilatation of the arterial supply by VIP together with the relaxation of the vessels of the cavernosal tissue allows them to fill under arterial pressure stretching the chambers until they become stiff against their covering of unyielding tunica albuginea, and the veins (emissary) that pass obliquely through the tunica become occluded greatly reducing penile vascular drainage. The flaccid urinary penis has been converted into the erect rigid sexual penis some 7 to 8 cm longer. The rigidity is essential for successful vaginal penetration and to stimulate its walls (especially the anterior) during penile thrusting. The striated muscles of the pelvic region, namely the ischiocavernosus and bulbocavernosus, are not

normally involved in creating penile erection[32] although they can be voluntarily contracted in short bursts to aid its rigidity. The engorged corpus spongiosum is less rigid than the cavernosal chambers making the glans of the penis softer and less damaging to the female labia and vagina.

(c) Internal genitals

The genital fluids of the testes, epididymis, and accessory genital glands of the male are involved in emission. These glands are the bulbo-urethral (Cowper's gland), the prostate (approximately 30 per cent of the total volume of the ejaculate), and the paired seminal vesicles (approximately 60 per cent of the volume of the ejaculate). The fluids from all these together with that of the glands of Littré that line the penile urethra, constitute the ejaculate or semen which has a characteristic odour and rapidly forms a coagulum in contact with air. Subsequently enzymes in the semen break down the coagulum and release the trapped sperm.

(d) Emission

This phase begins with the movement of the various genital fluids into the ducts initiated by the neurally induced contraction of smooth muscles in the capsules of the testes, epididymis, and seminal vesicles. The secretions spurt into the prostatic urethra, and the sphincter of the bladder neck closes to prevent reflux into the bladder. When this happens the male experiences the sensation of 'ejaculatory inevitability' and knows that he will ejaculate within a second or two and that conscious suppression of the ejaculatory reflex is now impossible. The contractions of the smooth muscle of the glandular capsules together with the contraction of the vas deferens and peristalsis in the urethra move the semen along into the penile urethra.

(e) Ejaculation

Within a second or two later the bulbocavernosus muscle of the perineal region contracts clonically, initially at about 1 per 0.8 s, squeezing the urethra and forcing out the ejaculate. As ejaculation proceeds, the interval between each striated muscle contraction gets longer and their force weaker until they gradually die out.[15,32] Their number can vary between 5 and 60. Most of the ejaculate is expressed within the first half dozen contractions. If the striated muscles are paralysed the semen is squeezed out only by the smooth muscle peristaltic contractions which produce a dribbling ejaculate with no projectile force and little pleasurable quality.

(f) Male orgasm

Orgasm, the supreme ecstatic pleasure is experienced just before the striated contractions occur and is then associated, throbbingly, with each subsequent contraction slowly decreasing in intensity and dying away as do the contractions. It is felt as an intense pleasurable throbbing/pumping in the penis and pelvic area and can last from 5 to 60 s. Most males groan with each squirting contraction. Kinsey *et al.*[8] marshalled the evidence showing that orgasm and ejaculation were separate mechanisms. Briefly, orgasm occurs without ejaculation in preadolescent males, in some adult males orgasm does not occur until a few seconds after ejaculation, a few adult males are anatomically incapable of ejaculation but have orgasms, and males who have been prostatectomized cannot have ejaculations but some can have orgasms.

The intensity of orgasm usually varies with the duration of the sexual arousal (the longer it is maintained the greater the subsequent orgasm), the erotic excitement and novelty of the arousing stimuli, and previous ejaculation, especially the interval from the last one (initial ejaculations have usually better orgasms than subsequent ones). Males have a post ejaculation refractory time (PERT) and usually cannot have an erection or another ejaculation until some time has passed. The PERT varies with age and can be anything from minutes, when young, to hours or days when older.[15] It is not known where this inhibitory mechanism resides but animal work suggests that it is in the brain rather than the spinal cord.[33] Some men claim to be able to learn to inhibit ejaculation and yet have repeated serial orgasms.[34]

It has been stated that the larger the ejaculate volume the greater is the orgasmic pleasure,[15] the studies however were flawed because they used men who increased semen volume by abstaining from ejaculation for days. This confounds the effects of semen volume with that of ejaculatory abstinence which itself enhances subsequent sexual pleasure. In fact semen volume does not appear to be the arbiter of pleasure or the trigger for ejaculation.[35] Drugs can induce a 'dry ejaculation' but the pleasure of the orgasm appears unimpaired,[33] and in young boys the pleasure of the early dry orgasm is not noticeably changed when semen becomes added to the ejaculation around puberty.[36]

An ignored feature is whether there is a typology of male orgasms. Most orgasms arise from penile stimulation but they can also be activated by per rectum digital stimulation of the prostate gland. No laboratory study of these orgasms has ever been made but anecdotal reports say that they feel deeper, more widespread and intense and last longer than those from penile stimulation.[37]

Female genital functions during normal sexual arousal

(a) External

(i) Labia

The external female genitalia consist of the outer (majora) and inner (minora) labia containing erectile tissue that surround the vaginal introitus. Normally the outer labia meet and cover the introitus, but in some women the inner labia protrude even when they are sexually unaroused. Sexual arousal creates vasocongestion especially in the labia minora which protrude through the majora adding approximately 1 to 2 cm to the length of the vagina. The labia minora become erotically sensitive to touch and friction when engorged.

(ii) Clitoris

Although the clitoris is the homologue of the penis, its precise anatomical structure is still uncertain. The most recent description by O'Connell *et al.*[38] is of a triplanar complex of erectile tissue with a midline shaft lying in the medial sagittal plane about 2 to 4 cm long and 1 to 2 cm wide, which bifurcates internally into paired curved crura 5 to 9 cm long, and externally is capped with a glans about 20 to 30 mm long with a similar diameter. Two vaginal bulbs of erectile tissue are closely applied on either side of the urethra. The shaft's erectile tissue consists of two corpora cavernosa surrounded by a fibrous sheath (tunica albuginea) and the whole is covered by a clitoral hood formed in part by the fusing of the two labia minora. The uncertainty concerns the location and extent of the female corpus spongiosum. Some describe it as wrapped around the urethra, others state that the vaginal (vestibular) bulbs on either side of the vaginal wall are spongiosus tissue and unite ventrally to the urethral meatus to form a thin strand of erectile tissue ending

in the glans. Recent studies by van Turnhout *et al.*[39] have clarified the situation. They confirmed by dissections in fresh cadavers that the bilateral vestibular bulbs terminate into the glans clitoridis.

With sexual arousal, the blood flow to the clitoris is increased probably by a mechanism involving its vipergic (VIP) and nitrinergic (NO) innervation leading to its tumescence (swelling) but, contrary to many inaccurate descriptions, without true erection (i.e. without rigidity). The enhancement of its blood flow is paralleled by an increased sensitivity to touch and friction especially of the glans.

(iii) Periurethral glans

There is a triangular area of mucous membrane that surrounds the urethral meatus, extending from just below the glans of the clitoris to the entrance of the vagina. This area has been called the 'periurethral glans'[25] and is thought to be erotically stimulated, especially during penile thrusting, as it is known that the tissue is pushed and pulled into and out of the vagina by the penile movements.[25] The periurethral glans is actually part of the corpus spongiosum if we accept the anatomical designation of van Turnhout *et al.*[39] which suggest that it is the homologue of the male glans. The extent, mobility, density of innervation, and sensitivity of this erotic site may explain why some women find it easy to reach orgasm during penile thrusting alone.

(b) Internal

(i) Vagina

No single structure can describe the vaginal shape. In sexual quiescence it is a potential space with an H-shaped cross-section and an elongated S-shaped longitudinal section culminating in a cul-de-sac, the anterior wall of which is penetrated by the cervix. The anterior and posterior walls touch but their film of basal vaginal fluid prevents adhesion. This basal fluid is a mixture of fluids from the vagina itself (basal transudate) with uterine and cervical secretions. The squamous epithelial lining of the vagina actively transports sodium ions from the vaginal fluid back into the blood. As fluid follows this ion movement osmotically the vagina is continually producing and reabsorbing its own fluid[25,40] normally lower in sodium and higher in potassium compared to plasma.

Because sexual activity is intermittent, the basal vaginal blood flow is maintained normally at a minimal level by a high adrenergic-mediated vasoconstrictive tone and vasomotion. The latter is the mechanism by which tissue viability is maintained at a basal level by not having all the capillaries open at the same time but rather each one opens and closes randomly to supply by demand its surrounding tissue needs of oxygen and metabolic substrates. On sexual arousal, the blood supply to the vaginal walls is increased by the liberation of VIP from the vipergic neural innervation. This increases the flow through the open capillaries and recruits new ones until all are open and vasomotion disappears,[41] Within seconds this creates blood-vessel engorgement and an increased plasma transudate filters out of the capillaries and percolates between the cells of the epithelium saturating its limited reabsorptive capacity. The newly formed neurogenic vaginal transudate, with its higher sodium ion concentration, creates a lubricating film on the vaginal surface which is essential for painless penile penetration and thrusting. Poor or inadequate lubrication can lead to dyspareunia (painful coitus) and subsequent sexual dysfunction. On cessation of sexual arousal or after orgasm the blood flow returns to the basal level, the fluid is reabsorbed back into the blood following the continuous absorption of sodium ions by the vaginal epithelium and vasomotion is restored.

(ii) Coitus and the vagina

The cul-de-sac of the vagina is expanded during sexual arousal and the uterus with cervix is lifted clear of its posterior wall (vaginal tenting).[15] This vaginal tenting is an important reproductive feature that delays the transport of sperm allowing the ejaculate to decoagulate and initiate motility and pre-capacitation changes that facilitate the process of sperm capacitation (see Levin[40,41] for references). In the ventral–ventral ('missionary') coital position, penile penetration and thrusting stretches and stimulates the structures of the anterior vaginal wall which include the urethra, the 'G spot' (see below), and neural structures in Halban's fascia. All these (the anterior wall erotic complex) are thought to be capable of creating erotic excitement when so stimulated, giving rise to a significant part of the sexual pleasure normally experienced by most women during coitus.

(iii) The erotic structures of the anterior vaginal wall: urethra, 'G spot', and Halban's fascia

The urethra, approximately 4 cm long, is invested with erectile tissue which becomes engorged on sexual arousal. Ultrasound imaging during coitus has shown that the thrusting penis stretches the urethra.[42] There is an area on the anterior vaginal wall a few centimeters from the introitus, at or around the junction of the urethra with the bladder, that becomes swollen and on strong pressure stimulation can induce orgasm. This urethral area was first identified by Grafenberg[43] but the observation was overlooked until its rediscovery by Perry and Whipple[44] who named it the 'G spot' in recognition of the original discoverer. Anatomically, it probably represents the 'paraurethral' or 'periurethral' glands now referred to as the 'female prostate'. In some women these produce at orgasm a small amount of fluid secretion loosely referred to as the 'female ejaculate' (see[25,44] for references). These glands are in the space between the bladder trigone and the neck of the urethra which is filled with fibroelastic mesenchymal lamina rich in vascular lacunae and contains nerve fibres and pseudocorpuscular terminals. This area, known as Halban's fascia[45] when stimulated by pressure (penile or digital) creates intense sexual pleasurable feelings.[44–46] As any pressure stimulus on the anterior vaginal wall will in fact stimulate the G spot, Halban's fascia and the urethra at the same time it makes it difficult to apportion the generation of sexual pleasure to any specific structure.

The involvement of the spinal cord in activating the female erotic structures during sexual arousal has been poorly studied and little is known of possible mechanisms.

(c) Female orgasm

As in the male, the female orgasm creates supreme ecstatic pleasure usually accompanied by throbbing striated muscle contractions, especially of the ischiocavernous and bulbospongiosus muscles, but other pelvic-striated muscles can also be involved.[15,37] Most females groan or moan during these contractions. The induction of orgasm in women by coital stimulation alone is not as frequent as that in the male, about half not achieving orgasm unless clitoral stimulation is also used. The reason for this difference is usually ascribed either to the greater inhibitory education about sexual pleasure experienced by women or the lack of correct genital

stimulation. A major difference between males and females is that females can be multiorgasmic because they do not have a PERT after orgasm.[15,23,33] There is mounting evidence that, unlike the unitary concept of the **DEOR** model, the erotic stimulation of different genital sites (especially the anterior vaginal wall compared with the clitoris) induces different types of orgasmic response both subjectively and physiologically.[44,47,48]

Brain activation during human sexual arousal

Before the advent of brain imaging by functional magnetic resonance imaging (fMRI) or positron emission tomography (PET) to identify which areas are activated by and during sexual arousal and orgasm, only limited information was obtained by observing the effects of brain lesions on behaviour, epileptic case studies, electroencephalography (EEG) activity, and rare electrical recordings and stimulations of specific brain areas.[27] Inferences about human sexual arousal mechanisms often had to be made from animal experiments but the problem of species differences always was the spectre in the wings (see comment below).

One type of brain imaging (blood oxygen level dependent [BOLD]) relies on the concept that activation of neurones requires an increased demand for oxygen which normally entails an increase in their blood supply bringing oxygenated blood. The change in the magnetic susceptibilities of the oxygenated and deoxygenated blood is measured and is an index of the increase or decrease in flow to the neuronal area. In the PET technique a short-lived radioactive tracer (often ^{15}O) is injected intravenously and its concentration in the brain area of high blood flow localized by the radioactivity. Both techniques rely heavily on extensive computer programs to correct for a variety of essential artefact corrections one of the most important being corrections for movement. The usual protocol underlying most studies of sexual arousal is to first measure the activity of the brain area under study during a non-sexual basal state (looking at neutral videos) then switching to viewing sexually arousing videos. By subtracting the activity of the neutral from the aroused measurements the remaining activity is assumed to be due the sexual arousal per se. One difficulty is what level (threshold) of activity of a site is to be regarded as physiological. Investigators tend to choose their own criteria making direct comparisons between different studies difficult. Another difficulty is that many areas of the brain are multifunctional (e.g. the amygdala, the periaqueductal grey, the cerebellum) and are thus activated/deactivated by different stimuli (viz., pain, pleasure, fear, anger, emotional processing) the activation/deactivation may be an epiphenomenon of the arousal rather than its cause. Finally, it takes a few seconds to build up a brain scan but neuronal activation takes just hundredths of a second; the image will always lag behind the actual activation so that identifying what is the primary initiator of brain arousal will not be apparent.

Despite all the above caveats about brain imaging one outstanding conclusion is now clear from all the various studies—that there does not appear to be a single site creating arousal or orgasm, multiple site co-activation (also referred to as a neural network) is the rule in both males and females. While a number of the features of brain activation appear common to sexual arousal in the brains of both sexes, the amygdala and hypothalamus are said to be more strongly activated in men when viewing identical sexual stimuli. According to Holstege's group,[47] the first to map brain areas active during ejaculation/orgasm, the strongest activated primary region during male erection/orgasm is the ventral tegmental field region, the midbrain lateral central tegmental field, the zona incerta, the suprafascicular nucleus, the ventroposterior, midline and intralaminar nucleus, and the cerebellum. Decreased activity was seen in the amygdala and adjacent entorhinal cortex. This decrease in the amygdala is said not to occur during women's arousal.[48] Another group.[49] imaging the brain in sexually aroused males reported increased neural activity in areas that included the right frontal cortex, the inferior temporal cortex, the left anterior cingulate cortex, and the right insula. However, only a subset of these areas (anterior cingulate, insula, amygdala, hypothalamus, and secondary somatosensory cortex) were involved in creating a full erection.

Imaging studies undertaken by Komisaruk and Whipple[48] used both women who were paraplegic and some able-bodied women who had the rare ability to create orgasm by mental activity (thoughts) alone. In the former group, where arousal was induced by cervical vibratory stimulation, a large number of sites, including the hypothalamus, were activated by the stimulus used to induce orgasm but in the mental activity group, the only sites activated by thought were regions of the nucleus accumbens, the paraventricular nucleus of the hypothalamus, the hippocampus, and anterior cingulate cortex. The authors suggested that these sites may be specifically related to activate the female orgasm. Interestingly, the amygdala was not activated during these 'thought' induced orgasms. How 'normal' the 'orgasm by thought' group are is yet to be ascertained.

It is unfortunate that while there are now a number of independent studies on brain imaging during sexual arousal the resultant descriptions of the areas claimed to be the activated or deactivated are not in agreement. Part of the problem is that different stimuli, duration of stimuli, data handling, and processing protocols have been used but even these do not explain all the differences. Thus, at present, it is not possible to give a detailed and reliable account of brain activation during sexual arousal.

Summary

Normal human sexual function can be characterized simply by its biological mechanisms which are of obvious importance, not least to reproduction.[41] The mechanisms have changed little over the centuries, but their expression as behaviour, when moulded by historical time, social class, ethnic grouping, religion, and society, creates the changing complex concept of human sexuality. Indeed, it has been said that human sexuality is more about fertilizing relationships than eggs! While we have increased hugely our knowledge about many of the mechanisms involved in human sexuality, the impact of a highly successful oral therapy for erectile dysfunction being an obvious example, those of the brain and spinal cord are practically unexplored. What creates human sexual desire and sexual excitement and what causes them to fade away, where in the brain is the pleasure of orgasms created, why do men have a PERT but not women, are just a few of the fascinating questions that remain to be answered.

4.11.2 The sexual dysfunctions

Cynthia A. Graham and John Bancroft

Introduction

Sexual relationships are central to the lives of most of us. The sexual component of those relationships can go wrong in various ways. This may be secondary to other difficulties in the relationship, mental health problems, specific sexual vulnerabilities of the individual, or the impact of disease or medication on sexual response. This chapter will describe the more common sexual problems and their prevalence. Evidence related to aetiology of sexual problems and treatment evaluation will be briefly reviewed. In the final section of the chapter, guidelines for the assessment and practical management of sexual problems will be presented.

Historical aspects and some basic concepts

Since 1970, when Masters and Johnson[1] published their groundbreaking book on the treatment of 'human sexual inadequacy', there have been two lines of development in this field, relatively detached from each other until recently: psychological methods of treatment, collectively known as 'sex therapy' and medical interventions, initially focused on erectile problems in men.

The involvement of the medical profession has been substantial, although predominantly involving urologists. Initially there were surgical procedures to implant penile splints or to improve the vascular supply to the penis, and the use of vacuum devices to induce erection mechanically. This was followed by the discovery that injection of smooth muscle relaxants, such as papaverine, phentolamine, or prostaglandin into the erectile tissues of the corpora cavernosa induced erections. Self-injections became widely prescribed. To avoid the need for penile injections, which were not popular among male patients, preparations of prostaglandin for intra-urethral administration became available. This era of medical intervention was characterized by a veritable industry of investigative procedures in attempts to identify local causes for erectile dysfunction (ED). Erectile problems were clearly differentiated into 'organic' and 'psychogenic' subtypes. There was, however, a notable lack of attention to how the brain and psychological processes interacted with these peripheral mechanisms.

Then came the 'Viagra revolution' in the early 1990s. The first oral phosphodiesterase 5 (PDE-5) inhibitor, sildenafil (Viagra®), was found to be effective in enhancing erectile response to sexual stimulation when taken about 1 h before sexual activity. This led to the next phase in the 'medicalization' of male sexual dysfunction, with a shift to the primary care physician as the principle source of treatment and a dramatic reduction in the amount of diagnostic assessment.

The progress of sex therapy has been limited since Masters and Johnson.[1] It has continued to be used, with various adaptations of the original 'sensate focus' approach, incorporating principles of psychoanalytic techniques[2] and cognitive behaviour therapy.[3] The main shortcoming has been inadequate outcome research on the efficacy of these methods.

The next phase in this recent history followed the commercial success of PDE-5 inhibitors for men, with an inevitable quest for a 'Viagra for women'. This has so far proved elusive, but has confronted the 'sexual medicine' community with the complexity of women's sexuality and the need to conceptualize it differently to the sexuality of men.

At the same time, evidence has emerged that treatment of ED with sildenafil and more recent PDE-5 inhibitors, although initially successful in the majority, was being discontinued by a substantial proportion of men.[4] In addition, the female partners of men taking these drugs do not always welcome the associated changes in the sexual relationships.[5] We are now moving into the most recent phase where the 'psychological' and 'organic' approaches, and the professional groups that have been identified with them, have started to interact. There is increasing recognition of the need to integrate psychological and medical methods of treatment,[6,7] but with the important proviso that, at least initially, treatment should focus on the couple and not the individual.

One important aspect of this evolving story is how we define a 'sexual dysfunction', with connotations of abnormal or impaired function, and how it is distinguished from a 'sexual problem' in a more general sense. This issue was epitomized by a publication in the *Journal of the American Medical Association* on the epidemiology of 'sexual dysfunction'.[8] In this widely cited paper, 43 per cent of women and 31 per cent of men were identified as having a 'sexual dysfunction', described as 'a largely uninvestigated yet significant public health problem' (p. 544). The authors commented, 'With the affected population rarely receiving medical therapy for sexual dysfunction, service delivery efforts should be augmented to target high-risk populations'(p. 544).

This dramatic example of 'medicalization', based on extremely limited information from a national survey not designed to assess sexual dysfunction, was effectively challenged by Mercer and colleagues, using data from the UK National Survey of Sexual Attitudes and Lifestyles (NATSAL).[9] This used exactly the same questions as in the Laumann *et al.* study,[8] with the important difference that it was more specific about duration of problems, asking whether particular problems had lasted 'at least 1 month', or 'at least 6 months' during the last year (Laumann *et al.* had asked if symptoms had occurred 'for several months or more' during the last year). Overall, 53.8 per cent of women and 34.8 per cent of men reported at least one sexual problem lasting at least 1 month during the previous year. In contrast, the prevalence of problems lasting 'at least 6 months in the previous year' was 15.6 per cent for women and 6.2 per cent for men. This showed that transient problems were very common, more persistent ones much less so. In both the American and the British study, such problems were related to other problems in the participants' lives, particularly involving impaired mental health (e.g. depression), relationship problems, or significant life stresses.

Relevant to the question of when a sexual problem becomes a 'dysfunction' is a theoretical approach, called the 'Dual Control Model', developed at the Kinsey Institute. This postulates that sexual response results from an interaction between excitation and inhibition, involving relatively discrete neurophysiological systems in the brain.[10] A central assumption of the model is that individuals vary in their propensity for both sexual excitation and sexual inhibition and that 'normal' levels of inhibition are adaptive, reducing sexual responsiveness in circumstances where sexual

activity is best avoided. It is predicted that high levels of inhibition may be associated with vulnerability to sexual dysfunction and low levels with an increased likelihood of engaging in high-risk sexual behaviour.[10]

This faces us with the seemingly obvious but fundamental challenge of deciding whether a loss of sexual interest or responsiveness is an understandable or even adaptive reaction to current circumstances, or is a result of 'malfunction' of the sexual response system, which can appropriately be called a 'sexual dysfunction'. This challenge is also central to the relatively new phase of integrated treatment, in which assessment identifies the key factors causing the sexual problem and how they should best be treated. A strategy for carrying out such assessment, which we have called the 'three windows approach', will be outlined below.

Clinical features of sexual problems

Sexual problems in men

The most common problems presented by men are ED and premature ejaculation (PE). Delayed or absent ejaculation is a relatively infrequent complaint. Low sexual desire may be the presenting problem, although in most cases this is combined with ED, and it is not always clear which came first.

(a) Erectile problems

Penile erection is a tangible and fundamental component of a man's experience of sexual arousal and the lack of erection in a sexual situation often has significant negative effects. Irrespective of whether or not there are peripheral explanations for impaired erections (e.g. vascular disease), the reactions of the man and his partner have a major influence on how problematic the erectile difficulty becomes. Erectile difficulties vary in severity; in some men the problem only occurs on a proportion of occasions of sexual activity. The difficulty may be in getting an erection or in maintaining it long enough for satisfactory sexual intercourse.

(b) Low sexual desire

For many men, sexual desire is linked with erectile responsiveness. Many men with low sexual desire also report a reduction in 'spontaneous' erections. However, a man can experience low sexual desire without having any erectile difficulties, although he may require more direct tactile stimulation to achieve erections.

(c) Premature ejaculation (PE)

Ejaculation results from a combination of orgasm and seminal emission, with muscular contractions as part of the orgasmic response resulting in expulsion of the seminal emission. PE is essentially a problem when the man is unable to delay orgasm and ejaculation as he would wish. Not surprisingly, this has led to considerable inconsistencies of definition in the literature. In severe cases, emission occurs before vaginal entry and the orgasmic component may be so reduced that the usual muscle spasms do not occur, resulting in semen seeping out of the urethra rather than being 'ejaculated'.

Premature ejaculation has been categorized as 'primary' (i.e. lifelong) or 'secondary'. Secondary PE is often confounded by erectile problems. If a man is taking a long time to get an erection, he may reach the stimulus intensity required for ejaculation before or soon after erection is achieved.

(d) Delayed ejaculation

Delayed or absent ejaculation occurs in men, although it is much less common than rapid ejaculation. A man might have difficulty ejaculating only during sexual activity with his partner and in some cases only during penetrative intercourse, or the problem may be evident even during masturbation. Delayed or absent ejaculation is a common side effect of selective serotonin re-uptake inhibitor (SSRI) medications, which often prevents orgasm in women as well, suggesting that the primary effect of such drugs is on the triggering of orgasm.

(e) Pain during sexual response

Pain may be associated with prolonged sexual arousal not terminated by ejaculation/orgasm. Such pain is usually experienced in the testes. Pain felt in the urethra may occur during ejaculation. Neither problem is common.

Sexual problems in women

(a) Loss of sexual arousal and/or desire

Most surveys have suggested that low sexual desire is the most common sexual problem reported by women. However, low sexual desire is a heterogeneous problem category and the relationship between sexual arousal and sexual desire in women is particularly complex. Many women do not differentiate between 'arousal' and 'desire'[11] and awareness of 'desire' is usually accompanied by some degree of central arousal, whether or not any genital response is perceived.[12] It has been argued that sexual desire in women is much more likely to be 'receptive' and triggered by a desire for intimacy with one's partner.[13] It is therefore not surprising that there is considerable overlap or comorbidity between problems related to sexual arousal and desire in women.[8]

Although traditionally seen as the counterpart to penile erection in men, vaginal response is not central to the experience of sexual arousal in women. Vaginal dryness may be a problem because of the likelihood of discomfort or pain with intercourse when the vagina is not adequately lubricated, but this symptom does not necessarily indicate lack of arousal. Conversely, a woman may experience lack of sexual arousal and yet have vaginal lubrication. The relevance of vaginal response to sexual arousal in women therefore remains unclear. An increase in vaginal blood flow has been consistently demonstrated in women reacting to sexual stimuli, whether or not they find the sexual stimulus appealing; this led Laan and Everaerd[12] to call this an 'automatic' response. There is no obvious counterpart to this in men. Tumescence of the clitoris, on the other hand, may be more directly comparable to male genital response but this is less easily assessed and less clearly perceived by women, compared with penile erection in men.

Persistent genital arousal disorder (PGAD) is a recently recognized but fairly uncommon sexual problem in women. It is characterized by genital and breast vasocongestion and sensitivity which persists for hours or days and is only temporarily relieved by orgasm; genital sensations are unaccompanied by any subjective sense of sexual desire and excitement but instead are perceived as intrusive. There is no male equivalent to this problem, probably because the post-orgasmic refractory period is more substantial in men.

Much less frequent than loss of sexual arousal or desire is extreme aversion to, and avoidance of all sexual contact with, a sexual partner. This can occur in women and in men.

(b) Problems with orgasm

Difficulty in achieving orgasm is not uncommon in women. Often this is situational in that orgasm is possible with masturbation, but not during sexual interaction with the partner. The capacity to experience orgasm varies considerably across women. Some women reach orgasm easily if sufficient arousal occurs, others may require more specific or more intense stimulation, and an estimated 10–15 per cent are unable to experience orgasm throughout their lives.[14] In identifying a problem as primarily orgasmic, one needs to first establish that appropriate sexual arousal has occurred.

(c) Problems with sexual pain and vaginismus

Pain during attempted or complete vaginal entry (dyspareunia) is a common sexual problem in women with a wide range of possible causes. Sexual pain is also frequently associated with lack of sexual desire and/or arousal. Vaginismus has traditionally been defined as recurrent or persistent involuntary spasm of the musculature of the outer third of the vagina that makes vaginal penetration difficult or impossible. This definition has recently been questioned because of a lack of empirical evidence that vaginal spasms occur in women diagnosed with vaginismus.[15] Vulvar vestibulitis syndrome (VVS) is a condition associated with pain on touching the labia or vaginal introitus. The question of whether these are primarily 'sexual' or pain disorders is currently under debate.[16]

Classification of sexual problems

DSM-IV and ICD classification

The current Diagnostic and Statistical Manual of Mental Disorders (DSM) classification[17] defines sexual dysfunction as characterized by 'disturbance in sexual desire and in the psychophysiological changes that characterize the sexual response cycle and cause marked distress and interpersonal difficulty' (p. 493). There is Hypoactive Sexual Desire Disorder and Sexual Aversion Disorder, defined in the same way for men and women. Female Sexual Arousal Disorder is defined as 'a persistent or recurrent inability to attain, or to maintain until completion of the sexual activity, an adequate lubrication-swelling response of sexual excitement' (p. 502) and, for the male version, erection is the relevant response. Orgasmic Disorder (i.e. delayed or absent orgasm) and Dyspareunia are defined in basically the same way for men and women. Vaginismus is a specifically female diagnosis and Premature Ejaculation an exclusively male disorder.

The International Statistical Classification of Diseases and Related Health Problems[18] covers sexual dysfunctions in one and a half pages, compared with nearly 30 pages in the DSM. The basic categories of dysfunction are similar to those of DSM, but there are few, if any, actual diagnostic criteria given for any of the dysfunctions. ICD-10 also does not require that personal distress or interpersonal problems are present for a diagnosis to be made. Instead, there is the statement 'sexual dysfunction covers the various ways in which an individual is unable to participate in a sexual relationship as he or she would wish' (p. 355).

There has been increasing dissatisfaction with the current classification of sexual dysfunction for women.[19,20]. Major areas of criticism include the high comorbidity between diagnoses of sexual dysfunction and the 'genital' focus of the diagnostic criteria and concomitant neglect of psychological and relationship factors. In response, alternative models of sexual response[13] and women-centred definitions of sexual problems[21] have been proposed.

Epidemiology

There have been at least 12 representative community-based surveys that have assessed the prevalence of sexual problems.[22] Prevalence rates for specific problems vary considerably and whereas several of the studies claim to be reporting prevalence of sexual 'dysfunctions',[8] it is now accepted that the detailed clinical assessment required to identify a sexual dysfunction cannot be undertaken by large-scale surveys.[23] Consequently, more recent surveys have used terms such as 'problems'[9,24] or 'difficulties'.[25] Variability in reported prevalence rates can in part be attributed to variations in how sexual problems are defined, their duration, and how and whether 'distress' about changes in sexual functioning is assessed. In studies of female sexual problems, there has been only limited overlap between what women perceive as problematic and what the researcher or clinician identifies as a problem.[26,27] The variability of prevalence rates is shown in Tables 4.11.2.1 and 4.11.2.2, which compare a number of population-based surveys involving women and men.

There has been more consistency across studies in the associations found between factors of possible aetiological relevance and sexual functioning. In women, sexual problems are more frequent in those with mental health problems and relationship difficulties.[8] In a survey of women aged 20–65 years, all in heterosexual relationships, 24.4 per cent reported marked distress about their sexual relationship and/or their own sexuality.[26] The best predictors of distress were markers of mental health and the quality of the emotional relationship with the partner. Physical aspects of sexual response in women such as arousal and orgasm were poor predictors of distress.

In men, age has a predictable negative effect on erectile function. In one study, complete erectile failure was reported by 5 per cent of men at age 40 and 25 per cent at age 70.[28] A similar age effect is found with loss of sexual desire. In another study, absence of any sexual desire was reported by 2 per cent of men aged 45–59 and 18.2 per cent aged 75+.[29] Contrary to popular belief, PE does not show a clear negative relationship with age.

The association between age and sexual problems in women is more complex. Whereas level of sexual interest typically decreases with age, older women are less likely to regard this as a problem.[26] Older women are much less likely to be in a sexual relationship than older men; the presence or absence of a partner also seems to influence women's sexuality to a greater extent than it does for men.[29] The impact of the menopause is also complex. Although the post-menopausal decline in oestrogens is relevant to vaginal lubrication, other factors such as mental health and the quality of the sexual relationship are more important determinants of sexual well-being.[30]

Aetiology

Before considering the factors that can cause sexual problems, it is worth underlining the important way that sexual function differs from most other physiological response systems. Although involving physiological mechanisms, sexual responses are most often experienced in the context of a relationship. This highlights the

Table 4.11.2.1 Prevalence of specific female problems (%) found in seven community-based surveys

Study	Low sexual interest	Impaired arousal	Impaired lubrication	Impaired orgasm	Pain	Total (one or more problems)
Richters *et al.* (2003)[25]1						
At least 1 month	54.8	–	23.9	28.6	20.3	
Mercer *et al.* (2003)[9]1						
At least 1 month	40.6	–	9.2	14.4	11.8	53.8
At least 6 months	10.2	–	2.6	3.7	3.4	15.6
Bancroft *et al.* (2003)[26]3	7.2	12.2	31.2	9.3	3.3	45
Laumann *et al.* (1999)[8]1	31.6	–	20.6	25.7	15.5	43[a]
Fugl-Meyer and Fugl-Meyer (1999)[59]1	33.0	–	12.0	22.0	6.0	47
Dunn *et al.* (1999)[24]2	–	17.0	28.0	27.0	18.0	41
Osborne *et al.* (1988)[37]2	17.0	–	17.0	16.0	8.0	33

importance of keeping the interactive relationship components in mind when trying to assess and treat sexual problems. Socio-cultural factors are also crucial to understanding how sexual problems are experienced. Much of the focus in medical treatments of sexual problems has been on the individual patient, with relationship and socio-cultural aspects largely ignored. The more specific aetiological factors can now be considered using the 'three windows approach'.[26]

The first window—the current situation

Through the first window, a variety of factors in the individual's current relationship and situation may be relevant. Relationship problems, particularly resentment and insecurity within a relationship, are of particular importance. For many individuals, feeling secure and being able to 'let go' are necessary for them to enjoy sex. Other factors that may be important include: poor communication between partners about their sexual feelings and needs; misunderstandings and lack of information; unsuitable circumstances and lack of time e.g. fatigue, lack of privacy, and work pressures; concerns about pregnancy or about sexually transmitted diseases; and low self-esteem and poor body image.

Various mechanisms may mediate the effects of the above situational factors on sexual functioning. Reactive inhibition, as postulated by the Dual Control Model,[10] may well be involved in those circumstances associated with a negative emotional response. With stress and fatigue, the mechanisms are less clear, but may entail a transient reduction in the capacity for excitation (i.e. sexual arousability).

Table 4.11.2.2 Prevalence of specific male problems (%) found in five community-based surveys

Study	Low sexual interest	Erectile problem	Premature ejaculation	Delayed ejaculation	Total (one or more problems)
Richters *et al.* (2003)[25]1					
At least 1 month	24.9	9.5	23.8	6.3	–
Mercer *et al.* (2003)[9]1

The second window—vulnerability of the individual

Although a wide range of factors can impact on our sexuality, it is also clear that individuals vary substantially in the extent to which they are affected by such factors, particularly in terms of an associated inhibition of sexual response. Such vulnerabilities are likely to have been evident in earlier episodes in the current relationship or in earlier relationships.

(a) Negative attitudes

Long-standing attitudes, usually stemming from childhood, that sex is inherently 'bad' or immoral are likely to interfere with an individual's ability to become involved in and enjoy a sexual relationship.

(b) Need to maintain self-control

In some individuals, a difficulty in 'letting go' sexually reflects a more general need to maintain self-control, particularly in the presence of another person.

(c) Earlier experience of sexual abuse or trauma

There is now an extensive literature on the impact of sexual abuse on subsequent sexual adjustment. Whereas the mediating mechanisms are not well understood and are likely to be complex and varied, a history of such experience should be regarded as potentially relevant to current sexual difficulties.

(d) Propensity to sexual inhibition

The Dual Control Model, discussed earlier, has led to psychometrically validated measures of propensity to sexual excitation and inhibition in men[31] and women.[32] These are new measures and research exploring their relevance to vulnerability to sexual problems has only recently started. However, using these measures, close to normal distributions of scores for both sexual excitation and inhibition proneness have been reported in men[31] and women.[32] As predicted, a clear association between low sexual excitation and/or high sexual inhibition propensity and erectile problems in men has been found, but no association with PE.[33] One study explored a possible genetic basis for such individual variability in men and found evidence of heritability for propensity to sexual inhibition but not excitation.[34] In women, a strong relationship between sexual inhibition scores and reports of sexual problems was found.[35] Particularly important was one inhibition subscale (labelled 'arousal contingency') that reflects susceptibility for sexual arousal to be easily affected by situational factors e.g. if the circumstances are not 'just right' or if the woman is distracted. Although further research is needed, these measures of sexual inhibition and excitation may prove valuable in explaining patterns of impaired sexual response and helping in the selection of appropriate treatment. As yet no other personality-related or trait measure has been shown to have clinical value in this respect.

The third window—health-related factors that alter sexual function

The variety of health-related factors are considered under three headings: mental health, physical health, and sexual side effects of medication.

(a) Mental health and sexuality

Psychiatric problems are commonly associated with sexual problems.[36,37] Reduction in sexual interest, and to some extent sexual arousability, is generally accepted as a common symptom of depressive illness.[38] In contrast, sexual interest tends to be increased in states of elevated mood such as hypomania.[39] In a study of men and women with primary loss of sexual interest, the large majority had experienced previous affective disorder, with reduced sexual desire being established during, and persisting after, one of these earlier depressive episodes.[40]

We would expect reactive inhibition of sexual interest or response in circumstances eliciting negative mood (i.e. 'reactive depression'). With more endogenous depression, however, reduction of the excitatory component of sexual response is also evident. This is shown clearly in the impairment of nocturnal penile tumescence (NPT) that typically occurs with depressive illness. NPT, while not completely understood, probably results from a 'switching off' of inhibitory tone during REM sleep. This therefore allows expression of 'excitatory tone', presumably impaired in depression with associated metabolic changes.

With anxiety, the clinical evidence is much more limited. Higher rates of sexual dysfunction in patients with anxiety disorders have been reported.[41] In the Zurich Cohort Study, a longitudinal study of men and women aged 20–35 years, loss of sexual interest was more prevalent in patients with generalized anxiety disorder, but was not associated with panic disorder, agoraphobia, or social phobia.[42] In another study, patients with panic disorder were more likely to report sexual problems, particularly sexual aversion, than social phobics; PE was the most common sexual problem in men with social phobias.[43]

Non-clinical, community-based studies have also demonstrated a relationship between mood and sexuality. In the Massachusetts Male Aging Study, an association was reported between ED and depressive symptoms, after controlling for other potential confounding variables such as age and physical health.[44] Angst[42] found a relationship between depression and loss of sexual interest, particularly marked in women. In a US survey of heterosexual women, scores on a brief measure of mental health were strongly predictive of women's distress about their sexual relationship and their own sexuality.[26]

Although most studies have focused on negative effects of mood disorders on sexual interest and response, there is evidence that a minority of individuals experience increased sexual interest during negative mood states. Angst[42] reported that among depressed men, 25.7 per cent reported decreased, and 23.3 per cent increased, sexual interest, compared with 11.1 per cent and 6.9 per cent, respectively, of their non-depressed group. In contrast, among depressed women, 35.3 per cent reported decreased sexual interest and only 8.8 per cent reported increased interest (compared with 31.6 per cent and 1.7 per cent, respectively, of their non-depressed group). This paradoxical pattern of increased sexual interest during negative mood states has also been reported in non-clinical samples of men[45] and women.[46] Although the origins of this pattern are not yet understood, it may well be problematic in various ways; for example, associated with sexual risk-taking or leading to sex being used as a mood regulator.

The impact of schizophrenia on sexuality is complex. Given the importance of dopaminergic neurotransmission to various aspects of sexuality, and the fact that most anti-psychotics are dopamine antagonists, one might expect amplification of sexual interest or response in some form, at least during the more florid type one stage of the illness. Sexual thoughts and behaviours are common in

schizophrenia and there may be a relative increase in sexual activity. However, this is typically autoerotic or 'compulsive' without any real 'object-relational' quality.[47] In view of the effects of this illness on interpersonal functioning, this is not surprising. Early studies suggested that loss of sexual interest was less likely in schizophrenia than in other types of psychiatric illness, although female schizophrenics were more likely to report a reduction in sexual interest than males.[47] 'Pre-schizophrenic personality', evident in the history of many cases, may also be associated with an interference with normal sexual development.

(b) Physical health and sexuality

The impact of poor physical health on sexuality may be relatively non-specific. For example, loss of well-being and energy associated with chronic illness is likely to cause reduced sexual interest and arousability. Psychological reactions to the illness or condition (e.g. the effects of breast cancer on a woman's body image and hence her sexual enjoyment) may also be important. In addition there are a variety of ways in which the health problem can directly affect sexual interest and/or response. In most cases we find the evidence much clearer in men than in women.

(i) Damage to the neural control of genital response

This can involve peripheral mechanisms (e.g. autonomic neuropathy and peripheral neuropathy) or disease in the spinal cord (e.g. multiple sclerosis). Injury or surgery causing nerve damage may be involved (e.g. spinal cord injury, prostatectomy, or hysterectomy). The most likely consequences are ED in men and impaired vaginal response in women. There is no clear relationship between neural damage and PE but interference with normal seminal emission can occur, with resulting loss of ejaculation or retrograde ejaculation when, due to nerve damage to the pelvic muscles, the seminal fluid passes backwards into the bladder during ejaculation. Brain abnormalities, such as epilepsy or cerebral tumour, can affect central control of sexual response, the precise effect depending on the site of the abnormality or tumour. In some cases the result is loss of sexual interest and arousability; rarely there is disinhibition of sexual behaviour.

(ii) Impairment of vascular supply of the genitalia

Genital response is dependent on increased arterial inflow as well as alteration in venous outflow. Vascular impairment can result from peripheral vascular disease, affecting the small vessels, or obstruction in a main artery. ED is also common in men who have ischaemic heart disease.

(iii) Alteration of endocrine mechanisms affecting sexual interest, arousal and response

In males any cause of lowered testosterone (T) levels is likely to produce loss of sexual interest and, to a varying extent, impairment of erectile response. Hypogonadism, if severe enough, will also be associated with loss of seminal emission (and usually orgasm).

In women, lack of oestrogen is associated with impaired vaginal lubrication. The effects of sex steroids, either oestrogens or androgens, on sexual interest and arousability, are much less predictable. The evidence is consistent with there being a proportion of women who depend on T for their normal level of sexual interest, but there are many women who can experience substantial reduction in T without obvious adverse sexual effects. The role of oestrogen in the more central aspects of women's sexuality also remains unclear.[48]

Hyperprolactinaemia, usually resulting from pituitary adenomas and hypersecretion of prolactin, may be associated with loss of sexual interest, and in men, with ED. However, this is not always the case. The precise role of prolactin in human sexuality is not understood. Its central control by dopamine and serotonin contributes to the complexity. Adverse effects of hyperprolactinaemia on sexuality are probably more likely in men than women.

(iv) Metabolic disorders

Various forms of metabolic disturbance, such as that associated with hepatic or renal disease, may be associated with adverse effects on sexual interest and response, though the mediating mechanisms are not understood.

Some diseases affect sexuality through more than one of the above mechanisms. Diabetes mellitus is a good example. ED has long been recognized as a complication of diabetes and is more common in Type 1 than Type 2 diabetes. In diabetic men, ED can result from small vessel vascular disease and also autonomic and peripheral neuropathology. Diabetes is associated with hypogonadism in men. Lowered sexual interest and impairment of genital response have also been reported in diabetic women.

(c) Side effects of medication

In considering the complexities of pharmacological effects on sexual function, it is helpful to distinguish between excitatory and inhibitory mechanisms. In the brain, sexual excitation depends to a considerable extent on dopamine (DA) and noradrenaline (NA). DA is involved in the 'incentive motivation system' and is hence relevant to sexual interest. It is the D2 receptor that is most relevant to these sexual effects. It is also involved in the hypothalamic control of genital response. NA, when acting centrally, is involved in central arousal, a key component of sexual arousal though not specific to it. In the periphery, depending on the receptor involved, NA can have inhibitory or enhancing effects on smooth muscle relaxation, a critical aspect of genital response. There are three principal NA receptors of relevance: (i) alpha-1, which is post-synaptic and mediates smooth muscle contractions, inhibiting genital response, (ii) alpha-2 which is principally pre-synaptic, where it increases re-uptake of NA and hence reduces the amount of NA at the synapse, and (iii) beta-2, a peripheral receptor which mediates a relaxing effect of NA on smooth muscle in the urogenital system and elsewhere. Serotonin (5-HT) has a central role in the inhibitory system. The two most relevant receptors are the 5-HT2 receptor, which mediates the inhibitory effects and the 5-HT1A receptor, which is pre-synaptic and, comparable to the alpha-2 receptor, reduces 5-HT transmission. We can now consider the main adverse sexual effects resulting from medication; for a review, see.[49]

(d) Anti-depressants

The clearest examples are the SSRIs which, by inhibiting the 5HT-1A receptor, increase serotonergic transmission. The most predictable effect, in both women and men, is inhibition of orgasm and ejaculation. This effect is being exploited in the treatment of PE, with the development of short-acting SSRIs which can be used as needed prior to sexual activity. Other negative effects include reduced sexual interest and arousability, though they are less predictable and not always easy to distinguish from the sexual effects of the affective disorder being treated. Tricylic anti-depressants also commonly produce sexual side effects. Two anti-depressants which

have less sexual side effects are bupropion, which is metabolized into a DA and NA re-uptake inhibitor, and nefadazone, which has a 5-HT2 antagonist effect.

(e) Anti-psychotic medication

These drugs, used for the treatment of schizophrenia and other psychotic disorders, involve a balance of DA antagonist and 5-HT agonist effects. Sexual side effects occur in around 60 per cent of men and 30–90 per cent of women using these drugs. The most common side effects are ED and ejaculatory difficulties in men and orgasmic dysfunction in women. It is not clear to what extent these effects are due to the DA antagonist or 5-HT agonist effects, or a balance of the two.

(f) Anti-hypertensive medication

Many drugs used to treat hypertension interfere with male sexual response. In the case of alpha-1 antagonists (e.g. prazosin), the peripheral effects would be expected to enhance erection, by reducing adrenergic contraction of erectile smooth muscle and indeed priapism is an occasional problem. There is a low incidence of sexual side effects, mainly failure of ejaculation, and central alpha-1 blockade might reduce central arousal. Beta-blockers (e.g. propanalol), by blocking smooth muscle relaxation and leaving the alpha-1 induced contraction unopposed, commonly cause ED. Centrally acting anti-hypertensives (e.g. guanethidine) also interfere with sexual response, impairing erection, and blocking ejaculation. Clonidine, an alpha-2 agonist, causes erectile problems in about 25 per cent of cases. In this case the principal effect is likely to be reduced central arousal. For a review of the effects of anti-hypertensive medication on male sexual response, see.[50]

The effects of drugs on women's sexuality have received far less attention. Research has mostly focused on difficulties in achieving orgasm. As orgasm only occurs after sufficient sexual arousal, these effects may reflect impairment of arousal but this has not been adequately assessed. Steroidal contraceptives, although associated with markedly reduced levels of free T, decrease sexual interest only in a minority of women.[51] This, again, has been little studied and it remains possible that the adverse effects on sexual interest only occur in those women whose sexuality is 'T dependent'.[51]

Management of sexual problems

In this section we will briefly describe the principles of sex therapy and the main forms of pharmacological treatment, followed by an outline of the process of assessment and selection of a suitable treatment plan. The growing awareness of the limitations of pharmacological treatments administered on an individual basis, discussed earlier, has led to recognition that an integration of psychological and pharmacological methods, with emphasis on the couple, may be the most appropriate treatment model in most cases.

Sex therapy

Although the approach first introduced by Masters and Johnson[1] has been adapted in various ways, the core treatment techniques remain. Originally developed for helping couples, the techniques can be modified for use with individuals and with same-sex as well as heterosexual couples.

The key elements of the therapeutic process are:

(a) clearly defined tasks are given and the couple asked to attempt them before the next therapy session

(b) those attempts, and any difficulties encountered, are examined in detail

(c) attitudes, feelings, and conflicts that make the tasks difficult to carry out are identified

(d) these are modified or resolved so that subsequent achievement of the tasks becomes possible

(e) the next tasks are set, and so on

The tasks are mostly behavioural in nature. They are chosen to facilitate the identification of relevant issues but in some cases are sufficient in themselves to produce change. The behavioural programme is in three parts. In the first part the couple are asked to avoid any direct genital touching or stimulation and to focus on non-genital contact, alternating who initiates and who does the touching. These first, non-genital steps are effective in identifying important issues in the relationship, such as lack of trust or counter-productive stereotypical attitudes (e.g. once a man is aroused, he can't be expected not to have intercourse). Once this stage can be carried out satisfactorily, and related problematic issues dealt with, the programme moves on to the second part, which allows genital touching to be combined with non-genital touching, with penile–vaginal intercourse still 'out of bounds'. In this second part more intra-personal problems, such as long-standing negative attitudes about sex, or the sequelae of earlier sexual trauma are likely to emerge. In the third part, a gradual approach to vaginal–penile contact and insertion is undertaken. Here the most relevant issues are 'performance anxiety' and fear of pain.

As the behavioural tasks reveal key issues that need to be resolved before moving on to the next stage, a variety of psychotherapeutic approaches, including cognitive behavioural techniques, can be utilized. Although the stage at which particular issues emerge does vary from case to case, there is a tendency for problems identified through the 'first window', particularly those related to lack of trust and unresolved resentment, to appear during the first stage of the programme. Intra-personal issues (e.g. as seen through the 'second window') are more likely to be recognized during the second stage.

The goals of therapy include helping the individual to accept and feel comfortable with his or her sexuality and helping the couple to establish trust and emotional security and to enhance the enjoyment and intimacy of their sexual interaction. An important point is that these goals do not include reversal of specific sexual dysfunctions. There are exceptions; for example, there are specific behavioural techniques to deal with PE and vaginismus (for details of these techniques, see Bancroft.[52] However, the overriding principle is that, assuming there is no abnormality of the basic physiological mechanisms involved in sexual response, normal sexual function (in terms of sexual desire, arousal, and genital response) will return once the above goals are achieved. In cases where impairment of physiological mechanisms does exist, the above goals of sex therapy are still helpful and integrate well with the use of pharmacological treatment.

Practical aspects

Although sex therapy varies in duration, 12 sessions over 4 to 5 months is typical. The therapist adjusts to the particular needs of the individual or couple. Treatment begins weekly with the interval between sessions extended once major issues like unexpressed

resentment or communication problems have been dealt with. The last two or three sessions are spaced out over a few months so that the couple have an opportunity to consolidate their progress and cope with any setbacks before termination. Open-ended arrangements about length of treatment are best avoided. A specified number of sessions are agreed on at the outset with the proviso that progress will be assessed and a decision made on that basis whether to continue for longer.

A more complete description of the sex therapy process is provided by Bancroft.[52]

Pharmacological treatments for men

(a) Erectile dysfunction. Phosphodiesterase 5 inhibitors

The most important development in this field was the serendipitous discovery that sildenafil (Viagra®), a PDE-5 inhibitor, enhances erectile response. Dose titration is usually required, with available tablets containing 25, 50, or 100 mg. For more severe cases of ED, 100 mg taken about 1 hour before sexual activity is required. The maximal effects last for about 4 h. The most common side effects, that are dose-related, are headache, flushing, and dyspepsia.

Two further PDE-5 inhibitors have been developed and are now in use: tadalafil (Cialis®) and vardenafil (Levitra®). They are both comparable to sildenafil in their efficacy, the main differences being their speed and duration of action. Tadalafil should be taken at least 30 min before sexual activity and has a half-life of 17.5 h; the treatment effect can persist for 24–36 h. Vardenafil is pharmacokinetically similar to sildenafil, but is more potent, with a dose range 5 mg to 20 mg. They are similar in their side effects, though the duration of these relate to the half-life of the drug. For all three drugs, the most important and dangerous drug interaction is with nitrates used for ischaemic heart disease; this is a strong contraindication for the use of PDE-5 inhibitors.

There is now an extensive literature demonstrating the efficacy of sildenafil in the treatment of ED, which has been well reviewed by Rosen and McKenna.[53] Overall, treatment is effective in about 75 per cent of cases. The effectiveness of tadalafil and vardenafil has also been demonstrated.

In spite of their efficacy, the continuing use of PDE-5 inhibitors appears to be limited. In a recent large study done in eight countries, 2912 men identified with ED were followed up; 58 per cent of them had sought medical help for the ED, but only 16 per cent of men maintained their use of PDE-5 inhibitors.[7] Various reasons were given for discontinuation, including lack of appropriate information from the physicians, fear of side effects, partner concerns, and distrust of medications.

(b) Anti-adrenergic drugs

Alpha-2 antagonists may enhance sexual arousal by their central NA effects. One example is yohimbine, which has a modest therapeutic benefit over placebo and is generally well tolerated. Phentolamine is an alpha-1 and alpha-2 antagonist used medically to treat hypertensive crises. It has been used, in combination with papaverine, to induce erection by intra-cavernosal injection, presumably mediated by its alpha-1 antagonist effect. Phentolamine administered systemically can also improve sexual arousal, presumably by blocking both the peripheral alpha-1 receptors and enhancing central arousal by blocking the alpha-2 receptors in the brain. Some evidence of beneficial effects of phentolamine has been reported, although long-term follow-up revealed high attrition.

(c) Dopamine agonists

The main effects of dopamine agonists, such as apomorphine, are to induce genital response, probably via the hypothalamic oxytocinergic system. Early studies with apomorphine in men, while showing positive effects on erection, also demonstrated substantial side effects (mainly nausea and dizziness). Sublingual administration was developed to reduce such side effects and a number of placebo-controlled studies have shown this to improve erectile function[54] but the occurrence of side effects remains a limiting factor.

(d) Melanocortin agonists

A recent development has been bremelanotide (PT-141), a metabolite of melanotan-II, and a melanocortin analogue, which probably works through the same oxytocinergic system as apomorphine. Side effects similar to those with apomorphine occur, and further phase 3 research is required before the clinical value of this compound is established.

(i) Premature ejaculation

The orgasm inhibiting effect of SSRIs (see above) has been exploited in the treatment of PE. Paroxetine, sertraline, and fluoxetine, among others, have all been shown to be effective in this respect. However, continued use is required, and effects may not be apparent during the first week. This raises the issue of side effects and the need to avoid sudden withdrawal.

More recently, PDE-5 inhibitors have been explored as a treatment for PE. However, the benefits are not clear cut and may be restricted to cases of 'secondary' PE. The most likely mechanism of action is reduction of the smooth muscle contraction involved in seminal emission.

(ii) Delayed or absent orgasm/ejaculation

At present there is no accepted pharmacological treatment for delayed or absent ejaculation or orgasm.

(iii) Low sexual desire

The most treatable but relatively infrequent cause of loss of sexual desire in men is hypogonadism. Where androgen deficiency is evident, T replacement is indicated. Currently the most favoured route of administration is transdermal, either using cream or skin patches. One advantage of the transdermal route is that the hormone is absorbed into the skin and then released more gradually into the circulation, maintaining relatively physiological levels. In comparison, intra-muscular injections of T (e.g. T enanthate) produce supraphysiological levels in the circulation, which then steadily decline. Oral routes are complicated by first pass through the liver.

If loss of sexual desire is associated with hyperprolactinaemia, treatment with dopamine agonists, such as bromocriptine, is indicated.

Pharmacological treatments for women

At present pharmacological methods for treating sexual dysfunction in women, although generating much interest and controversy, are very limited. Most attention is currently being paid to the use of T for treating low sexual desire. As considered earlier, the evidence of a role for T in women's sexuality is inconsistent and the likelihood is that it is important for some women and not others.

The most convincing evidence of the benefits of T are in women who have been ovariectomized and have therefore experienced a substantial reduction in their androgen levels. Much of this evidence, however, indicates that supraphysiological levels of T result from treatment; thus, it remains uncertain whether the benefits result from correction of T deficiency or pharmacological effects of high levels of T. For this reason, and because of uncertainty about possible long-term risks, there has been a reluctance to approve such treatments, particularly in women with intact ovaries.[48]

Attempts to treat sexual desire/arousal problems with PDE-5 inhibitors have so far proved unsuccessful, although there may be subgroups of women who benefit. Other pharmacological approaches which are being explored in women include the use of phentolamine, apomorphine, bupropion, and bremelanotide (PT-141). But further research is required before any of these can be recommended for clinical use. For more details of the above treatments, see Bancroft.[52]

Evaluation of treatments

Sex therapy

In a 1997 review, Heiman and Meston[55] concluded that there was evidence for empirically validated treatments for orgasm problems in women and ED in men. There was inadequate support for effective treatments for low sexual desire, sexual aversions, dyspareunia in women and men, and delayed orgasm in men. What is striking is that of the 90 studies involving psychological treatments cited in this review, only two were published since 1990, and 60 of them before 1980.

In the decade since this review, there have been a few controlled trials involving cognitive behaviour therapy (CBT) for women with vaginismus,[56] vulvar vestibulitus,[57] and couples presenting with problems of low sexual desire,[58] all suggesting positive effects. Further outcome studies of psychological therapies that identify predictors of successful outcomes are badly needed.

Combined psychological and medical treatment

There have now been a number of studies in men that have compared combined psychological and pharmacological treatments, with either used separately. These have been reviewed by Althof[6] and include studies combining psychotherapy with sildenafil, and counselling with intra-cavernosal injections or with vacuum devices. In each case, the combination produced significantly better results than the medical treatment alone.

Planning a treatment programme

Assessment

When couples present with sexual difficulties, one of them is usually regarded as having the problem. However, both partners should be carefully assessed whenever possible. There are three stages to assessment; first, to facilitate the decision about whether sex therapy is appropriate; second, to identify issues relevant to the sexual problem that need to be resolved, and third, to determine whether medication or other treatments are required.

Keeping in mind the distinction between a sexual problem that is adaptive or appropriate given an individual's current circumstances and one that is maladaptive (and can perhaps be considered a 'dysfunction'), we can assess each individual's case through the three conceptual 'windows' described earlier. Are there problems in the couple's current relationship or situation, which would make inhibition of sexual responsiveness in either partner understandable or adaptive? Does either individual give a history that suggests vulnerability to sexual problems? Are there are any mental or physical health issues or medication use in either partner that could be having a negative effect on sexual interest or response?

(a) The initial interview

Although not all of the details can be obtained during the initial interview, assessment of the following topics should be carried out: the nature of the problem, including an assessment of level of sexual interest and response in each partner; identification of other assessments that may be needed (e.g. physical examination, blood tests); commitment and motivation of each partner to improving the relationship; and, assessment of the mental state of each partner. If both partners are present, each should be interviewed separately following a conjoint interview. As far as possible, questions should be asked about each individual's sexual history, the nature of the current relationship, contraceptive use and reproductive history, and alcohol or recreational drug use.

At the end of the initial interview, the clinician should provide a preliminary formulation of the nature of the problem and the types of intervention that may be helpful. Whatever treatment methods are used, it is important to continue to see the couple together to monitor progress and provide counselling as needed.

If there is no evidence of causal factors of the kind viewed through the 'first' or 'second' windows (see above), then a trial of pharmacological treatment may be appropriate. In such cases a physical examination and, where relevant, laboratory investigations would normally be arranged before starting treatment. It is important to have a good 'clinical baseline' before embarking on pharmacological interventions.

If there are any indications of problems or issues, particularly of the kind that invoke inhibition of sexual response, which need to be resolved, then pharmacological interventions should not be considered as a first step. In many cases, more assessment is required before such factors can be adequately assessed. There are then two options: (i) further interview(s) to explore such issues or (ii) starting on a programme of sex therapy. The rationale for the second option is as follows. The initial two stages of sex therapy (i.e. involving non-genital and then genital touching with no attempts at vaginal intercourse) are particularly effective at identifying relevant issues underlying the problem. Furthermore, the process involved in those early stages is likely to benefit any sexual relationship, even those without obvious problems. After three or four sex therapy sessions, a re-appraisal would be made and a decision taken whether to continue with sex therapy alone, or to combine it with an appropriate pharmacological method. For example, with a couple where the man has erectile problems, it is easier to assess the indications for the use of a PDE-5 inhibitor after the couple have gone through the first two stages of the programme where there is no 'performance pressure' and no need for an erection to occur. Similarly, it is often informative to see what impact this behavioural programme has on the individual who has complained of reduced sexual desire, before attempting to deal with the problem pharmacologically or hormonally.

Ideally, the use of the pharmacological method should then proceed in combination with the continuation of the sex therapy programme. In that way a gradual transition to a satisfying sexual relationship can be achieved without renewed 'performance pressures'. If, however, progress continues to be made with sex therapy, then the addition of pharmacological interventions may not be necessary. It should be explained to the couple that, whereas pharmacological treatments often have beneficial effects on sexual response, they do not 'cure' the problem, which is likely to recur once the medication is stopped. Furthermore, there are often side effects that have to be dealt with. There is, however, some evidence that when medication is combined with sex therapy, the pharmacological component can be gradually withdrawn, or only used intermittently.

Ethical aspects of clinical management

In assessing individuals or couples with sexual problems it is clearly important to assure them that the information they provide will be treated as highly confidential. It is appropriate to have separate case files for sexual problem clinics, rather than files used in other clinics. In this way the files can be kept secure. Some overview of the information presented to the clinic by the referring clinician should be provided at the start of the assessment. Information to be passed back to the referring clinician by letter or word of mouth should be agreed with the client(s) in advance, particularly if any highly sensitive issue emerged during the assessment. When assessing a couple, and seeing each partner separately, it is important to establish whether each individual agrees to any information not known by the other being shared during the joint sessions (e.g. details of previous sexual relationships). When offering a course of treatment or further assessment, the individual or couple should be fully informed about what is involved before being asked to make their decision.

A more challenging ethical issue relates to cultural values. Much of the process of sex therapy involves the therapist encouraging and 'giving permission' for specific forms of sexual interaction, as well as more general patterns of interaction within the relationship (e.g. 'self asserting' and 'self protecting'). It is important for the therapist to keep in mind that many of these principles are based on western middle class values. When working with a couple from a different culture, or even a different social class to the therapist, there should be awareness, openness, and discussion about contrasting values of cultural or religious origin. In this way differences can be negotiated, rather than have therapist values imposed.

When to seek specialist help

The treatment programme described above can be applied by psychiatrists in practice providing that they (i) are comfortable asking detailed questions about sexual behaviour and response, (ii) have experience working psychotherapeutically with couples, and (iii) are familiar with cognitive behavioural methods of treatment. They have the advantage over many non-medically qualified sex therapists of being able to prescribe medications in combination with a behavioural approach to sex therapy.

Specialist help should be obtained if there is evidence of a physical condition which requires detailed assessment and treatment, or if, after a reasonable trial of integrated psychological and pharmacological treatment, the sexual problem remains unresolved. In some such cases, the specialist help should be from someone with expertise in sexual medicine (e.g. urologist, gynaecologist). In other cases, where the psychological aspects remain unclear or difficult to resolve, referral to an experienced sex therapist is appropriate.

4.11.3 The paraphilias

J. Paul Fedoroff

Clinical features

Definition of the condition

The characteristic essential to all paraphilias is the presence of a persistent and/or recurrent, sexually motivated interest that causes harm. This definition has several implications.

Interest versus act

Paraphilias can exist even if they have never been acted upon. By definition, all paraphilias begin with a sexual thought and, like non-paraphilic interests, the majority of sexual fantasies are never fulfilled in reality. Sexual acts are only paraphilic if they are motivated by harmful sexual interests. For example, an individual with paedophilia (sexual interest in children) may act on this interest by masturbating while viewing non-pornographic children's television shows. However, an individual who unintentionally downloads pictures of children from the Internet while meaning to download adult pornography should not be considered paedophilic (even though he or she may still be criminally liable).

Persistent versus opportunistic

Paraphilias are characterized by their persistence. Therefore a single paraphilic thought or activity, especially if it occurs during unusual circumstances, is unlikely to be indicative of a true paraphilia. For example, a woman who while on a vacation and under the influence of alcohol exposes herself once to group of strangers in a bar, would not normally be considered to have exhibitionism (sexual arousal from exposure to strangers). Opportunistic activity that is not sexually motivated, even if it is ongoing, is also exclusionary. A pimp who coerces women to exchange sexual activities for drugs or money, would not meet criteria for sexual sadism even though he repeatedly engages in opportunistic sexual activity with otherwise unwilling participants because, for the pimp, the motivation is financial rather that sexual.

Harm versus happenstance

Many sex acts are intimate. Therefore it should come as no surprise that participants can be harmed. Unfortunately whenever sexual activities are considered, 'harm' tends to be defined somewhat solipsistically. Paraphilias are characterized by sexual interests or behaviours in which harm is more or less inevitable rather than accidental or random. For example, although sexual intercourse may expose the participants to a number of dangers including sexually transmitted diseases, possibly unintended degrees of intimacy, or subsequent events (e.g. pregnancy), by and large, consensual sexual activity between adults does not inevitably lead to disaster.

In contrast, true paraphilic interests are by definition, harmful. For example, a woman who can only become sexually aroused if she is choked to unconsciousness (asphyxophilia), exposes herself to unintended harm including cerebral anoxia and possible death. The paraphilias associated with crime (e.g. voyeurism, exhibitionism, frotteurism, criminal sadism, and paedophilia) involve non-consensual imposition of sexual activity onto others. Other non-criminal paraphilias (e.g. transvestic fetishism) become problematic when they interfere with the ability to maintain a reciprocal emotional relationship. Most men with transvestic fetishism do not seek therapy and there is no indication they should, unless the interest begins to cause harm. Paraphilic transvestites are sufficiently dependent on cross-dressing that it causes distress. Transvestic fetishism is a good example of a paraphilic condition in which the individual symptoms (wearing women's clothing while masturbating or engaging in sexual relations) are not problematic. However, when the sexual interest becomes so pervasive that it interferes with consensual sexual relations, a diagnosis is permissible. Transvestic fetishism is very responsive to treatment with selective serotonergic re-uptake inhibitors prescribed at doses low enough to avoid inhibited orgasm.

Pathologic versus unconventional

While paraphilias are characterized by deviant sexual interests, unconventional interests alone are not sufficient to meet criteria for a true paraphilic condition. This is a persistent source of confusion in two specific situations.

(a) Homosexuality

A primary sexual interest in the same sex (homosexuality) is statistically rare. However, there is nothing about a primary same-sex interest that necessarily leads to harm to anyone. Sexual interest in a woman is no more harmful for a heterosexual man than it is for a lesbian woman. Although homosexuality is statistically and socially unconventional, the absence of inevitable or likely harm excludes same-sexed sexual interest from being paraphilic.

(b) Sadomasochism

Sexual arousal from control (sadism) or from being controlled (masochism) illustrates a second way in which unconventional sexual interests may fail to meet criteria for designation as a paraphilia. While harm is a necessary criterion for paraphilias, it is not sufficient. For example, while many conventional sports involve competition and attempted domination of an opponent, the activity is not primarily sexually motivated. Therefore, although boxing involves the intentional attempt to render an opponent unconscious via infliction of a cerebral concussion (knockout), pugilism is not a paraphilia because it is not primarily sexually motivated.

The converse is also true. Many men and women engage in interactions that are sexually motivated and which involve negotiations about power and control, domination and submission. These themes have become highly organized and regulated within social groups under the general category of 'BDSM' (bondage, domination, submission, sadism, masochism). Publications describing the BDSM 'lifestyle' universally champion the credo: 'safe, sane, and

consensual'. Therefore, men and women who engage in 'BDSM' sexual activities, although they may involve statistically and/or socially unconventional activities, do not meet criteria for any paraphilia disorder. In fact, it is arguable that anyone who is sexually aroused by the idea of engaging in 'safe, sane, and consensual' activities is *less* paraphilic than those with conventional sexual interests who are willing to compromise some of these meritorious criteria in pursuit of conventional sexual interactions. For a more complete discussion of sexual violence and sexual sadism.[1]

Classification

Table 4.11.3.1 consists of a partial list of the over 100 paraphilic disorders described in the literature. Classification of the paraphilias remains controversial. This is due to two issues. The first is that many paraphilias have been assigned names based on Latin or Greek etymology. For example, retifism refers to a paraphilic interest in shoes more commonly known as a 'shoe fetish' while 'renifleurs' are individuals with sexual arousal from the smell of urine. More complete listings of paraphilic disorders has been

Table 4.11.3.1 Paraphilic sexual disorders

Paraphilia	DSM- IV TR	ICD-10	Essential feature: persistent sexual arousal towards	Comments
Acrotomophilia	302.9	F65.9	Amputees	
Apotemnophilia	302.9	F65.9	Being an amputee	
Asphyxiophilia	302.9	F65.9	Being asphyxiated	Also known as 'autoerotic asphyxia'
Biastophilia	302.9	F65.9	Non-consensual adult intercourse	Also known as paraphilic rapism or raptophilia
Exhibitionism	302.4	F65.2	Exposure to strangers	
Fetishism	302.81	F65.0	Inanimate objects	Not vibrators
Frotteurism	302.89	F65.8	Rubbing groin without consent	ICD has no specific listing
Mysophilia	302.9	F65.9	'Filth'	Typically involving 'soiled' (worn) panties
Necrophilia	302.9	F65.9	Corpses	
Paedophilia	302.2	F65.4	Children	ICD does not differentiate
Attraction				
Males				
Females				
Both				
Exclusivity				
Incest only				
Exclusive				
Non-exclusive				
Polyembolokoilamania	302.9	F65.9	Insertion of objects	Associated with Smith McGinnis syndrome. (Not clearly paraphilic)
Scoptic syndrome	302.9	F65.9	Being castrated	
Scoptophilia	302.9	F65.9	Consensual viewing	Paraphilic only if problematic
Sexual masochism	302.83	F65.5	Loss of control	ICD combines into Sadomasochism
Sexual sadism	302.84	F65.5	Non-consensual control	ICD combines into sadomasochism
Somnophilia	302.9	F65.9	sleeping sexual partner	
Telephone scatalogia	302.9	F65.9	Obscene phone calls	
Transvestic fetishism with gender dysphoria	302.3	F65.1	Wearing clothes of the opposite sex	ICD does not subclassify
Urophilia	302.9	F65.9	Urine	
Voyeurism	302.82	F65.3	Spying	
Paraphilia NOS	302.9	F65.9	Paraphilias not otherwise specified	ICD: Disorder of sexual preference unspecified
Other disorders of sexual preference		F65.8	Other paraphilic disorders	

published (c.f. Love, 1999). In addition, many of the paraphilias involve sexual interest in the characteristics of the sexual partner(s). Often some interest in assuming the same characteristics is evident and receives a unique name. The most obvious example is sado-masochism which the DSM classification divides into sadism and masochism while in the ICD classification the two complimentary conditions are combined.

The second problematic diagnostic issue in the classification of the paraphilias concerns the need to describe both unconventional sexual behaviours and problematic sexual behaviours. For example, while sexual arousal from cross-dressing is unconventional, it technically does not meet criteria for transvestic fetishism unless it causes distress. In the case of paraphilias involving criminal interests (e.g. paedophilia) issues arise if a person reports persistent sexual interest in children but no distress or wish to act on the paedophilic interest. Newer diagnostic criteria likely will address this issue.

Diagnosis and differential diagnosis

Similar to most psychiatric conditions, paraphilic disorders are diagnosed primarily on the basis of self-reported symptoms. Paraphilias differ from most other psychiatric disorders in two ways: (i) many paraphilias involve illegal interests and (ii) objective measures of the primary criteria (in this case sexual interest) are available.

Illegal sexual interests

Paraphilic interests do not necessarily lead to illegal activities, and vice versa. Therefore, 'Not all paedophiles are child molesters and not all child molesters are paedophiles'.

With few exceptions, individuals with paraphilic interests not only know they have abnormal sexual interests but also wish they could replace them with 'normal' ones. Many confuse fantasy with reality, thinking that illegal sexual interests are equivalent to having committed a sex crime. A major issue in the diagnosis of paraphilic disorders is distinguishing between legal and psychiatric concerns (see Management section below for further details).

In addition to legal issues, clinicians should also consider several other diagnostic issues:

(a) False accusations

At one time accusations by children of sexual assault by adults were considered to be almost certainly true since it was assumed that children could not know about sex. A typical assertion would be that a child could not possibly describe acts such as sexual intercourse or ejaculation unless they had been sexually assaulted. Clearly this was before the widespread availability of pornographic videos, DVD's, cable TV networks, and the Internet.

Beginning in the 1990s, adults began to report they had been sexually abused as children but had only recently recovered their memories of the assault. In part this trend seems to have been due to two factors: the decision in the United States to reset the time at which the statute of limitations required a sexual offence to be reported to the time at which the offence was recalled; and the believe that failure to recall sexual abuse was a sign that it had occurred.

(b) False confessions

While less frequent, false reports of paraphilic interests have also been described.[2] The most frequent presentation of false paraphilic symptoms takes the form of a man or woman with depression who reports obsessions involving often exceptionally troubling sex crimes. While a detailed phenomenologic examination of this phenomenon has not been published, several characteristics are typical. The individual often has a history of a mood disorder or is in circumstances in which affective disorders are more likely (e.g. post-partum). The sexual obsession typically involves children to whom the patient has access (it is rare for the patient to report spontaneous fantasies of sexual interactions with unknown children). Most importantly, the fantasies are extremely ego-dystonic. Asked if they ever masturbate to their paraphilic fantasies, they typically respond with horror and, unlike those with true paraphilias, often describe self-loathing indicative of a change in self-esteem due to depression. A danger of false confessions or admission of false paraphilic interests has also been noted in men and women with intellectual disability.

(c) Co-morbid conditions

People rarely seek treatment on their own specifically for paraphilic disorders. This is due to unfortunately widespread false beliefs that (i) there are no effective treatments for paraphilias, (ii) embarrassment about discussing paraphilic symptoms, and (iii) in the case of paedophilia, the mistaken belief that reporting a sexual interest in children necessarily requires that the patient be reported to the police (please see Management below for more comments on this problem). Since paraphilias themselves rarely motivate helpseeking, clinicians should include other conditions in the differential diagnoses both as alternative explanations for the problem and as co-morbid conditions that may be present in addition to the paraphilia. The most frequent of these are mood disorders, substance abuse problems including alcohol, marital disorder, and legal problems.

Less common are organic disorders including brain injuries.[3] Surprisingly, given the importance of sex hormones in the development and expression of sexual characteristics, endocrine disorders affecting the sex hormones are rarely implicated. This may be because testosterone in men with normal or elevated hormone levels are more closely associated with violence and aggression than with alterations in the direction of sexual interest.[1] One exception is hypogonadism associated with Klinefelter's syndrome. In some men with Klinefelter's syndrome, paraphilic problems become apparent when testosterone is prescribed to correct hypogonadism. In those men with Klinefelter's syndrome and paraphilic interests, addition of testosterone appears to unmask rather than cause previously unexpressed paraphilic conditions.

A more controversial question involves a possible association between paraphilias and intellectual disability. Some research has supported the hypothesis that, as a group, men with paedophilia have below average intelligence. However, alternative explanations are possible. For example, most men with paedophilia come to attention when they are arrested. The fact that men with intellectual disability are more likely to be arrested and are over-represented in the criminal justice system may skew the data. Those who live in supervised housing are also more likely to have private activities not only discovered by staff but also labelled by staff as deviant. In addition, men with intellectual disability frequently have impairments in social skills that can certainly contribute to problematic sexual behaviours independent of paraphilic interests. This phenomenon has been described as 'counterfeit deviance'.[4]

One meta-analytic study supporting an association between paedophilia and intellectual disability found the mean I.Q. of sex offenders to be only five I.Q. points below the mean I.Q. of non-sexual offenders.[5] While cognitive ability is important in determining level of risk and in planning treatment (see below) it would be a diagnostic mistake to confirm or refute a diagnosis of paedophilia on the basis of intelligence.

A further area of controversy involves the question of whether having one paraphilia predisposes to having other paraphilias? The answer depends on whether the assessor is a 'lumper' or a 'splitter'. John Money viewed paraphilias as 'vandalized lovemaps' that were unique. He argued that a paedophile might begin by spying on children, then surreptitiously touching them, then engaging in sexual relations. It was his view that it was more accurate to label the disorder as paedophilia (since this explains the motivation behind the varied behaviours) as opposed to making a diagnosis of voyeurism, frotteurism, and paedophilia. Clearly both approaches have strengths and weaknesses. Most important is to be aware of both diagnostic methods when evaluating incidence or prevalence reports.

Epidemiology

Prevalence of paraphilic disorders

Any discussion of the number of people with paraphilic disorders in the population must begin with a series of caveats. The most important is the fact that the majority of the information available is derived from studies of men convicted of sex crimes. This is a significant problem since not all paraphilias are associated with sex crimes. The problem is compounded by the fact that many paraphilic disorders remain undiagnosed either because assessment was never requested, clinicians did not gather sufficient information, or because the person with the paraphilic disorder was unwilling or unable to disclose the symptoms. Further degrees of confusion and subsequent dispute are added by inconsistent application of existing diagnostic criteria (for example confusing child molesters with paedophiles) or by differing opinions about whether or not to subdivide paraphilic disorders (e.g. diagnosing a person who lures children into sexual activity by exposing to them as a paedophile or as both a paedophile and an exhibitionist). To date, insufficient attention has been paid to the importance of precise definitions of what is being measured, the difference between point and period prevalence, and the potentially significant differences attributable to independent characteristics of the populations being studied. For example, a report on the incidence of 'sexual sadism' based on a point prevalence study of sexual assault of women and children in a country in which war is being waged, while important, has little to do with an analysis of the period prevalence of sexual sadism in, for example, North America. There is also an widespread but unwarranted assumption that studies based on criminal populations can be easily generalized to other populations.

Fortunately, with these above caveats in mind, a significant resource to answer epidemiologic questions is now available both in text form and, more importantly, in the form of a constantly updated Internet Web site: http://www.kinseyinstitute.org/ccies/. This Web site, currently under development and hosted on the Kinsey Institute web page, provides free access to reports by noted sexologists on sexual behaviours in 60 countries and six continents. Included in the chapters on most countries are sections dealing with both paraphilic disorders and 'unconventional sexual behaviours'. This is important since different cultures may place different significance on sexual behaviours both in public and private. The fact that each chapter is multi-authored by sexologists who live in the country being described also likely adds to the credibility of the information.

From perusal of the information available several statements about the epidemiology of paraphilic disorders can be made with reasonable confidence.

(a) Men are more likely than women to be arrested for sexually motivated crimes

Most (but not all) illegal activities are non-consensual. Those that are sexually motivated have a high likelihood of being associated with a paraphilia. Data to support this observation is derived primarily from review of the unequal ratio of men and women convicted of sex crimes. While there are increasing numbers of women (especially adolescent females) being convicted of child sexual abuse, men are still the vast majority. From a criminologic perspective men seem more willing to commit crimes of all types, especially those that involve confrontation (verbal, physical, and sexual). This is of significance since two widely employed actuarial risk assessment instruments, the Violence Risk Appraisal Guide (VRAG) and Sex Offender Risk Appraisal Guide (SORAG) rely heavily on the Hare Psychopathy Checklist (HPCL) which itself has been associated with criminal activity independent of sexual interest. This may explain why some researchers believe that a combination of high scores on the HPCL combined with deviant scores on phallometric testing are associated with high risk of re-offence (either violent and sexual) (for more information please see the Hare Web site listed below).

(b) With the exception of internet-related sex crimes, the frequency of sex crimes of all types are on the decline

This welcome finding has been reviewed extensively elsewhere.[6] It is important to note that while this trend of decreasing frequencies of sex crimes excludes countries in the midst of war or major political and social upheaval, the trend is occurring worldwide. Unfortunately the reason for this trend is unknown. One controversial explanation is a wider availability of pornographic materials, beginning with videotapes in the 1980s and now exploding with the Internet. One study noted, during a time of increased availability of pornographic materials, an 85 per cent decrease in numbers of juvenile offenders in Japan from 1803 in 1972 to 264 in 1995.[7] The increase in Internet-related crimes combined with an apparent decrease in other types of sex crimes invites the unproven speculation that one may be substituting for the other.

(c) Paraphilic disorders are not new

A final important point to be made about the epidemiology of paraphilic disorders is that they are not new. Historic texts on the topic clearly describe not only sex crimes but also the same phenomenologic characteristics seen by clinicians today. If there is a change, it is towards increasingly earlier detection of paraphilic behaviours, not only at a younger age,[8] but also before criminal acts have been committed.

Table 4.11.3.2 summarizes generally accepted prevalence estimates for the DSM-IVTR paraphilias.

Table 4.11.3.2 Frequency/prevalance of paraphilias

Paraphilia	Prevalence/frequency	Comments
Exhibitionism	No reliable data	40–60% of females report having been exposed to Evidence suggests a decrease in frequency of exhibitionism after age 40
Fetishism	No reliable data	Depending on population studied, rates range from 0.8% to 18% of men
Frotteurism	No reliable general population data	Only paraphilia claimed to decrease in frequency after age 25 (DSM-IV-TR p. 570)
Paedophilia	Frequency: 300 000 abused children per year in the USA	1988 data; does not account for repeat offences
Sexual sadism	3% to 20% of general population	Data do not distinguish between criminal and non-criminal sexual interests
Sexual masochism	5% to 10% of general population	Data does not distinguish between criminal and non-criminal sexual interests
Transvestic fetishism	1% of men	True prevalence unknown in part due to idiosyncratic diagnostic criteria
Voyeurism	No reliable data	Most studies of voyeurism involve offenders with co-morbid paraphilic interests

Aetiology

Like most psychiatric disorders, the ultimate causes of paraphilic disorders are unknown. Like most groups of psychiatric disorders, they undoubtedly have multiple contributing factors.

Four major explanatory perspectives have been identified: 'disease', 'behavioural', 'dimensional', and 'life story'.[9] Each perspective has had advocates that can be traced to the beginning of the twentieth century.

The disease perspective

The disease perspective is perhaps the most familiar to physicians since it is based upon an attempt to combine signs and symptoms into syndromes or disorders via pathophysiologic mechanisms.

In 1886 Krafft-Ebing published *Psychopathia Sexualis: A Medico-forensic Study* in which he described a large series of patients with a variety of sexual disorders, whom he had examined in his forensic psychiatry practice.[10] Using a disease perspective he advanced the hypothesis that masturbation caused a physiologic imbalance that was a major causal factor in development of sexual deviancy. Krafft-Ebing was widely criticized for his acceptance and perpetuation of the degeneration theory of masturbation (the now discarded theory that masturbation itself could cause progressive degrees of physiologic harm leading to increasingly severe psychopathology), and for his failure to clearly differentiate between extreme and mild forms of sexual deviancy.

While *Psychopathia Sexualis* is now considered a landmark text in human sexuality, its acceptance was limited because it was published at a time when other etiologic explanations for the paraphilias were becoming important. One criticism of Krafft-Ebing's disease perspective was his tendency to focus on illness rather than wellness or normality. In this context, Brautigam's criticism of Krafft-Ebing's *Psychopathia Sexualis* foreshadows current criticisms of etiologic theories of the paraphilias that rely on the disease perspective:

> This first great and distinguished complete presentation and inventory of that field has the character of a large catalogue of perversions. In a picture book-like series are offered the most monstrous cases of his time and history, particularly cases collected by Krafft-Ebing himself as a widely sought medico-legal consultant. The perversions are described in their most extreme forms. This collection of brutal necrophiliacs, anthropophages, sexual murderers,and sodomites, of cunning and cultured sadists, masochists, and transvestites has in its degree of deviation never been surpassed. By this extreme presentation Krafft-Ebing has moved sexual disorders away from general sexuality.[11]

Magnus Hirschfield was a contemporary of Krafft-Ebing who also employed a disease perspective in an attempt to identify abnormal pathophysiology in individuals with identified sexual problems. Although he is best known for his studies of castrated males and for his emphasis on the importance of hormones on sexual behaviour, Hirschfield also drew an important distinction between the simple description of observed behaviours and proof of their aetiology. His argument that describing a behaviour was not sufficient to explain its cause led him to distinguish between homosexuality, transsexualism, and fetishistic transvestism, in which the same behaviour (cross-dressing) could be shown to have different motivations and therefore presumably different causes.[12] His observation that sexual orientation and behaviour may have variable determinants was important since it emphasized the need to look for underlying causes of behaviour from a disease perspective while at the same time opening the door for collaboration with behavioural researchers.

Behavioural perspective

Although Albert Moll felt that sexual disorders could be treated with 'association therapy' (a precursor to modern behaviour modification therapy), he felt learning alone could not account for all sexual deviations:

> Were a single sexual experience, and, indeed, the first sexual experience to induce a lasting association between sex drive and the object of the first sexual experience, then we would have to find sexual perversion everywhere. Where are there to be found people who initially satisfied their sexual impulse in a normal manner?[13]

By extending consideration of sexual development from childhood to adulthood, Moll was able to answer Brautigam's criticism of Krafft-Ebing's research by studying normal as well as abnormal sexuality.

Albert Moll and Alfred Binet, used behavioural perspectives to study sexuality by directing attention to the associations between behaviours and their reinforcers. Binet re-examined the case histories of Krafft-Ebing's patients and argued that sexual deviations which had been presumed to be caused by disease or degeneration could have been caused by learned associations. He noted that many of the reported cases he studied also had 'chance associations' that could explain the development of the sexual deviation. These observations implied that, given a specific set of reinforced

experiences, any individual could become paraphilic. The proposition that all people could potentially acquire paraphilias if they were unfortunate enough to have been exposed to the necessary abnormal formative experiences was more fully developed by investigators using a dimensional perspective.

Dimensional perspective

The dimensional perspective is characterized by an avoidance of rigid categorical classifications in favour of continuous descriptors. Variations in sexual interests, including paraphilic interests, are explained as statistical extremes of normal behaviour without necessarily implying that a disease process is present. From a dimensional perspective, paedophilia would be understood as an extreme variation of the widespread tendency to equate youth with sexual attractiveness. The work of Haveloch Ellis is a good example of this approach to sex research. He is most well known for his six volume *Studies in The Psychology of Sex*.[14] A major theme in Ellis' work is the avoidance of a disease perspective as the sole explanation for sexual deviations. Instead of paraphilic disorders, he focused primarily on homosexuality and suggested that homosexuality could be 'latent'. Since degree of 'latency' is a continuous variable it was possible to consider homosexuality as a dimension rather than a disease. This dimensional perspective was later exploited by Kinsey[15] who developed his famous Kinsey scale of sexual orientation that rated men and women on a six point scale. Both Ellis and Kinsey shifted attention from the differences between homosexuals and heterosexuals to their similarities. In this way their work complemented research using disease or behavioural perspectives as well as the work of investigators using a fourth perspective, which focused primarily on the individual's 'life story'.

Life-story perspective

The life-story perspective is characterized by a search for the 'meaning' behind behaviour. This perspective appeals to the self-experienced aspect of life, so life-story perspectives tend to be very compelling and persuasive. For example, in North America, it is rare to find a man with transvestic fetishism that does not recall being dressed as a girl for Halloween. A problem with this approach is that it is often difficult to determine which 'story' is the correct one, or even if a single meaningful connection can be found. For example, there is no evidence that men with transvestic fetishism are more likely to have been dressed as girls when they were children than were other men. Sigmund Freud often used sexual motives to construct a life story that was difficult to disprove. Freud's research method consisted chiefly of interviewing patients and interpreting recurring themes in literature and art. While this approach may seem highly susceptible to bias, it has been surprisingly successful, not only for Freud but for other researchers who have adopted this method of direct interview combined with longitudinal follow-up, to understand the meanings of sexual acts and decisions. The explanations that individuals themselves develop to explain their behaviours are often as important and enlightening therapeutically as their 'true' causes.

Integration of the four perspectives

While each of the four described perspectives provide a unique basis on which to base explanatory theories about the origins of paraphilic disorders, none is mutually exclusive. In the twentieth century, some behaviourists began to acknowledge the importance of non-observable factors such as 'instinct'[16] and later, 'motivation'. Other theorists,[17] while recognizing the importance of behaviourism, emphasized that the 'motivated behaviours' of sleeping, eating, and mating could not reasonably be reduced to simple stimulus response associations. If motivated behaviours could not be fully explained from a single research perspective perhaps an integration of approaches would be more helpful. A good example of an integrated etiologic theory to explain paraphilias is the one advanced by John Money who theorized that all children are born with the potential to develop a full range of sexual interests analogous to the observation that all healthy children at the time of birth are capable of learning to speak any human language. Which language (and by analogy which sexual interests) each child eventually expresses is determined by learning during critical periods of neurologic development.

From extensive research involving patients with genetic and endocrine disorders that interfered with normal anatomic and physiologic sexual development, he theorized that sometime before the onset of puberty, a 'lovemap' was established. He defined lovemap as: 'a developmental representation or template, synchronously functional in the mind and the brain, depicting the idealized lover, the idealized love affair, and the idealized programme of sexuoerotic activity with that lover, projected in imagery and ideation, or in actual performance'.[18] He hypothesized that an individual's lovemap became 'neurologically embedded' or 'imprinted', analogous to the way an individual's native language becomes a 'native tongue'. He believed that each person has a single lovemap (analogous to having a single native language or 'mother tongue') but that each person may never be fully aware of the true nature and details of the lovemap (analogous to not learning the full vocabulary of grammar of a native language). Paraphilias represented what he termed 'vandalized' lovemaps resulting from an abnormal experience during the 'critical period' during which lovemaps are formed.

Course and prognosis

While the incidence of paraphilias (especially those that involve criminal activities) in men is at least 10 times the incidence in women,[19] the majority of both males and females do not develop paraphilias. In addition, unlike sexual orientation, for which there is some evidence of important genetic or at least prenatal influences,[20] and excluding a single retrospective report of possible familial co-morbidity,[21] there is no current evidence of any prenatal factors that cause paraphilic disorders. Similarly the hypothesis that being the victim of sexual abuse predisposes victims to become sex offenders has also been challenged.[22] There is an increasing recognition of the fact that adolescents are capable of committing sex crimes.[8] This edited book concluded that, 'approximately 20 per cent of all rapes and between 30 per cent and 50 per cent of child molestations are perpetrated by adolescent males'. The increasing number of facilities designed to assess and treat juvenile sex offenders, male and female, supports self-report descriptions of paraphilic behaviours beginning in adolescence.

Most crimes (both sexual and non-sexual) are committed by young adult males. One problem in assessing the literature on the frequency of paraphilic behaviours in this age group is the frequent failure to distinguish between current paraphilic acts

and those that are recalled. For example, it is not uncommon for a middle-aged man with exhibitionism to recall frequent exhibitionistic activities from his youth[2] but there is no reason to believe that the recollections of the sexual exploits of exhibitionists are any more reliable than the recollections of non-paraphilic men.

To summarize, it is often assumed that anyone who has a paraphilic interest has acted on it. In fact, the DSM-IV diagnostic criteria B requires that the interest has been acted upon or at least caused harm to someone. While cases have been described in which a person engaged in sexual activity without awareness (e.g. engaging in sexual acts while asleep),[23] for the most part, thought precedes action. In fact, it is arguable that a person who fantasizes about paraphilic activities is more paraphilic than one who commits a paraphilic act while fantasizing about a non-paraphilic activity.

Most paraphilic thoughts begin around the time of puberty. If the 'vandalized lovemap' explanation of paraphilias is correct, faulty development of sexual interest likely occurs prior to puberty but is not expressed until there is sufficient increase in sex drive for it to be manifested, first as fantasy and later, by action.

Prognosis is an area of considerable controversy. However, accumulated evidence indicates that the majority of convicted sex offenders do not re-offend (likely fewer that 15 per cent). In addition, evidence indicates that treatments are improving in efficacy (see below).

Evaluation of treatments

In this section 'treatment' refers to intervention with intent to reduce the frequency of unwanted paraphilic symptoms. Studies on the treatment of paraphilic disorders necessarily include participants with diagnosed paraphilias who have not only sought treatment but who have also volunteered for a treatment and have at least started the treatment under study. This represents a group that for obvious reasons may be unrepresentative of the true paraphilic population, the majority of whom likely never seek treatment.

Treatment recommendations should be individualized across paraphilic and co-morbid disorders and to account for individual variation. For example, the treatment approach for an exhibitionist with anti-social personality disorder and heroin dependency will be very different from the treatment of a woman with paedophilia or an adolescent with intellectual disability and transvestic fetishism.

In the past half-century there have been three major innovations in the treatment of paraphilic disorders that have led to significant improvement in prognosis. The first of these was the use of anti-androgen medications.

Interventions to reduce testosterone

Surgical castration has shown a high degree of success, at least in terms of reducing recidivism rates in sex offenders, with reported rates of recidivism after 30 years of follow-up as low as 2.2 per cent for convicted rapists. While this is a remarkable success rate, surgery for this purpose has been criticized on ethical grounds and because reversible interventions, in the form of anti-androgen medications have became available. For a review of the efficacy of castration in the treatment of the sex offender.[24]

Anti-androgens administered either by mouth or by intra-muscular injection were first used in the late 1950s as an alternative to surgical castration. The most common oral anti-androgens prescribed for this purpose are cyproterone acetate (Androcur) (CPA) and medroy-progesterone acetate (Provera) (MPA). Both of these medications are also available in a formulation suitable for intra-muscular injection. Reviews of treatment efficacy of both of these medications are also available.[24]

A review of eight studies involving a total of 452 sex offenders who received treatment with MPA for between 1 and 13 years, recidivism ranged from 1 per cent to 17 per cent.[25] Unfortunately, anti-androgen treatment of sex offenders has been a victim of its own success. Because the success rates were so high in open studies, and because the consequences of recidivism are so great, randomized double-blind treatment studies have been difficult to justify from an ethical perspective. Gonadotropin hormone releasing hormone (GnRH) partial analogs significantly reduce serum testosterone by down-regulating receptors in the anterior pituitary resulting in a decrease in luteinizing hormone which in turn decreases production of testosterone by leydig cells in the testes. Reviews of the apparent impressive efficacy of anti-androgens and GnRH analogs are available.[26]

Selective serotonin re-uptake inhibitors (SSRIs)

Numerous reports have confirmed the apparent efficacy of SSRI and related medications in the treatment of men with paraphilic disorders.[27] Two important prescribing issues are important:

(a) There is no evidence that the efficacy of SSRIs in the treatment of paraphilic disorders is due to suppression of sex drive. Many medications that are more effective in reducing sex drive appear to have little effect on paraphilic interest.

(b) There is no evidence that higher doses of SSRIs are more effective than low doses. In fact, if the prescribed SSRI causes inhibited orgasm, this may be counter-therapeutic since there is a tendency for individuals with paraphilic sexual interests to resort to paraphilic fantasies or acts in order to facilitate orgasm.[28,29]

Psychotherapy

The evidence in support and against various psychotherapeutic interventions has recently been reviewed.[30] Most reviews of psychotherapeutic interventions for paraphilic disorders focus on group therapy (the most common intervention in prisons) or individual psychotherapy (most common in private practices). However, other interventions are also important including marital therapy, family therapy, spousal therapy, occupational therapy, and substance abuse therapy.

Treatment of sex offenders based on psychologic interventions were carefully reviewed by a collaborative group using meta-analytic techniques.[31] A total of 43 published studies involving a total of 9454 sex offenders (5078 treated and 4376 untreated) were analysed. While noting methodologic limitations, there were two important findings: (i) sexual recidivism rates were lower in treated groups (12.3 per cent) than in comparison groups (16.8 per cent) and (ii) efficacy of psychologic treatments appear to have improved since the 1970s. The final results of one important study were not included in the Hanson *et al.* meta-analysis. This was a longitudinal study with stratified randomization into a group that received

relapse-prevention group therapy ($n = 167$) or a group that did not ($n = 225$); a third group was matched to the first two groups and consisted of sex offenders who did not volunteer to participate in the study ($n = 220$). Treatment for the first group consisted of 2 years in custody, group relapse-prevention therapy followed by a 1 year mandated programme after release to the community. While results were complicated by a dropout rate in the treatment group of 27 per cent, the third group consisting of 'non-volunteer' controls was found to have the lowest long-term rate of sexual recidivism (19.1 per cent at 12 years follow-up). In comparison, the sub-group that entered therapy but discontinued prematurely had a 35.7 per cent sexual re-offence rate compared to the group that completed the prescribed treatment which had a 21.6 per cent sexual re-offence rate at 12 years follow-up. The final conclusion of this study was that a treatment effect for the cognitive behavioural programme did not produce a significant treatment effect.[32]

The failure to demonstrate the efficacy of 'relapse-prevention' as it was constituted 20 years ago has been regarded by some as a major setback in the field. However, the fact that even in the worst outcome group the majority of sex offenders were not known to have re-offended, the fact that the treatment programme under investigation was 'manualized', and the fact that other important treatment interventions were not employed, makes any conclusion that sex offenders can not be treated unwarranted.

Management

General principles

Summaries of management strategies for individuals with paraphilic disorders and/or sex offence histories are available.[30,33] Specific recommendations for the more commonly encountered paraphilic disorders and for specific paraphilic disorders should also be consulted.[2] An initial approach to the management of paraphilic disorders is summarized in Fig. 4.11.3.1.

Individuals with paraphilic disorders typically are in extreme crisis when they present for treatment. It is important to assist the individual to not only understand that sexual urges are controllable but that sex acts are the person's responsibility. This is often a surprise to people with paraphilias who have lived with the false belief that the difference between themselves and the rest of the world is a lack of will power. It is important to assist in maintaining and establishing a healthy social support system, ideally including family members, spouses, employers, church members, and trusted friends. Group therapy is particularly helpful in assisting to confront cognitive distortions and in demonstrating that others not only do not re-offend but are capable of establishing healthy and fulfilling lives. Medications can be prescribed with the aim of decreasing sexual anxiety and impulsivity (SSRIs), moderating sex drive (anti-androgens), or eliminating sex drive (GNRH

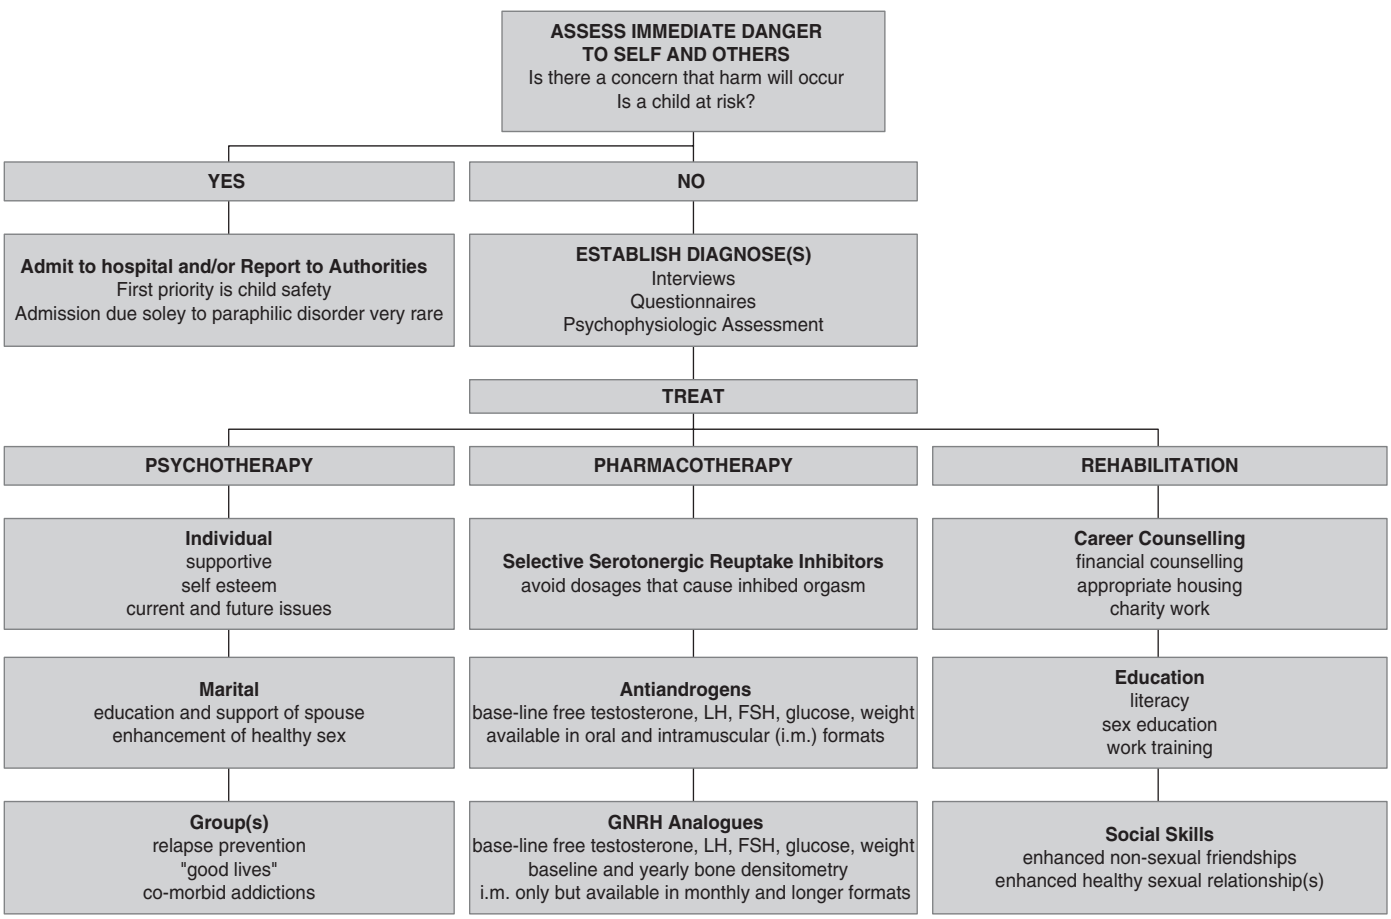

Fig. 4.11.3.1 Management of the paraphilias.

analogues). It is vital, particularly when treating men with paraphilias who have been incarcerated, to assist them in establishing pro-social lifestyles. This includes advice about appropriate work (e.g. avoiding jobs that require contact with children in the case of paedophiles), finding work (some clinics maintain lists of employers willing to hire men they know are in treatment), and ways to spend leisure time in constructive and pro-social ways. A part of the therapy often neglected is the establishment of healthy sexual activities to replace the problematic sexual interests and acts for which therapy was initiated. This frequently involves marital or couple's therapy. Some clinics establish 'spouses' groups to provide independent support, education, and treatment of the spouses of individuals with paraphilias.

In addition, the following general principles are recommended:

(a) Identify for whom you are working

Many paraphilic disorders predispose to unconventional or criminal activities. Most countries now have mandatory reporting requirements for incidents of known or potential sexual abuse of any identifiable child. It is extremely important to establish the limits of confidentiality prior to or at the first meeting. Many clinics post a description of the rules of confidentiality under which they operate. Sometimes it is difficult to be certain for whom one is working. A quick rule of thumb is to ask who is paying for the work and to whom reports will be sent.

(b) Facilitate disclosure

Men and women seeking assessment and treatment for paraphilic disorders almost always think they are the first (and worst) case of their type ever seen. They fear they will be led from the clinic room in handcuffs and be featured on the front page of the following day's newspaper. It is important to dispel these misconceptions not only because it will allow for a more in-depth assessment but also because it is important to dispel a 'me-against-authority' mentality which is common amongst individuals who see themselves as 'outsiders'.

Objective measures of sexual preference (e.g. phallometric testing) are available.[34] Their utility is enhanced if they are used as 'truth facilitators' rather than as 'lie detectors'.[35] While tests based on deception such as surreptitious measurement of time spent viewing pictures are currently widely used, their future utility is questionable since they are valid only if the deception is effective.

Perhaps the greatest truth facilitator is scrupulous adherence to disclosed rules of confidentiality.

(c) Establish what the problem is

Typically, individuals with paraphilic disorders present in crisis. However, the crisis often has only peripheral connection to the paraphilia. For example, a woman may have sexual masochism but seek treatment due to complications arising from major depression or substance abuse. This is true even if she insists that all her problems would end if she could be cured of her masochistic interests. As reviewed above, paraphilic disorders often occur together with other psychiatric, medical, and relationship problems. Clinicians should be wary of limited differential diagnoses, especially those that attribute all problems to a single paraphilia in isolation.

(d) Identify why the patient is seeking treatment now

Most paraphilias begin in childhood or at the time of puberty. However, teenagers rarely self-present for assessment of paraphilic disorders. Therefore, most adults with paraphilic disorders may be assumed to be seeking treatment for a variety of reasons besides having suddenly discovered they have (for example) paedophilia. Frequent motivations include: criminal charges, discovery of problematic behaviours by spouses or family members, and emergence of co-morbid problems such as depression or substance abuse.

For treatment to be successful it is very important to establish what the person seeking treatment thinks is the problem. Failure to do so significantly reduces the likelihood of keeping the person in therapy, establishing a therapeutic relationship, and ultimately the prognosis for a successful outcome.

(e) Avoid one-sided treatment plans

Paraphilic disorders by definition involve an interaction between the most abstract and 'high-level' cognitive processes (sexual fantasies), limbic and sub-cortical neural pathways (sexual arousal patterns), and society. Treatment plans based on single perspectives are unlikely to succeed. Most importantly, it is vital to pay attention to the worldview of the person seeking treatment. While the theory they have may be incorrect, ignoring it is likely to lead to frustration.

(f) Intervene quickly

A common mistake is to assume that because a paraphilia has been present for a long time, that it will take a long time to alleviate the symptoms. Many individuals with paraphilias think they must first review their childhood and all their previous offences before they can think about altering their current problematic behaviours. This is false. On the basis of current evidence, treatment should focus on current and future behaviours with an expectation that sexual behaviours of all types are under voluntary control. Requests to 'taper' problematic sexual behaviours should be dealt with as intentional or unintentional efforts to delay effective intervention.

(g) Be persistent

Successful treatment is not only multi-faceted but above all persistent. A useful strategy is to present treatment as a series of 'experiments' based on feedback about the effectiveness of interventions. Treatment should be presented with the expectation of success. A review of the fact that the majority of outcome studies find that the likelihood of sex offenders to recidivate is less that the likelihood of patients with major depression to have a recurrence of their life-threatening illness, is often an inspiring surprise to people entering therapy.

(h) Be inclusive with treatment

Begin with a thorough assessment and consideration of a complete differential diagnosis. If there are indications of co-morbid problems (e.g. foetal alcohol syndrome, genetic disorders, mood disorders, psychotic disorders, personality disorders, etc.) further investigations and interventions should proceed without delay. Once a diagnosis has been made, all the treatment options should be reviewed with the person seeking treatment (see above). Risks and benefits of treatment options (including the risk of declining treatment) should be thoroughly reviewed. Choice of treatment should be a collaboration between the clinician and person seeking treatment, but ultimately should be informed and voluntary. Typically treatment should include both individual and group psychotherapy. If the person has a sexual partner, couple's therapy is often of assistance. Pharmacologic treatment can include SSRIs

(often more effective at doses used for depression as opposed to the higher doses used for obsessive–compulsive disorder), anti-androgens and/or GnRH analogues. Acceptance of treatment with anti-androgens is increased by explaining that treatment effects are reversible. More information about treatment options is available.[2]

(i) Be optimistic

The frequency of sex offences is dropping. The effectiveness of treatment of sex offenders (who are not necessarily paraphilic) is improving. Sex offender re-offence rates are below 15 per cent. New as well as established treatments are available.

Beyond eliminating criminal and harmful sexual behaviours, a key to successful therapy is the establishment of non-criminal and beneficial sexual interests and behaviours. Remarkably, the literature on treatment of paraphilic disorders almost completely ignores the concept of establishing non-paraphilic sexual behaviours as a treatment goal. This is a mistake. Adult men and women rarely want to 'give up' sex. However, if they are provided with the opportunity to improve their sex lives they frequently become enthusiastic (and successful) participants.

Acknowledgements

Dr Fedoroff gratefully acknowledges Drs J. Bancroft, F. Berlin, J. Bradford, E. Coleman, P. Fagin, R. Rosen, and the late J. Money for their significant influences on his thinking about the paraphilias. However, none should be held responsible for any of the opinions expressed in this chapter.

4.11.4 Gender identity disorder in adults

Richard Green

History

The behavioural phenomenon of transsexualism (now gender identity disorder) is ancient. It has been recorded for centuries and in a broad range of cultures.[1] The historic behavioural picture is comparable to that seen clinically.

In the first half of the twentieth century medical reports of sex reassignment surgery were described in Europe, primarily in Switzerland.[2] In the 1930s a wide-selling biography *Man into Woman* described a Dutch painter who underwent surgical sex reassignment.[3] Contemporary interest in transsexualism surged in 1952 when George Jorgensen, an American, travelled to Denmark and underwent hormonal and surgical treatment to become Christine Jorgensen.[4] The resultant international publicity yielded hundreds of people worldwide applying to the Danish doctors for similar treatment.[5]

By the mid-1960s there were surgeons scattered in several countries performing sex reassignment. Then in the United States at the Johns Hopkins Hospital and the University of Minnesota Hospitals and in the United Kingdom at Charing Cross Hospital, comprehensive sex reassignment programmes commenced. Extensive publicity was given to the Johns Hopkins programme as initially reported in the *New York Times* in 1966. It described the rationale for the programme and in the words of its director, 'if the mind cannot be changed to fit the body, then perhaps we should consider changing the body to fit the mind'.[6]

In 1966 the first professional text on transsexualism was written by Harry Benjamin, widely acknowledged as the 'father of transsexualism'.[7] In 1969 the first multidisciplinary text was edited by the author and John Money.[6] During the past 35 years the recognition of transsexualism, or gender identity disorder, as a treatable condition requiring psychiatric, endocrine, and surgical intervention has been accepted.

Epidemiology

The prevalence of gender identity disorder in adults is estimated from a comprehensive appraisal in the Netherlands at 1 in 10 000 males and 1 in 30 000 females.[8] At nearly all clinical centres the ratio of male-to-female patients ranges from 3:1 to 4:1, in favour of males. In some East European centres the ratio is 1:1 or reversed.[9]

Diagnosis

Diagnostic criteria of gender identity disorder in adults in DSM-IVTR[10] include a stated desire to be the other sex, a desire to live and be treated as the other sex, or the conviction that he or she has the typical feelings and reactions of the other sex. There is a preoccupation for removal of primary and secondary sexual characteristics and for procedures to alter physically the sexual characteristics to simulate the other sex. The condition is not associated with physical intersex. ICD-10 diagnostic criteria are similar but there is no mention of intersex exclusion.[11]

Origins

The search for the origins of transsexualism continues with an increasing bias towards those that are physiological. Some 20 years ago there was a false prophet in the guise of the HY antigen, on the Y chromosome believed to be influential in the development of the testes. A series of male transsexuals were found to be lacking this antigen and the tentative conclusion reached was that its absence resulted in a failure to masculinize the brain in the direction of a male identity.[12] However, the author's collaborative effort to replicate that study was not successful as all the male transsexuals studied appeared to have normal HY antigen.[13]

A more recent finding from the Netherlands implicates the brain region known as the bed nucleus of the stria terminalis. In a series of six male transsexuals studied at post-mortem over a 10-year period the size of the nucleus was comparable to that of typical females and not males.[14] A criticism of this study is that the long-term oestrogen treatment for these males may have altered the size of the nucleus. In response the researchers argue that males treated with anti-male hormone drugs or oestrogen for prostate cancer do not have an alteration in the nucleus size from typical males. However, this treatment may not be comparable to that given to transsexuals. Another criticism is that the sex difference in size of the nucleus does not manifest until early adulthood whereas the symptoms of GID often manifest earlier.

Research with male transsexuals has revealed what might be indirect markers reflecting biological distinctions. In agreement with other researchers' findings that male homosexuals have a greater likelihood of having older brothers,[15] our homosexually oriented male transsexuals also have more older brothers.[16] A theory behind this finding is that there is a progressive immunization with each pregnancy by the pregnant mother against the male foetus reflecting antigenicity of the Y chromosome. This would disrupt typical male development.

A higher ratio of aunts to uncles on the mother's side has also been found in our male transsexuals[17] a finding previously

reported by another researcher for male homosexuals.[18] A theory here is that a semilethal factor has been operant in one generation (against uncles) that in the subsequent generation influences brain development resulting in an atypical behavioural pattern (homosexual or transsexual development). The finding is explainable with genomic imprinting where a gene can be dormant in one generation depending on which parent transmitted it.[17]

We also find that both male and female transsexuals are more often non-right-handed.[19] Hand use preference begins in utero and may reflect hormonal levels or cerebral dysfunction.

For female transsexuals, a series of reports indicates a higher rate of polycystic ovarian disease.[20] Although such women secrete higher levels of androgen than typical females in adulthood, prenatal levels are unstudied. However, nearly all patients with polycystic ovarian disease are not transsexual and most female transsexuals do not have polycystic ovarian disease.

Treatment

There have been no randomized controlled trials of treatment and clinical management has evolved from decades of experience.

Prior to recognition of transsexualism as a disorder deserving medical and psychiatric attention many patients self-mutilated or committed suicide[7] Transsexual patients are helped by sympathetic assessment and intervention. However, transsexuals can be difficult patients to treat. It is a rare disorder in which patients make their own diagnosis, 'I am transsexual', and prescribe their own treatment, 'I want sex-change hormones and surgery'. Patients can be demanding and impatient for the therapist's acquiescence. They may be resentful for having to see a psychiatrist, holding the opinion that the desire for hormonal treatment and surgery should be sufficient, and psychiatric agreement should be unnecessary. Some patients will threaten self-mutilation or suicide if their demands and time schedules for demands are not met. Patients need to know that psychological stability is a key ingredient to successful negotiation of the cross-gender living trial period 'Real Life Experience' (see below) and recommendation for surgery, and that suicidal behaviour is a contraindication to going forward.

The general psychiatrist should take a full psychosexual history with emphasis on the onset and development of the gender dysphoria, attempts at treatment, and the patient's long-term goals and appreciation of the obstacles to be confronted. General psychiatric and medical status needs to be understood. A referral is to be made to a specialist centre.

During the past 30 years medical doctors and psychologists specializing in the treatment of transsexualism have worked to develop effective intervention strategies. Early on there was some optimism that extensive, prolonged psychotherapy could modify the patient's gender identity to conform to the patient's birth sex. However, in the vast majority of cases, this was not possible.

During the past 20 years one project undertaken by the Harry Benjamin International Gender Dysphoria Association, the professional body dedicated to the study and treatment of transsexualism, has been setting an extensive series of requirements for evaluation and treatment of gender identity disordered people. This set of guidelines is known as the *Standards of Care*.[21] Their principal purpose is to assure that people presenting with dissatisfaction continuing to live in the sex role to which they were born undergo comprehensive psychiatric and other medical evaluation and enter into an appropriate treatment programme. The programme includes, in addition to ongoing psychiatric or psychological monitoring, possibly endocrine therapy and, depending on the outcome of the graduated trial period of cross-gender living, possibly sex reassignment surgical procedures. The philosophy of treatment is to do reversible procedures before those that are irreversible. Thus, clothing change, name change, and cross-gender role socialization, would precede endocrine treatment with its gradual somatic changes, followed, in carefully selected cases, by surgical treatment.

The screening and evaluation of patients given the opportunity to demonstrate that they will benefit from cross-gender living, perhaps culminating in surgical treatment, is known as the 'Real Life Experience'. This requires that patients live full-time for at least a year and preferably 2 years in that role. The experience includes high doses of cross-sex hormones and full-time employment or full-time student status in the new role for at least a year. If patients can demonstrate to themselves and mental health experts that they have successfully negotiated the 'Real Life Experience' and are adjusting better in this new gender role, they can be referred for surgery.

Hormonal effects

Response to hormonal treatment is variable. This is particularly notable and potentially problematic for males. As with people born female, breast development spans a continuum. Patients may erroneously believe that more oestrogen will result in greater breast development. They neglect the fact that people born female have quite adequate female hormone production but the limiting factor is tissue response. In addition to breast development, male patients report increased hip and buttock fat, skin softening, and loss of sex drive and erection capacity. Vocal retraining is required and perhaps surgical alteration of the larynx to effect a woman's voice. Facial hair removal is required. Some patients opt for major facial contour reconfiguration, performed by a few cosmetic surgeons.

Androgen treatment to the female results in voice deepening, facial hair growth, general body hair growth, menses cessation, clitoral hypertrophy, and increased sex drive. Testosterone effects are very pronounced. The deepening voice and beard growth and perhaps scalp hair loss can metamorphose the female's appearance dramatically.

Surgery

Genital surgical treatment for the male includes penectomy, orchidectomy, and creation of a neovagina. The neovagina may be created from penile skin, perhaps augmented by other skin, or from a portion of large intestine.[22] The cosmetic result is usually very good. The extent of sexual responsivity with the neovagina is mainly anecdotal. Many patients report the subjective experience of orgasm but describe it in a different form from that experienced prior to surgery as a male. Very few physiological measures of the sexual response cycle have been reported with postoperative transsexual patients.[23]

Female transsexuals undergo bilateral mastectomy, and usually hysterectomy and ovariectomy. Genital surgery is an option taken

by perhaps half because of the limitations of phalloplasty. Two major approaches are utilized. One is creation of a micropenis from the androgen enlarged clitoris with relocation of the urethra to enable micturition while standing. Prosthetic testes can be incorporated into the labia sutured together. The microphallus will not permit vaginal penetration for intercourse but is erotically sensitive.[24] Alternatively, phalloplasty involves major surgical interventions with scarring at donor sites, particularly the arm.[25] The neophallus is not as close cosmetically to a natural penis as some patients want. It can be made more rigid with an inflatable implant and a conduit for urine may be surgically created. A procedure anastomosing a nerve from the arm to that enervating the clitoris offers promise of erotic sensation along some of the neophallus.

Sex reassignment outcome

Follow-up reports on operated transsexuals are generally quite favourable. An early review of several follow-up studies,[26] reported on 283 male-to-female transsexuals. Results were judged satisfactory for 71 per cent, uncertain for 17 per cent, and unsatisfactory for 12 per cent. For 83 female-to-male transsexuals results were judged satisfactory for 81 per cent, uncertain for 13 per cent, and unsatisfactory for 6 per cent. A more recent report considered reassignment successful in 46 of 50 male-to-female transsexuals and successful in all 61 female-to-male transsexuals.[27] In another study, of 55 male-to-female transsexuals, none regretted surgery and none had significant doubts regarding their reassignment status as women. Of 25 female-to-male transsexuals, at least 90 per cent were judged successful.[28] In a review of the English language literature over a 10-year period for operated transsexuals, 90 per cent of male-to-female transsexuals were judged to be satisfactory and 95 per cent of female-to-male transsexuals were similarly judged successful.[29] The criteria for success in some studies include objective measures of psychological and vocational status, in others the criterion is limited to an absence of regret over the reassignment process.

One study is notable because it effected some randomization of treatment conditions.[30] It was reported on 40 male-to-female transsexuals approved for surgery at Charing Cross Hospital, London. As patients qualified for surgery they were randomly assigned to two groups. Half were operated on in 3 months and the other half were kept on a waiting list for about 2 years. All patients completed a standardized assessment at acceptance for surgery and at the end of 2 years. The group that received the earlier surgery showed significant improvement in a range of psychometric measures and maintained employment. The unoperated group showed no improvement in psychological testing and deteriorated in employment.

Family management

Transsexual patients are often married and have children. When possible, the family should become part of the treatment process. Typically relations are strained with the marital partner of the transsexual and divorce is usual. Particularly when children are involved an effort should be made to deal with the feelings of betrayal or abandonment from the transsexual's spouse that contaminate the continuing relationship between transsexual parent and children. Often there is concern by the parents that the patient's transsexualism will impact adversely on the children. There is concern specifically in areas of gender identity of the children and peer group reactions to the knowledge that one of their age mate's parents is transsexual. However, in the author's research of 34 children of transsexuals who were living with or in regular contact with the transsexual parent, there were no instances of gender identity disorder in the children and no instances of peer group alienation that were especially problematic.[31] Children typically have many questions about the transsexual transformation of that parent that can be answered by the clinician, perhaps with the transsexual present.

The third sex

A recent development in the pattern of patients presenting clinically are those with a transgendered identity, popularly known as 'the third sex'. These males or females do not request 'sex change'. Rather, they want, if male, to be demasculinized and, if female, to be defeminized. Thus males may want castration and penectomy but no oestrogen treatment and no vagina, and females may want mastectomy, perhaps hysterectomy, but no androgen treatment and no phallus.

These patients pose a dilemma for clinicians. The crux of patient management for gender identity disorder is the 'Real Life Experience' (see above), including cross-sex hormonal treatment, the prelude to possible surgical alteration. Reversible procedures precede those that are irreversible in this management strategy. But with third-sex patients, no 'Real Life Experience' is possible. They do not have a trial period. Guidelines for testing the rationality and stability of their requests need to evolve from the body of clinicians currently attempting management of this unique population.

Transsexual patient subgroups

Professionals not experienced in the treatment of large numbers of male-to-female transsexual patients are often unaware that a substantial minority, perhaps a third, are not sexually oriented to male partners. Many of these patients have been married and are fathers, and many will be bisexual or remain sexually attracted to females only after surgery and live as lesbian women. A much smaller number of female-to-male transsexuals are sexually attracted to male partners and live as gay men after reassignment surgery.

In addition to the subtypes of transsexuals based on their sexual orientation, some male transsexual patients evolve through a diagnostic phase more closely fitting fetishistic transvestism. These patients have been more masculine in general lifestyle and appearance than other male transsexuals, cross-dressing has been sexually arousing, and they have usually been heterosexually oriented. However, with the passage of time gender dysphoria increases and fetishistic components of cross-dressing diminish or disappear. Many have been sexually aroused by fantasies of themselves as women.[32] They have been termed 'autogynephiles'. There is some evidence that males evolving through a fetishistic cross-dressing phase, presenting as somewhat older at gender identity clinics, have a poorer prognosis after surgery. However, it is primarily the progression through the 'Real Life Experience' that becomes the critical management guideline for patients, irrespective of their background.

Gender identity as a disorder

A growing movement among transsexual people argues for removal of gender identity disorder from the psychiatric and medical lists of disorders or diseases. These advocates argue that their sexual identity is normal male or female and that surgical correction of their anatomical anomaly is all that is required to allow them to live as normal men or women. Their condition is depicted as distinctive from the recognized traditional forms of mental disorder such as schizophrenia or major depression. Furthermore, carrying a psychiatric diagnosis is stigmatizing. One argument for inclusion of transsexualism in the APA diagnostic manual of disorders is that it follows the criteria of other entries, that is subjective distress and social disadvantage. Another considers third-party payment for treatment. It is unlikely that medical insurance carriers, private or governmental, would fund intervention for a non-medical condition.

Additionally, there is objection by some persons with gender identity disorder to being referred to as transsexual. They prefer the designation 'transwoman' for what has been known as male-to-female transsexualism, and 'transman' for female-to-male transsexualism.

Legal issues

Cultural and legal approaches to transsexualism vary widely across nations and cultures. They are beyond the scope of this chapter. However legal issues in the United States and United Kingdom can be summarized as follows.

Part of the 'Real Life Experience' of cross-gender living includes employment in the desired gender role. However, transsexuals may be the object of employment discrimination based on their transsexualism. In the United States, transsexuals were denied federal protection 20 years ago when the court held that the anti-sex discrimination statute protected men and women, but not transsexuals.[33] Finally, in 2004, another federal court extended employment protection.[34] In the United Kingdom, in 1997, a ruling on an English case before the European Court of Justice held that anti-sex discrimination law, to which all European Union members were subject, did include transsexuals. Thus discrimination in employment was illegal.[35]

Changing sex on one's birth certificate can be an important step in the life of the postoperative transsexual. In its absence, the person's legal sex may remain in the preoperative status, and pose obstacles to a full life. Marriage is a key issue. In the United Kingdom, until recently, postoperative transsexuals could not have a new birth certificate issued and change their legal sex. Thus a male-to-female transsexual could not marry a male and a female-to-male transsexual could not marry a female. This changed in a statute enacted in 2004.[36] In the United States most states permit some birth certificate change. However, that change may not be recognized in another state.

4.12.1 Personality disorders: an introductory perspective

Juan J. López-Ibor Jr.

The goal of psychiatry is the study of mental illnesses. In this chapter we consider the degree to which personality disorders can be considered as mental illnesses.

Basic notions

Personality is the quality that makes each one of us both different from others and consistently recognisable throughout our lives. Hence, there are two approaches to study personality. One is transversal, consisting on description of archetypes of human beings. One of the first to take this approach was Theophrastus (372–287/5 BC) who in his book *The Characters*, portrays thirty-two such prototypes. Some of them can be are easily recognized by present-day psychiatrists, for instance those typified by poor impulse control: The offensive man (*bdeluria*), the unsociable man (*authadeia*), the show-off (*alazoneia*) and the slanderer (*kakologia*); by obsessive traits: the superstitious man (*deisidaimonia*) or by paranoid traits: the suspicious man (*apistia*). The corresponding contemporary approach consists of the isolation of psychological traits or dispositions, to describe permanent inclinations to behave in a preset way.

The longitudinal approach to the study of the personality is based on the notion that there is an initial seed that develops through the lifetime. Sir Francis Galton (1822–1911) was among the first to consider the inheritance of individual differences in humans, although for centuries breeders of dogs, horses or bulls for bullfighting, had been selecting animals for mating on to select desired characteristics whether is be hunting, running or fighting.

Twin and developmental studies have been used. For example, The 'New York Longitudinal Study'[1] on infant temperament started in the early 1950s and examined how temperament influences adjustment throughout life. Kagan *et al.*[2] followed up a cohort of babies to age 14-17 years and reported that those who were highly reactive when they were babies were more likely to be 'subdued in unfamiliar situations, to report a sour mood and anxiety over the future and to be more religious'.

There are two key features of personality, one of which is temperament and the other character. The two together constitute personality.

Temperament is the innate predisposition to behave in a particular manner. Historically the concept was part of the theory of the four humours, which had corresponding temperaments: *sanguine* (the individual is led by his own pleasure to live), *choleric* (the individual has a feeling of power and shows it), *melancholic* (the individual is dominated by doubts and ruminations) and *phlegmatic* (the individual lacks any links to life, lives without effort nor pleasure). Current research on the biological basis of personality has renewed the interest in temperament.

Character is a configuration of habits, a disposition, consisting in the actualised aspects acquired through learning and shaped by experience.

Psychiatry and abnormal behaviours

Descriptions of individuals with behavioural characteristics of a negative moral or social value exist in every culture and most societies have established institutions in which the marginalized have been confined, as recorded by Foucault.[3] The distinction between immoral behaviour and mental illness was established in France at the end of the eighteenth century, coinciding with the birth of modern psychiatry. The Marquis de Sade was expelled from the Chârenton Hospital because, in words of the director, 'he is not ill, his only madness is vice'.[3] Pinel (1745–1826) considered that, in the case of the young man who in an attack of rage threw a woman into a well, although his ability to judge was clear and intact and although he presented no delusional ideas, his behaviour was characteristic of a mental patient. Consequently, this murderer was diagnosed as suffering from *manie sans délire* and his madness was classified as **reasoning madness** (*folie raisonnante*).[4] This reasoning is similar to that of Cleckley 150 years later who proposed that the social maladaptation of psychopaths is of such high degree that should considered as the result of an underlying psychotic disturbance, being personality disorders are a *mask of sanity*.[5]

Prichard,[6] defined the concept of moral insanity from which, together with the moral degeneration described by Morel (1809–1873),[7] the modern concepts of psychopathy and personality disorders are derived.

Difficulties in the study of personality disorders

Two factors have prevented the development of scientific knowledge in this field: first the negative evaluation of the concept of moral insanity, and second the dualism inherent in psychopathology.

The stigma of personality disorder

The diagnosis of personality disorder generally implies the idea of intractability and frequently leads to a lack of proper medical care. This attitude is the expression of a negative, moralising, and, according to Tyrer *et al.*,[8] delusional attitude of the doctor towards the patient. Cusack and Malaney[9] posed the question as to whether patients with antisocial personality disorders are 'bad' or 'mad'. They attempted to establish differential criteria in order to show that if patients with an antisocial personality disorder are not 'mad', then they must be considered as 'bad' and therefore must be delivered to the judicial system, after diagnosis and treatment of secondary symptoms. In 1999, the UK Government 1999 introduced a new concept: Dangerous and Severe Personality Disorder (DSPD). This subsequently became a treatment and assessment program for individuals who satisfy three requirements: 1) have a severe disorder of personality, 2) present a significant risk of causing serious physical or psychological harm from which the victim would find it difficult or impossible to recover, and 3) the risk of offending should be functionally linked to the personality disorder.[10, 11]

Dualism in psychopathology

Dualism has been present in psychiatry since its origins as specialty. According to Griesinger:[12]

> *It is time that [mental medicine] should be cultivated as a branch of brain pathology and of [the study of] the nervous system in general, and to apply serious diagnostic methods used in all branches of medicine. . . . Besides this purely medical element, mental medicine has another essential one and which gives a special and proper character to this part of the healing art; it is the psychological study of the aberrations of the intelligence observed in mental illnesses.*

The radical separation between mental-brain illnesses and 'aberrations of intelligence' is fundamental to modern psychopathology. Schneider[13] distinguished between psychoses as pathological conditions of the brain (disease or defective structure) and variations of the psychic way of being. Abnormal personalities, personality disorders, and neurotic disorders belong to the second category.

Schneider[14] defines some **abnormal personalities** in a statistical sense, to describe those individuals whose form of feeling, experience and behaving differs to a certain degree from what is considered to be normal for most individuals in a social group. Some of these are **psychopathic personalities** who, as a result of their abnormality, suffer or make others suffer. It should be stressed that according to Schneider's statistical definition of personality and the dualism of his psychopathological system, the only possible criterion to define a clinical condition in the absence of a brain disease is the suffering, the pathos. Suffering is for Schneider the reason why some people ask for medical care, but not a sufficient criterion for to determine the presence of an illness. Schneider had to add suffering inflicted on others (social suffering) in order to be able to include certain kinds of abnormal personalities characterized by the absence of personal suffering (heartless psychopaths, sociopaths).

It seems acceptable to consider as a patient someone who suffers and asks for clinical care although the criterion for suffering is a weak one when compared with the presence of an illness of an organ. On the contrary, the criterion of induced suffering which characterises some psychopathic personalities, defined following Schneider, is not acceptable in medicine and it is surprising that this has been little criticised. The clue lies in Schneider's definition of personality which *excludes* any biological substrate.[15] The effect of viewing psychopathies as simple variations was to reduce the amount of neurobiological research into the neuroses and personality disorders because they were not considered amenable to natural scientific methods. The study of the personality was left the new psychoanalytical and psychological theories.

Nowadays it is impossible to maintain such a reductionistic perspective, and it is recognised that the morbid nature of personality disorders can be understood through the study of changes in its biological substratum. There are not two kinds of mental disorders, the psychosis which are the consequences of brain illnesses, and the variations of the psychological way of being (neurosis and personality disorders), but two inherent aspects to each disorder. It is essential to consider psychological and psychopathological aspects of psychoses, as well as the brain dysfunction of the variations of the psychic way of being.

Models of personality

The study of personality by the different schools of differential psychology provides a solid background to help to understand the disorders of personality. Unfortunately, these studies have been

conducted from different and sometimes contradictory perspectives, which are summarized in the following sections.

Categorical perspective

The categorical perspective is deep rooted in the psychiatric tradition. Categorical models consider discontinuous personality categories. This type of model is used in DSM-IV[16] and ICD-10[17] because of the need for a specific diagnostic, i.e. a categorical approach.

In modern nosology the categorisation of illness is based on the symptoms present and not on their aetiopathology, and says nothing about the nature of the disorders themselves. In the case of personality disorders, the categorisation does not affirm or deny that they are disorders or illnesses, nor does it indicate where the symptoms differ from non-morbid behaviour patterns.

This approach is supported by the notion of ideal types of Weber (1864- 1920), introduced into psychiatry by Jaspers (1883–1969) and more recently by Schwartz and Wiggins.[18] Ideal types are constructs to understand reality: An ideal type is formed by a unilateral accentuation of one or more perspectives and by the synthesis of a great deal of individual phenomena. A type describes the perfect case. Recently Doerr[19] has argued that the ideal types, when well described, become almost real types.

The experimental approach

The experimental approach looks for general laws on personality and establishes causal relations between personality variables. Wundt (1832–1920) studied the effects of modifications of stimuli on the intensity and quality of the subject's experiences introduced them. Pavlov (1849–1936) studied the conditioning of the responses to stimuli and the experimental neurosis. The behavioural approach to the personality was introduced by Watson (1878–1958) who applied objective methods to the study of human behaviour and to the relationship between stimuli and responses. Hull (1884–1952) expanded behaviourism to include learning, feelings, expectations, achievements, goals and motivations. This led to the notion that the stimulus response relationship is influenced by cognitive processes. Perception, memory, language and other functions influence the processing of information of the surrounding world and the information coming from oneself (*self*). Skinner (1904-1990) created a theory of the operating conditioning, result of a non-adaptative learning. From these perspectives, the personality is viewed as a computer which introduces, stores, transforms and produces information, including the contents of the information as well as the process in itself.[20]

The psychoanalytical approach

Freud (1856-1939)[21] proposed in the course of his life three different models of personality: The first was the speculative neuropsychological model of the *Project of a psychology for neuropsychiatrists* (1897) based on the concepts of psychic energy and psychodynamic. The second was the topographic model of the *The Interpretation of Dreams* (1900) where Freud described the conscious, preconscious and unconscious levels. The third is the structural model of *The Ego and the Id* (1923) and of *Inhibition, Symptoms and Anxiety* (1926) where Freud introduced the notions of the Id, the Ego and the Super-Ego. This last model led to a new perspective, the psychology of the Ego and the description of defence mechanisms which have a strong impact on the study of personality in clinical settings. Defence mechanisms distort reality to adapt the subject to it and to reduce anxiety. Some of them are more normal (promote adaptation to the environment), others are pathological (maladjusted or maladaptative).

The correlational approach

The correlation approach explains the individual differences based on personality traits and applying a dimensional model based on statistical correlation. Karl Pearson (1857–1936), the founder of mathematical statistics introduced the correlation coefficient (correlates of cognitive flair with variables like age, gender, weight, height and so on). Charles E. Spearman (1863–1945) applied to research on the traits of personality, a factorial analysis that groups different qualities around a series of correlational factors or dimensions.

Traits are the basic elements of a personality and individual differences are defined and classified along dimensions. The theoretical assumption is that the structure of personality is common to all individuals; it differs in the different combination of traits. Trait is a disposition to respond in a determined way to a determined situation. Traits characterize persons through brief and precise descriptions on stable ways to behave, and as behaviour is consistent, it is possible to predict behaviours. This approach has paved the way to basic dimensions of individual differences.

Dimensional models

Jung (1875-1961) made the first important contribution to the dimensional concept of the personality, based on the concept of trait or disposition.[22] A trait is a permanent inclination towards behaving in a determinant way. Traits are distributed along dimensions which make it possible to classify individuals according to their personality. The different dimensional models are based on the supposition that we all share the same personality structure, differing in the different combination of the mentioned traits. These models have benefited from the innovative statistic techniques, which allows to group different qualities of the individual character around factors of correlation or dimensions.

This dimensional approach raises several questions. How many traits define personality? Are the traits universal? Do traits relate only to manifest behaviours or are they part of feelings, values or thoughts? The problem of the number of dimensions that define personality led to the search for external validators such as biological, cultural and genetic factors. Eysenck[23] identified there are three basic types of personality: extroversion-introversion, neuroticism and psychoticism, each one including multiple levels of traits. For Eysenck and Eysenck,[24] the concept of arousal level is essential. Every individual has an optimal activation level of specific systems of the central nervous system—the better they feel, the better they will perform. This approach has been developed by many authors including Zuckermann,[25] who described sensation-seeking behaviour, Oreland *et al.*,[26] and Siever and Davis,[27] who proposed new traits and dimensions.

Cloninger[28] initially proposed three dimensions: novelty-seeking, harm avoidance, and reward dependence. Latter, he attempted to overcome the dichotomy between dimensional and categorical models by using four temperamental dimensions (novelty-seeking, harm avoidance, reward dependence, and persistence), which are life-long and stable, and three character dimensions (self-direction,

co-operation, and self-transcendency) which are variable and susceptible to environmental influences and development.[29]

The five-factor model, based on factorial studies and individual differences[30] has been widely accepted. It comprises the personality dimensions openness, conscientiousness, extraversion, agreeableness, and neuroticism, known by the acronym OCEAN. About 40 per cent of individual personality differences can be explained in terms of heredity.[31] In the five-factor model the same proportion does not apply to each factor; openness to experience appears to have the greatest hereditary input, whereas conscientiousness appears to have the least.

Mathematical tools allow recombining the data in order to find higher order factors of the Big Five. Two of them have appeared in many studies: 1) related to the Big Five trait dimensions Agreeableness, Conscientiousness, and Emotional Stability (meta-trait alpha) and 2) the dimensions Extraversion and Intellect (meta-trait beta).[32] Other have found some extra traits to be added to the Big Five, such as honesty-humility.[33]

An interesting approach is lexicographic, which is based on the examination of relations among personality-descriptive adjectives that are indigenous to various languages. They tend to reveal a structure corresponding closely to the Five-Factor Model, with some differences in the nature of the Agreeableness and Emotionality/Neuroticism factors and also in the existence of a sixth factor, Honesty-Humility.[34] This has been found in different languages such a tagalong with some differences (a Filipino extra factor resembled a Negative Valence or Infrequency dimension).[34] A study with college students yielded seven major dimensions; many of the factors were similar to recognized lexical personality factors. Big Five Conscientiousness and Neuroticism were each strongly associated with a single proverb dimension (interpreted as Restraint and Enjoys Life, respectively). Big Five Agreeableness, Extraversion, and Intellect/Imagination were all associated with several proverb dimensions. Agreeableness was most strongly associated with proverb dimensions representing Machiavellian behaviour and strong Group Ties, and both Extraversion and Intellect showed particularly notable associations with an Achievement Striving dimension. The two remaining proverb dimensions, which represented a belief that Life is Fair and an attitude of Cynicism, could not be accounted for by the Big Five.[35]

Critics of this approach have argued that a) little progress has been made in this area, b) structural models have little direct relevance for psychopathology research, c) the principal methodological tool of structural research–factor analysis–is too subjective to yield psychologically meaningful results and 4), some clinically relevant aspects, such as alexithymia or impulsivity, do not appear in the studies on the structure of personality.

Alexithymia positively correlates with Neuroticism (N) and negatively with Extraversion (E) and Openness (O), whereas no significant relations were found with Agreeableness (A) and Conscientiousness (C).[36] Impulsivity. The term impulsive madness was used in German literature and Jaspers[37] put it in relation to nostalgia and displacement. The balance between social and individual norms is related to the origin of mental disorders. Durkheim[38] introduced the concept of **anomia** when describing a particular form of suicide in individuals who perceive that their own norms and values are no longer relevant and that their relation to the community is weak or non-existent. However, the opposite may also occur. Kraus[39] coined the term **hypernomia** for premorbid personality traits of depressive patients, which consist in an exaggerated form of adaptation to social norms. This personality type is the converse of the impulsive madness that can be characterized as **hyponomic**. We have proposed the term **dysnomic** for obsessive patients[40] who show a distorted adaptation to social norms. For example, patients with obsessions and compulsions related to cleanliness usually appear to be extremely dirty because of their fear of contamination and their unrealistic compulsions, which are based more on 'magic' control than on efficient behaviour oriented towards concrete goals.

The common link in the psychopathology of obsessive-compulsive disorders and the group of impulsive disorders experienced by the **impulsivists**[41] is poor control of the impulses, in the sense that novel interior or exterior experiences are not converted into adequate behavioural patterns. Rather, obsessives abandon actions uncompleted and impulsivists behave in a disorganised manner (acting out). In both cases, 'the irrelevant substitutes the relevant'.[42]

Today, the trend is to look for a classification of personality disorder which will be dimensional, either by selecting one of the existing models by developing a common, integrative representation including the important contributions of each of the models.[43]

Models of personality and personality disorders

The ideal goal of a single structural framework to be applied to normal and abnormal personality is not easy to reach. In a study with the Eysenck Personality Questionnaire-Revised (EPQ-R) the three clusters of personality disorders of DSM found equivocal support. Exploratory principal components analysis and confirmatory factor analysis found four broad factors of personality disorder that overlapped with normal personality traits: an asthenic factor related to neuroticism; an antisocial factor associated with psychoticism; an asocial factor linked to introversion-extraversion; and an anankastic (obsessive-compulsive) factor. In spite of this, there is growing agreement about the number and type of broad personality disorder dimensions; similar dimensions may be found in clinical and non-clinical samples, suggesting that those people with personality disorders differ quantitatively rather than qualitatively from others; and there is substantial overlap between normal and abnormal personality dimensions.[44] For Livesley *et al.*,[45] personality disorders are quantitatively extreme expressions of normal personality functioning developed around four factors: Emotional Dysregulation, Dissocial Behaviour, Inhibitedness and Compulsivity. In the same year, the same group published some different results in another study:( ) they found 16 basic dispositional traits (anxiousness, affective lability, callousness, cognitive dysregulation, compulsivity, conduct problems, insecure attachment, intimacy avoidance, narcissism, oppositionality, rejection, restricted expression, social avoidance, stimulus seeking, submissiveness, and suspiciousness) and three higher-order patterns (emotional dysregulation, dissocial behaviour, and inhibitedness).[46]

Markon *et al.*[47] have delineated an integrative hierarchical account of the structure of normal and abnormal personality. This hierarchical structure integrates many Big Trait models proposed

in the literature. Similarly, O'Connor[48] reanalyzing the published studies found high level of support for both theoretically and empirically based representations of the five-factor model approach to personality disorders. The five-factor model personality dimensions of Neuroticism, Extraversion, and Agreeableness are the most apparent in the DSM-III-R conceptualizations of the personality disorders.[49,50] The five-factor model structure is present although with some variance in the current DSM-IV cluster set.[50]

Mulder and Joyce[51] have attempted to construct a simplified system for the classification of personality disorders related to normally distribute human personality characteristics. A four-factor solution of personality disorder symptoms was obtained and they labelled these factors 'the four As': Antisocial, Asocial, Asthenic and Anankastic. The factors related to the four temperament dimensions of the Tridimensional Personality Questionnaire (TPQ), but less closely to Eysenck Personality Questionnaire (EPQ) dimensions. The four factors were similar to those identified in a number of studies using a variety of assessment methods and this lends some credibility to our findings.

The masking of sanity becomes evident in some dissocial, psychopathic and even criminal behaviours that are the expression of underlying disorders. The issue is very relevant because those can be treated. One example is attention deficit hyperactivity disorder (ADHD) which has important forensic implications. For decades there has been an interest in predicting which children will become psychopaths in order to establish primary prevention interventions. Lynam[52] described the fledgling psychopath, characterized by symptoms of hyperactivity-impulsivity-attention problems and conduct problems are at the greatest risk for becoming chronic offenders. Other authors[53,54] have strongly argued against the clinical-forensic utility of tests designed to assess juvenile psychopathy.

The problems of axis II of the diagnostic and statistical manual

There are several reasons in favour of an independent axis for personality disorders. First it is important not to forget personality in the diagnostic process, especially when using symptomatic classifications (DSM-III / IV and ICD-10). Second, personality may be a predisposing factor, or something essential for the response to treatment and for prognosis.[54] Third personality traits are egosyntonic: they include traits that the subject has accepted as an integrative part of him/herself in a progressive way (when compared to axis I disorders and non-psychiatric illnesses which are something 'that occurs').

Seen from a theoretical perspective, personality disorders may be considered as the expression of the personality's functioning, which is essential for patients, be they psychiatric or not.[45]

But there are also reasons to combine Axis I and Axis II. The better a personality disorder is known and the more biological correlations are found in it, the higher the probabilities it has to be moved to Axis I: Epileptic personality (adhesivity, gliscroidy) became long ago organic disorder of the personality, cyclothymic personality became cyclothymia and depressive personality (at least in part), dysthymia in DSM-III. Schizotypal personality is schizotypal disorder in ICD-10 and several studies emphasise the strong relation of borderline personality disorder and mood (affective) disorders.[55]

Although through most of the 20th century, from K. Schneider to DSM-IV, personality disorders and mental illnesses were studied as separate fields, there has been increasing recognition of the substantial overlap of – and comorbidity between – disorders both within and across axes and interest in the joint study of normal and abnormal personality.[56] In comorbid cases, the personality disorder could be a predisposing factor, a consequence, or an attenuated form of the mental disorder, or it could be independent of the mental disorder. The fact that the association between a mental disorder and a personality disorder is not always fortuitous has been shown by the observation that effective treatment of the former can lead to the disappearance of the latter, as has been demonstrated in the treatment of obsessive-compulsive patients with pharmacotherapy and behavioural therapy.[57]

The main difference between mental and personality disorders may be that the latter are early onset variants with a very chronic course. According to the hypothesis of a spectrum of disorders, personality disorders can often be treated by the same method as those applied to the major psychiatric disorders to which they are related. Patients with anxious or avoidant personality disorder may respond to anxiolytic medication, patients with borderline personality disorder may respond to lithium and antidepressives, patients with schizotypal personality disorder may respond to antipsychotic agents, and patients with disorders characterised by poor impulse control may respond to antidepressives with a selective serotonergic action.

The diathesis-stress model

The diathesis-stress model has been used to explain the relationship between personality and mental disorders. Supposedly broad, innate temperament dimensions, sometimes correlated with somatic characteristics such as body type (Kretschmer [1888–1964]), develop and differentiate themselves through both biologically and environmental events into a hierarchical personality trait structure. At their extremes, are risk factors (diatheses) for psychopathology, especially given adverse life experiences (stress). Rosenthal[58] defined this model as an inherent constitutional predisposition which only becomes apparent under the impact of environmental stress.

The onset early in life, the variability of expression dependent on setting, the greater association with more severe disorders and the acceptance as intrinsic components of functioning by most suffering from personality disorders support the notion that they are diatheses rather than disorders.[59]

Personality disorders have been considered as belonging to the spectrum of major psychiatric disorders. However, it must be remembered that external events, such as brain damage (organic personality disorders), or the psychological impact of a catastrophic event may also lead to personality changes. Severe psychiatric disorders may have a repercussion on the personality of the patient, and other illnesses may also have this effect. For example, chronic pain (of organic nature) can be accompanied by a profound personality change (algogenic psychosyndrome). Hypochondria or dissociative symptoms and traits may become relevant only after the patient has suffered an illness, or a problem related to diagnosis or treatment, or a problem involving the patient–physician relationship.

Recent research has focused on the impact of social conditions in the neuroendocrine regulation of the individual, especially

regarding the adaptation to stressful situations. In patients with borderline personality disorder and suicidal impulsive behaviour we have found when compared to the control group, high basal concentrations of cortisol (suggesting a high level of stress) and a very blunted response to the stimulus (suggesting a reduced capacity to respond to external stimulus).[60] A clue to the interpretation of these results lies in the work of Sapolsky,[61] who has studied the adaptation to stress of baboons in the Serengeti savannah in Africa. Males of a lower rank have consistently high concentrations of the stress hormone hydrocortisone in their blood, whereas the concentration is lower in the dominant males. However, in the dominant males hydrocortisone concentrations increase rapidly at times of stress and decrease once the situation is resolved, whereas the lower-order males, who live in a permanent state of stress, are unable to initiate more adaptive resources (increase hydrocortisone secretion) when new stressful events appear. These patterns are the consequence and not the cause of the rank (if the opposite were true, the baboons who were physiologically better able to respond to stressful situations would achieve a higher rank). During periods of revolution, members of the colony hold successively different ranks and, although there is always one dominant animal, the stability of the society is lost and with it the stress-adapted physiology of the dominant males who show prolonged increased hydrocortisone concentrations like the rest of the group. When calm is established again, the normal pattern related to the hierarchical rank of the baboons is restored regardless of what their cortisol secretion pattern was prior to the revolution.

Relational disorders

This model can be applied to the relational disorders or processes. On one side every clinician has the experience of persons whose behavioural problems happen in specific environments (i.e., the family) or in relation to specific persons (i.e., the spouse) while their behaviour is totally normal in the rest of circumstances. Another observation is the case of personality disorders that once beginning to improve after a therapeutic intervention, the whole atmosphere around him or her changes. The patient himself and their relations start to consider that the personality as not a stable and incorrigible set of traits but something that can change for the better. However, it is the influence of child psychiatrists looking for childhood antecedents of mayor psychiatric disorders of adulthood[62] and family therapists that have requested a new diagnostic category to describe these situations.

It has also been claimed that in order to be able to proceed along this line, some problems have to be addressed, although the same may also be present in diagnostic categories accepted in DSM-IV and ICD-10. The main one are: 1) the little consensus on assessment means; 2) the complexity of relational assessment, which results in a lack of well-accepted, evidence-based operational definitions; 3) insufficient empirical testing of relational issues; and 4) the resistance to labeling social difficulties as disorders.[63]

These difficulties can be surmounted if new diagnostic perspectives are implemented. One is the concept of diseases as harmful dysfunctions a view which holds that disorders are harmful failures of biologically selected functions. There are evolutionarily selected functions that depend for their performance on the nature of the interaction between individuals. These relations can fail, even when both individuals are normal, because of mismatches between normal variations. Thus, there are genuine relational dysfunctions that, when harmful, are relational disorders.[64] The Structural Analysis of Social Behavior (SASB) has operationalised interpersonal theory for the research of relational aspects of psychopathology and becoming a useful diagnostic tool.[65]

The research agenda for DSM-V recognizes that the diagnosis of relational disorders is one of the most important gaps in the current DSM-IV.[66] Specific recommendations include developing assessment modules, determining the clinical utility of relational disorders, determining the role of relational disorders in the aetiology and maintenance of individual mental disorders, and considering aspects of relational disorders that might be modulated by individual mental disorders.

Personality disorders vs. personality variants

It is necessary to establish a clear distinction between personality disorders and personality variants, and to view the former as true morbid entities. ICD-10 allows us to differentiate, at least theoretically, personality disorders that appear in the chapter on mental disorders from personalities relevant for medicine in Chapter Z.[67] Personality disorders should be characterised by the presence of symptoms, and relevant personalities by their traits. Symptoms are used as diagnostic criteria in a categorical classification, while psychological traits can be classified according to dimensions.

Personality variants relevant to medicine, although not morbid, play an important role in the aetiopathogenesis of illnesses or are important for prognosis and rehabilitation. The study of the variants of personality also reminds the practitioner of the necessity to identify the uniqueness of the patient's personality.

The frontiers with normal personality are not well explained or justifiable threshold,[68] except for schizotypal disorder and borderline disorder. There are great variations between the different versions of DSM (DSM-III - DSM-III-R) leading in the case of schizotypal disorder to a reduction of prevalence from 11 per cent to 1 per cent.[69]

On the other hand, normal the population also presents maladaptative variants of traits such as: neuroticism, irritability, vulnerability, anxiety, depression, impulsivity, low consciousness, rush, negligence, hedonism, immorality, unreliable, irresponsibility, high antagonism, manipulation, disappointment, exploitation, aggressiveness, cruelty, heartless.

In everyday practice there is a need for categorical approach, essential to define the frontiers of clinical activity, for research, for management and for forensic questions and also of a dimensional approach, to identify functions and its alterations, relevant for interventions with patients. This could be done investigating in new personality models, adopting the multi-axial version of ICD-10[70] (Table 4.12.1.1.), implementing diagnostic system that include a nosographic approach and idiographic perspective[71] or adopting

Table 4.12.1.1 Multiaxial formulation of ICD-10

Axis I	Clinical disorders (DSM-IV axis I, II and III): personality disorders understood as morbid states of the personality
Axis II	Disablement
Axis III	Relevant non morbid circumstances, including variants of the personality (i.e., Type A behaviour) Normal personality traits (i.e.: five factors model)

Table 4.12.1.2 Proposed five axis system (Charney *et al.* 2002)

Axis I: Genotype	Identification of disease-/ symptom-related genes, of resiliency/protective genes and genes related to the therapeutic response and side effects of psychotropic drugs
Axis II: Neurobiological phenotype	Identification of intermediate phenotypes (neuroimaging, cognitive function, emotional regulation) related to genotype and to targeted pharmacotherapy
Axis III: Behavioural phenotype	Range and frequency expressed behaviours associated with genotype, neurobiological phenotype and environment, related to targeted therapies
Axis IV: Environmental modifiers or precipitators	Environmental factors that alter the behavioural and neurobiological phenotype
Axis V: Therapy	Therapeutic options base don the data of axes I to IV

a new multiaxial system[72] (Table 4.12.1.2). Several authors have claimed for a functional psychopathology. Van Praag[73] has recommended a two-tier diagnosis: 1) nosological diagnosis and 2) psychological dysfunctions correlated with biological variables.

The cosmetic of the personality?

Cosmetic or palliative pharmacotherapy is to use a psychotropic agent to make feel better to a person who is not ill. It usually intents to mitigate unwanted or unaccepted personality traits in order to attain a higher order of social normality and acceptability. Kamer[74] has described how a selective serotonin uptake inhibitor used for the treatment of depression and for other psychiatric alterations can remove personality traits in some people. He has considered traits previously considered as an expression of human misery or, in some cases, as the consequence of negative childhood experiences. Kamer even questions whether there could be a 'pandemic' of cosmetic psychopharmacologies which would lead to the disappearance of phenomena such as anguish which are essential for personal realisation in the arts, religion, and creativity. For example, fluoxetine can make non depressed people feel more vital, mentally more alert and become more popular, leading to an increased feeling of wellness. Shyness became a treatable illness when paroxetine was found to improve the symptoms of social phobia and atomoxetine can change the life conditions of adults with a history of ADHD. Most of these cases are probable subthreshold clinical conditions, something which may lead to a change in diagnostic habits, lowering thresholds or modifying criteria. For instance the DSM criteria of suffering or disablement are value loaded, and new values, such as wellbeing may be introduced.

Conclusions

During the last few decades there has been an impressive growth in research and knowledge on personality disorders. There is a strong growing evidence that they are "real" disorders that can be managed in ways similar to the rest of psychiatric disorders. There is also a growing consensus on the need for a new classification able to capture the nuances beyond the rigidity of present nosological systems. There is also a need for a clearer delimitation from normal personality variants something that will have important impacts, for instance in forensic settings or for reimbursement purposes.

4.12.2 Diagnosis and classification of personality disorders

James Reich and Giovanni de Girolamo

Definitions of personality disorders

There has been considerable interest in the study of personality and personality disorder (PD) since early times and in many different cultures. However, as noted by Tyrer *et al.*[1] 'The categorization of personality disorder did not receive any firm support until the time of Schneider'. Schneider[2] regarded abnormal personalities as 'constitutional variants that are highly influenced by personal experiences' and identified 10 specific types or classes of 'psychopathic personality'. The classification system proposed by Schneider has deeply influenced subsequent classification systems[1]: of the 10 types of PD identified by Schneider, eight are closely related to similar types of PD as classified in DSM-III.[3] Many of these categories are also represented in DSM-IV[4] and ICD-10.[5]

Personality is defined in the second edition of the WHO *Lexicon of Psychiatric and Mental Health Terms*[6] as 'The ingrained patterns of thought, feeling, and behaviour characterising an individual's unique lifestyle and mode of adaptation, and resulting from constitutional factors, development, and social experience'. Personality disorders, according to the ICD-10 diagnostic guidelines[5]:

> . . . comprise deeply ingrained and enduring behaviour patterns, manifesting themselves as inflexible responses to a broad range of personal and social situations. They represent either extreme or significant deviations from the way the average individual in a given culture perceives, thinks, feels, and particularly, relates to others. Such behaviour patterns tend to be stable and to encompass multiple domains of behaviour and psychological functioning. They are frequently, but not always, associated with various degrees of subjective distress and problems in social functioning and performance.

For example, a dependent PD in a favourable environment might not cause dysfunction, but nevertheless might be considered a disorder since it is clinically identical to the same disorder that usually causes dysfunction.

DSM-IV[4] defines a PD as 'an enduring pattern of inner experience and behaviour that deviates markedly from the expectations of the individual's culture'. The pattern is manifested in two or more of the following areas: cognition, affectivity, interpersonal functioning, and impulse control. The pattern is inflexible and pervasive across a broad range of situations, has an early onset, is stable and leads to significant distress or impairment.

Personality traits, according to DSM-IV,[4] 'are enduring patterns of perceiving, relating to and thinking about the environment and oneself that are exhibited in a wide range of social and personal contexts. Only when personality traits are inflexible and maladaptive and cause significant functional impairment or subjective distress do they constitute PDs.'

ICD and DSM classifications of personality disorders

Table 4.12.2.1 lists the specific PDs as classified in ICD-9,[7] ICD-10, DSM-IIIR,[8] and DSM-IV.

In the ICD-10 classification, which does not have a multiaxial system for the separate recording of the personality status, PD can be diagnosed together with any other mental disorder, if present. Although a multiaxial system for ICD-10 is being developed, this will not include a separate axis for PDs, as in DSM-IV.

Despite the importance given to behavioural manifestations for the classification and assessment of PDs, personality traits and attitudes are also considered when a diagnosis is made. The ICD-10 diagnostic guidelines subdivide PDs 'according to clusters of traits that correspond to the most frequent or conspicuous behavioural manifestations'. As stressed by Widiger and Frances,[9] the reliance on behavioural indicators can improve inter-rater reliability, which reduces the amount of inferential judgement required for the diagnosis, but it does not ensure that the same diagnosis will be made at different times. Moreover, the diagnosis of a PD cannot be based on a single behaviour, as any given behaviour may have multiple causes (e.g. situational and role factors).

There have been four studies that have explored the diagnostic categories for PDs contained in ICD-10 and compared them with the DSM classification. The first[10] was carried out among 177 American clinicians who found some degree of overlap between the different categories. When the authors compared the diagnostic categories in ICD-10 with those in DSM-IIIR, they found that only anankastic (ICD) and obsessive–compulsive (DSM) PDs showed a high level of correspondence. The second study[11] looked at 52 outpatients and compared DSM-IIIR to ICD-10. It found fair concordance for the diagnosis of 'any PD', but poor agreement for individual PDs; the ICD-10 tended to overdiagnose PDs relative to DSM-IIIR. The third report[12] compared ICD-10 and DSM-IV in 58 patients with panic disorder. There was good agreement for the presence of 'any PD', and a reasonable agreement between individual diagnoses (κ ranged from 0.51 to 0.83.), with a tendency for ICD-10 to overdiagnose PDs relative to DSM-IV. In the fourth study,[13] ICD-10 criteria were found to have satisfactory inter-rater reliability in a sample of homeless adults.

In the American taxonomic system, a multiaxial classification was first introduced in DSM-III. With the development of DSM-IIIR, more than 100 changes in the classification of PDs were introduced compared with DSM-III.[14,15] While the multiaxial and categorical style of classification was maintained, the diagnostic criteria were revised to form a list of symptoms for each PD, of

Table 4.12.2.1 Comparison of different classification systems of personality disorders: ICD-9, ICD-10, DSM-IIIR, and DSM-IV

ICD-9	ICD-10	DSM-III-R	DSM-IV
Paranoid personality disorder	Paranoid personality disorder	Paranoid personality disorder	Paranoid personality disorder
Schizoid personality disorder	Schizoid personality disorder	Schizoid personality disorder	Schizoid personality disorder
Personality disorder with predominantly sociopathic or asocial manifestations	Dissocial personality disorder	Antisocial personality disorder	Antisocial personality disorder
	Emotionally unstable personality disorder:		
Explosive personality disorder	Impulsive type	NA	NA
NA	Borderline type	Borderline personality disorder	Borderline personality disorder
Histrionic personality disorder	Histrionic personality disorder	Histrionic personality disorder	Histrionic personality disorder
Anankastic personality disorder	Anankastic personality disorder	Obsessive-compulsive personality disorder	Obsessive-compulsive personality disorder
NA	Anxious [avoidant] personality disorder	Avoidant personality disorder	Avoidant personality disorder
NA	Dependent personality disorder	Dependent personality disorder	Dependent personality disorder
Affective personality disorder	Other specific personality disorders	Passive-aggressive personality disorder	NA
Asthenic personality disorder		Schizotypal personality disorder	Schizotypal personality disorder
		Narcissistic personality disorder	Narcissistic personality disorder
		Self-defeating personality disorder	NA
		Sadistic personality disorder	NA
			Personality disorder not otherwise specified

which only a certain number were required for a diagnosis to be reached. In DSM-IIIR, each category of PD comprised 7 to 10 criteria, with the presence of four to six criteria required for diagnosis. DSM-IIIR contained 11 PDs (see Table 4.12.2.1), plus two new disorders (self-defeating PD and sadistic PD) that were not included in DSM-III but were considered as diagnostic categories needing further study. As in DSM-III, the 11 PDs were divided into three clusters:

- cluster A (the 'odd' or 'eccentric' cluster), which included paranoid, schizoid, and schizotypal PD;
- cluster B (the 'dramatic' or 'erratic' cluster), which included histrionic, narcissistic, antisocial, and borderline PDs; and
- cluster C (the 'anxious' cluster), which included avoidant, dependent, obsessive–compulsive, and passive–aggressive PDs.

One study in the United States examined changes in personality diagnoses using DSM-III versus DSM-IIIR.[16] For some categories there was a considerable difference in the frequency of diagnosis: for example, there was an 800 per cent increase in the rate of schizoid PD and a 350 per cent increase in the rate of narcissistic PD diagnosed by the clinicians when DSM-IIIR criteria were applied.

DSM-IV was designed to be a conservative evolution from DSM-IIIR; however, some differences in diagnoses between DSM-IIIR and DSM-IV can be expected.[17] In general, the different DSMs should not be considered interchangeable unless there is specific data supporting agreement of a diagnosis across systems. As shown in Table 4.12.2.1, DSM-IV includes 11 PDs as in the DSM-IIIR classification; slight changes were introduced in the diagnostic criteria, and a new category 'PD not otherwise specified' added. Passive–aggressive, self-defeating, and sadistic PDs (provisionally included in DSM-IIIR) were dropped. The overall effect of these changes will be to increase the concordance between the DSM-IV and the ICD-10 classification systems compared with that between DSM-IIIR and ICD-10. DSM-IV also includes the three clusters present in DSM-IIIR.

Similarities differences between ICD-10 and DSM-IV

Table 4.12.2.1 shows that for seven categories of PD (paranoid, schizoid, dissocial/antisocial, histrionic, anankastic/obsessive–compulsive, anxious/avoidant, and dependent), there is a specific correspondence between ICD-10 and DSM-IV. For three categories, there are differences in nomenclature between the two systems; in particular ICD-10 uses the term 'anankastic' instead of 'obsessive–compulsive', to avoid the erroneous implication of an inevitable link between this type of personality and obsessive–compulsive disorder. ICD-10 also uses the term 'dissocial' instead of 'antisocial', to prevent any possible connotation of stigmatization, and the term 'anxious' instead of 'avoidant'. Moreover, while DSM-IV classifies borderline PD as a specific category, ICD-10 includes it as a subcategory of emotionally unstable PD. Narcissistic and passive–aggressive PDs (present in DSM-IV) are included in ICD-10 under the category of 'other specific PDs'. Finally, while DSM-IV includes schizotypal PD as a PD, ICD-10 classifies it in the overall group of 'Schizophrenia, schizotypal and delusional disorders', to highlight the contiguity between this disorder and the schizophrenia group disorders, as shown by genetic and clinical studies. DSM-IV has the category 'Personality disorders not otherwise

specified', while ICD-10 has the category 'Other specific personality disorders'.

Changes in the conceptualization of DSM personality disorders since the last edition of this chapter

Empirical research has advanced in the years following the original chapter in an earlier volume. These changes have impacted our understanding and use of DSM measurement instruments. These changes are that the personality disorders as described by DSM are not as enduring as we once thought. The instruments to measure the DSM PDs have modest agreement at best on the categorical level. Finally these instruments do not seem to adequately fit most of the disorders diagnosed which are diagnosed in the remainder category, 'Personality Disorder NOS'.

1. Research indicating lack of enduring quality of personality disorders.

There has now been considerable research indicating that some aspects of personality are state like. This was a line of research pursued by Reich[18,19] and later confirmed by others.[20] This means that some personality traits may disappear relatively rapidly—the state component. Experienced researchers have also found that even when personality disorders are selected for long-term study by careful methods, significant percentages of these will not be found on retest within a 6 month to several year periods.[21,22]

2. Modest agreement of personality DSM personality disorder instruments.

Research has been fairly consistent from the beginning of DSM instruments that while they may measure aspects of clinical relevance even well-designed instruments of the same design (self-report or semi-structured interview) are compared on categorical diagnoses, the agreements are usually modest at best.[23] (The results improve somewhat when using dimensional measures.) In addition when personality disorders are measured in a clinical population very few fit into the established categories and most wind up in the 'remainder bin' of personality disorder NOS.[24]

3. The problem of chasing changing criteria.

Each time the wording of a questionnaire is changed it can make significant difference in the outcome of the questionnaire or survey even though the changes may seem minor. This means that for every change in a version of the DSM, the DSM personality test developers would theoretically have to do extensive reliability and validity testing all over again. Unfortunately this is a time-consuming and expensive process which is beyond the resources of most DSM test developers. What happens instead is that either they do not update their instrument or update only the questions to conform to the new DSM criteria without doing new validity testing. Although these updated tests may have 'face validity' they (understandably) do not have extensive reliability and validity testing.

4. Conclusions from intervening research on DSM personality instruments.

At the end of the day we are left with the DSM personality measurement instruments being limited by the conceptualizations behind them which may be incorrect. These errors may either by in the enduring nature of the personality disorders and the nature of the proper categories or the nature of the specific criteria for a category. These measures then become good dimensional measures of various aspects of personality pathology and a rough clinical guide for 'disorder'. However, no one should expect that what one of these instruments is measuring is really the same as another. They do, however, conform to the DSM nomenclature.

Categorical versus dimensional styles of classification

In general, researchers involved in the assessment of personality traits tend to use dimensional measures based on normal populations. In contrast, those concerned with personality types and, even more, clinicians concerned with PDs, tend to employ categorical concepts and assessment measures based on these concepts.[15]

Each of the two approaches has specific advantages and disadvantages. The drawbacks of the categorical approach are represented by the difficulty of classifying patients who are at the boundary of different categories or who do not meet the diagnostic criteria for any specific PD, but who still have significant pathology. Other points that should be addressed include the wide variation of symptomatology found within each given category, the need for heterogeneous categories, such as 'mixed' and 'atypical', the need to simplify necessarily complex conditions, the need to define valid cut-off points, and the use of a nominal rather than an ordinal scale.

Those in favour of a dimensional approach argue that PDs differ from normal variations in personality only in terms of degree, and to some extent this is supported by empirical data.[25,26] However, there is evidence that some dimensional models do not account for all of the abnormal personality traits (see discussion on the 'Big five' models below.)

Moreover, it is still unclear whether normal and abnormal personality traits are the same or whether they are qualitatively different. Two main findings seem to support the latter hypothesis: first, normal personality traits are at least moderately heritable, while abnormal personality traits appear less heritable; second, the prevalence rates of PDs found in surveys are much greater than would be expected from the prevalence rates of normal personality traits in the general population. Some researchers[27] have even suggested that an extreme form of a normal personality trait is not necessarily pathological. Although some authors argue that there is no difference between normal and abnormal personality traits,[25] and this is still an area of open inquiry, it does appear more and more likely that there are some abnormal personality traits that differ from normal ones. It is possible that different models may be appropriate in different situations.

1. 'Big Five' personality measures and DSM-IV personality disorders

Since the first edition of this chapter there has been a fair amount of research using the 'big five' personality factors. There is evidence that the big five factors can account for some, but not all of the pathological personality pathology described by the DSM system.[28] However the amount of information also depends on the specific instrument with some with more facets or detail being more able account for aspects of pathological personality. These would be instruments such as the NEO-PI[29] and the five factor model of Cloninger.[30] Also of possible greater utility are dimensional instruments which were designed from the start to measure

abnormal as well as normal personality. These include the Schedule for Non-adaptive and Adaptive Personality (SNAP)[31] and Dimensional Assessment of Personality Pathology (DAPP).[32] Also worth noting is a method by Widiger which combines a five factor self-report with a five factor interview in order to obtain more comprehensive personality information.[33]

2. Other non-DSM personality measures from which DSM PD diagnoses can be derived.

There is one measure of DSM-IV personality which is derived from the interpersonal circumplex model. This is the Wisconsin Personality Disorders Inventory (currently in version IV).[34] Although from a fairly different theoretical perspective from the DSM-IV it does have translations to make some DSM-IV diagnoses.[35]

Another unique approach is the Shedler–Westen Assessment Procedure which does not have a patient interview but rather has a clinician who knows the patient do a Q sort procedure. The process is based on distinguishing personality disorders based on prototypes. This procedure can be translated into DSM personality diagnoses. It tends to create fewer diagnoses because the number of descriptors that can be used is limited by the Q sort procedure.[36]

The Millon Clinical MultiAxial Inventory (now in version three) is a very commonly used personality measure. It is now based on evolutionary theory according to its manual. One of the best validated instruments in data-based terms. Unfortunately this data is mostly published in its own manual and not the journal literature. As the population that the instrument was validated on included some fairly severe disorders it is not clear how well the findings would translate into a less severely ill population.[37]

Assessment methods for personality disorders

Table 4.12.2.2 shows the main methods currently available for assessing all PDs. Additional instruments for assessing specified PDs have also been developed—some of the methods listed are

Table 4.12.2.2 Some commonly used assessment methods for all DSM personality disorders

Name of the instrument	Author(s) [a]	Method of assessment	Number of Questions	Time required (minutes)
Diagnostic Interview for Personality Disorders (DIPD)	Zanarini	Semistructured interview with patient using DSM-IV criteria	398	60–120
Dimensional Assessment of Personality Disorders (DAPP-BQ)	Livesley & Jackson	Dimensional based of normal and abnormal personality. Has components of DSM-IV PDs	290	45
International Personality Disorder Examination (IPDE)	Loranger *et al.*	Semistructured interview with patient using ICD-10 and DSM-IV criteria	537	150
Millon clinical Multiaxial Inventory (MCMI)	Millon	Self-report by patient using DSM-IV criteria	175	20–30
NEO Personality Inventory-Revised (NEO PI-R)	Costa & McRae	Comprehensive measurement of normal and abnormal personality traits.	240	30–40
Personality Assessment Schedule (PAS)	Tyrer *et al.*	Semistructured interview with informant (s) can derive ICD-10 and DSM-IV diagnoses.	24	60
Personality Diagnostic Questionnaire –Revised (PDQ-4)	Hyler *et al.*	Self-report by patient or informant(s) using DSM-IV criteria	99	30
Personality Disorders Interview-IV	Widiger *et al.*	Semistructured interview with patient using DSM-IV criteria	325	60–120
Schedule for Nonadaptive and Adaptive Personality (SNAP)	Clark	Self report by patient using DSM-IV and dimensional criteria	375	30–60
Shedler-Westen Assessment Procedure	Westen & Shedler	Clinician rated Q sort procedure. Gives abnormal traits, symptoms and defences and can generate DSM-IV diagnoses	200	No interview, based of clinician knowledge of client.
Structured Clinical Interview for DSM-IV Personality Disorders (SCID-II)	First & Gibbon	Semistructured interview with patient using DSM-IV criteria	303	60–90
Structured Interview for DSM Personality Disorders-IV (SIPD)	Pfohl *et al.*	Semistructured interview with patient or informant(s) using DSM-III criteria	337	90
Temperament and Character Inventory (TPQ)	Cloninger *et al.*	Self-report by patient. Temperament and Character dimensions.	240	30–40
Wisconsin Personality Disorders Inventory (WISPI)	Klein *et al.*	Self-report by patient using DSM-III-R criteria. Correlated with interpersonal object relation theory.	214	30

[a] For specific references to each instrument please see references.[30, 31, and 33]

new, while others have been revised two or three times.[38,39] The following points related to these methods need to be mentioned.

1 The interview measures have generally shown a satisfactory inter-rater reliability, while test–retest reliability has not been well established. However, three methods do show some evidence of good test–retest reliability—the Personality Assessment Schedule (**PAS**),[40] the International Personality Disorder Examination (**IPDE**),[41] and the Structured Clinical Interview for Personality Disorders (**SCID-II**).[42] Many of the methods have been standardized on psychiatric inpatient or outpatient populations; their applicability in epidemiological community studies is largely unknown.[43,44]

2 The various measures tend not to agree with each other on specific diagnoses.[38,39] A measurement on one standardized instrument is not necessarily the same as the measurement on another.

3 Some authors, mostly developers of interview instruments, have in the past stated that self-report measures are not as valid for the measurement and study of personality as interview measures. These arguments tend to be based on the finding that self-report instruments do not agree well with interview instruments, and that a PD diagnosis cannot be made without a clinical interview. The first argument does not hold water, since none of the interview instruments agree well with each other either. Whether self-report instruments can reliably diagnose a PD (as opposed to personality traits) is an open question. However, dimensional interview instruments have high test–retest reliability (some for as long as 30 years) and have been, and will continue to be, a valuable component of personality research, especially where the focus is on dimensions.[45] Self-report instruments measuring DSM disorders tend to disagree with each other in a similar way to the interview instruments. In conclusion, the instrument chosen for any given clinical or research endeavour should reflect the ability of the individual instrument to meet the specific needs of the project. Most researchers now believe that using a self-report, which may be more sensitive but less specific is a good prelude to a semi-structured interview measure.

4 Standardized testing of personality and clinician impression do not tend be in good agreement. This is due both to the tendency of instruments to report more disorders and for clinicians to use idiosyncratic criteria in their diagnoses.[46,47] Standardized measures are a must, however, if the data is to be used for research or public policy purposes.

5 Most personality measurement instruments are affected by the comorbid presence of a non-personality emotional disorder (Axis I disorder in the DSM system). Some structured interviews try to correct for this by asking patients about times when they were not suffering from an Axis I disorder; however, when the Axis I disorder is chronic, this may be difficult to achieve.[41,42] This problem also affects the ability of questionnaires to differentiate between current Axis I disorders and PDs, as this self-judgement of patients who are suffering from a psychiatric condition is frequently impaired.[41] The PDE, PAS, and SCID-II may be less affected by this problem.

6 There is disagreement among experts about the use of informants. Many authors have argued that, besides the patient, a key informant should also be interviewed, given the likelihood that many patients will not reply reliably to questions about their personality and the possibility that informant ratings will differ substantially from patient ones.[41,48] However, even if an informant is interviewed, it is often unclear which source to use to score the test if the interviewee and informant disagree. This tends to reduce their value. More recent research indicates that informants may be of value if their information is in certain areas that are easily observable to then and then are incorporated into the evaluation process in a standardized way.[49]

7 Discriminant validity refers to the ability of a diagnostic system and measurement system to diagnose non-overlapping disorders. Discriminant validity is not high with the ICD-10 and DSM-IV PDs.[50] This means that it is the rule, rather the exception, that multiple personality diagnoses will be made: some studies have provided evidence of this assumption. For instance, in four studies that examined personality comorbidity in a total of 568 patients, the average percentage of multiple diagnoses was 85 per cent.[51] To what extent this reflects the real coexistence of different disorders—with distinct patterns of symptoms, correlates, and course—or if it is simply the effect of an insufficient discriminant validity of current diagnostic systems has still to be clarified.

4.12.3 Specific types of personality disorder

José Luis Carrasco and Dusica Lecic-Tosevski

Cluster A personality disorders

Paranoid personality disorder

Pervasive suspiciousness, mistrust, hypersensitivity to criticism, and hostility are the essential features of paranoid personality disorder. These individuals live a restricted emotional and interpersonal life because they fear the malevolent intent of others. As a rule, paranoid people are ready to counter-attack, provoking repeated confrontations. In this way, they induce hostility and resentment in others.

The term paranoia may lead to some confusion if it is not properly delimited. Paranoid had been used as an adjective to label various delusional representations or syndromes. Kraepelin[1] differentiated paranoia as a distinct condition characterized by chronic and highly systematized delusional ideas (see Chapter 4.4). Schneider[2] described people with this paranoid personality as fanatic psychopaths, stressing their intensity, and rigidity in confrontation with others. He denied any relationship with paranoia. Freud[3] and other psychoanalysts construed the paranoid character as a pattern of mistrust and feeling of being attacked, based on distortions and externalization of the person's inner world.

Paranoid personality disorder was included in DSM-III with criteria of suspiciousness, mistrust, hypersensitivity, and restricted affectivity. This last criterion does not appear in DSM-IV and ICD-10, since restricted affectivity is neither necessary nor specific for paranoid personalities. Instead, emphasis is placed on mistrust and sensitivity to setbacks. The DSM-IV criteria for paranoid personality disorder are shown in Table 4.12.3.1.

Table 4.12.3.1 DSM-IV diagnostic criteria for paranoid personality disorder

A. A pervasive distrust and suspiciousness of others such that their motives are interpreted as malevolent, beginning by early adulthood and present in a variety of contexts, as indicated by four (or more) of the following
1 Suspects, without sufficient basis, that others are exploiting, harming, or deceiving him or her
2 Is preoccupied with unjustified doubts about the loyalty or trustworthiness of friends or associates
3 Is reluctant to confide in others because of unwarranted fear that the information will be used maliciously against him or her
4 Reads hidden demeaning or threatening meanings into benign remarks or events
5 Persistently bears grudges, i.e. is unforgiving of insults, injuries, or slights
6 Perceives attacks on his or her character or reputation that are not apparent to others and is quick to react angrily or to counterattack
7 Has recurrent suspicions, without justification, regarding fidelity of spouse or sexual partner
B. Does not occur exclusively during the course of Schizophrenia, a Mood Disorder With Psychotic Features, or another Psychotic Disorder and is not due to the direct physiological effects of a general medical condition.

Note If criteria are met prior to the onset of Schizophrenia, add 'Premorbid', e.g. 'Paranoid Personality Disorder (Premorbid)'

(a) Epidemiology

The prevalence of paranoid personality disorder is estimated at about 0.5 to 1 per cent in the general population and at 10 to 20 per cent among psychiatric patients. The disorder is more commonly diagnosed in males.

(b) Aetiology

This personality disorder has a familial relationship with delusional disorders and with schizophrenia,[4] and has been included in the so-called schizophrenic spectrum.[5] Deficits in cortical dopamine activity may be associated with a poor conceptual organization that could in turn be responsible for suspiciousness and distorted interpretations.[6]

Mistrust and lack of confidence may reflect deficits arising in early developmental stages and resulting in a lack of basic self-confidence.[7] Lack of protective care and affective support in childhood could perhaps facilitate the development of paranoid features.

(c) Clinical picture

Paranoid individuals do not often ask for help from psychiatrists. They have no wish to be cured; instead, they believe that they have to be protected from other people's hatred and attacks. Subjects with this personality disorder suspect that others are acting to harm, exploit, or deceive them. These suspections are based not on objective evidence, but on internal conviction and an attempt to find a rational explanation for the supposed wrongs.

Paranoids are reluctant to confide in others; they tend to feel that others are plotting against them, and that the enemy may be found in unexpected places. They do not readily tell others about their suspicions. The disorder may be manifested by irritability, unusual defensive or self-protective behaviours (e.g. locking doors and closing windows and curtains to avoid being spied on, and hiding papers or documents), or emotional detachment.

Paranoid people lack confidence in others. They doubt the loyalty or trustworthiness of friends and partners, and check their behaviour repeatedly for evidence of malevolent intentions. They assume that others are not trustworthy, to the extent that they cannot believe it when friends demonstrate their loyalty. They withhold personal or significant information from friends, fearing that it will be used maliciously against them. They do not form close friendships and are often isolated. When in trouble, paranoids do not expect help from friends or others close to them; instead, they expect to be attacked or ignored.

Many of the suspicious and distrustful attitudes of paranoids are perpetuated by their intense interpersonal sensitivity. They react intensely to any comment or event that may relate to them. Hidden meanings that are demeaning and threatening may be read into benign events or the remarks of others. Unintended errors by colleagues or public servants are taken as deliberate attempts to harm or deceive them. Humorous remarks or jokes may be interpreted as attacks on their character. Paranoids are easily hurt, and their pride is easily damaged by minor critical comments or questioning. They are excessively preoccupied with attacks on their reputation or character, and minor slights may arouse major hostility and a

counter-attack. They bear grudges and harbour hostile feelings for a long time, and are unwilling to forgive the insults, injuries, or slights that they think they have received.[8]

Pathological jealousy is a common presentation of paranoid individuals. They have unreasonable doubts about the loyalty and faithfulness of their partners, based on little or no evidence. They may try to gather trivial and circumstantial facts to justify their beliefs. To avoid betrayal they attempt to gain complete control of intimate relationships, continuously questioning, and challenging partners about their whereabouts and intentions.

The interpersonal world of paranoids is a consequence of their suspiciousness and distrust. They have difficulty in relating to others, especially with close relationships. Hostility is always present and can be manifested as excessive argumentativeness, recurrent complaint and confrontation, or hostile aloofness.[8] Although they may appear rational, unemotional, and cold, the affect of paranoids is labile and oversensitive and they may be hostile, stubborn, and sarcastic. This mixture of secretive, cold, hostile, and sarcastic behaviours often elicits a hostile response in others, which confirms the paranoid person's beliefs.

Paranoids blame others for their shortcomings. They are querulous and quick to counter-attack, so that they may become involved in frequent litigation. Since they do not confide in others, paranoids need self-confidence and a sense of autonomy and independence. They need to control people who might be harmful. While they do not accept criticism, they are highly critical.

One group of paranoids are close to Schneider's 'fanatics'.[2] They have hidden grandiose fantasies of power and negative views of other people, especially those belonging to another group who come to be considered as natural enemies. They simplify issues and avoid any ambiguous perspective. Some form cults or other tightly knit groups with people who share their paranoid belief systems.

(d) Course

Paranoid features may be present in childhood and early adolescence in the form of hypersensitivity, social anxiety, poor peer relationships, and eccentricity. These features sometimes elicit teasing from other children, which in turn may aggravate the paranoid attitudes.

In situations of stress, individuals with paranoid personality disorder may respond with brief psychotic episodes. During these episodes, they may have frank delusional ideas or distorted perceptions. Some paranoid personality disorders are the premorbid state for a delusional disorder or even schizophrenia.

Individuals with this personality disorder may be at increased risk for agoraphobia, obsessive–compulsive disorder, and substance abuse or dependence. This personality disorder is often co-diagnosed with schizoid, schizotypal, narcissistic, and avoidant personality disorders.

(e) Differential diagnosis

Paranoid personality disorder should be distinguished from suspicious attitudes towards examination among immigrants, ethnic groups, or political groups. Members of these groups may display defensive and mistrustful behaviours owing to lack of familiarity with the language or the rules of a society, or in response to perceived neglect or rejection. Their behaviour may elicit further rejection from the majority, thus reinforcing the defensive behaviours.

Paranoid personality disorder is distinguished from delusional disorder, paranoid schizophrenia, and depression with psychotic symptoms, all of which are characterized by periods of persistent psychotic symptoms. Paranoid personality disorder present before the occurrence of these syndromes should be diagnosed as 'premorbid'.

People with schizotypal personality disorder are suspicious, have paranoid ideas, and keep their distance from others. However, they also experience perceptual distortions and magical thinking, and are usually odd and eccentric. Schizoid personality disorder is characterized by aloofness, coldness, and eccentricity, but these individuals usually lack prominent suspiciousness or paranoid ideation. Individuals with **avoidant personality disorder** are hypersensitive and do not confide in others. However, their lack of confidence is based on fear of being embarrassed or found inadequate rather than fear of other people's malicious intentions. Some antisocial behaviour by paranoid individuals originates in a wish for revenge or counter-attack, rather a desire for personal gain as in antisocial personality disorder. Paranoid features are often present in narcissistic individuals who fear that their imperfections could be revealed. The differential diagnosis should be based on the predominance of persistent need of praise versus persistent suspiciousness and distrust.

(f) Treatment

Antidepressant and anxiolytic treatment may be useful for anxiety and depression resulting from a paranoid response to stressful situations. Low-dose antipsychotics may be indicated during brief psychotic episodes or when ideas of reference are present.

Psychological treatment is difficult owing to the lack of insight. The approach is to attempt to gain the patient's confidence, avoiding early confrontation of distorted ideas, followed by a slow gentle attempt at cognitive restructuring.

Schizoid personality disorder

Schizoid personality disorder is characterized by a persistent pattern of social withdrawal. Schizoid individuals show discomfort in social interactions and are introverted. They are seen by others as eccentric, isolated, or lonely. DSM-IV diagnostic criteria are shown in Table 4.12.3.2.

This type of personality became recognized in the first two decades of the twentieth century. August Block's description of the shut-in personality and Eugen Bleuler's description of autism distinguished between shy and lonely persons and those who engage in relationships only in fantasy. Psychoanalysts included this term in their writings and developed an approach based on deficient object relations and individuation.[9] Some schizoid personalities have probably been sweet children who were very easy to care for, although giving less joy to their parents and eliciting less stimulation and fewer expressions of emotion than more expressive children.[7]

(a) Epidemiology

The epidemiology of schizoid personality disorder is not clearly established. Recent studies give a median prevalence of 0.5 to 1 per cent (see Chapter 4.12.5).

(b) Aetiology

A familial association may exist between schizotypal personality disorder and schizophrenia.

Table 4.12.3.2 DSM-IV diagnostic criteria for schizoid personality disorder

A.	A pervasive pattern of detachment from social relationships and a restricted range of expression of emotions in interpersonal settings, beginning by early adulthood and present in a variety of contexts, as indicated by four (or more) of the following
	1 Neither desires nor enjoys close relationships, including being part of a family
	2 Almost always chooses solitary activities
	3 Has little, if any, interest in having sexual experiences with another person
	4 Takes pleasure in few, if any, activities
	5 Lacks close friends or confidants other than first-degree relatives
	6 Appears indifferent to the praise or criticism of others
	7 Shows emotional coldness, detachment, or flattened affectivity
B.	Does not occur exclusively during the course of Schizophrenia, a Mood Disorder With Psychotic Features, another Psychotic Disorder, or a Pervasive Developmental Disorder and is not due to the direct physiological effects of a general medical condition

Note If criteria are met prior to the onset of Schizophrenia, add 'Premorbid.' e.g. 'Schizoid Personality Disorder (Premorbid)'.

(c) Clinical picture

People with schizoid personality disorder appear cold, reserved, distant, and unsociable. They lack involvement in everyday events and in the concerns of others. They rarely tolerate eye contact, usually give short answers, and appear uneasy when asked about emotions or feelings. However, they may invest much energy in abstract ideas such as those of mathematics or philosophy.

There is a characteristic lack of emotional expression and low energy. Speech is typically slow and monotonous, and seems to lack associated emotion. Affect is excessively serious or constrained, although some inner fear may be detected by an experienced clinician. If they try to be humorous, they usually give a child-like impression. Psychomotor activity tends to be lethargic, lacking gesture, and rhythmic movement. They may seem absorbed in insignificant matters, keeping quiet and not annoying anybody, as if in their own world. They do not express joy, anger, sadness, or other emotions. Interpersonal communication tends to be formal and impersonal, although not irrational. Threats, real or imagined, are dealt with by fantasized omnipotence or resignation. Aggressive acts are infrequent.

People with schizoid personality disorder characteristically seem to lack interest in the lives and concerns of others. When in a group, they stay unnoticed and detached, seeming indifferent to criticism or praise or to the reactions of others. Schizoids are attracted to solitary hobbies, and may be successful in lonely jobs that others find difficult to tolerate. Many prefer working at night. Usually, they do not seem to suffer because of this detachment and they have no desire for closeness or intimacy. They seldom have close friends or relationships, except with immediate relatives. Their sexual lives may be poor or exist only in fantasy, and some postpone mature sexuality indefinitely. They do not usually marry, although some, especially schizoid women, may passively agree to marriage. However, schizoid individuals may make emotional attachments with animals or inanimate objects.

Schizoid personalities lack insight, and generally have a poorly developed sense of identity and a poor capacity for evaluating interpersonal events. They may appear to be self-absorbed and engage in excessive daydreaming. However, some schizoid individuals have original and creative ideas.

(d) Differential diagnosis

Schizoids have better occupational functioning than patients with **schizophrenia** or **schizotypal personality disorder**, and, although isolated, can have successful careers. Schizophrenic patients exhibit delusional thinking or hallucinations and psychotic episodes. Schizotypal individuals show greater eccentricity and oddness than schizoids, and also have perceptual and thought disturbances including magical thinking.

People with **paranoid personality disorder** may also show social detachment and lack close relationships. However, they show more social engagement than schizoids and may have a history of aggressive behaviour.

Emotional constraint is also present in **obsessive–compulsive personality disorder**, but obsessional patients are more involved in everyday life and concerns, and may be worried by criticism. People with **avoidant personality disorder** are also detached and aloof. However, although they actively avoid interpersonal contact because of fear of rejection or being found inadequate, they have an intense desire for close relationships.

(e) Course

Schizoid personality disorder is usually apparent in early childhood. As with all personality disorders, it is usually long-lasting; however, it is not necessarily lifelong although there is seldom any rapid or profound change. If their deficits are moderate and social circumstances are favourable, some schizoids achieve social and vocational adaptation.

Although this personality disorder is sometimes a precursor of schizophrenia, the number of schizoid patients who go on to develop schizophrenia is unknown.

(f) Treatment

Because they lack insight and have little motivation for change, schizoids seldom seek treatment. Motivation for change may depend on life circumstances and external pressures.

Low-dose antipsychotic medication is useful in some situations. Antidepressants and psychostimulants have also been used with some positive effects.

The psychotherapy of patients with schizoid personality disorder must be based on gaining a therapeutic alliance. Unlike paranoid patients, they may become involved in therapy and reveal fantasies, imaginary friends, and fears of unbearable dependency. Ambivalence may appear because of fear of dependence on the therapist, who must keep the necessary distance to allow a tolerable relationship for the patient.

Social skills training is sometimes useful in improving their awareness of social cues.

Schizotypal personality disorder

Schizotypia is a controversial term in psychiatry. The term was used by Kretschmer[10] to denominate the phenotypic characters that antedated the development of schizophrenia. Nevertheless, the term schizotypal personality disorder was not included in psychiatric classifications until the publication of DSM-IIIR in 1987.[11] Before

Table 4.12.3.3 DV-IV diagnostic criteria for schizotypal personality disorder

A. A pervasive pattern of social and interpersonal deficits marked by acute discomfort with, and reduced capacity for, close relationships as well as by cognitive or perceptual distortions and eccentricities of behaviour beginning by early adulthood and present in a variety of contexts, as indicated by five (or more) of the following
   1 Ideas of reference (excluding delusions of reference)
   2 Odd beliefs or magical thinking that influences behaviour and is inconsistent with subcultural norms (e.g. superstitiousness, belief in clairvoyance, telepathy, or 'sixth sense'; in children and adolescents, bizarre fantasies or preoccupations)
   3 Unusual perceptual experiences, including bodily illusions
   4 Odd thinking and speech (e.g. vague, circumstantial, metaphorical. overelaborate, or stereotyped)
   5 Suspiciousness or paranoid ideation
   6 Inappropriate or constricted affect
   7 Behaviour or appearance that is odd, eccentric, or peculiar
   8 Lack of close friends or confidants other than first-degree relatives
   9 Excessive social anxiety that does not diminish with familiarity and tends to be associated with paranoid fears rather than negative judgements about self

B. Does not occur exclusively during the course of Schizophrenia, a Mood Disorder With Psychotic Features, another Psychotic Disorder, or a Pervasive Developmental Disorder.

Note If criteria are met prior to the onset of Schizophrenia, add 'Premorbid', e.g. 'Schizotypal Personality Disorder (Premorbid)'.

that date, schizotypal individuals were allocated either with schizoids or with schizophrenics, and were usually labelled as latent schizophrenics or pseudoneurotic schizophrenics. However, the validity of this nosological entity is still controversial and, despite its acceptance in DSM-IV, ICD-10 does not recognize it as a separate personality disorder. Instead, ICD-10 includes the schizotypal syndrome among the psychotic disorders and not as a personality disorder, based on the biological affinities of schizotypal individuals with other schizophrenic patients. DSM-IV diagnostic criteria are shown in Table 4.12.3.3.

(a) Epidemiology

Schizotypal personality disorder is present in 0.5 to 3 per cent of the general population, with no demonstrated differences between sexes. It is more commonly diagnosed in relatives of schizophrenic patients, and the incidence is much higher in monozygotic than in dizygotic twins (33 per cent versus 4 per cent).[4]

(b) Clinical picture

The essential feature of schizotypal individuals is a pattern of peculiarity and oddness in interpersonal relationships with resulting social detachment and lack of close relationships. Because of their distorted reality processing schizotypal individuals feel intensely uncomfortable in the presence of others. Conversely, others feel uneasy in the presence of schizotypals because of their unusual ways of thinking and expressing emotions.

Like schizoids, schizotypals have a decreased desire for intimate contacts, although they may sometimes express unhappiness about their lack of relationships. As a consequence they do not have close friends or confidants other than relatives. They experience intense anxiety in social situations with unfamiliar people. They can interact if necessary, but they prefer to keep aloof because they feel different and are not interested in the concerns of others. Their anxiety in these situations is not based on feelings of inadequacy or fear of humiliation. Rather, it is due to suspicion of the motivation of others, and therefore it is not alleviated as time passes and the situation becomes more familiar. Thus schizotypals feel progressively worse and more reluctant to confide in other people.

Individuals with schizotypal personality disorder often have ideas of reference that is interpretations of casual events as having specific and unusual meanings related to themselves. However, these ideas do not achieve the pathological conviction of delusions. Similarly, these individuals may be preoccupied with superstitions or paranormal phenomena. They may feel that they may read other people's thoughts or influence their behaviour by the power of thought. Their magical thinking is often manifested by ritualized behaviours aimed at avoiding harmful events.

Perceptual disturbances are frequent in schizotypal personality disorder. An experience of a sixth sense is typical, with the 'ability' to notice someone's presence. Distorted perceptions are present in the form of sounds perceived as calling voices or shadows transformed into figures and faces.

Thought processing and speech are characteristically affected. Speech may be constructed in an unusual and idiosyncratic way-generally loose, digressive, or vague, but without actual derailment or incoherence. Responses may be either excessively concrete or far too abstract, and words may be used in unusual ways.

The interpersonal relationships of schizotypal individuals are primarily affected by paranoid and suspicious ideation. They may believe that colleagues at work want to damage their reputation. In addition to the social anxiety of these individuals, this leads to a stiff and constricted contact and affect. They are considered odd and eccentric by others: they have peculiar mannerisms, dress in an unusual and unkempt manner, adopt extravagant postures and clothing combinations, do not obey normal social conventions, and generally avoid eye contact.

(b) Course

Schizotypal features may be present in childhood and adolescence in the form of solitariness, academic underachievement, hypersensitivity, and bizarre fantasies. Schizotypals do not seek treatment because of their personality disorder, but rather because of the presentation of associated depression, dysphoria, and anxiety. In response to stressful situations, these patients may experience transient psychotic episodes lasting from minutes to hours. In some cases, clinical symptoms and duration reach the degree of brief psychotic disorder, schizophreniform disorder, or schizophrenia, with the schizotypal personality disorder as the premorbid state. The prevalence of major depressive episodes is notoriously high, as is co-diagnosis with paranoid, schizoid, avoidant, and borderline personality disorders.

(c) Differential diagnosis

Delusional disorder, **schizophrenia**, and **mood disorder with psychotic symptoms** have to be excluded based on the greater intensity and persistence of psychotic symptoms.

In childhood, it can be difficult to distinguish schizotypal personality disorder from other forms of disorders characterized by odd behaviour, isolation, eccentricity, and peculiarities of

language. These include **autistic disorder**, **Asperger's disorder**, and some **language disorders**. The differentiation with communication disorders is based on the prominence of language symptoms in these children and the compensatory efforts to communicate by gesture and other means. Autism and Asperger's disorder present an even more intense social isolation and indifference, stereotyped behaviours and interests.

Paranoid and **schizoid personality disorders** lack the perceptual and speech impairment of schizotypal personality disorder, as well as the marked eccentricity and oddness. **Avoidant personality disorder**, while including social anxiety and isolation, differs from schizotypal personality disorder in that avoidants have an intense desire for closeness, which is constrained by fear of rejection. Schizotypals do not have a desire for relationships. **Borderline personality disorder** has a high rate of co-occurrence with schizotypal personality disorder and frequently the two disorders cannot be differentiated. Brief psychotic episodes in people with borderline personality disorder are more dissociative-like and generally follow affective shifts in response to stress or frustration. Social isolation in borderline personality patients is generally due to repeated interpersonal failures rather than a persistent lack of desire for relationships and intimacy.

Finally, schizotypal personality disorder must be diagnosed in the cultural context of the patient. It should be noted that some perceptual peculiarities and magical beliefs may be due to culturally determined characteristics. For example, mind reading, voodoo, shamanism, evil eye, and so on should not be considered as personality disorders in some cultural areas.

(d) Treatment

Low-dose antipsychotic medication may be useful for ideas of reference, perceptual disturbances, and other psychotic-like symptoms. Antidepressants are effective when depressive states are associated.

The psychological management of schizotypals should include a prolonged period of gaining the confidence of the patient. However, a particularly careful approach must be adopted owing to the peculiar thought processing of these patients.

Cluster B personality disorders

Antisocial personality disorder

Antisocial personality disorder is characterized by a pattern of disregard for the safety and the rights of others, without feeling remorse. Individuals with this disorder are unreliable, manipulative, incapable of lasting relationships, and unable to conform to social norms. The disorder starts early (before the age of 15), is pervasive, and manifests in variety of contexts. Although social deviance is one of the core features of antisocial personality disorder, it is not synonymous with criminality. Antisocial personality disorder uncomplicated by other disorders is not often met in clinical settings, except forensic psychiatry. However, owing to its impact on family and social environment, it has major public health significance and has been extensively studied in academic psychiatry, psychoanalysis, law, sociology, theology, and literature.

The description of antisocial personality in the last 1970s was mainly based on criminal behaviour[12] and the disorder was conceptualized as synonymous of criminality. Later classifications modified this approach and focused on the personality traits and emotional patterns described in classic descriptions included the classic personality traits leading to the current DSM-IV and ICD-10 classification criteria for antisocial personality disorder. (Tables 4.12.3.4 and 4.12.3.5).

Table 4.12.3.4 SM-IV diagnostic criteria for antisocial personality disorder

A. There is a pervasive pattern of disregard for and violation of the rights of others occurring since age 15 years, as indicated by three (or more) of the following 1 Failure to conform to social norms with respect to lawful behaviours as indicated by repeatedly performing acts that are ground for arrest 2 Deceitfulness, as indicated by repeated lying, use of aliases, or conning others for personal profit or pleasure 3 Impulsivity or failure to plan ahead 4 Irritability and aggressiveness, as indicated by repeated physical fights or assaults 5 Reckless disregard for safety of self or others 6 Consistent irresponsibility, as indicated by repeated failure to sustain consistent work behaviour or honour financial obligations 7 Lack of remorse, as indicated by being indifferent to or rationalizing having hurt, mistreated, or stolen from another
B. The individual is at least age 18 years
C. There is evidence of conduct disorder with onset before 15 years
D. The occurrence of antisocial behaviour is not exclusively during the course of Schizophrenia or a Manic Episode.

(a) Epidemiology

A prevalence rate of about 3 per cent is consistently found in the general population, and it is more frequent in males than females, with sex ratios ranging from 2:1 to 7:1. It is more common among younger adults, people living in urban areas and lower socio-economic groups.[13]

Table 4.12.3.5 ICD-10 diagnostic criteria for disocial personality disorder

Personality disorder, usually coming to attention because of a gross disparity between behaviour and the prevailing social norms, and characterized by (a) callous unconcern for the feelings of others (b) gross and persistent attitude of irresponsibility and disregard for social norms, rules and obligations (c) incapacity to maintain enduring relationships, though having no difficulty in establishing them (d) very low tolerance to frustration and a low threshold for discharge of aggression, including violence (e) incapacity to experience guilt and to profit from experience, particularly punishment (f) marked proneness to blame others, or to offer plausible rationalizations, for the behaviour that has brought the patient into conflict with society
There may also be persistent irritability as an associated feature. Conduct disorder during childhood and adolescence, though not invariably present, may further support the diagnosis.
Includes: amoral, antisocial, psychopathic, and sociopathic personality (disorder)
Excludes: conduct disorders, emotionally unstable personality disorder

(b) Aetiology

The aetiology of antisocial personality disorder is complex and multifactorial, involving biological, early developmental, and social determinants.

Twin, adoption, and family studies have demonstrated that genetic factors strongly contribute to the development of antisocial personality.[14] Antisocial personality in males is often associated with hysteria in women of the same family which suggests that the two conditions might be alternative expressions of the same genetic endowment, belonging to 'spectrum conditions'.[15] Longitudinal studies of hyperactive children have reported high rates of later (adult) antisocial behaviour, and have suggested a 'developmental' relationship between antisocial behaviour and childhood hyperactivity.

Aggression in antisocial personality disorder is associated with indexes of reduced brain serotonin activity such as low levels of the serotonin metabolite 5-hydroxyindole-acetic acid in the cerebrospinal fluid and[16,17] low platelet monoamine oxidase activity. Reports on minimal brain dysfunctions resulting on frontal-lobe deficiencies and lack of inhibition have also been described.

Parental deprivation, inconsistent maternal care, family violence, and severe childhood physical) abuse have been reported as strong predictors for development of antisocial personality disorders.[12,18]

Social disintegration and chronic criminality can cause episodic antisocial behaviour, reflecting a normal adaptation to an abnormal social environment.[19] However, the multifactorial origin of the antisocial personality disorder and its early onset and manifestations indicate that it cannot be attributed to cultural conflicts and social determinants.

(c) Clinical features and diagnosis

Patients with antisocial personality disorder often appear quite normal, charming, and understanding. However, their history reveals disturbed functioning in the domains of behaviour and self-concept, love and sexuality, interpersonal relations, and cognitive style.[20]

Reckless behaviour unaffected by punishment is typical of antisocial individuals, who are also exploitative, manipulative, demanding, and lacking in a sense of responsibility. An easy-going hedonistic attitude may be interrupted by rage, cruelty, and violence. The absence of internalized moral values is manifested by lying, truancy, running away from home, thefts, fights, substance abuse, and illegal activities may be typical experiences, beginning in early childhood.

An impaired control of impulses and a reduced ability to anticipate the negative consequences of behaviour is typical associated to a marked intolerance to anxiety. Antisocial individuals are egocentric, and unable to feel genuine guilt and remorse. They exhibit intense and persistent anger usually expressed as hostility towards others and they have an incapacity for reflective mourning or sadness. Frequent suicide threats and attempts are also common, as is somatic preoccupation.

Interpersonal relationships of antisocial subjects are characterized by manipulation, exploitation, instability and incapacity for love, and comprehension. Sexual perversions, abuse, and paedophilia are frequent. They display deficient parenting and social dysfunction, and resistance to authorities is pronounced.

The cognitive style of antisocial subjects is characterized by glibness, superficiality of knowledge, and paranoid view of reality.

(d) Comorbidity and differential diagnosis

Antisocial personality disorder is frequently comorbid with **depression**, which usually has atypical features. **Bipolar disorder** (manic phase) and **mental retardation** (learning difficulties) should be excluded. Substance abuse may be comorbid from childhood, and antisocial behaviour may be secondary to premorbid alcoholism type 2. **Atypical schizophrenic disorder** (pseudopsychopathic schizophrenia), **temporal-lobe epilepsy**, or a **limbic-lobe syndrome** should also be excluded.

The presentation of antisocial and criminal behaviour in borderline personality disorder is frequent. However, borderline behaviours are marked by intense affective instability and reactivity and may show some remorse or guilt. Unlike antisocial patients, borderline personality disorders do not lack the capacity for intimacy and emotional investment of others and do not show sadistic behaviours. Self-aggression and suicide attempts are much more prevalent among BPD than in antisocial personality.

Aggressive and defiant behaviours are often present in histrionic personality disorder. Although some aetiologic relationship among both disorders might be possible, as described above, histrionic patients are more impulsive and emotionally driven than antisocial and display intense emotions related with attachments and losses.

(e) Course and prognosis

Antisocial behaviour is most pronounced in early adult years, and gradually decreases with age. Professional motivation and establishing a stable couple or partnership may have beneficial effects. Maturation of the personality might also take with depression or hypochondriasis emerging when rage and aggression are abandoned. Substance abuse and promiscuity are risky behaviours for developing HIV infection.

(f) Treatment

Medication is used to deal with incapacitating symptoms, such as anxiety, rage, depression, and somatic complaints. Selective serotonin reuptake inhibitors, lithium, carbamazepine, clonazepam, and other anticonvulsants have been used to control aggressive behaviour but the effects are much less pronounced than in borderline personality disorder or intermittent explosive disorder. Psychostimulants such as methylphenidate may be useful if there is evidence of attention-deficit hyperactivity disorder. Benzodiazepines are contraindicated since they might cause behavioural disinhibition.

Efficacy of psychotherapy is very little in antisocial patients. Fear of intimacy causes difficulties in establishing a therapeutic alliance, which should be oriented to find alternative defence mechanisms to acting-out and to self-defeating behaviours. Therapeutic communities based on the principles outlined by Maxwell Jones[21] with a general social adjustment as a main task, might give positive results.

Borderline personality disorder

Borderline personality disorder (BPD) is the denomination of a syndromal picture characterized by intense affective instability and impulsivity together with an unstable sense of self-identity. It is often manifested by impulsive self-aggression and suicide attempts, substance abuse, chronic feelings of emptiness, and persistent pattern of severely unstable interpersonal relationships.

The term borderline was first used by Stern[22] in 1938 to denominate a group of syndromes placed in the border between neuroses and psychoses and included also the current label of schizotypal personality disorder and a group of disorders currently classified as psychotic disorders. Only some decades later the term borderline began to be understood as a disorder of character[23] and introduced in DSM-III as a personality disorder, after being separated from schizotypal personality disorder.

Borderline personality disorder derives but is not fully equivalent to the concept of borderline personality organization developed by Kernberg.[24] BPO is a stable permanent state based on three criteria: diffuse identity, primitive defence mechanisms (splitting, denial, and projective identification), and intact reality testing. This personality organization can be found not only in BPD but also in other severe personality disorders and Axis I conditions.

Borderline personality disorder itself can be found in association with so many Axis I and Axis II disorders that its validity as an independent diagnostic category is still weak compared with other personality disorders. Some authors have suggested that borderline personality disorder reflects rather a state of severely impaired personality function than a discrete diagnostic entity.[25] Others have suggested that BPD is an atypical variant of affective disorder and should be included in the affective disorder spectrum.[26] In the ICD-10, this disorder is named as 'emotionally unstable personality disorder', with two subtypes: impulsive and borderline. Borderline subtype is specifically linked to the presence of self-identity weakness and diffusion.

(a) Epidemiology

The number of people suffering from borderline personality disorder ranges from 1.5 to 5 per cent of general population with wide differences between studies because of lack of reliable measures. The prevalence is greater in clinical samples of patients at the outpatient clinics, ranging form 10 to 15 per cent. The disorder is more common in women than in men and is commonly initiated between 18 and 35 years old.[27]

(b) Aetiology

Several factors have been associated with a higher prevalence of borderline personality disorder, including genetic, biological, and developmental findings.[28] Family studies indicate that parents of patients with BPD have a greater incidence of mood disorders but not of schizophrenia. Additionally, there is also high family incidence of antisocial personality disorder and alcoholism.

Among the biochemical findings, those indicating a brain serotonin deficiency are the more consistent. Reduced levels of 5-hydroxyindoleacetic acid in cerebrospinal fluid and blunted prolactin response to serotonin agonists have been demonstrated in association with impulsive aggression, which is a core feature of BPD.[29] Hypothalamic-pituitary—adrenal axis dysfunctions, suggesting increased feedback inhibition, as well as increased sensitivity of some areas of the amigdala, have been reported in samples of BPD patients. Current available data suggest that BPD might be associated with abnormal emotional reactivity in the limbic areas and insufficient regulatory function at the cingulated and prefrontal areas of the brain.[30]

The role of childhood trauma in the development of borderline personality disorder could be crucial. Higher incidence of childhood traumatic experiences, both for sexual/physical abuse or for neglect, has been demonstrated in these patients.[31] Other proposed developmental factors include deficiencies in self and identity development linked to attachment failures with parental figures in the early developmental phases.[32,33]

The onset of BPD needs the interaction of predisposing factors, both biological and developmental, and environmental precipitants. BPD patients seem to be extremely sensitive to frustrations in the intimate relationships, which are commonly detected at the onset of the disorder.

(c) Clinical features and diagnosis

Impulsivity and affective instability, self-aggression, identity disturbance, and unstable/intense interpersonal relationships are the most characteristic manifestations of borderline personality disorder.

Identity weakness and diffusion explain several aspects of borderline personality disorder (Table 4.12.3.6). It is clinically manifested by contradictory character traits and sense of discontinuity of the self and feelings of emptiness.[34] Probably related with this is also the intolerance to be alone and the desperate efforts to avoid abandonment by significant others. The chronic feeling of emptiness is recurrently intensified and unbearable leading to drug abuse and self-defeating behaviours.

The affect of borderline patients is chronically dysphoric and irritated. Their unstable mood is a mixture of depressed affect, anger, loneliness, and emptiness. Impulsive–aggressive behaviour is a core feature of borderline personality disorder and is related with this abnormal affective state.

Cognitive style of borderline patients are easily suggestible and frequently change their decisions. Things and people are seen in black-and-white terms. Transient and brief psychotic episodes are frequent in BPD patients associated with unstructured stressful

Table 4.12.3.6 DSM-IV diagnostic criteria for borderline personality disorder

A pervasive pattern of instability of interpersonal relationships, self-image, and affects and marked impulsivity beginning by early adulthood and present in a variety of contexts, as indicated by five (or more) of the following

1. Frantic efforts to avoid real or imagined abandonment. **Note:** Do not include suicidal or self-mutilating behaviour covered in Criterion 5
2. A pattern of unstable and intense interpersonal relationships characterized by alternating between extremes of idealization and devaluation
3. Identity disturbance: markedly and persistently unstable self-image or sense of self
4. Impulsivity in at least two areas that are potentially self-damaging (e.g spending, sex, substance abuse, reckless driving, binge eating). **Note:** Do not include suicidal or self-mutilating behaviour covered in Criterion 5
5. Recurrent suicidal behaviour, gestures, or threats, or self-mutilating behaviour
6. Affective instability due to a marked reactivity of mood (e.g. intense episodic dysphoria, irritability, or anxiety usually lasting a few hours and only rarely more than a few days)
7. Chronic feelings of emptiness
8. Inappropriate intense anger or difficulty controlling anger (e.g. frequent displays of temper, constant anger, recurrent physical fights)
9. Transient stress-related paranoid ideation or severe dissociative symptoms

situations. Psychotic symptoms may have a typical dissociative-like nature or present as transient self-referential ideation. Rejection sensitivity and suspiciousness usually colours the interpretations of behaviours of others.

Borderline patients are both intensely dependent and hostile towards significant others. Interpersonal relationships are unstable, intense, demanding, clinging, and characterized by alternation between extremes of idealization and devaluation, deriving from the defence mechanism of splitting. Infatuations are followed by devaluation of love objects. There is a tendency towards promiscuity and perversions.

(d) Comorbidity and differential diagnosis

Borderline personality disorder is frequently comorbid with **affective disorders** (major depression, dysthymia, and 'double depression'), **anxiety disorders**, **somatization disorder**, **post-traumatic stress disorder**, and **alcohol abuse**.

Differential diagnosis has to be made with **type II bipolar disorder**. Bipolar patients more often present emotional lability from sadness/apathy to euphoria while BPD patients are characterized by intense and reactive affective instability and shift rather from sadness to tolerable dysphoria. Intermittent explosive disorder also shows impulsive and aggressive behaviours but lacks identity disturbances and affective instability typical of BPD. Mild mental retardation might have intense irritability, lability, and impulsive/aggressive behaviour but lacks chronic feelings of emptiness and self-identity diffusion. Transient psychotic episodes and stress-related referential ideas of BPD should be differentiated from pervasive psychotic-like experiences of schizotypal personality disorder.

Borderline personality disorder has been shown to be associated with most personality disorders, especially with those from the dramatic cluster. The high prevalence of comorbid personality disorders may result from overlapping of diagnostic criteria or reflect the confirmation that there is the underlying borderline personality organization of all severe personality disorders. However, some features like chronic feelings of emptiness, self-mutilation, short-lived psychotic episodes, intense and episodic drug abuse, and intense ambivalent dependency in close relationships suggest a primary diagnosis of BPD.

(e) Course and outcome

Borderline patients often experience profound dysfunction in many important aspects of life including education, jobs, partner relationships, and marriage. Alcohol and psychosexual problems are also frequent. Repeated suicide attempts and premature death from suicide are frequent complications of borderline personality disorder; therefore suicidal gestures and intentions should be always taken seriously. It has been reported that 8 to 10 per cent per cent of all persons with borderline personality disorder commit suicide.[35]

The long-term outcome of borderline patients has not been studied, but the diagnosis is rarely made in patients aged over 40. It is speculated that neural structures and defence mechanisms mature with age and that these changes, together with social learning, reduce symptomatology.

(f) Treatment

Pharmacotherapy is targeted to symptoms such as affective changes (depression, anxiety, rage, dysphoria), cognitive disturbances (brief psychotic episodes or interpretative distortions), and impulsive behavioural dyscontrol.[36] New antidepressants, including SSRIs and venlafaxine, have shown positive effects in treating a broad spectrum of acute symptoms, including depression, hostility, irritability, anxiety, obsessive–compulsive symptoms, suicidal attempts, and impulsivity. Antipsychotics and anticonvulsants may help some patients, even in the absence of EEG or organic changes. There are still no clinical predictors for efficacy, therefore, a pragmatic approach is indicated with patients being treated with two or three drugs in a sequential trial.[36] Suicidal and abusive use of drugs prescribed and non-compliance may be serious problems for treatment of BPD.

Various psychotherapeutical modalities are used, including psychodynamic psychotherapy, supportive psychotherapy, and dialectical–behavioural therapy.

A more structured form of psychoanalytic approach, involving expressive psychotherapy and an active role of psychotherapist have been proposed specifically for BPD. The aims are confrontation of maladaptive defences and interpretation of transference, focusing on the 'here and now', without attempting the achievement of a full genetic reconstruction.[37]

Short-term psychotherapy is useful for managing crises or introducing long-term forms of therapy. Supportive psychotherapy is suggested for more fragile borderline patients, who are prone to serious regression in treatment. In practice, supportive therapy, with a psychoeducational component, has been the most frequently used form of treatment for borderline personality disorder. It is also possible to combine elements of intensive dynamic therapy with supportive therapy, depending on the ego strength of the patients.[38]

Dialectical–behavioural therapy[39] is based on cognitive techniques associated with reality confrontation. The major aim is emotional self-regulation and behavioural self-control and is particularly indicated for control of suicidal and impulsive behaviours and treatment of emotional reactivity.

Histrionic personality disorder

(a) Definition

Histrionic personality disorder derives from the concept of hysterical personality, supported by descriptive literature and clinical tradition but not so much by valid empirical research. It is characterized by excessive emotionality and attention seeking, and by dramatic, colourful, and extroverted behaviour. Egocentric, dependent, and demanding interpersonal relationships are typical of this disorder, which begins in early adulthood and is present in a variety of contexts. The DSM-IV and ICD-10 diagnostic criteria for this disorder are shown in tables 4.12.3.7 and 4.12.3.8.

It was included in scientific medicine by Kraepelin,[40] who described multiple symptoms, including capricious and inconsistent behaviour, histrionic exaggeration, and a life of illness, which captured the core pattern of the illness. Freud[41] recognized the relationship between hysterical neurosis and what he called the 'erotic personality, whose major goal in life is the desire to love or above all to be loved'. Psychoanalytic theorists often distinguish hysterical ('healthier') and histrionic ('sicker') personalities, where the latter has borderline organization and is an exaggeration of the former. Differences between the two concepts are shown in Table 4.12.3.9.

Table 4.12.3.7 DSM-IV diagnostic criteria for histrionic personality disorder

A pervasive pattern of excessive emotionality and attention seeking, beginning by early adulthood and present in a variety of contexts, as indicated by five (or more) of the following

1 Is uncomfortable in situations in which he or she is not the centre of attention
2 Interaction with others is often characterized by inappropriate sexually seductive or provocative behaviour
3 Displays rapidly shifting and shallow expression of emotions
4 Consistently uses physical appearance to draw attention to self
5 Has a style of speech that is excessively impressionistic and lacking in detail
6 Shows self-dramatization, theatricality, and exaggerated expression of emotion
7 Is suggestible, i.e. easily influenced by others or circumstances
8 Considers relationships to be more intimate than they actually are

(b) Epidemiology

The prevalence is found to be 2 to 3 per cent of the general population and 10 to 15 per cent in clinical settings.[42] No significant difference has been found in terms of race and education and is more frequently diagnosed in women than in men. However, some cultural biases associated with sex role stereotypes and emotional expressiveness could lead the lower diagnostic rates in men.[43]

(c) Aetiology

Some studies suggest that histrionic personality runs in families, but evidence for a biological or learning transmission is not yet consistent.[44] Traits such as extraversion, emotional expression, and reward dependence have a strong genetic origin and might be constitutional. Biological findings associated with impulsivity, such as serotonin deficiency, can be found in histrionic patients with marked emotional instability and impulsive behaviours. It has been proposed that histrionic personality in women is genotypically linked to antisocial personality in men.[45]

From a development perspective, histrionic personality is considered to be a result of abnormally intense attachment with parental figures. The erotization component of this attachment in the oedipical phase was classically emphasized in the psychoanalytic research, although recent approaches suggest that there oral/dependent factors, derived from anomalies in earlier phases are of greater importance in the development of the disorder.[46]

Table 4.12.3.8 ICD-10 diagnostic criteria for histrionic personality disorder

Personality disorder characterized by at least three of the following:

(a) self-dramatization, theatricality, exaggerated expression of emotions
(b) suggestibility, easily influenced by others or by circumstances
(c) shallow and labile affectivity
(d) continually seeking for excitement, appreciation by others, and activities in which the patient is the centre of attention
(e) Inappropriate seductiveness in appearance or behaviour
(f) Overconcern with physical attractiveness

Associated features may include egocentricity, self-indulgence, continuous longing for appreciation, feelings that are easily hurt, and persistent manipulative behaviour to achieve own needs

Includes: hysterical and psycho-infantile personality (disorder)

Table 4.12.3.9 Types of histrionism

Hysterical personality	Histrionic personalitya
Neurotic personality organization	Borderline personality organization
Integrated identity	Diffuse identity
Predominance of repression	Predominance of splitting
Intact reality testing	Intact reality testing (proneness to distortion)
Integrated superego	Marked superego defects
Strongly bonded families	Disturbed, often broken families
Steady educational and vocational careers	Erratic careers
Capable of maintaining long-term friendships	Chaotic interpersonal relationships
Suggestible in triangular relationships	Diffuse suggestibility
Inauthenticity	Multiple identifications
Changing moods	Frequent dysphoria
Sexual inhibition	Promiscuity, perverse tendencies
Competitiveness with the same sex	Less differentiated behaviour toward sexes
Genital traits	Oral/pregenital traits

[a] Includes hysteroid, hysteriform, oral hysteric, and sick hysteric personality disorders. After Akhtar.[31]

(d) Clinical features and diagnosis

Emotionality, dramatization, exhibitionism, egocentricity, and sexual provocativeness are typical of histrionic personalities. However, behavioural expression is not always as manifested and other emotional and cognitive aspects may help for diagnosis.

Histrionic individuals are inappropriately seductive and aggressively demanding. They are self-centred, crave for novelty and excitement, and are prone to temper tantrums. Histrionic subjects are hyperemotional and impulsive, but their emotional enthusiasm is superficial and transient and their mood is labile. They describe their emotions in an inappropriate and exaggerated way in an attempt to obtain attention. Histrionic individuals are suggestible, demanding, accusative, and guilt inducing. In intense stressful situations they can show a dissociative-type of indifference and infantilism.

Histrionic personalities are inclined to sexualize all non-sexual relations, often indiscriminately, not only with a chosen partner but also with a wide variety of persons in various social, occupational, and professional relationships. Pseudosexuality is often accompanied by frigidity. A romantic outlook or a superficially adoring attitude often disguises needs for dependency and emotional attachment to a significant protective figure. Sicker individuals may be promiscuous, and may engage in multiple perverse activities.

Cognitive style is global, impressionistic, and diffuse, and lacks sharpness of detail. Non-verbal communication is better than verbal, speech is inhibited, and education is often superficial. Speech may show malapropisms or slips of the tongue.

The basic belief of histrionic personalities is that others should be impressed, and their basic strategy is dramatization. They blossom when they are the centre of attention and are highly disappointed when they are not, and draw attention to themselves by acting and speaking in a charming flirtatious way. Histrionic individuals quickly respond to others in an intimate way, often treating superficial acquaintances as if they were friends.

(e) Comorbidity and differential diagnosis

There is current evidence that **somatization disorder** (Briquet's syndrome) and **conversion disorder** can occur in conjunction with histrionic personality disorder, as well as **dissociative disorder** and **brief reactive psychosis**.[21] Differential diagnosis should not be difficult, because histrionic personality disorder is a lifelong disturbance with a chronic course, unlike Axis I disorders which are episodic. **Hypomanic and manic states** may be accompanied by seductive behaviour and exaggerated expression of emotions, but can be distinguished from histrionic personality by their episodic nature and the presence of other characteristic symptoms.

A great deal of overlap has been found between histrionic personality disorder and other **Axis II disorders**, defined by DSM-IIIR criteria; of these, the borderline, narcissistic, antisocial, and dependent personality disorders are the most frequent.

Borderline patients have more chaotic interpersonal relationships, make frequent suicide attempts, and are prone to regressive episodes of a psychotic nature. Histrionic individuals share sexual promiscuity, corruptibility, shallow emotions, and a self-centred attitude with antisocial personalities.[47] However, they do not show sustained, calculated, and ruthless disregard of social norms. Narcissists may also seek attention, but they want to be admired for their superiority while histrionic persons are clinging and dependent. Unlike narcissists, histrionic individuals have empathy for other persons. However, the features of the two disorders can be combined.

(f) Course and prognosis

Depressive symptoms, suicide attempts, and frequent use of medical services are common. Histrionic personality may gradually improve with age, as if a maturation of histrionic infantilism occurs over the years.

(g) Treatment

Depressive and anxious symptoms are frequent in histrionic personality disorder and can be alleviated with the use of antidepressants and anxiolytic medications. However, extreme care should be taken for treatment due to the vulnerability of these patients for medication abuse and non-compliance.

Supportive therapy is indicated for acutely distressed histrionic patients, as well as for those at the sicker end of the continuum. Psychoanalytic techniques in histrionic patients[47] are oriented to clarification of the patient's covert inner feelings. Patients are often demanding, want to take a special place in the therapist's life, and act out during therapy sessions, threatening to abandon treatment or undertake dangerous actions. Clear limits should be set and demanding dependent behaviour should not be rewarded.

Narcissistic personality disorder

Narcissistic personality disorder is characterized by an exaggerated sense of self-importance with a lack of sustained positive regard for others. Grandiosity (in fantasy or behaviour) and constant craving for admiration and external gratification are additional features of this disorder. They are present in a variety of contexts and begin by early adulthood.

(a) Historical perspective

The term narcissism originates from the Greek myth of Narcissus who was infatuated with his own reflection in the mirror-lake. Its contemporary usage has many meanings and implications, from its colloquial usage denoting self-centred persons, often with pejorative connotations, to a pathological clinical syndrome. Despite the popularity of the construct, there is still considerable disagreement on the aetiology and phenomenology of narcissistic personality disorder. There is little empirical evidence regarding its description, clinical utility, and validity.

A narcissistic personality has a pathological grandiose self, which hides a diffuse and aimless inner identity. Kernberg argues that self-hatred, rather than self-love, lies at the root of pathological narcissism, and distinguishes between narcissism in the broad sense and the specific pathological structures of the narcissistic personality. According to Kernberg, narcissistic patients function on a borderline level. Malignant narcissism,[37] which develops when primitive aggression infiltrates the pathological grandiose self, lies at the extreme end of a continuum. It is a combination of narcissistic personality disorder, antisocial behaviour, egosyntonic aggression or sadism directed against others, and a strong paranoid orientation (Table 4.12.3.10).

Narcissistic personality disorder was officially accepted in DSM-III. Somewhat refined criteria were adopted in DSM-IV (Table 4.12.3.11), because some studies showed a substantial lack of diagnostic reliability when the DSM-III criteria were used. Narcissistic personality disorder is not included in ICD-10, being mentioned only in the category 'Other specific personality disorders'.

Table 4.12.3.10 Types of narcissism

Normal	Pathological	Malignant
Infantile	Grandiose self-image	Grandiose self-image
Regression or fixation to infantile narcissistic goals in personality disorders (personality traits)	Low self-esteem Primitive defences Superego defects Borderline organization	Aggression Paranoid traits Antisocial behaviour Explosive traits Borderline organization
Adult		
Healthy self-esteem regulated by normal self-structure		
Integrated object representations		
Capacity for deep object relations		
Integrated superego		

After Kernberg.[32,37]

Table 4.12.3.11 DSM-IV diagnostic criteria for narcissistic personality disorder

A pervasive pattern of grandiosity (in fantasy or behaviour), need for admiration, and lack of empathy, beginning by early adulthood and present in a variety of contexts, as indicated by five (or more) of the following

1 Has a grandiose sense of self-importance (e.g. exaggerates achievements and talents, expects to be recognized as superior without commensurate achievements)
2 Is preoccupied with fantasies of unlimited success, power, brilliance, beauty, or ideal love
3 Believes that he or she is 'special' and unique and can only be understood by, or should associate with, other special or high-status people (or institutions)
4 Requires excessive admiration
5 Has a sense of entitlement, i.e. unreasonable expectations of especially favourable treatment or automatic compliance with his or her expectations
6 Is interpersonally exploitative, i.e. takes advantage of others to achieve his or her own ends
7 Lacks empathy, i.e. is unwilling to recognize or identify with the feelings and needs of others
8 Is often envious of others or believes that others are envious of him or her
9 Shows arrogant haughty behaviours or attitudes

(b) Epidemiology

The prevalence of narcissistic personality disorder in the community has been found to be around 0.5 per cent.[48] Its prevalence in clinical populations is estimated to range from 1 to 3 per cent, and is more frequently diagnosed among males.

(c) Aetiology

Although no demonstrating evidence is yet available, some aspects of narcissism might be related with inappropriate seeking for excitement and reward and associated to monoamine function abnormalities at the mesolimbic reward systems.

Severe frustration with early objects is considered important in the defensive genesis of narcissistic personality disorder. Behind the compensatory grandiose self, a hungry and inferior real self-resides, as the core problem of narcissistic personality disorder. Often, high parental expectations and harsh criticism of the child is present in the family.

(d) Clinical characteristics and diagnosis

Narcissistic patients only seek for help when depressed or involved in interpersonal problems.

An often engaging and attractive appearance masks intense preoccupation with self-regard and an unusual absence of concern for others. Narcissistic individuals may be energetic, capable of consistent work, and socially successful, but this is done in order to obtain admiration. Their successes provide no inner satisfaction and always end with frustration and a feeling of emptiness. Narcissistic grandiosity is often masked by opposing tendencies (false modesty, social aloofness, and a pretended contempt for status). Pathological lying is frequent.

Narcissistic individuals feel bored when the external glitter wears off and there are no new sources to feed their self-esteem, which is extremely fragile. Lacking emotional depth, they do not have genuine feelings of sadness or longing. Anger and resentment laden with vengeful wishes are frequent as a reaction to injured self-esteem. Chronic intense envy is present, as are defences against such envy, particularly devaluation, omnipotent control, and narcissistic withdrawal. They have frequent mood swings, and hypomanic exaltation is often part of the clinical picture.

Narcissistic persons are unable to fall in love, and only have fantasies of ideal love. Sexuality is trivialized, and intercourse is a purely physical pleasure. Promiscuity, perverse fantasies, devaluation of objects, and boredom in relationships are frequent.

Interpersonal relationships are frequently manipulative and exploitative. They idealize people whom they expect to feed their narcissism, but depreciate and treat with contempt others (often former idols) from whom they do not expect to receive anything. They lack empathy and concern for others, who are welcome only as an applauding crowd and as mirrors of success.

Typical defence mechanisms (omnipotence, omniscience, intellectualization, rationalization, idealization, and devaluation) are derived from splitting.

(e) Comorbidity and differential diagnosis

Narcissistic personality disorder is often comorbid with major depression, dysthymic disorder, substance abuse, and anorexia nervosa. Patients meeting criteria for narcissistic disorder have a high overlap with **histrionic, borderline, and antisocial personality disorders**, and also with **schizotypal, paranoid, and passive–aggressive personality disorders**.

Narcissistic personality disorder may display some features of bipolar disorder (manic and hypomanic episodes). However, the mood swings are of limited duration and change rapidly, while insight is maintained and the general integrity of the personality is preserved.

Narcissistic personality disorder is strikingly similar to borderline personality disorder. Phenomenologically, grandiosity is the best discriminator between the two disorders.[49] In narcissistic personality disorder, there is also better impulse control, greater social adjustment and anxiety tolerance, less frequent suicide attempts, and less danger of regressive fragmentation and psychotic episodes.

Narcissistic individuals, especially those manifesting malignant narcissism, may demonstrate antisocial behaviour. However, antisocial individuals are more impulsive and less capable of concentrating on work and career, and they are devoid of guilt feelings. Similarities with histrionic and obsessive–compulsive personalities are superficial, since people with these disorders have a capacity for empathy and a concern and love for others.

(f) Course and prognosis

Patients often become depressed or defensively hypomanic during middle age, when their internal life gradually deteriorates owing to a vicious circle of frustrations and disappointments and diminishing narcissistic supplies. Hypochondriasis and anxiety disorders are frequent complications.

(g) Treatment

Anxiolytic agents and antidepressants may be helpful for alleviating target episodes of mood and anxiety symptoms.

(i) Psychotherapy

Individual psychotherapy is aimed to the analysis of idealizing transference and interpretation of self-grandiosity. However, during

the first stages only supportive therapy is recommended with interpretations delayed until confident and integrated attachment with therapist is achieved.

The treatment of narcissistic individuals inevitably arouses serious countertransference problems, because of the emotional detachment, demanding behaviour, and devaluative actions of narcissistic patients. The therapist should have worked through his or her own narcissism and retain an empathic and non-judgemental attitude.

Cluster C personality disorders

Avoidant personality disorder

Avoidant personality disorder was first introduced into psychiatric classification in DSM-III.[11] Before this, such patients were included among the schizoid or dependent patients. The emphasis on avoidant behaviour as a consequence of an intense sensitivity to rejection led to the differentiation of this new personality type.

The characteristic behaviour of the avoidant personality is active isolation from the social environment. Unlike schizoids, who are characterized by passive social isolation, avoidant subjects turn inward to protect themselves because they are extremely sensitive to rejection.[50] They desire interpersonal relationships but they avoid any chance of disapproval. Thus, only relationships that are likely to lead to complete non-critical acceptance are established. The extreme sensitivity to criticism is based on intense feelings of inferiority, poor self-concept and low self-esteem. This disorder is termed anxious personality disorder in ICD-10, since anxiety is considered to be the basic affective feature. The DSM-IV criteria for avoidant personality disorder are shown in Table 4.12.3.12.

(a) Epidemiology

The prevalence of avoidant personality disorder is estimated to be less than 1 per cent in the general population, but almost 10 per cent in clinical populations. No differences between sexes are found.

(b) Aetiology

Some familial transmission is possible, perhaps involving learning and identification, but genetic transmission may also be involved.[51] The biological mechanisms involved in anxiety disorders and social phobia may have a role in the development of this personality disorder. It has been suggested that hypersensitivity of brain areas involved in the separation-anxiety response and overactivity of serotonin limbic neuronal circuits may underlie the avoidant temperament trait.[51]

Psychosocial factors mediate the extent to which biological vulnerability is expressed. Children who are belittled, criticized, and rejected by parents have decreased self-esteem, resulting in social avoidance. These problems are reinforced and perpetuated at school and may generate the expectation of rejection from everyone.[50]

Table 4.12.3.12 DSM-IV diagnostic criteria for avoidant personality disorder

A pervasive pattern of social inhibition, feelings of inadequacy, and to negative evaluation, beginning by early adulthood and present in a variety of contexts, as indicated by four (or more) of the following

1 Avoids occupational activities that involve significant interpersonal contact, because of fears of criticism, disapproval, or rejection
2 Is unwilling to get involved with people unless certain of being liked
3 Shows restraint within intimate relationships because of the fear of being shamed or ridiculed
4 Is preoccupied with being criticized or rejected in social situations
5 Is inhibited in new interpersonal situations because of feelings of inadequacy
6 Views self as socially inept, personally unappealing, or inferior to others
7 Is unusually reluctant to take personal risks or to engage in any new activities because they may prove embarrassing

(c) Clinical picture

Avoidant people are characterized by extreme shyness. They appear distant from others and do not express wishes, demands, or opinions. However, this behaviour contrasts with an extreme internal need for warmth and closeness. This contradiction is explained by an exaggerated sensitivity to rejection by others. People with this personality disorder are easily hurt and humiliated by comments from others, which they misinterpret as degrading and disapproving. They tend to be shy, quiet, and inhibited. They say nothing rather than risk being wrong, and they react strongly to any possible indications of mockery or criticism. They usually appear anxious, self-doubting, and insecure when speaking, often use self-defeating expressions, and try to please others. Their tense and fearful demeanour may elicit ridicule from others, which confirms their insecurity. They are concerned with reacting to scrutiny by blushing or crying, which is a cause of further interpersonal avoidance. These patients often choose occupations where no social interaction is needed, and strongly avoid talking in public. The avoidant person lacks intimate relationships with friends or sexual partners unless they anticipate non-critical acceptance.

Patients with avoidant personality disorder perceive themselves as inept and inadequate, and assume that they are unattractive. They tend to see others as negative and potentially harmful. They are inattentive and repeatedly distracted by intrusive thoughts, but they attend intensely to signals of rejection. These people tend to make negative evaluations of situations and exaggerate risk. They have a low tolerance for dysphoric affects, which they avoid by escaping. Escape from reality through fantasy is their usual way of satisfying their needs and relieving frustration.

At interview they may be quite open if they feel accepted. This happens when good rapport is made, which is often easier in clinical than in social situations. However, social limitation outside the office may be intense. Avoidant patients usually feel ashamed about many aspects of their lives and are excessively self-critical, although most of the concerns expressed seem to be trivial.

(d) Course

Avoidant personality disorder may follow childhood fear of strangers and shyness and isolation during school years. However, most shyness in childhood gradually dissipates in adolescence. When it evolves into avoidant personality disorder, the shyness may worsen in adolescence when social and interpersonal relationships become more complex and demanding. The disorder tends to remit or to become less evident in older people.

Avoidant personality disorder is often associated with depressive episodes, dysthymia, and anxiety disorders, particularly social phobia.

(e) Differential diagnosis

It is often difficult to differentiate avoidant personality disorder and social phobia of the generalized type. Impairment and distress due to the phobic situations is more intense in social phobia, which may have started in middle adulthood rather than adolescence. It is not clear whether the disorders are alternative manifestations of the same condition, or are separate disorders.

Hypersensitivity to rejection and criticism, low self-esteem, and feelings of inadequacy are also features of dependent personality disorder. While the avoidant patient avoids contact, the dependent patient focuses on being cared for. However, the disorders often co-occur and must be diagnosed together.

Schizoid and schizotypal personality disorder are also characterized by social isolation. However, avoidants want to have relationships and suffer for their isolation, while schizoids and schizotypals accept isolation.

People with paranoid personality disorders lack confidence in others. However, avoidants do not confide in others because they fear being found inadequate, whereas paranoids fear malicious intent.

(f) Treatment

Anxiety and hypersensitivity to rejection may improve with anxiolytic medication, β-blockers, monoamine oxidase inhibitors, and antidepressant medication. Medication should be combined with psychological treatment based on reinforcing assertiveness and self-esteem, and restructuring cognitive distortions concerning the self and others. Conscious and unconscious dependency needs should be addressed.

Dependent personality disorder (JLC)

Individuals with this disorder show a persistent and global pattern of behaviours directed at avoidance of the loss of intimate others. To attain this goal, they relinquish their own needs, opinions, expression of feelings, and even their self-identity. In exchange, they get others to take over responsibility for major areas of their lives and to protect them. Their self-concept is characterized by weakness and helplessness, while others are perceived as powerful and protective.

These people were formerly included in different classificatory categories. They belong to the abulic type of Kraepelin and of Schneider[2] and were considered as immature personalities.

(a) Aetiology

Classic hypotheses attributing dependent personality to fixation in oral phase of psychosexual development have given way to others indicating that the cause is rather deprivation than overgratification in the oral phase.

Dependent personality was recognized first in DSM-III.[11] The description has changed little in DSM-IV (Table 4.12.3.13) and ICD-10.[52] The crucial feature in both systems is the urgent need of patients to be cared for by others, with dependence, attachment, and fear of abandonment. Lack of self-confidence was required in DSM-III, but was eliminated from recent classifications because it is not specific to this disorder.

(b) Clinical picture

Dependent patients are passive. They rarely express needs or feelings, especially those that are sexual or aggressive. They tend to avoid responsibilities or decisions in major areas of their lives, such as work and financial or interpersonal relationships. Instead they get others, particularly family or partner, to decide for them or to provide continuous guidance. They depend on others (often one other person, usually the partner or a parent) to decide where they should go, what they should do, and even which clothes they should wear. They manifest self-doubt, pessimism, and a need for affection. They lack aggressiveness and appear helpless. The dependent patient avoids jobs that demand taking responsibility and managing others, and becomes anxious when forced into such situations. These patients seek intensely for companionship and do not tolerate being alone. They may function at an adequate level if in a close and protective relationship, but when left alone they are unable to survive. They believe that they are incapable of functioning independently and require constant assistance. They do not initiate projects, but wait for others who, they believe, will do them better. However, dependent individuals can perform such tasks for other people whom they want to please and to whom they want to attach themselves.

They accept unpleasant tasks, are self-sacrificing, and tolerate verbal, physical, or sexual abuse. Abusive relationships may be accepted as long as the attachment is preserved and is not excessively distorted.

An excessive and unrealistic fear of abandonment is constant in dependent individuals. When an intimate relationship is terminated by separation or death, dependent individuals urgently seek another person who will provide the care and support they seek. Thus they become rapidly and indiscriminately attached to other persons when left alone.

These people are pessimistic, self-doubting, and have low self-esteem. They belittle their capacities and successes and present themselves as inept. They take criticism as a proof of their ineptness and confirmation of their lack of self-confidence.

Table 4.12.3.13 DSM-IV diagnostic criteria for dependent personality disorder

A pervasive and excessive need to be taken care of that leads to submissive and clinging behaviour and fears of separation, beginning by early adulthood and present in a variety of contexts, as indicated by five (or more) of the following

1. Has difficulty making everyday decisions without an excessive amount of advice and reassurance from others
2. Needs others to assume responsibility for most major areas of his or her life
3. Has difficulty expressing disagreement with others because of fear of loss of support or approval. **Note** Do not include realistic fears of retribution
4. Has difficulty initiating projects or doing things on his or her own (because of a lack of self-confidence in judgement or abilities rather than a lack of motivation or energy)
5. Goes to excessive lengths to obtain nurturance and support from others, to the point of volunteering to do things that are unpleasant
6. Feels uncomfortable or helpless when alone because of exaggerated fears of being unable to care for himself or herself
7. Urgently seeks another relationship as a source of care and support when a close relationship ends
8. Is unrealistically preoccupied with fears of being left to take care of himself or herself

(c) Epidemiology

Recent studies have found a median prevalence of 0.7 per cent (see Chapter 4.12.5). Although dependent personality disorder is diagnosed more frequently in women, structured interviews have not shown significant differences between the sexes. Cultural factors may affect the reported prevalence, as passivity, politeness, and submission are normal in some societies.

(d) Course

Dependent personality features present in adolescence may evolve positively in adulthood or lead to a personality disorder. Dependent individuals are at increased risk of depressive, anxiety, and adjustment disorders, particularly in relation to loss of close relationships. Dependent personality disorder may follow separation anxiety in childhood, or chronic physical illnesses in childhood requiring long periods of care and attention.

(e) Differential diagnosis

Dependent personality disorder has some similarities with histrionic personality disorder. Histrionic patients, like dependent patients, adjust their conduct to please other people. Their lives are centred in these others. However, people with histrionic personality disorder obtain attention and care by seductive or manipulative behaviours, whereas people with dependent personality disorder wait passively for others to care for them.[7]

Like people with avoidant personality disorder, dependent individuals may feel devastated by minor criticism or lack of attention from others. However, they lack the sense of embarrassment and social shyness of the avoidant, and fear loneliness or abandonment.

People with dependent and borderline personality disorders share an excessive fear of abandonment. However, borderline individuals react to separation with feelings of emptiness and rage, and are demanding, in contrast with the submissive and appeasing attitude of dependent individuals, which is directed towards finding another person to provide support.

Dependent personality disorder must be differentiated from normal dependent behaviours in specific life situations; for example, elderly people with chronic or debilitating disease may become dependent.

(f) Treatment

Pharmacological treatment is indicated only when depressive or anxiety symptoms are present, especially when associated with separation or loss.

In psychotherapy, the therapist must avoid the development of excessively dependent attachments. Self-confidence and self-esteem should be enhanced and the patient helped to enjoy the feeling of personal autonomy and independence. Cognitive restructuring and social skills training are often useful in bringing these changes about.

Obsessive–compulsive (anankastic) personality disorder

While DSM-IV labels this personality disorder as obsessive–compulsive personality disorder (Table 4.12.3.14), ICD-10 prefers the term anankastic, previously used in European psychiatry to refer to fearful, insecure, and compulsive individuals. The cardinal feature of this disorder is an exaggerated and pervasive attempt to control. Anankastic patients need to control those who are close to them, to control every uncertainty, and to control their own thoughts and emotions. The anankastic lacks an internal sense of security and tries to make the external world totally predictable. The anankastic is afraid of his own internal aggressive drives and avoids free emotional expression. Others perceive this kind of personality as characterized by inflexibility and stubborn inefficiency.

Table 4.12.3.14 DSM-IV diagnostic criteria for obsessive–compulsive personality disorder

A pervasive pattern of preoccupation with orderliness, perfectionism, and mental and interpersonal control, at the expense of flexibility, openness, and effciency, beginning by early adulthood and present in a variety of contexts, as indicated by four (or more) of the following

1. Is preoccupied with details, rules, lists, order, organization, or schedules to the extent that the major point of the activity is lost
2. Shows perfectionism that interferes with task completion (e.g. is unable to complete a project because his or her own overly strict standards are not met)
3. Is excessively devoted to work and productivity to the exclusion of leisure activities and friendships (not accounted for by obvious economic necessity)
4. Is overconscientious, scrupulous, and inflexible about matters of morality, ethics, or values (not accounted for by cultural or religious identification)
5. Is unable to discard worn-out or worthless objects even when they have no sentimental value
6. Is reluctant to delegate tasks or to work with others unless they submit to exactly his or her way of doing things
7. Adopts a miserly spending style toward both self and others; money is viewed as something to be hoarded for future catastrophes
8. Shows rigidity and stubbornness

(a) Epidemiology

The prevalence of obsessive–compulsive personality disorders is about 1 per cent in community samples and up to 10 per cent in psychiatric patients, especially those with depressive and anxiety disorders. It is most frequent among males. Some obsessive–compulsive traits are sanctioned in some cultures, and a personality disorder should not be diagnosed unless the traits are markedly beyond the average for the culture.

(b) Aetiology

Biological factors and learning seem to be involved in the aetiology of obsessive–compulsive personality disorder. The personality may be partly inherited.[53] Early psychodynamic theories linked obsessive personality to the anal phase of psychosexual development between the ages of 2 and 4, when libidinal drives come into conflict with parental attempts to socialize the child, especially in sphincter control and toilet training. Later psychoanalytic theory[54] emphasized earlier manifestations of the child's autonomy versus parental wishes. The expression of drives and emotions, including anger, is shaped by parental responses and may evoke shame and criticism.

This dynamic sequence is reinforced in societies which are strongly influenced by the Protestant work ethic, in families where individual emotions are subordinated to the group, and in societies in which open expression of emotions is discouraged.

(c) Clinical picture

The behaviour of an obsessive–compulsive personality has been consistently described as one of orderliness. The patient is preoccupied with details, and pays attention to rules, procedures, schedules, and punctuality. Patients with obsessional personalities often produce their own detailed lists of symptoms and are annoyed if any item is neglected or misinterpreted. They repeat actions and check for mistakes, despite the inconvenience and annoyance that result from this behaviour. As a consequence, their conduct is frequently inefficient. For example, the combination of unproductive perfectionism and rigidity may lead to difficulty in finishing a written report on time because of excessive correction and rewriting. Since this striving for perfection and order is time consuming, other areas of their lives often appear disorganized. One room or one desk drawer may fall into disarray, or parts of their social or family lives may be disorganized.

People with obsessive–compulsive personality focus on work and productivity. It is difficult for them to take vacations or even to have free time. They do not enjoy leisure activity, which they may consider a waste of time. Often, they need to take work home to alleviate their anxiety. Hobbies and leisure pursuits become formally organized activities. They insist on perfect performance of sports or games and transform them into a serious task requiring careful organization and hard work. Leisure activities may be an unpleasant experience for the others involved, owing to the insistence on rules and standards.

Stubbornness is another characteristic of these people. They need things to be done in their way, and realistic arguments do not usually make them change their insistence. They need others to submit to their way of doing things, and often believe that no one can do the tasks as perfectly as they can. They give detailed instructions, insisting that their way is the only way of doing things, and are irritated if others suggest alternatives. Therefore, they generally insist in doing everything themselves and are unable to delegate, which increases their inefficiency at work. Paradoxically, their stubbornness is associated with doubt. Indecisiveness is a constant characteristic unless they have structured guidelines. They fear making mistakes or misjudgements, and delay repeatedly until they have enough data to take what they consider the only right decision. When rules do not dictate the correct answer to a problem or when procedures for tasks are not laid down, decision-making or task initiation may become a lengthy and painful process.

People with this personality disorder are characterized by excessive conscientiousness and scruples. They are inflexible about matters of morality, ethics, or values. Moral principles and standards of performance have to be followed rigidly, and respect for authority and rules is absolute. Failure to do these things leads to irritation, anger, and self-criticism.

These people are stingy and mean, and often live with standards far below their actual socio-economic status. They dislike spending, believing that money should be saved in case of future difficulties. They have great difficulty in discarding worn-out or worthless objects, believing that they might be useful some day. They may hoard objects such as newspapers or broken appliances, even when they have no sentimental value.

These people are humourless and lack spontaneity of emotional expression. Usually they do not express anger directly. However, they are often angry in situations in which they are unable to control the behaviour of themselves or others. Anger is generally manifested by indirect aggressive acts (such as leaving a small tip or not providing minor help when expected). Their management of anger is closely related to their attitude of dominance–submission towards authority figures. They may be excessively submissive to a person in authority whom they respect, but obstructive with an authority figure whom they do not respect.

The affect of the obsessive person is controlled and stilted. It is not flat or blunted, but constricted. They do not laugh or cry, and feel uncomfortable with people who express their feelings. Their mood is usually serious but may appear anxious or depressed. In a clinical interview they may sit in a stiff unnatural posture, and seldom make spontaneous comments about their emotions. They usually relate their history in a pedantic and circumstantial manner. If interrupted by a question from the doctor, they have to finish their monologue before answering. When asked about feelings, they answer with lists of facts and circumstances. They can label emotions and feelings, but are unable to display them.

In summary, obsessive personalities love order, neatness, and sameness, and hates novelty, spontaneity, and change. They need control, security, and certainty, and avoid creativity, art, and excitement. They mitigate anxiety by following strict rules and repress emotional expression by avoiding spontaneity. They fear their inner fragile and aggressive emotional world.

(d) Course

Like other personality disorders, obsessive–compulsive personality disorder is present in early adulthood and tends to be persistent and constant. However, some adolescents with marked obsessive traits become warm, loving, and tender adults. On the other hand, intense obsessional traits in adolescence are occasionally a premorbid stage of schizophrenia ('pseudoneurotic schizophrenia'). The developmental relationship between obsessive–compulsive personality disorder and obsessive–compulsive disorder is controversial. In the past, it was suggested that most obsessive–compulsive personality disorder evolved to a full obsessive–compulsive disorder, indicating that the two syndromes were expressions of the same basic disorder. More recent investigations[55] indicate that most obsessive–compulsive disorder patients do not have a comorbid obsessive–compulsive personality disorder. A variety of psychiatric disorders may present in a patient with obsessive personality, but depressive and anxiety disorders are the most common, followed by phobic, somatoform, and obsessive–compulsive symptoms. Hypochondriacal syndromes are commonly found in obsessive individuals when they lose control of situations.

Persons with this personality disorder may do well in jobs that demand working with detail, order, and structured procedures, and may adjust to interpersonal relationships with submissive spouses. However, they are particularly vulnerable to unexpected changes in their occupational and social environment. Late-onset depression is a common occurrence in obsessive–compulsive personalities.

(e) Differential diagnosis

The main difficulty in diagnosing obsessive–compulsive personality disorder is to differentiate it from obsessive–compulsive disorder. The latter diagnosis is made when occupational and personal functioning is severely impaired as a consequence of doubt, indecisiveness, hoarding, or any other obsessive behaviour. In many, but not all, cases of obsessive personality, the traits and behaviours

are egosyntonic and no resistance is present, in contrast with obsessive–compulsive disorder.

The perfectionism of obsessive personalities may be present in narcissistic personality disorder. However, narcissistic individuals tend to believe that they have achieved perfection, while obsessive individuals tend to be highly critical of their own achievements.

Social detachment and the lack of empathy and warmth may suggest schizoid personality disorder. However, obsessive individuals constrain their emotional expression to keep control of a situation, while schizoids lack the fundamental capacity for affective display or intimacy.

Not all individuals with obsessive traits have obsessive–compulsive personality disorder. Obsessive traits can be adaptive in some situations; it is only when they are maladaptive, inflexible, and persistently cause functional impairment that a personality disorder be diagnosed.

(f) Treatment

Pharmacological treatment may be tried in patients with anxiety and distress due to intense doubts, indecisiveness, and scruples. Benzodiazepines may alleviate tension in these cases. Antidepressants with a serotonergic profile sometimes improve mood and global functioning.

Psychological cognitive treatment, focusing on perfectionism, rigidity, scrupulousness, and intolerance of failure, is the main therapeutic approach. Repressed aggression, guilt, and dependency needs should be addressed using a psychodynamic approach.

Other personality disorders (not included in DSM-IV)

Passive–aggressive (negativistic) personality disorder

(a) Definition

Resistance to demands for adequate social and occupational performance and negativistic attitude are considered to be central features of passive–aggressive personality disorder. A pervasive pattern of argumentativeness, oppositional behaviour, and defeatist attitudes are typical, and are thought to be a covert manifestation of underlying aggression, which is expressed passively and indirectly. Passive–aggressive personalities have interpersonal and cognitive dysfunction and severe impairment in terms of self-image, global mental health, and ability to function at work and in intimate relationships.[56]

Passive–aggressive personality disorder was officially included in DSM-I as the passive–aggressive personality 'trait disturbance' depicted as an immature reaction to military stress by helpless, passive, and obstructive resistant behaviour. However, passive–aggressive disorder was not included in DSM-IV because of the many unsolved problems related to its concept in previous classifications. Instead, it is placed in Appendix B of DSM-IV where it is alternatively called negativistic personality disorder. Research criteria are proposed which are expected to be empirically evaluated and to determine the validity and reliability of this diagnosis (Table 4.12.3.15).

There has been much debate as to whether passive aggression constitutes a personality disorder, a defence mechanism, or a specific maladaptive personality trait (coping style).[57] Surprisingly, empirical literature on the subject is scarce, although passive–aggressive behaviour has been widely recognized by clinicians. An overlap with other personalities has been shown, and it has never been included as a separate category in the *International Classification of Diseases*. The passive–aggressive dimension, as assessed by self-reports, is always high in depressed patients and is state-dependent.[58] Perhaps it would be best to conceptualize passive aggression as a continuum: a passive–aggressive defence mechanism may be normal in some situations, it could be a trait of many personality disorders, and when pronounced and long-lasting it should be designated as passive–aggressive personality disorder.

Table 4.12.3.15 DSM-IV research criteria for passive–aggressive personality disorder

A.	A pervasive pattern of negativistic attitude and passive resistance to demands for adequate performance, beginning by early adulthood and present in variety of contexts, as indicated by four (or more) of the following
	1 Passively resists fulfilling routine social and occupational tasks
	2 Complains of being misunderstood and unappreciated by others
	3 Is sullen and argumentative
	4 Unreasonably criticizes and scorns authority
	5 Expresses envy and resentment toward those apparently more fortunate
	6 Voices exaggerated and persistent complaints of personal misfortune
	7 Alternates between hostile defiance and contrition
B.	Does not occur exclusively during major depressive episodes and is not better accounted for by dysthymic disorder

(b) Epidemiology

The population prevalence ranges from 0.9 to 3 per cent, but in those cases in which a secondary co-occurring diagnosis was assigned, the secondary frequency of passive–aggressive personality disorder was about 10 per cent.[59] Some studies found a higher prevalence in women and others in men.

(c) Aetiology

The cause of the disorder is multidimensional, comprising biological, psychoanalytical, behavioural, interpersonal, and social learning perspectives.

Ambivalence is considered to be a core conflict of passive–aggressive personalities, which originates from fixation to the biting or sucking stages of the oral phase of psychosexual development. Some authors consider masochism to be another precursor of the passive–aggressive personality.

According to the behavioural model, passive–aggressive behaviour is the expression of anger in maladaptive verbal and non-verbal ways that do not lead to rewarding problem-solving Failure to learn appropriate assertive behaviour would be the main aetiological factor.[60]

The primary social factor influencing the development of passive–aggressive patterns would be contradictory parental attitudes in childhood which, being conflicting and incompatible, prevent the child from expressing his feelings directly and thus urge him to develop passive resistance.

(d) Clinical characteristics and diagnosis

Passive–aggressive personalities seek novel and stimulating situations in impulsive ways, while remaining unpredictable.[61] Procrastination and inefficiency are behaviours used to avoid responsibility, which they show by stubborn resistance to the fulfilment of expectations and claiming forgetfulness.

Passive–aggressive individuals easily become irritable and, gloomy and they are resentful and discontent with life. Accumulated anger may be expressed by verbal acting-out, after which passive–aggressive individuals feel guilty and gloomy. Since they have difficulties in expressing emotions directly, they are prone to diffuse somatic complaints, hypochondriasis, and psychosomatic disorders.

Interpersonal ambivalence is a core feature of passive–aggressive personality disorder. Negativism is particularly expressed towards authorities, with whom they are never satisfied and whom they criticize constantly. The argumentative self-detrimental behaviour of passive–aggressive personalities is often experienced by others as punitive and manipulative. Negative verbal comments, which are often caustic, and irritable and moody patterns of communication are typical.

Passive–aggressive individuals are cynical, sceptical, hypercritical, and mistrustful. Disillusioned with life, discouraged, discontented with themselves and with others, they are also pessimistic about the future. They persistently complain and blame others for their own bad luck, feeling themselves to be misunderstood martyrs and victims of destiny.

(e) Comorbidity and differential diagnosis

Passive–aggressive personality disorder is frequently comorbid with major depression, dysthymic disorder, anxiety, panic disorder, and hypochondriasis. Patients with depressive disorders are more aware of their feelings of inferiority and more likely to feel guilty, and their depressed mood is continuous rather than erratically hostile and moody, as in passive–aggressive personality.

Comorbidity with many personality disorders (histrionic, borderline, obsessive–compulsive, dependent, narcissistic) is also frequently observed. People with these personality disorders may use passive aggression as a defence mechanism. Suicide attempts are not as frequent as in histrionic and borderline personality disorders, and features of passive–aggressive personality are less dramatic, affective, openly aggressive, and severe.

(e) Course and prognosis

There are insufficient data on the course and prognosis of passive–aggressive personality disorder. When passive–aggressive people are unable to control their anger, they may experience anxiety, panic states, depressive episodes, chronic depression, and psychosomatic disorders. They are prone to alcohol abuse, and their careers are erratic and stunted despite their abilities (frequent changes of jobs are common). Suicide attempts may complicate this disorder.

(f) Treatment

(i) Pharmacotherapy

Target symptoms, such as depression, anxiety, and somatic complaints, should be treated. Benzodiazepines may be warranted and helpful in the initial period of psychotherapy. The side effects of medication are often the reason for complaints about their psychiatrist's inefficiency. Non-compliance is frequent, reflecting resistance to the therapist. Abuse of medicaments should be controlled and considered seriously.

(ii) Psychotherapy

Psychotherapy is the treatment of choice. Various modes are used, including supportive, psychodynamic, behavioural assertiveness training, and the paradoxical approach in group or individual settings. The goal of treatment should be to help the patient escape from the vicious circle of self-defeating behaviour and develop a mature way of expressing anger and other feelings.

Self-defeating (masochistic) personality disorder

Individuals with masochistic personality disorder persistently seek humiliation and failure, and submit to the will of others.

The term masochism was introduced to psychiatry by Krafft-Ebing in 1882. It is derived from a character in a novel by the German author Leopold von Sacher-Masoch, a man who endured torture, scorn, and humiliation from a woman. Later, Freud conceptualized masochism as the result of aggressive instinct directed towards the self instead of an external object. Reich[62] described the masochistic character as a person who suffered deep frustrations in early developmental stages and needed to express this frustration through suffering inflicted by the love 'objects'. Thus defiance is always present in the masochistic search for love. According to Horney,[63] helplessness and victimization may be a masochistic way of expressing hostility by making others feel shameful. Masochistic suffering may also be used to avoid reproach and responsibility and as a way of restoring a sign of personal value.

(a) Clinical picture

People with self-defeating personality disorder avoid pleasurable experiences and undermine their achievements. They neglect their appearance and live below their means. They accept and endure humiliation, expecting that others will sympathize with them. In this way, they fulfil their expectation that submission will bring love and care. They prefer to relate to people who abuse them and consider those who consistently treat them well to be boring.

These people fail to accomplish tasks of which they are capable and adopt an inferior role. When making appropriate demands, they feel that they are taking advantage of others and adopt an apologetic manner. For them, success is inversely related to inner security. Successful relationships do not make them feel confident, but increase their fears. They tend to believe that all experiences involve future frustration and pain. They may respond to positive personal events with depression and behaviour that negates their accomplishments. They look for people who will respond to their behaviour with disdain, rejection, or cruelty.

People with self-defeating personality disorder do not defend themselves against expressions of disgust and resentment directed towards them and rarely accuse or reproach others. They do not feel confident and are not assertive. They fear that optimism may lead to greater problems.

They are not worried by these attitudes. Rather, masochists believe that by exaggerating their weaknesses and inefficiency they will protect themselves from aggression by others. They feel protected when someone needs something from them, and many non-assertive masochists engage in self-sacrifice for their own protective feelings rather than for the welfare of others. What seems to be a comprehensive and self-sacrificing attitude reflects a lack of confidence and empathy.

The mood of these individuals is usually dysphoric, fluctuating between anxiety and sadness.

(b) Differential diagnosis

Since masochistic personality disorder is not included in DSM-IV, little research has been done on comorbidity or on the validity or specificity of this diagnosis.

Self-defeating attitudes, low self-esteem, and depression may be found in individuals with dependent, borderline, and depressive personality disorders. Some of the characteristics are also found in avoidant personality disorder.

Masochists are prone to mood disorder and dysthymia. Anxiety disorders are frequent. Their fears of abandonment are a persistent source of anxiety. Hypochondriasis and somatization are also common, sometimes as a way of obtaining attention.

(c) Treatment

Antidepressants and anxiolytics may be useful to alleviate a dysphoric state. Psychological treatment should take into account that masochistic patients sometimes induce an aggressive countertransference as a response to their own wish to be hurt. The therapist should gradually clarify the behaviours, which provoke hostile responses and seek to reward adaptive interpersonal behaviours. Training in assertiveness and social skills is sometimes helpful.

Sadistic personality disorder

Sadistic personality disorder is a controversial category, which is not included in either DSM-IV or ICD-10. Some authors, especially those working with perpetrators of abuse, support its inclusion in the diagnostic nomenclature, believing that it is a valid clinical entity, which deserves special treatment. Sadism as a term describing desire to inflict pain upon the sexual object was originally used by Krafft-Ebing.[64] Kernberg[32] connects two dispositions (sadistic and masochistic) into a sadomasochistic character, which includes 'help-rejecting complainers' and often has underlying borderline personality organization.

(a) Aetiology

Subjects with sadistic personality disorder often had a history of significant childhood loss and physical, emotional, or sexual abuse during childhood.[65] Despite their significant psychopathology, sadistic individuals are surprisingly highly functioning, with steady employment and intense long-lasting relationships.

(b) Clinical picture

Sadistic individuals demonstrate a long-standing maladaptive pattern of cruel, demeaning, and aggressive behaviour towards others in order to cause suffering and pain and to establish dominance and control. Sadistic persons are fascinated by violence, weapons, injuries, and torture, and are most frequently encountered in forensic settings among child and partner abusers.

(c) Differential diagnosis

The major distinction for the diagnosis of sadistic personality disorder is from antisocial personality disorder. Sadistic persons may simply represent an aggressive (antagonistic) subtype of psychopathy. Intimidation and sadistic control of others, as well as a fascination with weapons, martial arts, and torture, may be manifested by both antisocial and sadistic individuals. Moreover, both disorders may display 'malignant narcissism',[37] with an admixture of narcissistic, antisocial, sadistic, and paranoid features.

(d) Epidemiology

Existing data[66] suggest that sadistic personality disorder is relatively uncommon, although it may have a higher prevalence in specific forensic populations. Several studies found a high overlap with narcissistic, paranoid, and antisocial personality disorders, which raised the possibility that sadistic personality disorder may not be a distinct entity.

(e) Course

No data are available on the course of this disorder.

(f) Treatment

Sadistic individuals seldom seek treatment, and are usually encountered in forensic settings. No treatment has been successful for this disorder. Since the aetiology is probably multifactorial, there should be multiple approaches to treatment. The primary aim of treatment is control of cruelty and malignant aggression. As with antisocial personalities, selective serotonin reuptake inhibitors and lithium may be beneficial in regulating the serotonergic function that probably underlies the aggressive action, and carbamazepine and clonazepam may act to regulate ictal aggressive outbursts.

Psychotherapy is usually difficult because these individuals lack any desire to change and because there may be serious countertransference problems for the therapists. Small groups may be helpful because there is a dissolution of transference and peer confrontation is accepted more easily.

Depressive personality disorder

This personality disorder is not included in ICD-10 or DSM-IV, although it is considered as a subject for further study in the latter. However, the concept of depressive personality was well recognized in previous decades (e.g. by Kraepelin and Schneider). Depressive personality was seen as a pattern of brooding, pessimism, and low self-confidence,[2] and as a tendency to physical lassitude and suffering. Phenomenological accounts[67] emphasize dependency, orderliness, and adherence to social conventions. The psychoanalytic concept of masochism[47] overlaps to some extent with the classical depressive personality. More recently, Akiskal[68] has discussed the depressive personality as part of a spectrum of affective disorders, reviving Kretschmer's ideas[10] on the role of temperament as the base from where psychiatric disorders develop.

(a) Aetiology

Psychological and biological factors have been suggested as causes of depressive personality disorder. Early losses, inadequate attention from parents, and a punitive superego have been postulated by psychoanalytic authors. Others have suggested that a depressive temperament is genetically related to affective disorder.

(b) Clinical picture

People with depressive personality disorder are submissive, quiet, introverted, and unassertive. Their cognitive style is marked by pessimism, dejection, and self-reproach. They appear gloomy, joyless, cheerless, and unhappy. They are serious and lack a sense of humour. They do not believe that they deserve to be happy. They have a negative view of the past and present and do not expect things to improve. They anticipate failure and dwell on their negative perspective of life. They have a low tolerance to shortcomings and failures, which are seen as confirming their own pessimistic assumptions. They are prone to guilt and judge themselves severely.

Their self-esteem is low and they feel inadequate. They focus on the failings of others and are critical of themselves.

(c) Epidemiology

No data are available on the frequency of this disorder in the population.

(d) Differential diagnosis

Some clinicians doubt whether a distinction can be made between depressive personality disorder and dysthymic disorder. The diagnosis of depressive personality disorder emphasizes cognitive and behavioural aspects rather than the depressed mood. Also, dysthymia, although chronic, has a fluctuating course.

Dysthymic patents generally experience their symptoms as egodystonic, while people with depressive personality disorder think that they have a realistic view of their situation. People with depressive personality disorder may meet the criteria for dependent personality disorder and self-defeating personality disorder, and it is difficult to distinguish between these disorders.

(e) Course

Patients with depressive personality disorder have depressive episodes and dysthymia more frequently than other individuals, and may have difficulties in adapting to stressful or uncertain situations.

(f) Treatment

Antidepressants may be useful when the person is at higher risk for developing a depressive episode. Psychological treatment may be helpful, since these people have a good capacity for introspection and reality testing. Cognitive approaches can help patients to understand their negative views and derogatory attitudes. These patients usually establish a good therapeutic relationship with the clinician.

Personality changes

Enduring personality changes after traumatic experiences

ICD-10 has two categories for personality changes: those occurring after catastrophic situations, and those starting after psychiatric illness. Either diagnosis should be made only when there is evidence of a definite personality change, including cognition, behaviour, and interpersonal relationships. The changes must not be a manifestation of a current mental disorder or the residue of a previous mental disorder. It must not be an exacerbation of a pre-existing personality disorder.

The **aetiology** of the personality change presumably relates to the extreme existential experience of the catastrophic situation or the psychiatric illness.

Examples of catastrophic experiences include life in concentration camps, experiences of disaster, and prolonged exposure to other life-threatening situations. Personality changes following short-term exposure to life-threatening situations, such as a car accident, should not be included in this group, since such changes probably depend on a previous psychological vulnerability. In ICD-10, the symptoms of personality change after catastrophic experiences include hostility and mistrust of the environment, social withdrawal, feelings of emptiness or hopelessness, estrangement, and alertness or feeling on the edge.

When the personality change follows a mental disorder, the cause is related to the stressful experience and the perceived damage to the patient's self-image arising from the disease. Other people's attitudes towards the illness, the subjective emotional experience, and previous psychological adjustment are also important. Features of the personality change after mental disorders include feelings of being stigmatized and consequent withdrawal, passivity, and loss of interests, dependence, excessive demandingness and complaining, and dysphoric–labile mood.

Personality change due to a general medical condition (JLC)

This category, which is included in both ICD-10 and DSM-IV, describes syndromes affecting global features of behaviour, cognition, and emotions, and secondary to the physiological effects of general medical diseases.

The essential feature is a change in personality after a general medical disease. In childhood before a stable pattern of personality has been established, a marked deviation from normal development suggests the diagnosis.

A central feature is loss of control over the expression of emotions and impulses. Affect is commonly labile and shallow, although persistent mild euphoria or apathy may be present, especially when the frontal lobes are affected. The elevated mood of these patients is hollow and silly, unlike that of hypomania. Patients may appear childish, expansive, and disinhibited, but they may admit to not feeling happy. Others are indifferent and apathetic.

Exaggerated expressions of rage and aggression are usually present, often out of proportion to any stressor. Loss of impulse control is also shown in social and sexual disinhibition, inappropriate jokes, and overeating.

(a) Aetiology

In most cases this disorder is associated with structural damage to the brain. Head trauma, cerebral neoplasms, vascular accidents, multiple sclerosis, Huntington's disease, and complex partial epilepsy may all cause personality change, especially when affecting frontal and temporal lobes. Systemic diseases involving the central nervous system, including endocrine disorders, AIDS, lupus erythematosus and chronic metal poisoning, may have the same effect.

Patients with this disorder generally have a clear sensorium but may be inattentive and have some mild cognitive dysfunction. They do not show intellectual deterioration.

(b) Differential diagnosis

In dementia, personality change is accompanied by intellectual deterioration. However, personality change may predate the dementia. Distinction from schizophrenia and other personality disorders is based on the clinical history and the presence of a general medical disease capable of causing personality change.

(c) Treatment

If possible, treatment is directed to the causative condition. Pharmacological treatment of specific symptoms may be useful when depression or inappropriate anger is present.

4.12.4 Epidemiology of personality disorders

Francesca Guzzetta and Giovanni de Girolamo

Introduction

tbegun to be scientifically investigated. This development has taken place because a number of standardized instruments to assess personality and PD in an empirical fashion have been developed, in parallel with the refinement of a valid and reliable diagnostic system based on a categorical approach.

The need for the epidemiological investigation of PDs seems justified for several reasons.

1 As seen in recent epidemiological surveys, PDs are frequent and have been found in different countries and sociocultural settings.

2 PDs can seriously impair the life of the affected individual and can be highly disruptive to societies, communities, and families.

3 Personality status is often a major predictive variable in determining the outcome of Axis I mental disorders and the response to treatment.

In this chapter, we review the epidemiological literature on PDs up to October 2007, focusing on studies carried out since the development of the DSM-III. First, community prevalence studies of PDs are reviewed. We then look at the prevalence of individual PDs in the community. Finally, we consider the prevalence of PDs in clinical populations, and in special settings (e.g. primary care, prisons, etc.).

Community epidemiological studies of unspecified personality disorders

Until the development of the DSM-III diagnostic criteria for PDs and the subsequent availability of standardized assessment instruments, epidemiological studies aimed at assessing the prevalence rate of PDs were hampered by severe methodological limitations, including differences in sampling methods and in diagnostic criteria, the known unreliability of PD diagnoses based on clinical judgement, and the lack of standardized assessment methods. Since 1980, twelve main studies with at least 200 subjects sampled have ascertained the prevalence rate of PDs in different community samples using assessment instruments specific for PD; they are shown in Table 4.12.4.1.

In these studies, the sample sizes ranged between 200 and 2053 subjects, with an average sample of 565.4; all surveyed individuals were evaluated by means of a specific PD assessment instrument, mainly a structured interview. While most studies were carried out in one stage, Lenzenweger *et al.*[6] first screened a large sample of university students with a self-administered Axis II inventory, and then interviewed a subgroup of 258 subjects using the International Personality Disorder Examination. The median prevalence rate of any PDs in these eight studies is 12.5 per cent.

Two large community studies[13,14] carried out in the USA were not included in Table 4.12.4.1 since PD prevalence rates were based

Table 4.12.4.1 Prevalence rates of personality disorders in epidemiological surveys

Reference	Country	Sample size	Sample features	Diagnostic Criteria	Assessment method	PD prevalence rate (%)
Black *et al.*[1]	USA	247	Relatives of obsessive-compulsive and normal control probands	DSM-III-R	SIPD	**22.3**[a]
Casey & Tyrer[2]	UK	200	Urban and rural residents	ICD-9	PAS	**13.0**
Coid *et al.*[3]	UK	626	Urban and rural residents aged 16–74 and selected in a 2 phase survey (weighted data)	DSM-IV	SCID-II	**4.4**
Crawford *et al.*[4]	USA	644	Individuals re-interviewed from previous surveys, mean age 33.1 years (range 27.7–40.1)	DSM-IV	SCID-II	**15.7**
Klein *et al.*[5]	USA	229	Relatives of normal controls	DSM-III-R	PDE	**14.8**
Lenzenweger *et al.*[6]	USA	258	University students age 18–19 years (two-stage procedure)	DSM-III-R	IPDE	**3.9**[b]
Maier *et al.*[7]	Germany	452	Normal controls, their partners, and relatives	DSM-III-R	SCID-II	**10.0**
Moldin *et al.*[8]	USA	302	Normal controls, parents and their children	DSM-III-R	PDE	**7.3**
Reich *et al.*[9]	USA	235	Urban residents	DSM-III	PDQ	**11.1**
Samuels *et al.*[10]	USA	742	Individuals re-interviewed from previous survey, aged 34–94 years (weighted data)	DSM-IV	IPDE	**9.0**
Torgersen *et al.*[11]	Norway	2,053	Individual from National Register (weighted data)	DSM-III-R	SIPD	**13.4**
Zimmerman & Coryell[12]	USA	797	Relatives of patients and normal controls	DSM-III	SIDP	**14.3**[a]

PAS, Personality Assessment Schedule, IPDE, International Personality Disorder Examination; PDE, Personality Disorder Examination; PDQ, Personality Diagnostic Questionnaire; SCID—II, Structured Clinical Interview for DSM-IV Axis II disorders; SIDP, Structured Interview for DSM-III-R Personality.

[a] Prevalence includes those with 'mixed' and 'not otherwise specified' disorder.

[b] Prevalence was 6.7% 'definite', 11% 'possible', including 'not otherwise specified disorder'.

on screening questions[13] and on a newly developed fully diagnostic structured interview carried out by lay interviewers rather than clinicians, which lacked any accompanying validity data.[14]

In the surveys considered here, the rate of PDs decreases in older age groups; although the sex ratio is different for specific types of PD (e.g. more schizoid, narcissistic, and antisocial PDs among males, more dependent, avoidant, and histrionic PDs among females), the overall rates of PD are about equal for both sexes. Finally, prevalence rates are generally higher in urban populations and lower socio-economic groups.

Community epidemiological studies of specified personality disorders

Table 4.12.4.2 lists the median prevalence rates for specified PDs based on studies that surveyed different types of randomly selected community samples. We will comment on some of the findings. The first column shows the number of studies on which the median prevalence rate is based.

Paranoid personality disorder

The median prevalence rate of paranoid PD is 1.6 per cent. In the study by Baron,[15] paranoid PD was remarkably more common among relatives of schizophrenic probands (7.3 per cent) than among relatives of control probands (2.7 per cent).

Schizoid personality disorder

There have been 13 studies evaluating the prevalence of schizoid PD in the community, with a median prevalence rate of 0.8 per cent. Baron[15] reported a rate of 1.6 per cent of schizoid PD among relatives of schizophrenic probands, but no cases among relatives of control probands.

Table 4.12.4.2 Median prevalence rates of specified personality disorders in epidemiological surveys

PD Category	Number of studies (*N*)	Median prevalence rate (%)
Paranoid	13	1.6
Schizoid	13	0.8
Schizotypal	13	0.7
Antisocial (dissocial)	24	1.5
Borderline	15	1.6
Histrionic	12	1.8
Narcissistic	10	0.2
Obsessive-compulsive	13	2.0
Avoidant (anxious)	13	1.3
Dependent	12	0.9
Passive-aggressive	8	1.7

Schizotypal personality disorder

The median prevalence rate of schizotypal PD is 0.7 per cent. However, in the study by Baron[15] schizotypal PD was remarkably more common among relatives of schizophrenic probands (14.6 per cent) than among relatives of control probands (2.1 per cent). In a similar fashion, Asarnow *et al.*[16] reported significantly higher rates of schizotypal personality disorders in relatives of probands with childhood onset of schizophrenia than in relatives of community controls (4.2 per cent vs. 0 per cent). These results provide additional support for the specific relationship between schizophrenia and schizotypal PD.

Antisocial (dissocial) personality disorder

Antisocial is the most studied PD. Its prevalence has been assessed in 24 epidemiological surveys, with a mean sample size of 2 943 subjects; nine studies used the Diagnostic Interview Schedule as assessment instrument. Antisocial PD seems to have a prevalence of around 1.5 per cent in the general population and to be substantially more frequent among males than females, with sex ratios ranging from 2:1 to 7:1. It is also more common among younger adults, those living in urban areas, and the lower socio-economic classes. People with a diagnosis of antisocial PD are also high users of medical services.

Borderline personality disorder

Borderline PD has been investigated in 15 studies. Swartz *et al.* [17] carried out a study among 1 541 community subjects (between 19 and 55 years of age) at the North Carolina site of the Epidemiologic Catchment Area (ECA) Program, using a diagnostic algorithm derived from the Diagnostic Interview Schedule (**DIS**). They found a rate of 1.8 per cent for borderline PD; the disorder was significantly more common among females, the widowed, and the unmarried. There was a trend towards an increase in the diagnosis in younger, non-white, urban, and poorer respondents. The highest rates were found in the 19 to 34 age range, with the rates declining with age. All borderline respondents had also a DIS DSM-III Axis I lifetime diagnosis.

Although some believe there is a preponderance of females with borderline PD, they do not always take into account that there is also a preponderance of females in the populations studied. There were two studies that did not find a higher female prevalence.[11,18]

Histrionic personality disorder

Histrionic PD has a median prevalence rate of 1.8 per cent, ranging from 0 per cent[3] to 3.2 per cent.[1] A study by Nestadt *et al.*[19] carried out at the Baltimore (Maryland) site of the Epidemiologic Catchment Area Program, ascertained the prevalence of histrionic PD in the community. The authors found a prevalence of 2.1 per cent in the general population, with virtually identical rates in men and women. No significant differences were found in terms of race and education, but the prevalence was significantly higher among separated and divorced persons. It should be noted that the study derived the diagnoses from instruments not originally intended to diagnose PDs; it might be possible that, in some cases, this study has identified personality traits rather than 'true' PDs.

Narcissistic personality disorder

No cases of narcissistic PD were found in five studies. However, Reich *et al.*[9] and Lenzenweger *et al.*[6] found rates of 0.4 per cent and 1.2 per cent respectively, even higher rates were found by Klein *et al.*[5] and Crawford *et al.*[4] who reported prevalence rates of 3.9 and 2.2 per cent respectively.

Obsessive compulsive (anankastic) personality disorder

The median prevalence rate of obsessive compulsive PD, obtained from 13 studies, was found to be 2 per cent, the highest of all PDs. The rate of compulsive PD was especially high in a study in which the Personality Diagnostic Questionnaire was used (6.4 per cent).[6] However, lower rates were reported with structured interviews. A community study, carried out at the Epidemiologic Catchment Area Program Baltimore site, found a prevalence of 1.7 per cent.[20] Males had a rate about five times higher than females. The disorder was also more frequent among white, highly educated, married, and employed subjects, and it was associated with anxiety disorders. However, the study derived the diagnosis from an interview originally not intended to diagnose PDs; this may mean that adaptive obsessive compulsive traits, rather than a 'true' PD, were identified. In the study by Black *et al.* [1] rates of obsessive compulsive PD were higher among relatives of probands with obsessive compulsive disorder compared to relatives of comparison probands (10.8 per cent vs. 7.9 per cent, respectively), however this difference did not reach statistical significance.

Avoidant (anxious) personality disorder

A total of 13 studies have investigated the prevalence of avoidant PD in community samples, with a median prevalence rate of 1.3 per cent. In the study by Asarnow *et al.*[16] avoidant PD occurred more frequently in relatives of schizophrenia probands compared to comparison control probands, also when controlling for schizoid or paranoid PD, and the authors suggest that avoidant PD might be a separate schizophrenia spectrum disorder, and not merely a sub-clinical form of schizoid or paranoid PD.

Dependent personality disorder

In 12 studies in which the frequency of dependent PD was assessed, the median prevalence rate was 0.9 per cent.

Passive-aggressive personality disorder

The median prevalence rate of passive-aggressive PD, obtained from 8 studies, was found to be quite high (1.8 per cent); interestingly, this type of PD has not been included either in DSM-IV or in ICD-10.

Epidemiological studies of personality disorders carried out in psychiatric settings

Table 4.12.4.3 lists the median prevalence rates for any PDs found in 61 studies carried out in inpatient and outpatient psychiatric samples and published between 1981 and October 2007. Only prospective studies that surveyed clinical samples (either inpatients or outpatients) of more than 100 subjects have been considered for

Table 4.12.4.3 Median prevalence rates of PDs among psychiatric patients in prospective studies including more than 100 subjects

Diagnostic category	Number of studies (*N*)	Median sample (*N*)	Median prevalence rates (%)
Alcohol and substance abuse	15	250	57.0
Affective disorder	19	200	49.2
Anxiety disorders	7	200	40.4
Any Axis disorder	20	131	51.0

this analysis. The second column shows the number of studies on which the median prevalence rate is based.

In these studies, subjects have been directly evaluated for the purpose of obtaining PD rates, by means of a standardized assessment instrument specific for PDs. Several other studies, which have evaluated only the prevalence of specified PDs in clinical samples, are not shown here.

In general, the prevalence of PDs among psychiatric outpatients and inpatients is quite high, with a substantial number of studies ($n = 29$) showing a PD prevalence rate equal or higher than 50 per cent of the sample. However, it is difficult to draw more definite conclusions from these studies, because of substantial differences in sampling, diagnostic criteria, timing of the assessment, assessment methods, availability of mental health services, prevalence of Axis disorders, and sociocultural factors.

There are, however, some consistencies across studies that deserve consideration. The most prevalent PD seems to be borderline, both in inpatient and in outpatient settings. The next most common PDs is histrionic, whereas schizoid PD is infrequently diagnosed. Borderline and histrionic PDs are also characterized by the lowest social functioning. They are especially common in inpatient settings, as their symptomatology often results in the patient being admitted to hospital due to their suicidal behaviour, substance abuse, and cognitive-perceptual abnormalities. In outpatient settings, dependent, and passive-aggressive PD are also common.

Especially in inpatient settings, many people who meet the criteria for one PD also meet the criteria for other PDs [21–23]. The highest comorbidity rate appears to occur with borderline PD, with the frequent coexistence of borderline and histrionic PDs, antisocial, schizotypal, and dependent PDs.

With regard to comorbidity between PDs and Axis I disorders, the most common and best-studied patterns are between substance abuse and PDs, affective disorders and PDs, and anxiety disorders and PDs (particularly borderline, antisocial, avoidant, and dependent PDs). Other clinically significant associations have been found between PDs and eating disorders: obsessive-compulsive, avoidant, and dependent PDs are most commonly associated with anorexia nervosa whereas borderline, avoidant, dependent, and paranoid PDs are the most common among individuals with bulimia.[24] High rates of PD (especially borderline and antisocial PDs) have also been detected in patients with selected medical conditions, such as HIV-positive patients.[25,26]

Some studies have assessed the treated prevalence of PD using administrative data (e.g. discharge figures, psychiatric case register data, etc.). In the United States, using data from the 1993 National Hospital Discharge Survey, Olfson and Mechanic[27] found that almost 12 per cent of patients discharged from public general hospitals had a diagnosis of PD, compared with 11 per cent of patients from non-profit hospitals and 5 per cent of patients from proprietary general hospitals.

Some investigations, which compared the hospital admission rates for PD over time, allow us to assess the impact of diagnostic changes. In Denmark, sex- and age-standardized rates of first-admitted borderline patients significantly increased during the 16-year interval between 1970 and 1985, and this might be explained in terms of a change in diagnostic habits.[28] In the United States, comparing the diagnoses given to inpatients in a large university-affiliated mental hospital in the last 5 years of the DSM-II era ($n = 5143$) with those given in the first 5 years of the DSM-III era ($n = 5771$), a marked increase (from 19 per cent to 49 per cent) was found in the diagnosis of PD, together with a decrease in the diagnosis of schizophrenia and a corresponding increase in the diagnosis of affective disorders.[29]

The epidemiological findings in treated samples are especially important if we bear in mind that the presence of a PD among those suffering from other mental disorders can be a major predictor of the natural history and treatment outcome. Therefore, an important clinical implication of these findings is that patients in treatment because of severe Axis I disorders must be carefully assessed with an assessment instrument specific for PDs, because of the high likelihood of diagnosing a PD and the subsequent need to adjust their treatment accordingly.

Epidemiological studies of personality disorders carried out in other settings

A few epidemiological studies on PDs have been carried out among patients attending primary healthcare settings; in these studies between 5 and 8 per cent of patients have been identified as having a primary diagnosis of PD.[21] When the assessment is made independent of the primary diagnosis, however, the average prevalence rate can rise several-fold because of state effects. In a consecutive sample of primary care *attenders*, a PD was diagnosed in 24 per cent of the sample (N=303) and was associated with the presence of common mental disorders and unplanned surgery attendance, indicating that PDs may represent a significant source of burden in primary care.[30]

In other institutional settings, such as prisons, several studies have found very high rates of PDs. In the United Kingdom, two large-scale studies have been completed; in the first, carried out among 750 prisoners representing a 9 per cent cross-sectional sample of the entire male unconvicted population, a PD was diagnosed in 11 per cent of the sample.[31] In the second study, a representative sample of the entire prison population of England and Wales was evaluated; a sub-sample was assessed with the SCID-II administered by a clinician.[32] The prevalence rates for any PD were 78 per cent for male remand prisoners, 64 per cent for male sentenced prisoners, and 50 per cent for female prisoners. In a large meta-analysis by Fazel & Danesh [33] of 28 studies,

including a total of 13 844 prisoners, antisocial PD was diagnosed in 47 per cent of subjects. High rates of borderline and antisocial PDs have also been found in a sample ($n = 805$) of women felons entering prison in a North American State.[34]

Conclusions

Up to 30 years ago, the epidemiology of PDs had not received the same amount of attention as that of many other psychiatric disorders. Since then the situation has changed, and we now have data on the prevalence of PD in the community and in psychiatric facilities. Community data come primarily from 12 studies, with a total sample of 6 785 subjects from four countries (Germany, Norway, the United Kingdom, the United States). There are excellent national and cross-national epidemiological data on antisocial personality disorder based on the same diagnostic methods. There are almost no data on other PDs from countries other than the United States, the United Kingdom, Germany and Norway.

One important methodological problem is that some PDs have a very low prevalence rate. Consequently, epidemiological surveys carried out among the general population may require very large samples in order to identify a sufficient number of cases to study demographic correlates and the association of PD with other psychiatric disorders. Future studies should try to address this problem and provide us with more definite epidemiological data. These data will also be invaluable in showing the validity of current classifications and in better delineating the boundaries between different PDs.

Further information

4.12.5 Neuropsychological templates for abnormal personalities: from genes to biodevelopmental pathways

Adolf Tobeña

The scaffolding of personality

Research on human personality has converged upon a 'consensual pathway' indicating that a small number of dimensions can provide the framework for describing the rich variety of human temperaments. These high-level temperamental traits are factorially derived from psychometric measures of individual variation in behaviour, feeling, and thinking,[1,2] and it is assumed that they may reflect the operation of brain systems that are probably multifaceted and multipurpose.[3–5] This global outline of the structure of personality depends on the notion that genetic and developmental dispositions combine with critical nurturing and social conditioning events to form the tapestry of human uniqueness within temperamental clusters. In other words, personality types are expressed through relatively clear-cut and stable phenotypic traits that are accessible to objective measurement at behavioural, emotional, and cognitive levels. These depend, in turn, upon the specific and early organization of particular neurocognitive and neuroendocrine templates.

A handful of 'superfactors' (broad traits or dimensions) apparently capture the essential components of the mosaic of terms and traits used to describe normal personality. These dimensions are *neuroticism*, *extraversion*, *agreeableness/friendliness*, *conscientiousness*, and *intellectual openness*. Neuroticism and extraversion always appear as main stars in these factorial *solutions* whereas the remaining three superfactors—conscientiousness (reliability/persistence), friendliness (as opposed to aggressiveness/hostility) and intellectual curiosity (openness/creativity)—have less regularity on such high-order taxonomies. A five-dimensional structure is advocated by many researchers though dissent is still strong regarding the nature and scope of these superfactors that would define the 'core' of human temperament.[6]

Biological rooting of personality types

Searching for biological substrates of personality dimensions would reinforce their validity as useful constructs but this endeavour was largely neglected by psychometricians devoted to purely descriptive studies and by clinical researchers as well. Some pioneers, like Hans Eysenck at the Institute of Psychiatry, London, tried to root behavioural trait variations within neurobiological concepts[1] following a venerable tradition, which can be traced back as far as Pavlov. These early proposals were rather rudimentary though they served as drivers of subsequent models which focused more tightly on certain brain subsystems as possible sites for the factors underlying normal and abnormal temperaments.[3–5,7–9] Jeffrey Gray, Robert Cloninger, and Larry Siever's ideas were among the more fruitful in an area which has grown steadily and is now an lively field of personality research.[9–11] Progress in basic neuroscience has made it possible to relate a variety of biological measures to paper and pencil or neurocognitive tests distinguishing normal and anomalous temperaments. Biological screening has also increasingly been applied to patients with personality disorders, using the clinical clusters as defined by Diagnostic Systems. Besides these attempts to build psychobiological profiles of normal and abnormal temperaments, converging evidence is used to advocate that categorical and dimensional models for diagnosing personality disorders should be integrated.[12]

To give a broad overview of an area that may be crucial to illuminate the genesis of personality disorders, I shall discuss the studies that, during the last decade, have tried to find genetic traces for personality traits that are both behaviourally consistent and biologically well rooted. Previous work using classical (familial or twin) methods had found substantial heritability estimates for several personality traits.[13] It was thus unsurprising that genetic tracking methods impulsed research aimed at showing that temperamental traits contribute to personality scaffolding via neuroendocrine targets specified by particular genes. I'll be discussing the outcome of some of these efforts and I'll explore afterwards how other basic temperamental traits, rooted within biodevelopmental processes, do mediate enduring neurocognitive organization resulting in long-lasting behavioural styles. Finally I'll outline new avenues for the neuropsychology of personality. My approach is deliberately selective, discussing relevant evidence rather than performing a systematic assessment of the field. For reasons of convenience and possible clinical relevance, I have selected some of the traits heralding sound biological foundations, although they are not necessarily prominent in the state-of-the-art dimensional '*solutions*' for normal and abnormal temperaments.

The genetic saga for novelty-seeking

In 1996 two independent teams reported[14,15] that a particular chromosomal 'locus' was associated with a well-established trait of human temperament—the hunger for novelty and excitement that lies behind sensation-seeking, risk taking, and impulsive behaviours.[5,10] A polymorphism in the sequence of the gene expressing the D4 dopamine receptor (D4DR), located on the short arm of chromosome 11, explained 10 per cent of the genetic variance due to this trait. Individuals with the longer repeat allele at exon III of the *D4DR* gene scored higher in novelty-seeking

behaviour (explorers, risk-seekers), whereas those with the shorter allele had lower scores (prudent, cautious). The first of these studies[14] investigated a heterogeneous sample of young Israelis, and showed the association to be independent of ethnicity (Ashkenazim versus Sephardim), sex, or age. The second study, carried out in the United States,[15] used a random sample of people who had initially been recruited in a search for chromosomal regions possibly associated with sexual orientation; this sample mainly comprised white men, although some ethnic minorities were also included. The personality questionnaires were different but very popular in personality research: the Israelis were evaluated using Cloninger's Tridimensional Personality Questionnaire (**TPQ**),[16] which gives direct scores of novelty-seeking, whereas the American study used the Revised NEO Personality Inventory[17] which measures the five superfactors mentioned above, from which scores for novelty-seeking were derived. The results of the two studies were highly concordant.

Despite the modest explanatory power of this reported association, the link between temperamental variability for one trait and a chromosomal polymorphism was the first hint for a direct relationship between a putative 'genetic marker' and a core dimension of normal personality. In this case, the potential genetic marker appeared promising because of the amount of basic and clinical research linking dopaminergic function with the regulation of stimulus-seeking and sensitivity to incentives. In theory, if similar degrees of explained variance were assignable to other sound gene markers associated to *approach/exploring* phenotypes, a substantial part of the heritability of the trait could be explained. Subsequent studies[18,19] failed to replicate these early findings in a consistent way and the optimism receded. The heterogeneity of the samples and the subtleties of the genetics of complex traits were blamed for the disparate results, though the research saga was quite productive: the links between dopamine receptor polymorphisms and novelty-seeking have been intensively searched and the race to find other markers for the same trait was impressive.

Metanalyses suggest that there are subtle connections between dopamine receptor gene variants and *approach/exploring* propensities as measured by personality questionnaires, though the strength of the contribution of every variant is small and hard to establish.[19,20] Moreover, parallel research has established suggestive connections between gene variants regulating other molecular targets (i.e. tryptophan hydroxylase, dopamine transporter, dopamine-beta-hydroxylase, serotonin transporter, MAOA, COMT) that modulate risk-taking behaviours and impulsivity. A handful of genes, thus contribute to differential vulnerabilities for addictive behaviours, a congruent result at the extreme of stimulus-seeking tendencies. Although further and more refined research is required, these data seem to confirm pioneer work, mostly with twins, which had consistently established that novelty-seeking behaviour was moderately heritable (40 to 50 per cent).

Genetics of fearfulness/neuroticism

The aforementioned American team that reported the first associations between novelty-seeking and variants of D4DR gene informed that there was an association between the neuroticism trait and a chromosomal region linked to serotonin neurotransmission involved in modulating anxiety-related traits.[21] The 5-hydroxytryptamine transporter protein (5-HTT) that promotes the reuptake of serotonin into cell membranes is encoded by a gene (*SLC6A4*) located in the q11–q12 segment of chromosome 17. The region governing the transcriptional control of the protein shows a polymorphism that influences its expression and functioning. Individuals carrying the short variant of the polymorphism show a reduced efficiency of serotonin reuptake compared with those possessing the longer variant. The study measured these parameters in the lymphoblasts of two independent samples totalling more than 500 volunteers. Using two different personality questionnaires (NEO and Cattell's 16PF Personality Inventory) and estimated scores on various dimensions of Cloninger's TPQ, the evidence showed that subjects who carried the short variant in the 5-HTT gene polymorphism had higher neuroticism (NEO), anxiety (16PF), and harm-avoidance (TPQ) scores. The results were equally consistent across and within pedigrees. Across the three personality measures, the 5-HTTLPR contributed a modest 3 to 4 per cent of the total variance and 7 to 9 per cent of the genetic variance in anxiety-related traits. It was suggested that, if other genes contributed similar dosage effects to anxiety traits, approximately 10 to 15 genes might be involved in the heritability of neuroticism.

The implication of the serotonin transporter in the potential genetic predisposition towards emotionality traits agrees with many other results. Serotonergic neurotransmission is involved in multiple brain functions with little or no relationship with fear/anxiety regulation, but there is a large body of evidence linking it with the modulation of adaptive responses to serious conflict and emotionally demanding situations.[3] Moreover, many drugs currently used to treat anxious/depressive dysphorias and personality disorders depend on mending serotonergic function. Finally, several studies have shown that variants of the 5-HTTLPR predict differential response on anxious phenotypes: fear-driven amygdala activation[22] and response to pharmacological challenges.[23] Therefore, although the exact role of serotonergic systems in the modulation of emotionality is not fully understood, it is improbable that the neurohormonal adaptations that participate in individual responses to serious emotional conflicts would not include serotonin modulation either through the cell transporter or through the extended family of serotonin receptors and their intracellular targets. Defensive adaptations require however the participation of other central neuromodulators: the CRH-ACTH regulatory cascade, γ-aminobutyric acid, neuropeptide Y, and substance P,[3] are major contenders in this respect and they can be expected to contribute to the genetic mediation of neuroticism.

Polymorphisms in anxious humans versus QTL-genes for fearful rodents

Dozens of studies investigated whether the particular polymorphism in the 5-HTT gene contributes to the tendency for individuals who score higher on neuroticism, in personality tests, to be at higher risk for 'internalizing disorders' (anxiety/depression) and personality disorders (anxiety/affective clusters). The global outcome of that research has been unreliable: though stringent metanalyses confirmed the original association with a modest relevance at explaining the trait variance,[23] subsequent results in large samples of siblings and singletons have been negative.[24] There are other lines of evidence, however, mainly from animal research, that support the claim of a possible genetic basis for fearfulness/emotionality. This evidence is derived from studies of the

psychogenetics of emotional susceptibility searching for chromosome loci. In many biological and behavioural tests, comparisons of several reactive and non-reactive strains of mice and rats obtained through artificial selection (forced interbreedings) have narrowed the search for genetic loci thanks to increasingly powerful methods of chromosomal mapping. In a pioneer work with progeny obtained by crossing two strains of mice selected for activity and defecation in an open-field test, three loci (QTLs) which explained most of the genetic variance in emotionality were found on chromosomes 1, 12, and 15 of the murine genome.[25] These data were confirmed and extended by measuring fear responses towards particular cues: the same segment of chromosome 1 was identified as a relevant 'locus' for emotional susceptibility besides other murine chromosomal zones.[9] The importance of the loci at chromosome 1 has been established in studies using heterogeneous and inbred stocks, combining techniques which have permitted to focus the suspicious segment to less than 1 cM and leading to the identification of the first gene linked to murine emotionality: Rgs2, a regulator of G-protein functioning which is highly expressed in the brain.[26] The complexities are nevertheless tremendous because even a QTL like that contains several genes each contributing a very modest part of variation on the phenotype of interest.[9,26]

Several research programmes were concurrently started to determine whether there is also concordance in the chromosomal marking of emotionality in strains of rats differing in fearfulness. The hypoemotional Roman high-avoider (**RHA**) versus the hyperemotional Roman low-avoider (**RLA**) rat lines represented a particularly interesting assay because of the very large body of evidence showing their usefulness as animal models of 'temperamental' styles.[27] Several plausible QTLs were detected but only those located on chromosome 5 and 15 predicted a wide array of anxious/fearful behaviours including spontaneous and learned fears.[28,29] The QTL located at the middle of rat chromosome 5 looks particularly promising because this region is partially syntenic with the human 1p segment where QTLs for neuroticism and liabilities for anxious/depressive dysphorias have been detected.[9,30] The search for plausible genes is, then, much more focused now though they will explain, in all probability, very modest portions of the phenotypic trait variance.[9]

Biodevelopmental mechanisms for affiliative traits

Affiliation (friendliness, sociability, gregariousness, empathy) is another core personality trait that can be measured consistently. Poor or distorted affiliative behaviour is the most predictive marker for a reliable diagnosis of personality disorder.[7,31] Deficits or alterations in affiliative tendencies may show a variety of clinical manifestations: extreme aloofness and detachment, manipulative, non-empathic or exploitative attitudes, and even definite asocial or antisocial tendencies. These behavioural styles appear, in different degrees and combinations, in several clinical categories of abnormal temperament. They could reflect alterations in the functioning of neuroendocrine systems specialized in mediating affective attachments, possibly including subsystems for social reward and social distress.[31] In this respect, an impressive amount of evidence has been gathered (mostly in animals but in humans as well) showing that prosocial behaviours, such as maternal nurturing, friendliness/gregariousness, playful/sexual behaviours, and even cooperativeness in economic interactions, share some neurochemical controls.[31–33]

Central oxytocin and opioid systems are among the more relevant of these modulatory molecules, because several types of attachments (mother–infant bonds, young peer bonds, pair-mating bonds, in-group tendencies) are dramatically altered when the functions of oxytocinergic or opioid systems in the brain are modified. Other centrally acting neuropeptides, such as prolactin and vasopressin, also contribute to particular types of species-specific social bonding. In addition, both the central regulatory monoaminergic systems and the corticotrophin–adrenal cascades that mediate stress adaptations help to organize responses to everyday social challenges.[31] The application of these ideas to personality is still in its infancy and requires the development of consistent scales to be related with sound biological markers.

Neuropeptides, social bonding, and early rearing practices

Theory and research in the psychobiology of social attachments[8,31] has linked the impact of early rearing practices (secure/nurturing mothering versus peer rearing or isolation) with the future organization and functioning of several neuroendocrinological systems. This research has mainly explored the function of the central modulatory monoamines norepinephrine, dopamine, and serotonin, and the hypophyseal–adrenal axis responses to social challenges. The evidence has shown that socially deprived monkeys differ physiologically, behaviourally, and cognitively from mother-reared infants in almost every aspect of what it means to be a social monkey; if the privation extends over the first 6 to 9 months of post-natal life, most effects persist into the adulthood. According to Kraemer[34]: 'The way in which socially deprived individuals orient to and respond physiologically to social stressors is altered and the kind of behavioural differences that seem to be the most important are those usually assigned to the domain of "temperament"'.

With the addition of the central neuropeptide systems that specifically modulate affiliative tendencies, the study of some crucial experiences during early infancy (and probably adolescence) will provide clues to the clarification of the role that developmental processes play in shaping attachment styles. Neural organization depends, to a great extent, on critical environmental inputs to produce enduring behavioural and cognitive adaptation in all domains. Therefore ontogenic factors must be particularly important in modelling social behaviour and in sustaining profiles of affiliative versus non-affiliative temperaments, in the same way as has already been demonstrated for other traits. For instance, in reactive/fearful monkeys, maternal and even grandparental rearing practices can significantly modify future neuroendocrine and behavioural adaptations[35] with parallel data obtained in rats.[36]

Affiliative genes?

These findings do not exclude the participation of genetic dispositions in attachment styles. Some authors have suggested that the operation of 'communicative' or 'affiliative' genes could prime individual tendencies through different sorts of emotional affects.[37] There is a paucity of data on the putative genetic basis of particular attachment styles. When a molecular approach has been used,

in rodents, to establish a genetic link between variants of the vasopressin V1a receptor gene with a conspicuous social behaviour such as monogamous pair bonding, the results have been spectacular. After substituting and inserting the V1a receptor gene characteristic of a monogamous species (the prairie voles), both promiscuous mice and meadow voles adopted the pattern of partner preferences and parental behaviours distinctive of the monogamous species. It has been shown, in fact, that socio-behavioural trait differences depend on polymorphisms on the regulatory region of the V1a gene.[38] In rodents and other mammals the neurochemical circuits in the brain regulating attachment/affiliative behaviours are increasingly detailed. In humans the task is just starting and will deeply influence personality research.

Biodevelopmental processes for aggressiveness

Aggressiveness is another temperamental trait that has a very well-founded biodevelopmental basis.[39] Dimensional descriptions of the structure of personality do not always include aggressiveness as a high-level factor, but it is embedded in other traits such as impulsiveness, poor control, or explosive/desinhibited behaviour. However, aggressiveness is a major behavioural trait that has to be taken into account in the routine management of mental disorders, and it is also a prevalent characteristic in personality disorders (generally as an excess, but sometimes because of its absence). In the past, it was extremely difficult to prove that individual variations in aggressive behaviour might be correlated with neurohormonal characteristics. However, this was because of inadequate methods of quantifying biological and behavioural variations.[40]

In humans, the link between lifelong aggressive profiles and familial/subcultural problems is strong indicating that lower socio-economic status, increased rates of abuse, coercive family interactions, and neglect or other adversities contribute to violent behaviour from infancy to adolescence and into adulthood.[39,41] But this cannot obscure the effects of enduring biological dispositions that could, in part, result from the influence of socio-environmental insults to the developing brain. Intensive research in behavioural neuroendocrinology and molecular neuroscience using animal models has shown that aggressive temperaments are associated with both genetic dispositions and critical developmental processes, which affect the function of neuroregulatory controls that either promote or inhibit aggression.

MAO-A functioning and aggression-proneness

It was not surprising, therefore, that an association between a specific gene and an aggressive disorder in humans was early reported[42]: the males of a Dutch family that carried a mutation of the gene for monoaminoxidase A (MAO-A gene situated at chromosome Xp11.23) had a record of severe aggressive incidents in different generations. Subsequent investigations in mice showed that ablating the gene for MAO-A resulted in the 'knockout' mutants being much more aggressive[43] MAO plays an important part in the breakdown of serotonin and other central monoamines, and previous research in humans had found consistent relationships between impulsive or 'poorly controlled' behavioural styles and low-MAO activity, a feature also seen in sensation-seekers. A common polymorphism in the promoter region of the MAO-A gene has been shown to interact with early abuse/neglect in longitudinal studies of large samples of children[44]: only abused kids carrying the genetic variant giving low-MAO-A activity are later at risk of antisocial tendencies or violent/criminal behaviour, during adolescence or young adulthood. Further studies with normative samples differentiated by this polymorphism have permitted to map, through structural and functional neuroimaging, cortico-limbic singularities associated with emotional regulation in the low-MAO-A carriers.[45]

Serotonin/vasopressin ratios

Many other genetically altered animals have been produced that are highly aggressive. Several of them typically show anomalies in serotonin function. Knockout mice that do not express the serotonin 5-HT1B receptors are much quicker to attack intruders[46] an action that can be blocked with targeted serotonergic drugs. All this adds to the evidence obtained from mentally ill patients presenting aggressive outbursts and from chronic offenders in prisons, which shows an inverse relationship between serotonergic function and violent attacks directed towards others or themselves. Taken together, the data appear to suggest that preserved brain serotonin function helps to attenuate aggressive impulses, probably by blocking other neuroregulatory systems that promote aggression such as sex steroids, insulin, vasopressin, and others. Vasopressin is involved in the establishment of pair bonds and territorial tendencies in mammals, and promotes aggressive behaviour when social/dominance challenges are perceived. There is evidence from adolescent and juvenile hamsters showing that proserotonergic interventions attenuate vasopressin-induced attacks. Patients with personality disorders[47] showed that cerebrospinal fluid levels of vasopressin were positively correlated with a life history of aggression, and with attacks against persons in particular. This was a more poweful relationship than the negative one usually obtained from measurements of serotonergic function and aggression. Other neuromodulators help serotonin to attenuate aggressive outputs: in animals, highly specific genetic techniques of knocking down or targeted regional brain expression of steroid and oxytocin receptors, have been used to identify ensambles of neuromodulators devoted to control aggressiveness, to the point of postulating a landscape of 50 genes to get a sound description to this function.[48]

A prospective landscape including other traits

Temperamental styles in animals show differential clustering of behavioural traits, which correspond to specific (and very complex) neurohormonal profiles. Sometimes, however, a specific genetic modification is sufficient to promote a fully differentiated temperament, as in the case of mice deficient in α-calcium–calmodulin-dependent kinase II (**α-CaMKII**) which show decreased fear responses and increased defensive aggression associated with low-serotonin levels[49] (Table 4.12.5.1).

It is possible that this may also hold for exceptional temperamental combinations in humans. However, we have already established that, when trying to explain the genetic contribution to basic ('universal') personality traits, a multigenic/interactional approach is compulsory to explain just part of the measured variance in each trait (Fig. 4.12.5.1). Nevertheless, this contribution can be very

Table 4.12.5.1 Summary of behavioural phenotypes in α-CaMKII mutant mice

Behavioural phenotype	Heterozygote	Homozygote
Fear-related responses	Decrease	Decrease
Offensive aggression	Normal	Decrease
Defensive aggression	Increase	Decrease
Pain sensitivity	Normal	Increase
Startle response	Normal	Increase
Vigilance	Normal	Increase
Mating	Decrease	Decrease
Maze learning	Normal	Decrease

important, as most of research involving twins has yielded estimates of just over 40 per cent for the genetic input to typical personality traits, with very modest estimations assignable to the so-called shared (familial/cultural) environment. Non-shared environmental influences (from the womb onwards) and genetic–environmental interactions make a well-known contribution to each individual temperament. These complex influences may act first by modelling the development of basic neuroendocrine regulatory systems that cope with natural and social challenges, and second by shaping the neurocognitive architecture that results in an autonomous and particular lifestyle. An interactional approach along these lines is now laying the foundation for a better description of the different factors that contribute to building the typical profiles of normal or abnormal personalities.[50,51]

Such a general scheme must include other traits, in addition to the ones considered so far. For instance, the detection of a substantial genetic contribution to the baseline level of happiness,[52] which all individuals show throughout life independently of the events or episodes that they encounter, must be important for

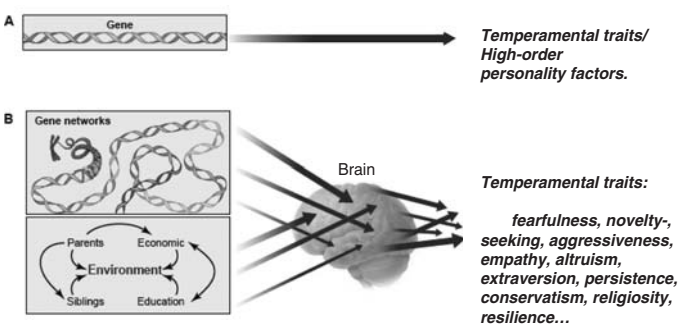

Fig. 4.12.5.1 Two views of the relationships between genes and personality. **A**. Early studies looked for linear relationships between gene markers and temperamental traits or high-order personality factors. **B**. Reality is likely to be far more complex with gene networks interacting with environmental inputs impacting on brain development and leaving enduring neural dispositions that, in turn, influence behavioural, cognitive, and affective styles (temperamental traits). (Reproduced from D. Harner. Rethinking behavior genetics, *Science*, **298**, 71–2, copyright 2004, with permission from the American Association for the Advancement of Science.).

personality diagnoses, because such a 'calibration point' has a direct relationship with the affective tone of optimism or pessimism. Moreover, other traits and measures in the domain of cognitive performance (e.g. attentional spans, perceptual/appraisal reliability, thinking styles, and memory biases) or of character (e.g. religiosity/transcendence, conservatism, altruism, self-directness/self-esteem, and the drive to achieve/enthusiasm) should be incorporated into the whole description of personality structure. This is essential if the aim is to produce a general framework powerful enough to contain the complex categories that clinicians have tried to construct on the basis of systematic observation for more than a century. Cloninger[8,11] and others have advanced proposals along these lines, which have functioned as useful steps to guide empirical work. It must be added that structural and functional neuroimaging techniques have been used to map relations between personality dimensions and brain's regional organization and patterns of activation/deactivation. Although these studies are very preliminary and have been done with convenient samples, they have offered hints of neurocognitive architectures, which tend to confirm, on a broad basis, the neurochemical mechanisms behind the main temperamental traits.[53–55]

Sophisticating the diagnoses of personality disorders

The evidence discussed so far is starting to have a major impact on the reconceptualizing of the approach that has been applied in psychiatry to the detection and categorization of the elusive profiles of normal and abnormal personalities. It is clear that anchoring some temperamental traits to a sound genetic or biodevelopmental base, and accruing a plausible neurocognitive architecture for it, will not provide a complete solution to the problems encountered in the aetiology and diagnosis of personality disorders. Many additional steps will have to be worked out. But in view of the increasing links that are being established between core personality traits and some genetic/developmental mechanisms, the task of building a solid neuropsychological framework, which would allow improved identification and differentiation of abnormal personalities no longer seems hopeless. In fact, such research is opening up many new avenues for understanding the effects of different factors (innate dispositions, neurodevelopmental organization, neurocognitive architectures, critical social transitions, and repeated stress episodes) on an individual's vulnerability to developing a personality disorder.

Hence, the use of behaviourally well defined and biologically well-established personality measures must be the starting point for achieving the fine-tuned diagnoses increasingly required in modern medicine. Complexity in measurement will increase, but there is no other way of obtaining data that are sufficiently valid to allow understanding of the classical personality disorders. It is hoped that advances in the neuropsychological detection of the more salient 'clinical' profiles within each of the personality subspaces or 'clusters' (at the level of either traits or dimensions), together with a refinement of the neurocognitive and neurohormonal data, will produce much better solutions. Some of the old-established and consistent categories of personality disorders will be confirmed, but it is possible that unexpected 'types' of abnormal personalities, with clinical relevance, will emerge. In this new

framework it may be easier perhaps to detect at an early stage those 'exceptional' and 'charismatic', although anomalous, personalities who often impose great social costs and dramatic consequences not only for themselves but also for the group or the society in which they live.[56]

4.12.6 Psychotherapy for personality disorder

Anthony W. Bateman and Peter Fonagy

Introduction

Psychotherapy has historically been the mainstay of treatment for personality disorder (PD). It remains so. Psychoanalysis was probably the earliest formal treatment for PD, which led to the first clinical descriptions of borderline personality disorder. A parallel but linked development was the application of psychoanalytic ideas in therapeutic communities which have been in existence for over 60 years and remain a treatment context and method for patients with PD. It was only in the 1960s that modified psychotherapeutic treatments were developed. Initially these were based on psychodynamic understanding of PD, but gradually other theoretically and practically driven models have developed, leading to the current situation in which there are behavioural, cognitive, dynamic, and supportive treatments offered in a range of contexts. Some of these methods have more empirical support than others. These methods will be described in this chapter.

Psychological therapies for personality disorders take place against the background of the natural course and outcome of the disorder. Until recently, the natural history of personality disorder had not been systematically studied. Several major cohort follow-along studies have yielded surprising data concerning the rate of symptomatic remissions in a disorder that was assumed to have a lifelong course.[1] For example, over a 10-year follow-along period, 88 per cent of those initially diagnosed with borderline personality disorder appeared to remit in the sense of no longer meeting DIB-R or DSM-III criteria for BPD for 2 years.[2] The symptoms that remit most readily, irrespective of treatment, appear to be the acute ones, such as parasuicide and self-injury, which are the most likely to trigger psychotherapeutic intervention. Temperamental symptoms, such as angry feelings and acts, distrust and suspicion, abandonment concerns, and emotional instability, appear to resolve far more slowly. In the Collaborative Longitudinal Personality Disorder Study (CLPS),[3] when remission was defined as 12 months at two or fewer criteria for PDs, over half of BPD and 85 per cent of major depressive disorder (MDD) patients were reported to remit over a 4-year period. Psychosocial functioning recovered far more slowly than acute symptoms.[1]

There is a considerable body of literature on psychotherapeutic interventions for personality disorders, but significant evidence

for effective treatment remains sparse. Much of the literature is dominated by expert opinion, which is not invariably the most helpful guide. In this chapter, we focus on psychological treatments where at least some evidence for treatment effectiveness exists. The evidence is strongest for borderline personality disorder (BPD). Treatment of some other personality disorders, for example schizoid, narcissistic, obsessive–compulsive, dependent, is evidenced mainly by clinical case reports in which theory is combined with clinical description and where, if outcome is measured at all, it is measured for the purpose of illustration and has little probative value.

Assessment of treatment

Any study that seeks to demonstrate the effectiveness of a treatment for PD must fulfil the following requirements:

(a) *Carefully define the target population*. This can be problematic, because the definition of personality disorder (PD) remains controversial, and there is little evidence that the categories of personality disorder have any predictive value in determining response to treatment. Comorbidity must also be considered. Lifetime comorbidity should not be an exclusion criterion for studies, but there is an argument for excluding individuals with current comorbidity. However, in clinical practice, such exclusion is almost impossible.

(b) *Adequately define the treatment and assessment of its specificity*. Personality disorder is a multifaceted condition that is susceptible to a variety of influences, and it justifies the use of complex interventions. These require complex evaluations, which increase the difficulty of interpreting results.

(c) *Establish that treatment is superior to no treatment* since personality disorders show gradual improvement over time.

(d) *Take account of Axis I disorders*. This can be done by excluding patients with Axis I disorders, but PDs are almost always associated with significant Axis I psychopathology. An alternative, which no trial has, to date, attempted, would be to assign patients to treatment group on the basis of matched Axis I disorders. In any case, it must be demonstrated that treatment impacts on personality rather than merely causing a change in mood or psychiatric symptoms.

(e) *Include adequate follow-up*, as some trials report reduced treatment effects during follow-up.

(f) *Address cost-effectiveness* relative to alternative interventions.

(g) *Study treatment effects in standard practice* (pragmatic trials) as well as under strict experimental conditions.

Research trials investigating the effectiveness of treatments for personality disorder have so far singularly failed to meet most of these requirements.

Adverse effects of psychotherapy for personality disorder

It is possible that some psychosocial treatments for personality disorder may have impeded the patient's capacity to recover following the natural course of the disorder and/or prevented them from taking advantage of changes in social circumstances. In Stone's[4] classic follow-up of patients treated nearly 40 years ago, a 66 per cent recovery rate was only achieved in 20 years, about four times longer than reported in the more recent studies. It seems unlikely that the nature of the disorder has changed or that treatments have become markedly more effective rather it is possible that treatments with these adverse effects are being offered less frequently now than in the past, perhaps because of changed patterns of health care, particularly in the United States.

Meta-analyses of psychotherapy and psychosocial treatments

It remains unclear whether the literature is robust enough to withstand the methodology of meta-analysis. The lack of good quality studies, especially randomized trials, the small number of patients in the trials, the heterogeneity of the personality disorders studied, and the variability of outcome measures across studies means that conclusions must remain tentative. One meta-analysis[5] included 15 studies that reported data on pre- to post-treatment effects and/or recovery at follow-up, including three randomized, controlled trials, three randomized comparisons of active treatments, and nine uncontrolled observational studies. They included psychodynamic/interpersonal, cognitive behavioural, mixed, and supportive therapies. All studies reported improvement in personality disorders with treatment. The mean pre–post effect sizes within treatments were 1.11 for self-report measures and 1.29 for observational measures. Among the three randomized, controlled treatment trials, active psychotherapy was more effective than no treatment according to self-report (ES = 0.75), though none of the controls employed an active therapy. Only four studies reported the percentage of cases no longer meeting the criteria for personality disorder. At follow-up (at a mean of 67 weeks), 52 per cent met this criterion. Treatment length was associated with the likelihood of recovery.

A subsequent meta-analysis[6] included psychodynamic therapy and cognitive behaviour therapy (CBT) in the treatment of personality disorders. There were 22 studies of psychodynamic therapy and CBT published between 1974 and 2001 that (1) used standardized methods of diagnosis, (2) applied reliable and valid instruments for the assessment of outcome, and (3) reported data that allowed calculation of within-group effect sizes or included assessment of recovery rates. Because only 11 of the 22 studies were RCTs, ESs were calculated on the basis of pre- to post-therapy change. Fourteen studies included psychodynamic therapy, and 11 studies included CBT. The psychodynamic studies had a mean follow-up of 1.5 years, compared to only 13 weeks for CBT. Psychodynamic therapy yielded an overall effect size of 1.46 ($k = 15$ contrasts), with effect sizes of 1.08 for self-report measures and 1.79 for observer-rated measures. For CBT ($k = 10$ contrasts), the corresponding values were 1.00, 1.20, and 0.87. For more specific measures of personality disorder pathology, a large overall effect size (1.56) for psychodynamic therapy suggested long-term rather than short-term change in personality disorders. For BPD, the ES for psychodynamic therapy was 1.31 ($N = 8$), and for CBT 0.95 ($N = 4$). Treatment length showed a positive but nonsignificant correlation with outcome in psychodynamic studies ($r = 0.41$); there were too few CBT trials for an equivalent analysis. In the 5 years since 2001, there have been nearly as many new randomized trials of treatments for personality disorder as were included in this meta-analysis, so a further systematic review including only randomized trials is due.

Psychotherapy for borderline personality disorder (BPD)

Several psychosocial treatments for BPD have emerged over the past decade, with one US guideline recommending psychotherapy as the primary treatment for this condition.[7] It is impossible to recommend one specific therapy, because information from research remains inadequate. It has become clear not only that several treatments may be of use, but also that any one treatment by itself, is helpful in only about a half of all cases.[8] Also, there is general consensus that some of the nonspecific elements of psychotherapy may be as important in determining the success of a treatment as the specific techniques. We reviewed treatments shown to be moderately effective and concluded that they share certain common features.[9] They tend to (a) be well-structured, (b) devote considerable effort to enhancing collaboration, (c) have a clear focus, (d) be theoretically highly coherent to both therapist and patient, (e) be relatively long-term, (f) encourage a powerful attachment relationship between therapist and patient, and (g) be well integrated with other services available to the patient. While some of these features may seem to pertain more to a successful research study rather than a successful therapy, the manner in which clinical treatment protocols are constructed and delivered is probably as important in the success of treatment as the intervention itself.

(a) Dynamic psychotherapy

Dynamic psychotherapy has long been recommended for BPD and has now been modified to target the characteristic features of the disorder. Almost all of the first studies examined inpatient treatment using prospective one group pre- to post-test designs.[10] These studies failed to rule out other plausible causes of change, such as passage of time or subsequent outpatient treatment. Stone's[11] report of up to 20 years follow-up of 550 inpatients, most of whom had received some sort of psychosocial intervention, indicated that 66 per cent of patients were functioning well. However, a naturalistic 5-year follow-up of individuals receiving inpatient treatment at the Cassel Hospital in London indicates the need for caution in ascribing benefits to inpatient treatment.[12] Whilst longer term follow-ups are to be applauded, they are hard to interpret, because other therapies are often given subsequent to the original treatment.

Several nonrandomized trials of dynamic psychotherapy have been undertaken by Stevenson, Meares, and colleagues. In an open trial for 48 patients receiving twice-weekly interpersonal-psychodynamic outpatient therapy for 12 months,[13] 30 per cent of the treatment group no longer met DSM-III-R criteria for BPD, while the waiting-list group changed little. Cost–benefit analysis found significant reduction in costs, largely attributable to reduced inpatient stays. A replication study[14] also found significant reduction in symptom severity with the same treatment.

A randomized study of 38 patients with BPD compared an 18-month programme of partial hospitalization using mentalization-based treatment (MBT) with standard psychiatric care.[15] Mentalization entails making sense of the actions of oneself and others on the basis of intentional mental states such as desires, feelings, and beliefs. Outcome measures included frequency of suicide attempts, acts of self-harm, number and duration of inpatient admissions, use of psychotropic medication, and self-report measures including depression, interpersonal function, and social adjustment. After 6 months, patients given MBT showed a statistically significant decrease on all measures in contrast to the control group which showed limited change or deterioration over the same period. This was sustained at the end of the 18 months of treatment and showed further improvement on follow-up after another 18 months. Long-term follow-up 5 years after the initial treatment suggested that the differences between the groups continued, but general social function remained impaired in both groups.[16] The treatment was cost-effective and has been manualized,[17] but as yet the active components remain unclear, and it has not been shown that positive outcomes are correlated with an improvement in mentalizing. (An outpatient version of MBT is currently being evaluated for borderline and antisocial PD in a further randomized controlled trial.) Although promising, this treatment needs further validation by research carried out independently of the originators. Favourable data has recently become available on the effectiveness of a similar programme established in the Netherlands.[18]

Transference-focused psychotherapy (TFP) has also shown good results. In a cohort study,[19] 23 female borderline patients were treated for 12 months. Compared with the year before treatment, the number of patients who made suicide attempts decreased significantly, as did the medical risk and severity of self-injurious behaviour. Also, compared with the previous year, there were significantly fewer hospitalizations and fewer days of psychiatric hospitalization. However, one in five patients dropped out of treatment. A subsequent trial compared TFP, DBT, and supportive therapy.[20] Ninety patients (all but nine of whom were women) were randomized. At the end of 1 year of treatment, the groups did not differ on global assessment of functioning, social adjustment, scores of depression and anxiety, and measures of self-harm. TFP patients improved significantly more than those receiving DBT or supportive therapy on irritability and verbal and direct assault. Patients who received TFP improved most in reflective function, an operationalization of the mentalization construct,[21] but it is not known whether improved reflective function relates to treatment gains at follow-up.

Schema-focused therapy (SFT) has been compared with TFP.[22] Treatment was given by therapists with approved training in the treatment methods administered treatment to 88 patients with borderline personality disorder. In an 'intent to treat' analysis, patients who received TFP showed significantly less improvement than those who received schema-focused CBT over 3 years, and TFP was more expensive. Both groups showed improvement, but changes in the combined measure of outcome in the schema-focused therapy group were greater and more prolonged than in the TFP group. There are several reasons for caution regarding these conclusions. (i) Differences in outcome between the groups can be accounted for almost entirely by the larger dropout early in treatment of patients treated with TFP and disappear when 'completers' are compared. It would be valuable to know why more patients dropped out from TFP at an early stage than from SFT. (ii) Follow-up is required to determine whether treatment gains and group differences are maintained. (iii) In the duration of the treatment period, around 40 per cent of patients could be expected to improve without the treatment.[23] This study also raises the question of how successfully a treatment (TFP) from the US can be transported to a European context.

(b) Group psychotherapy

Noncontrolled studies of day hospital stabilization followed by outpatient dynamic group therapy indicate its utility for BPD.[24] Marziali and Monroe-Blum used group therapy focused on relationship management and without the milieu and social components. A randomized controlled trial found equivalent results between group and individual therapy, suggesting that group therapy is more cost-effective.[25] Further studies are needed to confirm their findings, especially since dropout rates were high.

(c) Cognitive analytical therapy (CAT)

CAT has been manualized for treatment of BPD, and many are enthusiastic about its effectiveness. There are some indications that it may be effective. In a series of 27 patients with borderline personality disorder treated with 24 sessions of CAT, half no longer met diagnostic criteria for personality disorder at 6-month follow-up.[26] More definitive statements about efficacy await results of a randomized trial in progress. Ryle (personal communication) has indicated that patients treated with CAT showed significant improvement on a range of clinical measures but reported no difference between people receiving CAT and those undergoing other psychological treatments. Thus, the effects may be nonspecific. A second randomized trial is in progress comparing CAT with 'best available standard care' for adolescent patients with borderline personality disorder.[27]

(d) Cognitive therapy

Cognitive behavioural formulations of BPD are diverse. In a model derived from 'standard' CBT and modified for personality disorders, Beck and associates[28] define personality in terms of patterns of social, motivational, and cognitive-affective processes, thereby moving away from a primary emphasis on cognitions. However, personality is considered to be determined by 'idiosyncratic structures', known as schemas, whose cognitive content gives meaning to the person, and these schemas are the cornerstone of cognitive formulations of BPD. Young[29] has developed a treatment programme for BPD based on early maladaptive schemas (EMS). These are stable, enduring patterns of thinking and perception that begin early in life and are continually elaborated. EMS are unconditional beliefs linked together to form the core of an individual's self-image. Challenge to these beliefs threatens the core identity which is defended with alacrity, guile, and desperation since activation of the schemas may evoke aversive emotions. The EMS give rise to 'schema coping behaviour', which offers the best adaptation to living that the borderline has found. Schema-focused therapy (SFT) is only just being evaluated, but its adherence to the general requirements of an effective treatment enumerated above suggests that it should be reasonably successful. The recent report comparing SFT with TFP[22] is described above, but SFT has yet to be shown to be more effective than treatment as usual. It is possible that TFP simply induced more negative effects in patients than SFT.

A small ($N = 34$), randomized controlled trial assessed brief cognitive therapy, linked to a manual and incorporating elements of dialectical behaviour therapy, in the treatment of recurrent self-harm in people with cluster B personality difficulties and disorders.[30]

Manual-assisted cognitive treatment (MACT) is a complex six-session treatment based on the theory that deliberate self-harm and suicide attempts stem from distorted cognitive schemas and coping skills deficits.[31] It incorporates elements of bibliotherapy, CBT, and DBT, as well as psychoeducation in relation to self-harm and suicide attempts, and a functional analysis of specific episodes. The treatment also involves strategies to regulate emotion, such as distraction, crisis planning, and problem-solving strategies. Cognitive restructuring strategies and management of negative thinking are incorporated in the second phase of the programme, which includes components for the management of substance abuse and relapse prevention. Its brevity makes MACT a potentially valuable intervention from a public health standpoint. In a clinical trial, 34 self-harm repeaters with a parasuicide attempt in the preceding 12 months were randomly allocated to MACT or treatment as usual (TAU). The rate of suicide acts was lower with MACT, and self-rated depressive symptoms also improved. The mean treatment time was 2.7 sessions, and the average cost of care was 46 per cent less with MACT. A subsequent larger study ($N = 480$) did not find evidence that time to repeat parasuicide was extended following MACT, although there was a decrease in the cost of care.[32] A randomized controlled trial with 104 people with borderline personality disorder with a longer period of treatment (up to 30 sessions) found significant benefit with regard to suicidal behaviour but a nonsignificant increase in emergency presentations in the cognitive behaviour therapy group.[33] The CBT arm used less resources, although no significant cost-effectiveness advantage was demonstrated. Those who received CBT showed less evidence of dysfunctional beliefs, lower state anxiety scores, and less positive symptom distress.

Systems training for emotional predictability and problem solving (STEPPS)[34] is a group treatment offered as an adjunct to other treatments rather than as a sole intervention. It is a 20-week manualized programme of psychoeducation and behavioural management focusing on maladaptive schemas and including both professional and family carers. Subjects are encouraged to continue their usual care, including individual psychotherapy, medication, and case management, and are required to designate a mental health professional who would provide ongoing care and could be reached in a crisis. Data from 52 patients suggests some reduction in impulsive and suicidal behaviour and some improvement on measures of depression, but no follow-up data is yet available. An RCT is currently ongoing. In Holland, a retrospective assessment of the experience of 85 patients enrolled in STEPPS groups[35] reported significant improvement on all subscales of the SCL-90, particularly those assessing anxiety, depression, and interpersonal sensitivity. Patients and therapists reported moderate to high levels of acceptance for the treatment in both studies. As most of the effective programmes for BPD are long-term and expensive, a short-term efficacious treatment will be of great value. However, even if found to be effective in a clinical trial, its effectiveness will depend on the nature of the treatment as usual.

(e) Dialectical behaviour therapy (DBT)

DBT is a special adaptation of CBT, originally used for the treatment of a group of repeatedly parasuicidal female patients with borderline personality disorder. DBT is a manualized therapy[36] which includes techniques at the level of behaviour (functional analysis), cognitions (e.g. skills training), and support (empathy, teaching management of trauma), with a judicious mix of ideas derived from Zen Buddhism. The initial aim of DBT is to control self-harm, but its main aim is to promote change in the emotional

dysregulation that is judged to be at the core of the disorder. Thus, the goal of DBT goes far beyond self-harm reduction. The first trial[37] involved 44 females with borderline personality disorder who had made at least two suicide attempts in the previous 5 years, with one in the preceding 8 weeks. Half were assigned to DBT and half to the control condition. Assessments were made during and at the end of therapy and at a 1-year follow-up. Control patients were significantly more likely to attempt suicide spent significantly more time as inpatients over the year of treatment (mean 38.8 and 8.5 days, respectively), and were significantly more likely to drop out of the therapies to which they were assigned (attrition 50 per cent versus 16.7 per cent, respectively).

DBT was less superior at the 1-year follow-up. Follow-up was naturalistic, because the morbidity of the group was thought to preclude termination of therapy at the end of the experimental period. At 6-month follow-up, DBT patients continued to show less parasuicidal behaviour than controls, though there were no between-group differences in days in hospital. At 1 year there were no between-group differences in suicidal behaviour, but DBT patients had had fewer days in hospital. Treatment with DBT for 1 year compared with treatment as usual led to a reduction in the number and severity of suicide attempts and decreased the frequency and length of inpatient admission. However, there were no between-group differences on measures of depression, hopelessness or reasons for living.

The widespread adoption of DBT for BPD and other PDs is a tribute to both the effectiveness of the treatment and its acceptability to patients and families. Several studies have replicated the original Linehan study. Turner observed a decrease in parasuicidal acts and deliberate self-harm at 6 and 12 months in 12 patients treated with DBT compared to 12 treated with client-centred therapy.[38] Koons and colleagues[39] compared DBT with outpatient treatment as usual in 28 participants and found decreases in frequency of parasuicidal acts and self-injury at 3 and 6 months. Bohus and colleagues[40] explored an inpatient adaptation of DBT and found significant improvement in deliberate self-harm but a higher dropout rate. Other studies, however, have shown DBT to be no better than other active treatments such as the 12-step programme for opioid dependence[41] or treatment as usual in a UK context.[42]

Because of severity, symptomatology, and high rates of co-occurring disorders, BPD affects family members, and interventions addressing the needs of family members have been developed using a DBT frame.[43] In a study of a 12-week community-based BPD family education programme, Family Connections (FC),[44] family members showed significant improvements on burden, grief and empowerment, and a reduction in depression. However, the long-term effect of family interventions on the patient's well-being remains to be demonstrated.

It is uncertain which are the active elements of DBT-individual psychotherapy whether skills training, phone consultation, or the consultation team. Two studies examining the process of change in DBT[41,45] had inconclusive results. Nevertheless, adding a DBT skills training group to outpatient individual (non-DBT) psychotherapy does not seem to enhance treatment outcomes. Given that DBT is described as primarily a skills training approach, this finding might indicate that the central skills training component of DBT may not be of primary importance. However, individual DBT focuses on the strengthening of skills learned in the skills groups, and trying to combine a skills training group with an individual therapy that ignores or pays minimal attention to skill strengthening, may invalidate what the patient has learned about utilizing learned skills in an attempt to cope with everyday functioning. Disagreement remains regarding the policy of not admitting patients to hospital, except for a minimum period, since some studies show that the time and structure of an inpatient setting can be used to apparently good effect.[46]

(f) Therapeutic community treatments

A therapeutic community (TC) may be defined as an intensive form of treatment in which the environmental setting provides the core means through which behaviour can be challenged and modified, essentially through group interaction and interpersonal understanding. Therapeutic communities are described in Chapter 6.3.9. Several studies have been completed at the Cassel Hospital, a tertiary referral centre with a psychosocial residential treatment programme which includes daily unit meetings, community meetings, structured activities, co-responsibility planning for the running of the therapeutic community and other structured activities, and formal psychoanalytic psychotherapy (individual and small group). Patients in two different specialist psychosocial programmes (step-down and long-term inpatient) and in general psychiatric treatment as usual (TAU) were assessed at 12 and 24 months. By 24 months, patients in the step-down condition showed significant improvements on all measures.[47] Patients in the long-term residential condition showed significant improvements in symptom severity, social adaptation, and global functioning but no changes in self-harm, attempted suicide, and readmission rates. Over the same period, patients in the TAU group showed no improvement on any variable except self-harm and hospital readmissions. All three groups were followed for 72 months after intake. The specialist step-down condition led to significantly greater change than either the solely inpatient model or TAU in most key dimensions of functioning, even 5 years after the 12 months hospitalization.[48]

While the study appears to show that a step-down programme leads to significant improvement, this conclusion should be qualified by the study's design limitations, including the lack of random assignment to the three conditions and the naturalistic geographical allocation. Overall, these findings are consistent with the general view that extended hospital admission, even to a psychotherapeutically oriented unit, may engender pathological dependency and regression. Against this, a prospective study of 216 patients with severe personality disorder treated at the Menninger Clinic in two psychoanalytically orientated inpatient units[49] found positive change at discharge and 1 year follow-up, with no evidence of deleterious effects due to regression and dependency. As there are now many treatments for personality disorder, therapeutic communities must be evaluated by comparison studies using acceptable experimental designs if they are to be considered a serious treatment approach.

(g) Nidotherapy

Nidotherapy is the name of a new form of systematic management for chronic and persisting mental disorders that concentrates on making environmental changes to bring about a better fit between person and environment.[50] All types of environmental change—physical, social, and personal—are considered relevant.

Nidotherapy is a collaborative treatment 'involving the systematic assessment and modification of the environment to minimize the impact of any form of the disorder on individual or on society'.[50] The word is derived from the Latin nidus or nest, an environment adapted to the object that is occupying it. The therapeutic aim is not to change the person but rather to change the environment so it better fits the person. The therapist should repeatedly question whether interventions given in the course of management incorporate analytic, cognitive, or behavioural psychotherapy—if they do, the intervention is no longer nidotherapy. Nidotherapy involves seeing the world from the patient's standpoint, joint planning of agreed environmental targets, a concentration on finding ways to improve social function, sharing responsibility for the programme so that the patient is the final owner, and the use of independent arbitrators to resolve disagreements about the change that is needed. The programme has several phases: identification of the boundaries of the nidotherapy, full environmental analysis, implementation of agreed environmental change, monitoring progress, and resetting targets. It addresses the patient's physical, social, and personal environments.

This therapy is at its early stages, with little other than anecdotal evidence.[51] Nevertheless, it represents a healthy contrast to the behavioural, cognitive, and analytic approaches which dominate most psychosocial interventions. There is no doubt that a person's environment is an important determinant of their experience and behaviour. This is accepted regardless of theoretical perspective, yet none of these perspectives offers a model of how environments should be modified to be more in line with the capacities of the person who exists within them. Modifying situational constraints may indeed be an independent and effective adjunct to other treatment protocols for personality disorder.

(h) Summary

The findings from the above studies suggest that some of the problems encountered by people with BPD may be amenable to talking/behavioural treatments. Several studies show that the effort by the recipient of care in sticking with the care package is rewarded by a decline in anxiety, depression, self-harm, hospital admission, and use of prescribed medication. A review using Cochrane methodology[52] concluded that the studies are too few and too small to justify full confidence in their results so that current therapies remain experimental. The reviewers suggest that people with BPD, if offered entry into a randomized study of therapies, may wish to consider that outcomes of both experimental and control groups will probably be better than those of standard care outside the trial.

Psychotherapy for avoidant personality disorder

Avoidant PD is the most prevalent personality disorder in the general population.[53] However, avoidant personalities tend to suffer quietly and reject emotional involvement with others. Nevertheless, their distress and functional impairment are probably comparable to those of people with BPD.

Studies of the efficacy of treatment for avoidant PD have been hampered by the close connection of the condition to social phobia. About half of avoidant patients also have a social phobia. There is controversy over the distinction between generalized social phobia and avoidant personality disorder, many authors regarding the latter as an exaggerated type of social phobia.[54] Many studies of social phobia include individuals with avoidant personality disorder. Few trials explicitly focus on this disorder. Most APD patients are treated using behavioural methods including exposure, social skills training, and systematic desensitization. Early studies suggested treatment gains that were maintained for up to 1 year after finishing active treatment.[55]

For phobic anxiety, there is some agreement that the cognitive behavioural strategies involved in traditional treatment tend sometimes to fail with the more severely disturbed patients because of resistance evoked by maladaptive personality traits.[56] Most studies report a pattern of outcome similar to that for generalized social phobia, with similar rate of gains to those without APD but lower end-point functioning,[57] though some report a slower rate of change.[58] Massion *et al.*[59] report a 5-year prospective study examining the impact of personality disorders in 514 patients in the Harvard/Brown anxiety research programme. The presence of a personality disorder reduced the probability of remission in social phobia by 39 per cent. Much of this reduction was explained by the presence of avoidant personality disorder. Alden[60] found that while there were significant improvements on a range of measures, only 9 per cent of patients treated for APD rated themselves as completely improved.

Therapeutic strategies for severe cases of APD should be tailored to the core pathology of the disorder—(1) a despised and unworthy sense of self connected to a punitive and blaming internal other; (2) an avoidant interpersonal style; (3) affect phobia; and (4) pseudomentalization (intellectualization and pretend relations). In achieving somewhat better functioning for avoidant patients, short-term dynamic psychotherapy and cognitive therapy have been shown to have good results.[61] For the more severely disturbed avoidant patients, day treatment programmes are probably more effective[62] than outpatient therapy, where they tend to ossify.[63] An RCT of cognitive behaviour therapy versus psychodynamic therapy for AVPD[64] found greater benefit from cognitive behaviour therapy. Interpersonal therapy and supportive-expressive therapy have also been tried. Patients are often reported to have made substantial gains in all treatment programmes,[65] but many patients who complete treatment still demonstrate a low level of social function.

Psychotherapy for antisocial personality disorder (ASPD)

There are few evaluated therapies for ASPD. The disorder is a common comorbid diagnosis for individuals with substance abuse problems,[66] and a small number of trials have contrasted those with ASPD alone with those with ASPD and depression in the treatment of substance misuse. Outcomes with antisocial personality disorder alone are often poorer than when ASPD is associated with depression. Three studies[67–69] have reported that ASPD alone was an obstacle in the treatment of substance misuse.

Several studies (though few controlled trials) have examined the impact of treatment on individuals within the penal system, at least some of whom, it is likely meet criteria for antisocial personality disorder. Most studies focus on specific categories of offending behaviour (e.g. sexual offences), or on prisoners with problem behaviours, particularly violence.[70] Some studies have focused on individuals who manifest callous-unemotional traits.[71]

There are a few observational studies of individuals detained in high security settings using group CBT,[72] individual and group CBT in the context of a therapeutic milieu,[73] or psychodynamic therapy.[74] While improvements in functioning are noted, there are severe methodological problems such as the absence of control groups and highly reactive measurement of outcome.

Studies reviewed by Warren and colleagues[70] suggest the usefulness of cognitive behavioural or (less frequently) systemic group-based interventions of various kinds for mentally disordered offenders. These include: seven studies of problem-solving skills training, five studies of anger/aggression management, and three studies aimed at social skills problems. Three studies of problem-solving training reported no statistically significant positive effects, while a further three reported some positive results with measures of outcome closely linked to the intervention. Anger management studies were predominantly negative with no statistically significant positive effects reported by the majority of studies and positive results reported only with quite reactive measures or within quasi-experimental studies. Social skills interventions also enjoyed mixed success with either no statistically significant positive effects being reported or positive effects observed only with reactive measures or in uncontrolled studies. While it is not possible to claim that psychotherapy is effective in addressing problems associated with ASPD, there is sufficient preliminary data to justify further inquiry and to counter the therapeutic nihilism that usually pervades this field.

Psychotherapy for other personality disorders

Individuals with **paranoid PD** are highly suspicious of other people, including doctors, and are often unable to acknowledge their own negative feelings towards others. This fact alone means that treatment is problematic, but given that other characteristics include concern that other people have hidden motives, expectation of being exploited by others, inability to collaborate, social isolation, emotional detachment, and overt hostility, treatment becomes nearly impossible. This constellation of characteristics means research on this group of patients is very difficult to conduct, since researchers are inevitably seen as having hidden motives. Whatever treatment method is employed, the first step is the development of a moderately trusting relationship. There is no research specifically investigating the outcome of psychotherapeutic treatment for paranoid personality disorder. However, a number of studies have included patients with paranoid PD in assessment of treatment. In general, the presence of paranoid PD diminishes the effectiveness of psychotherapeutic treatment for other co-occurring personality disorders.

Most of the interest in **schizotypal** personality disorder (STPD) has been in its relationship to schizophrenia, and hence there is little data on outcome of treatment using psychosocial methods. The Chestnut Lodge follow-up study yielded some data suggesting that patients who had schizophrenia plus STPD and had been treated within the psychotherapeutic milieu did slightly better than patients without STPD.[75] This unexpected finding has not been explained.

Winston *et al.*[76] treated 32 patients with a range of personality disorders, predominantly in DSM-III-R cluster C, using two forms of brief psychodynamic therapy (short-term dynamic psychotherapy or brief adaptational therapy) with 40 weekly sessions and waiting-list control. Because of ethical constraints, waiting-list subjects began treatment after 15 weeks. Although both therapies used psychodynamic techniques, brief adaptational therapy employed more cognitive strategies. Contrasted to waiting-list controls, treated patients showed moderate improvements in symptoms and target complaints at post-therapy. Though there were few between-treatment differences, there was more variance in outcome for the patients treated with short-term dynamic therapy, suggesting that for some patients the technique was unhelpful. Gains appeared to be maintained at 18-month follow-up. A larger trial of these therapies with mainly cluster C disorder[77] led to similar findings.

Conclusions

Effectiveness

It is difficult to reach definitive conclusions about the effectiveness of psychotherapy in the treatment of personality disorders, chiefly because RCTs of psychological treatments for PDs are relatively scarce. There is evidence that personality disorders impact negatively on treatments for Axis I presentations. However, the strength and specificity of this evidence varies both across Axis I diagnoses and also across personality disorders.

Historically, studies of psychotherapy for personality disorder have focused on cluster B PDs. Borderline personality disorder is the best studied of the PD diagnoses both from a biological and a psychotherapeutic perspective. The recent growth in the evidence base indicates the feasibility of coherent research programmes with a patient group usually seen as presenting substantial problems of engagement. Evidence from randomized trials suggests that structured treatments employing DBT or a psychodynamic approach are more effective than routine care. Data gathered so far support the use of both behavioural and psychodynamic interventions, while evidence for more short-term cognitive interventions is somewhat equivocal. Since most studies present data from open trials or case-series, only two approaches can be considered 'evidence-based'. The available randomized trials of DBT and psychodynamic treatment are methodologically sound but limited in the latter case by relatively small sample sizes; further, both sets of studies were conducted in the context of clear leadership from the developers. Because, for the most part, contrast was to routine care, it is difficult to ascertain whether outcomes are due to the structured nature of the programmes or their therapeutic orientation.

In relation to antisocial personality disorder, research into treatments has been centred on patients seeking help for substance abuse or individuals seen within the penal system for problems associated with ASPD. There is no clear evidence of treatment efficacy for any one form of intervention. Conclusions in relation to ASPD are limited not only by the small number of trials but also by the methodological limitations of these studies, particularly reactive measures of outcome and complex multifaceted interventions (such as therapeutic communities) where effective transportable components of the treatment package are impossible to disaggregate.

Avoidant personality disorder has received only a modest amount of research attention. Individuals presenting with APD would normally be offered social skills training or cognitive (exposure-based) techniques which are likely to be successful, but the generalization of improvements to other social contexts has not yet been well demonstrated.

Implications for clinical practice

With the exception of cluster B disorders, many individuals with PDs present to services for help with Axis I disorders. Clinicians should be aware that while treatments normally recommended for these problems can still work, they may do so to a lesser extent than would be expected if comorbid PD were not part of the clinical problem. However, they should not assume that this will definitely be the case. The situation is somewhat different in the case of the so-called dramatic PDs. Many of the features of the behaviour of individuals with borderline or antisocial PD create such distress for the people around them that clinicians tend to privilege these features over symptomatic states related to comorbid Axis I disorders when setting goals for treatment.

There is little doubt that psychological therapies have a place in the management of personality disorders, but the methodological shortcomings of the studies so far conducted limit our ability to make practical recommendations. Given the nature of the problem (supposedly enduring problems of character) the fact that few trials conduct follow-up over a longer period or include a contrast or control group over follow-up is a grave limitation of the database. Only two studies (Chiesa's 72 months follow-up and the MBT 5-year follow-up) have demonstrated that post-treatment differences are maintained for extended periods. Clinical experience, somewhat contradicted by recent follow-along data, suggests that many individuals may show periods of complete remission followed by episodes of great severity, and therefore it is crucial to investigate the impact of treatment on this often chronic and cyclic course. DBT has good evidence for its immediate impact on behavioural problems of impulsivity and suicidality, but the evidence for long-term benefit without further treatment is less clear. Psychodynamic approaches aim to change the way the person thinks, and there is some evidence that this approach has some impact on mood states and interpersonal functioning. However, this emphasis on cognitive change requires longer term therapy, with some indication of slower rates of change but perhaps also more sustained gains over follow-up. While shorter interventions are likely to have lower immediate costs, longer ones would be justified if they were more cost-effective in terms of service utilization and other cost-offsets. However, evidence for these kinds of effects is scarce.

Debate about particular forms of therapy may be less relevant than attention to nonspecific factors, especially in the treatment of individuals with cluster B PDs. We have seen that successful approaches usually emphasize the importance of structure, a coherent theoretical base, a higher intensity of treatment than for many Axis I disorders, and especially, attention to the unique set of problems presented by the individual, with a clear psychological formulation guiding treatment. Decisions about which treatment to opt for might be best made with regard to pragmatic considerations rather than argument about which particular course is 'best'. It may even be better to offer patients intensive treatment initially and to follow with short bursts of treatment over a long period of time. The competence and training of senior clinicians who can offer supervision will be especially important, as will the skill mix of staff and the resources (including staffing level) available to the service. These 'nonspecific' issues may be especially pertinent when considering the performance of evidence-based treatments in routine practice. Since systemic factors may be as relevant to success as the type of treatment offered, pragmatic trials would be useful to give an indication of the conditions required to implement evidence-based therapies in routine services.

4.12.7 Management of personality disorder

Giles Newton-Howes and Kate Davidson

Introduction

The treatment of personality disorders is a complex but rapidly evolving subject. It is to some extent described elsewhere in Chapters 3.3, 4.12.6, 4.13.1, 5.2.9, 6.3.5, 6.3.9 8.5.6, 9.2.4, 11.3.2, 11.16, and 11.17, and so this chapter excludes a full discussion of psychodynamic interventions, therapeutic communities, interventions for older people and the management of both adolescent and adult offenders.`

Methodological difficulties in evaluating the efficacy of treatment

The requirements for establishing whether a treatment is effective for personality disorders are much more exacting than those for mental state disorders. These can usefully be described under four headings:

- duration of treatment
- comorbidity
- adherence to treatment
- outcome measures.

(a) Duration of treatment

For most mental state disorders it is relatively easy to choose the period over which efficacy has to be demonstrated. In conditions that develop suddenly (e.g. panic), treatment trials could be for a very short time indeed. For others, particularly when maintenance treatment is being evaluated, at least 6 months may be necessary to establish continued efficacy. In the case of personality disorders, it has been thought that efficacy of treatment could not be judged adequately without at least a 2 to 3 year treatment phase. Personality disorder was regarded as being unlikely to change in the short-term. However, these ideas are changing in the light of evidence from longer-term follow-up studies of patients with personality disorder that show that these conditions do change over time in a consistent and predictable manner with substantial numbers of patients achieving full remission in the longer term.[1] If these longer-term follow-up studies are replicated, it would suggest that therapy should aim to accelerate the process of recovery. Determining what constitutes an adequate amount of therapy and over what length of time is an empirical question. More recent studies have offered treatment over 1 year with a 1 year follow-up

to examine maintenance of effect[2,3] but other studies have chosen lengthier treatment phases of up to 3 years[4] with some reporting continued therapy in the follow-up phase which does not allow the effect of maintenance of the original effect to be judged.[5] More recent studies, examining the effect of psychological treatments, have included a 1 year follow-up. The purpose of this follow-up period is to determine if treatment effects are maintained following the termination of treatment. Such a requirement is not a purist position; if a treatment for personality disorder appears to be effective over a shorter period, this may be due to change in a concurrent (comorbid) condition. In addition, if a treatment is to be judged efficacious in personality disorder its effects should be lasting beyond the active treatment component.

(b) Comorbidity

Comorbidity has been defined as 'the presence of any distinct clinical entity that has existed or that may occur during the clinical course of a patient who has the index disease under study'.[5] The key word here is 'distinct'. True comorbidity implies the presence of two completely separate disorders in the same person which are not causally related to each other in any way. Co-occurrence ranges from true comorbidity to the presence of the same disorder in two or more different forms.[6]

Comorbidity is the norm for most personality disorders both with other personality disorders or with mental state disorders. Borderline personality disorder is a major offender in this regard. Only about 1 in 20 of such disorders constitutes the pure condition,[7] and multiple comorbidity with four or more disorders is common.

In deciding on the efficacy of any treatment for personality disorder it is impossible to be certain whether observed improvement is in the personality disorder or in a comorbid condition. This problem is made worse because personality assessment is allegedly confounded, or 'contaminated', by the effect of a concurrent mental state disorder. Thus personality status apparently changes during the presence of a mental state disorder such as depression, only to return to the baseline normal subsequently.[8,9] Apparent improvement in a personality disorder following a treatment may be entirely due to improvement in a concurrent mental state disorder. However, this conclusion does not mean that *personality function*, as opposed to *personality disorder*, does not change. The underlying personality may remain stable, but if the setting and circumstances change, and this includes mental state changes, there can be marked changes in adjustment and so the manifestation of disorder will also change.[10]

In view of these problems, a treatment for a personality disorder should ideally be tested in those patients who have that personality disorder only. As these patients are uncommon and atypical, it is difficult to interpret the data from clinical trials.

(c) Adherence to treatment

People with personality disorders do not usually form good relationships with therapists. Although this is in keeping with their problems with relationships elsewhere, it can be a major problem in any form of therapy. The problem is particularly marked with psychotherapy, in which long-held views are challenged by the therapist. The consequence is that many patients dropout of care, and sometimes no amount of therapeutic skill can maintain them in care.[11] The failure to maintain prescribed treatment, in whatever form, is a constant handicap in accumulating an evidence base for interventions in personality disorder. Even within personality disorder there are differences between sub-groups. Most therapeutic trials have been inpatients with borderline personality disorder while those with schizoid, paranoid, histrionic, narcissistic, and antisocial personality disorders appear much less frequently. This is probably related to treatment attitudes. Borderline, anxious, and avoidant personality disorders contain a much higher proportion of treatment seeking (Type S) personality disorders as opposed to treatment resisting (Type R) ones, which are most prominent in those with antisocial, schizoid, and paranoid personalities.[12]

Any study of personality disorder is likely to have a large proportion of dropouts and this complicates the interpretation of the effects of treatment. The exception is when patients are treated in restricted settings such as prisons and other closed facilities,[13] but as these circumstances are abnormal it is difficult to generalize from them.

(d) Outcome measures

The choice of outcome measures is a problem in the assessment of all psychiatric disorders, but difficulty is particularly great in studies of personality disorders. These disorders affect both the individual and society, and a range of outcomes can be measured to cover these possibilities. Forensic psychiatrists and the general public usually consider that the outcome of mentally disordered offenders is best measured by the frequency of reoffending. This is an easily measured and reliable statistic, but it does not necessarily record symptomatic or personality change, and may be distorted by a range of other factors (e.g. patients who spend a long time in hospital or prison are not likely to reoffend). Changes in symptoms also have limited use since they may be a consequence of changes in mental state disorders quite independent of personality. Repeated measures of personality status also have disadvantages since, as noted earlier, they may be affected by changes with concurrent mental state disorder. Personality also changes with ageing irrespective of treatment.[14]

Because of these difficulties, global outcome measures are often used to determine the degree of improvement in personality disorders in long-term follow-up studies, although a battery of measurements is normally used in short-term treatment studies. Unfortunately, there is no standardized set of measures of global outcome. It is reasonable to take into account symptomatic change, social functioning, quality of life, incidents of societal conflict (e.g. police contacts), and reports from informants. Even these may not correctly reflect change in personality status. Thus a person whose personality disorder does not change in any basic way may find an environmental niche in which the personality disturbance does not manifest itself as conflict. Such a person would show improvement on all the items listed above, but the improvement would be a consequence of environmental change, not of personality alteration.

(e) Minimum requirements for establishment of efficacy

The evidence base for effectiveness of treatment in personality disorders is also exacting:

1 The treatment should be effective when used in the pure form of the personality disorder (in an explanatory trial) and subsequently in other forms of the disorder in which comorbidity is more common (pragmatic trial).

2 Efficacy cannot be established satisfactorily unless the treatment is tested in a randomized controlled trial.

3 A suitable control treatment or management needs to be tested against the experimental treatment.

4 Efficacy should only be determined after a period of at least 1 year because of the long duration of personality disorder. More recent randomized controlled trials in borderline personality disorder examining psychological therapies have met these more demanding criteria.[15,16]

Dynamic psychotherapy

This is discussed in chapter 4.12.6.

Cognitive therapies

(a) Cognitive analytical therapy

Cognitive analytical therapy combines cognitive and analytical approaches and has been applied to the treatment of personality disorders, particularly the borderline group.[17] The clinical manifestations of this condition are postulated to be a set of partially dissociated 'self-states' which account for the clinical features of this disorder. Such patients typically describe rapid switching from one state of mind to another, experiencing intense uncontrollable emotions or alternatively feeling muddled, or emotionally cut-off. Such 'dissociative states' (different from the conditions of similar name formerly linked to hysteria) are said to be activated by severe external threats and to be maintained by repetitions of threat and reinforcement by memories or situations which are similar to the original source of threat.

Cognitive analytical therapy is concerned with the identification of these different self-states and helping patients to identify 'reciprocal role procedures', or patterns of relationships which are learned in early childhood and are relatively resistant to change.[18] The patient is taught to observe and try to change damaging patterns of thinking and behaviour which relate to these self-states and to become more self-aware. The therapist's role is to gather information about the patient's experience of relationships and the different states he or she experiences, including interpretation where necessary. Although the standard measure of evidence of effectiveness, the randomized controlled trial, has still not yet been reported for this treatment it has gathered an impressive group of adherents and has become widely used and now has a good theoretical and pragmatic base.[18]

(b) Cognitive behaviour therapy

In its original form, cognitive therapy for depression was used to help the patient to identify and modify dysfunctional thoughts and beliefs through the use of specific cognitive techniques such as Socratic questioning. The focus of therapy was here and now the aim was to return the patient to his or her usual functioning by relieving current symptoms. The cognitive model of personality disorder does emphasize cognitive, emotional, and behavioural factors but the origins of personality problems are regarded as originating in the temperament of the child, childhood development, and experiences. Early infant attachment patterns, the child's internal working model of relationships, self-identity, self-worth, and the emotional availability of the infant's caregivers are central to how the child develops and these shape the adult self-identity, interpersonal relationships in adulthood, and behavioural and emotional coping responses.[19]

One of the first tasks of cognitive therapy in personality disorders is to gain an historical account of the patient's childhood development and background from which the therapist can derive a cognitive formulation linking past difficulties and presenting problems. Through the formulation, and understanding of the patient's view of self and others, unique core beliefs are identified that are linked to affect and to overdeveloped behavioural patterns that prevent the individual from functioning in an adaptive manner, particularly in interpersonal contexts. Therapy focuses on beliefs that concern core concepts about the self and others that have developed from childhood onwards and associated behaviours that have developed as coping strategies. The content and meaning of the beliefs have had an impact on past and present relationships and are likely to impact the therapeutic relationship. These beliefs, formed through negative, possibly abusive and neglectful experiences with others, are likely to have resulted in low self-esteem, hypersensitivity to criticism, and poor relationships with peers, caregivers and others in adolescence. Once a clear understanding of the content of patient's core beliefs and associated overdeveloped or compensatory behavioural patterns has been established, patients are encouraged to test out their beliefs and assumptions about others by learning new, more adaptive strategies for relating to others and to themselves. In borderline personality disorder, typically patients hold beliefs such as 'I am a bad and inadequate person' and 'others will abandon or reject me'. Having formed these beliefs through experiences in childhood, borderline patients, for example, may have learnt to avoid close relationships, are highly sensitized to signs of disapproval in others and have developed a punitive, self-critical style of thinking and behaviour, including self-harm. The emphasis in cognitive therapy is in developing new ways of thinking about self and others and in testing out new ways of behaving that are less self-defeating and more likely to improve the patient's interpersonal skills.[19] In comparison with the treatment of Axis I disorders, cognitive therapy with personality-disordered individuals takes more sessions and spans a longer time because the underlying problems are more pervasive and ingrained. There are other important elements of cognitive and related therapies, of which schema therapy and dialectical behaviour therapy are the most prominent. One of these differences is on the emphasis and attention paid to the therapeutic relationship. In cognitive therapy for personality disorder, more emphasis is placed on establishing and maintaining a therapeutic alliance, as interpersonal difficulties which occur in the patient's life outside therapy are also likely to arise within therapy. This is based on the hypothesis that the patient's core beliefs are consistent across a wide range of settings and therefore are also likely to be manifest in therapeutic relationships. Patients are therefore likely to be highly sensitive to signs of criticism and approval in their therapists. The models of treatment for personality disorder proposed by Beck and Freeman,[20] Davidson,[19] Young,[21] and Linehan[22] have in common an attempt to integrate biological and psychosocial factors. All models of treatment recognize the importance of building a secure therapeutic relationship and transference and countertransference issues in therapy are increasingly recognized as important mediators of the therapeutic process. These therapies utilize cognitive techniques to repair breakdown in communication that can occur during therapy.

Cognitive analytical therapy[18] also gives special attention to this aspect of therapy.

One of the goals of cognitive therapy with personality-disordered patients is to take advantage of these interpersonal difficulties in treatment by identifying and modifying the beliefs underlying them and, by extension, other relationships. Although people with personality disorders can recognize difficulties, they experience the problems as egosyntonic[23] (i.e. accepted as normal because they are an intrinsic part of usual functioning). As a result, alternative and potentially more adaptive beliefs about the self and others need to be identified and evaluated to see if they are indeed more adaptive and embraced as a consequence. These alternative more adaptive beliefs require to be systematically reviewed and reinforced, and new behaviours and ways of relating to others need to be practiced repeatedly if changes are to be consolidated. To achieve these changes, the therapist usually has to adopt a more directive approach than in cognitive therapy for depression and other Axis I disorders, and throughout will be more concerned with identifying and overcoming cognitive, emotional, and behavioural avoidance which maintains core beliefs.

(c) Other related psychological therapies

(i) STEPPS

Systems Training for Emotional Predictability and Problem Solving (STEPPS) is affiliated to the other cognitive psychotherapies. It was developed by Nancee Blum in Iowa and has been extended across several states within the United States and to the Netherlands. It has some of the elements of standard cognitive behaviour therapy and dialectical behaviour therapy and is a manualized programme involving 20 2 h weekly group meetings; with specific goals (or lessons) identified for each session.[24] A randomized controlled trial has just been completed and this shows significant gains in some areas compared with treatment as usual (Black, 2007, APA meeting, San Diego, USA).

(ii) Schema-focused therapy

Schema-focused therapy[21] is now becoming increasingly used in the treatment of borderline and antisocial personality disorders. It is a compendium of cognitive behaviour therapy, object relations theory, and gestalt therapy, and also involving what Young calls 'limited reparenting'. It is given in a relatively intensive form—two to three sessions a week for 1–2 years—but has been shown to be both more effective and cost-effective than transference-focused psychotherapy in a trial of treatments for borderline personality disorder.[28]

(iii) Dialectical behaviour therapy

The era of evidence-based therapy in personality disorder began with a formal trial of dialectical behaviour therapy, a form of cognitive behaviour therapy linked to skills training and detached acceptance (or mindfulness), was compared with treatment as usual in a group of repeatedly self-harming female patients with borderline personality disorder.[28,69] The hypothesis that dialectical behaviour therapy was effective in reducing self-harm was supported. Now several other randomized trials have taken place that show that DBT is particularly effective in reducing self-harm[4,29,30] though in another study, DBT improved hopelessness, depression, anger, and suicidal ideation but showed no difference in suicide attempts.[31]

This treatment has also been used systematically in the treatment of borderline personality disorder and those with comorbid substance abuse.[30] According to Linehan,[22] borderline personality disorder is primarily a dysfunction of emotional regulation which is assumed to have resulted from biological irregularities combined with certain dysfunctional environments. Others in contact with the patient are postulated as reinforcing this dysfunction by discounting or, in Linehan's preferred term, 'invalidating' their emotional experiences. Borderline patients are emotionally vulnerable and have difficulty in regulating patterns of responses associated with emotional states. The maladaptive behaviours which form part of the borderline syndrome can be viewed as either the product of emotional dysregulation or as attempts by the individual at regulating intense emotional states by maladaptive problem-solving strategies. Dialectical behaviour therapy, as its name suggests, contains within it the notion of opposites; common themes that emerge in therapy with borderline patients, such as acceptance of things as they are (so that there is no need for suicidal action), and change (from former maladaptive types of response) may appear incompatible but are synthesized in the therapy.

The essentials of dialectical behaviour therapy[22] are manualized weekly individual psychotherapy, group psychoeducational behavioural skills training, and telephone consultation when considered necessary. Therefore the content comprises a variety of problem-solving techniques including teaching the patient skills to help regulate emotions and tolerate distress, methods for validating the patient's perceptions, and behavioural and psychological versions of meditation skills. Therapists are also trained in case management. 'Core mindfulness skills' are also part of the treatment and involve teaching the patient to observe, describe, and take part in events and responses to events without dissociating from what is happening. The treatment encourages patients to take a non-judgemental approach to events and interactions and to do what is effective in situations rather than what they may feel is the 'right' thing to do.

Summary of cognitive therapies

The collective view of the effectiveness of cognitive and dialectical behaviour therapies is that they are undoubtedly effective Leichsenring and Leibing[32] examined 25 studies (but very few randomized controlled trials) and found cognitive behaviour therapy to be effective (effect size 1.0) but with psychodynamic therapies the effect size was larger (1.46), but the authors emphasized these results were preliminary and need updating. More randomized controlled trials have been carried out into treatments for personality disorder in the last 4 years than in the previous 50 years and further reviews are needed. To date we only have good evidence of effectiveness for borderline personality disorder, but cognitive behaviour therapy has also been shown to be effective in a randomized trial of avoidant personality disorder.[33]

Nidotherapy

Nidotherapy is 'the collaborative systematic assessment and modification of the environment to minimize the impact of any form of mental disorder on the individual or on society'.[25] It was developed specifically for the care of patients with multiple personality and major psychiatric pathology and is particularly focused on Type R (treatment resisting personality disorders). It makes no attempt to treat the patient directly but instead attempts to change the environment so there is a better fit between individual and

setting. It is normally carried out individually by a nidotherapist working independently from other clinical services.[26] It has been tested in a randomized trial in which the main gain was in cost savings as patients spent less time in hospital[27] and has also been used for antisocial personality disorder for the reduction of aggression and improvement in social functioning (http://www.controlled-trials.com (ISRCTN96256106)).

Therapeutic community treatments

There has been some confusion regarding the term 'therapeutic community'. It can apply to any form of environment created for a specific treatment but was really introduced and defined in its modern context by Maxwell Jones[34] who created a structure that ran completely counter to that of the traditional (authoritarian) mental hospital. This can be defined as a socially cohesive structure depending on intensive group treatments carried out by its residents. This approach, the democratic therapeutic community, differs from other forms of more coercive communities linked to criminal justice in the United States, often used for substance abusers, which are called concept therapeutic communities.[35,36] Therapeutic communities have very strong advocates and the complexity of the intervention makes it difficult to create a suitable comparison group to act as a control for a randomized trial; to date no such trial has been carried out.

Drug treatment

Drugs are often used for treating personality disorders although it is important to note that none are licensed for the treatment of these conditions. As with other forms of treatment, borderline personality disorder constitutes the largest group in which drug treatment is being used and is therefore worth examining separately. The evidence base for drug treatment is growing and there are now sufficient randomized controlled trials to evaluate and for other studies to be ignored in this review.

Borderline personality disorder

Borderline personality disorder is one of the most heterogeneous of all groups within the personality classification and includes extensive comorbidity with other personality disorders as well as with mental state disorders, particularly mood and stress-related disorders. This hinders the interpretation of Table 4.12.7.1, noting the problems of evaluation referred to at the beginning of this

Table 4.12.7.1 Summary of randomized controlled trials of drugs in the treatment of personality disorder (borderline except where indicated)

Drug group	Individual drug	Size of trial—*n* (ref)	Main outcome measures	Results
Tricyclic antidepressants@	Amitriptyline	61[37]	Depression, aggression, global improvement	Amitriptyline no better than placebo
Selective serotonin reuptake inhibitors (SSRIs)	Fluoxetine	40[38]	Aggression depression,	Fluoxetine superior to placebo
	Fluvoxamine (cross-over study)	38[39]	Mood shifts, aggression, impulsivity	Positive effects of fluvoxamine on mood only
Antipsychotic drugs (both first and second generation)	Haloperidol	61[37] and 108[40]	Depression, hostility, impulsiveness	Haloperidol effective in reducing depression and hostility in first study but not in second
	Olanzapine (wide-dosage range)	40[41]	Aggression, depression, anxiety	Significant improvement in an unrecognized scale (Clinical Global Improvement-BPD) only
	Olanzapine (mean 5.3 mg)	28[42]	'Random effects regression modelling of panel data'	Alleged improvement on composite measure (unsatisfactory)
	Aripiprazole 15 mg/day*	52[43]	Hostility, anger, depression, self-harm	Significant improvement in all measures and reduction in self-harm
Monoamine oxidase inhibitors (MAOIs)	Phenelzine (60 mg/day)	108[40]	Depression, hostility, impulsiveness, anxiety	Phenelzine superior to haloperidol and placebo for anger and hostility
Mood stabilizers and anti-convulsants	Carbamazepine (7 mg/day)†	20[44]	Depression, hostility	
	Sodium valproate (850 mg/day)*	30[45]	Depression, aggression, hostility	
	Sodium valproate*	91[46]	Aggression	
	Lamotrigine*	27[47]	Self-rated anger	
	Topiramate*	56[48]	Anger	

*Patients recruited by advertisement.

†Patients recruited as inpatients.

@A study involving mainly cluster C personality disorders compared the tricyclic antidepressant, dothiepin, with cognitive behaviour therapy and self-help over a 2-year period and showed significantly better response to dothiepin[49] (but study not included as after 2 years there were many deviations from the original protocol.

chapter. The studies are complex, yet the numbers are generally small, the period of treatment variable (8 weeks to 6 months), the dosage of drugs is usually flexible, and the outcomes manifold (and so variable that it is almost impossible to combine the data systematically). Positive publication bias and recruitment of volunteers by advertisement diminish the relationship between this patients group and those in clinical practice.

(i) Antidepressants

Tricyclic antidepressants do not appear to be effective in borderline personality disorder and, interestingly, do not help depressive symptoms preferentially, suggesting that there are subtle differences between the despair and emptiness of the borderline personality disorder and the anhedonia of depressive illnesses. Selective serotonin reuptake inhibitors (SSRIs), have been used in many trials (including some not cited here in which comparisons of inadequately small numbers have been made with psychological treatments) and provide some evidence of a positive effect on aggression and impulsiveness in antisocial personality disorder.[38] Monoamine oxidase inhibitors show reduction of anger and hostility in one trial but conventional risk management uggests that this treatment should only be used in exceptional circumstances.

(ii) Antipsychotic drugs

Although antipsychotic drugs have been tested in the treatment of borderline personality disorder more frequently than any other drug treatment, the results are equivocal. Haloperidol may be effective[37] in the short-term, however continuation studies do not show sustained improvement.[50] Olanzapine has been tested in three trials and, apart from showing consistent weight gain in all of these, has not shown any real evidence of benefit for any of the core symptoms of borderline personality disorder. The only trial showing substantial benefit was carried out with aripiprazole in symptomatic volunteers[43]; as aripiprazole has a complex pharmacological profile with 5-HT and dopamine agonist and antagonist actions this could represent a novel intervention and is worthy of replication.

(iii) Mood stabilizers

Borderline personality disorder is characterized by rapid swings in mood and emotional lability is a core feature. It is therefore not surprising that mood stabilizers have been used in its treatment. Again the results are equivocal and this subject urgently needs the benefit of a large independent trial. The most impressive result has been shown with the anticonvulsant drug, topiramate, which reduces aggression and hostility[48,51] but this finding needs replication. Lithium may also be effective in aggression but a satisfactory level of evidence is lacking.

Critique of drug treatment for borderline personality disorder

The evidence for the value of drug treatment has been influenced greatly by a guideline issued by the American Psychiatric Association in 2001.[49] This was a bold attempt to give clear recommendations to clinicians desperate to find a way through the fog of uncertainty with the abyss of suicide yawning on one side and iatrogenic poly-poly-pharmacy (the patients with this disorder are multiple consumers of prescribed drugs) on the other. There were four recommendations:

1 psychotherapy—both psychoanalytic/psychodynamic therapy, and dialectical behaviour therapy 'have been shown to have efficacy'
2 pharmacotherapy for 'affective dysregulation symptoms' should'be treated initially with a selective serotonin reuptake inhibitor or related antidepressant such as venlafaxine'
3 treatment of 'impulsive-behavioural dyscontrol symptoms' also suggests 'SSRIs are the initial treatment of choice'
4 'low-dose neuroleptics are the treatment of choice for "cognitive-perceptual" symptoms'.

These were criticized heavily at the time for going far beyond the evidence[52–54] and for some treatments, notably cognitive behaviour therapy, neglecting available evidence,[53] and further data accrued over the ensuing years has reinforced these concerns.[15,28,55] The recommendations concerning drug treatments are particularly suspect. There is no evidence worthy of the name that justifies the sub-grouping of borderline personality disorder into 'affective dyscontrol', 'impulsive-behavioural dyscontrol', and 'cognitive-perceptual' categories and these appear to be entities created to justify the use of particular drugs rather than provide a valid subdivision of a complex disorder. The creation of these essentially pseudo-diagnoses allows general conclusions to be made that all the drug treatments are efficacious and that 'taken together, the results of these studies suggest that the choice of medication can be guided as much by tolerability and safety as by symptom presentation'.[56] On the evidence analysed dispassionately this conclusion applies equally well to placebo, whose tolerability and safety are unparalleled.

Flamboyant group (cluster B, not borderline)

The evidence for drug use in other cluster B disorders is very limited. There may be a limited role for the use of mood stabilizers in reducing anger in dissocial personality. Lithium was found to be effective[57] and this action has been found in other settings,[58] but not reproduced in dissocial personality disorder. Carbamazepine has also been found to reduce impulsivity[59] but this result requires replication.

Odd eccentric group (cluster A)

No placebo-controlled, explanatory trials in this group have been conducted and no pragmatic trials provide evidence for drugs that remain in use. A mistrust of treatment given by others limits research and is probably an intrinsic part of the condition.

Anxious fearful group (cluster C)

The diagnostic overlap between cluster C personality disorders and neurotic disorders makes drawing conclusion about drug treatment for this group difficult. No clear explanatory trails have been conducted and the evidence of the effectiveness of antidepressants is confounded by the presence of neurotic disorder.[60,61]

Management

The management of borderline personality disorder can now be directed by a combination of the evidence and clinical judgement. It is clear from the randomized trials of both pharmacological and psychological treatment that an organized plan of care leads to improvement. This includes a consistent approach, a constancy of

personnel and adequate access to inpatient care during crisis situations. The cognitively based therapies are effective and pragmatic, providing a higher degree of input to ensure effectiveness. The intermittent addition of low-dose haloperidol or aripiprazole may assist with worsening impulsivity. A trial of topiramate for anger or SSRIs for impulsivity may also be of value. These need to be trialed for a specific period, 4 to 8 weeks, with a clear plan to review or stop if effectiveness is not clear or deteriorates over time. The risks of prescribing need to be carefully weighed against the potential benefits. Polypharmacy increases risk with no evidence of benefit. It is ethically important to ensure all patients have the capacity to consent to treatment, particularly for unlicensed drug use. Because the treatment of personality disorder is among the most complex of complex interventions[62] it is likely that several treatments, given in combination in a systematic way, are best suited to many of those who have more severe personality disorders.

The management of other personality disorders remains largely guided by clinical experience. The general principles of service organization remain the same, however decisions regarding psychotherapy and pharmacotherapy need to be tailored to individuals with an expectation of building a body of patient-based evidence, as other evidence is weak. Regular review of a management plan minimizes the likelihood of harm from any one course of action or the neglect of the patient's presentation.

Some management options can now be considered to have a negative risk: benefit ratio. These include behaviour therapy alone, tricyclic antidepressant therapy, and monoamine oxidase therapy.

Organization of services for personality disorder

It is likely that the organization of care for those with personality disorder has a much greater part to play than any specific single treatment in the clinical success of management but it is also fair to add that this conclusion is not based on excellent evidence. What is, however, clear from the randomized trials of both pharmacological and psychological treatment is that an organized plan of care leads to great improvement in those with personality disorder irrespective of the exact nature of the intervention.

Services for the management of personality disorder can include the 'sole practitioner' model (a single therapist seeing the patient), the 'divided function' model (in which part of the patient's care is taken over by specially trained staff whilst others look after other parts), and the 'specialist team' model (in which a specific personality disorder service takes on all aspects of care). The general conclusion is that the 'divided function or specialist team model is probably best for reducing risk and improving outcomes'.[63] The general principles of management apply to all personality disorders although the consequences of ignoring them will be greater for the flamboyant cluster of personality disorders than for others.

(a) Consistency

One of the reasons why those with personality disorders create so many problems in therapy is that they are highly sensitive to perceived criticism and are therefore able to detect any inconsistency in their treatment. Sometimes this is a way of deflecting attention away from fundamental problems associated with the personality disorder, but they are nonetheless effective in creating a screen that prevents other issues from being addressed. Clearly the fewer the people involved in care, the less are the chances of creating inconsistency. Keeping the number of main workers to a small number, and maintaining good communication, is a sound goal.

(b) Constancy

It is helpful to avoid changes in staff as far as possible. This is of particular relevance in the treatment of borderline personality disorder in which changes in therapists often re-enact the problems of loss and despair that the patient experiences so commonly in relationships.

(c) Adequate inpatient support

Staff involved in hospital care often believe that people with personality disorders should be kept out of hospital. This belief is based on the observation that such people exploit the opportunities offered by admission and create circumstances whereby it is difficult to discharge them. Much of this is opinion and not founded on evidence. Patients with comorbid mental state and personality disorders actually have better outcomes if they have a hospital-oriented programme of care than treatment in the community, whereas the opposite is true in the absence of personality disorder.[64] However, this work was carried out before specific services for personality disorder were set-up in England, the first country in the world to create such services.[65] The initial pilot service has just been evaluated and the results are encouraging, but the problem remains that those who wish to seek treatment from these services comprise only a small proportion of the total who suffer.[72]

Problems with comorbidity

Perhaps the most important error in management is failure to recognize personality disorder when other psychiatric disorders are more prominent and appear to be the only presenting problem. This is becoming recognized in the development of treatment protocols. This problem is encountered widely in the mental health services among people presenting to emergency psychiatric clinics,[73] in services for the homeless mentally ill,[74] and among heavy users of psychiatric services[75] and those with multiple admissions.[68] In all these settings, personality disorder is often not recognized early enough. This is to some extent understandable as the assessment of personality disorder is difficult in, for example, a busy emergency clinic. Nevertheless, failure to achieve a predicted response is often due to an earlier failure to detect the presence of personality disorder.

Conclusions

Some years ago that most sceptical of academic psychiatrists, Michael Shepherd, in referring to the contents of a book entitled *Recent Advances in Psychiatry* commented that the content was more accurately defined as 'recent activities', as 'advances' was too generous a word. Whilst not going quite as far as this in regard to advances in the treatment of personality disorder it is fair to add that the promise of effective therapies across the spectrum of personality dysfunction remains a long way off and we must be very careful not to oversell the evidence. The complexity of personality disorders often requires complex intervention, however, until we are confident that single treatments are effective the arguments for evaluating them in combination have to be very strong on theoretical grounds to justify the cost.

We are still at the stage in which explanatory trials (ones demonstrating efficacy under optimal conditions) are at least as necessary as pragmatic ones (demonstrating benefit in conditions of ordinary practice). These need to be carried out with adequate numbers of patients (at least 50 in each treatment arm rather than an artificially derived sample size to justify a small number) and with good independent assessments carried out by research workers who are masked as much as possible from disclosure of treatment. These requirements are exacting but can be achieved.[67] We also need better pragmatic trials of patients seen in ordinary mental health practice whose treatment and characteristics are both representative and from whom it is possible to generalize findings with confidence. Currently there are very few studies that satisfy this requirement; one recent study combining an educational intervention with problem-solving is an exception.[68]

Despite the caution of these statements these are exciting times in the management of personality disorder. We are no longer listening to the once powerful lobby that claimed that patients with these conditions should not be treated by psychiatric services, or to the pessimists that still regard these conditions as untreatable. We are in the equivalent position as those in the early 1950s who suddenly became aware of the possibility that powerful treatments for severe mental illness were ready and waiting to be used. They do indeed appear to be within reach, but we must use them wisely.

Acknowledgement

The authors would like to thank Professor Peter Tyrer who co-authored the original chapter on which this is based.

4.13

Habit and impulse control disorder

Contents

4.13.1 Impulse control disorders

Susan L. McElroy and Paul E. Keck, Jr.

This chapter first defines impulse control disorders, and then summarizes available research on the clinical features, epidemiology, psychiatric comorbidity, family studies, psychobiology, and treatment response of the most common of these conditions (except for pathological gambling, which is reviewed in Chapter 4.13.2).

Definitions of impulse control disorders

Historically, impulse control disorders have been broadly defined as harmful behaviours performed in response to irresistible impulses.[1] In DSM-IV, an impulse control disorder is defined as the failure to resist an impulse, drive, or temptation to commit an act that is harmful to the individual or to others.[2] DSM-IV also stipulates that for most impulse control disorders, the individual feels an increasing sense of tension or arousal before committing the act and then experiences pleasure, gratification, or relief at the time of committing the act. In the text describing these disorders, DSM-IV states that after the act, there may or may not be genuine regret, self-reproach, or guilt. In ICD-10,[3] these conditions are classified as habit and impulse disorders and defined as repeated acts that have no clear rational motivation, cannot be controlled, and that generally harm the patient's own interests and those of other people. ICD-10 further states that the behaviour is associated with impulses to action.

In DSM-IV, impulse control disorders are listed in a residual category, 'Impulse control disorders not elsewhere classified', which includes intermittent explosive disorder (IED), kleptomania, pyromania, pathological gambling, trichotill16omania, and impulse control disorders not otherwise specified (NOS). Examples of impulse control disorders NOS are compulsive buying disorder, repetitive self-mutilation, pathological skin picking, and onychophagia (severe nail-biting).[1] In ICD-10, habit and impulse disorders are also listed as a residual category. Similar to DSM-IV, it includes pathological gambling, pathological fire-setting (pyromania), pathological stealing (kleptomania), trichotillomania, other habit and impulse disorders (which includes IED), and habit and impulse disorder, unspecified.

It should be noted that with mounting research, the impulse control disorders are increasingly viewed as complex conditions sharing, in addition to irresistible impulses to perform harmful behaviours, features of trait impulsivity, trait compulsivity, and mood dysregulation, as well as obsessive compulsive mood, and addictive disorders.[1]

Intermittent explosive disorder

Definition and clinical features

Intermittent explosive disorder (IED) is defined in DSM-IV as several discrete episodes of failure to resist aggressive impulses that result in serious assaultive acts or destruction of property (criterion A). Also, the degree of aggression expressed during an episode is grossly out of proportion to any precipitating psychosocial stressors (criterion B) and the explosive episodes are not better accounted for by another mental disorder or due to the direct physiological effects of a substance or a general medical condition (criterion C). Varying definitions of IED based on the DSM-IV criteria have been proposed and used.[4,5] One important set of research criteria for IED, for example, allows for less severe aggressive episodes, such as recurrent verbal outbursts against others without physical aggression, but requires that the aggressive episodes be recurrent and associated with distress or dysfunction.[4] Although ICD-10 lists IED under 'Other habit and impulse disorders', it does not provide specific criteria for its diagnosis.

Regarding phenomenology, persons with IED describe their aggressive episodes as explosive, uncontrollable, unpremeditated, and brief; often provoked by minor stimuli; and associated with various psychological and physical symptoms, especially changes in mood, awareness, and autonomic arousal.[4,6] The frequency of

episodes depends in part on how the disorder is defined. In the National Comorbidity Survey Replication (NCS-R), where the DSM-IV A criteria of 'several' episodes was operationalized to be three or more lifetime attacks, persons with IED had a mean of 43 lifetime attacks.

Many persons with IED describe problems with chronic or trait anger and frequent 'subthreshold' aggressive episodes in which they manage to resist enacting aggressive impulses or express them with less destructive behaviours (e.g. screaming rather than assault).[4,6] These subthreshold episodes are similar to the anger attacks (sudden episodes of intense anger with autonomic arousal) often described in patients with mood (bipolar and depressive) disorders.[7]

Of note, the relationship between IED specifically and impulsive aggression in general remains unclear and the two phrases are not necessarily synonymous. In particular, like other impulse control disorders, the aggression of IED usually involves elements of lack of control (e.g. compulsivity) and affect dysregulation (extreme anger, irritability and/or mood instability) as well as impulsivity. Thus, IED may be one form of impulsive aggression.

Epidemiology and course

Once thought to be rare, recent research has shown that IED is common in both clinical and general population samples. In the most rigorous study to date, the NCS-R, lifetime and 12-month prevalence estimates of DSM-IV IED in the general population were 7.3 per cent and 3.9 per cent, respectively.[5] The lifetime and 12-month prevalences of more narrowly defined IED (in which three episodes in the same year were required for diagnosis) were 5.4 per cent and 3.5 per cent, respectively. The disorder is also likely to be common in forensic populations but data are not available.

IED is probably more common in males than females. In the NCS-R, 9.3 per cent of men versus 5.6 per cent of women met lifetime DSM-IV criteria for the disorder. IED begins in childhood or adolescence; follows a chronic or episodic course; and is associated with distress, morbidity (e.g. injuries), and social and occupational impairment.[4-6] For example, in the NCS-R, IED had a mean age of onset of 14 years, was persistent over the life course (with averages of 6.2–11.8 years with attacks), and was associated with substantial role impairment.[5] However, the prevalence of the disorder was significantly lower among persons 60 years and older (2.1 per cent).

Associated psychopathology and comorbidity

IED often co-occurs with other psychiatric disorders.[4–6] In the NCS-R, 81.8 per cent of respondents with lifetime DSM-IV IED met criteria for at least one other lifetime DSM-IV disorder. Specifically, IED was significantly comorbid with all DSM-IV depressive, anxiety, and substance use disorders assessed after controlling for age, sex, and race. It was also significantly comorbid with oppositional defiant disorder, conduct disorder, and attention-deficit/hyperactivity disorder.

Importantly, the boundaries between IED and other conditions characterized by episodic and/or impulsive aggression have not been clearly delineated. Indeed, the comorbidity between IED and both bipolar disorders and Axis II disorders was not assessed in the NCS-R.[5] Comorbidity with Axis II disorders was not determined because the prevalence of these disorders was not evaluated. Comorbidity with bipolar disorders was not assessed because of how IED was defined; cases of IED with lifetime mania or hypomania were excluded from analysis (number not specified) so that the prevalence of IED was not overestimated by cases of bipolar disorder with anger attacks. Of note, although the relationships between IED and both bipolar and cluster B personality disorders remain unclear, clinical studies suggest that patients with IED have high rates of these conditions.[4,6]

Family studies

Family studies suggest that relatives of probands with IED have high rates of impulsive violent behaviour, substance abuse, and possibly mood and other impulse control disorders.[4,6,8,9] In a family history study of patients with temper outbursts meeting the first two DSM-III criteria for IED, non-adopted patients were significantly more likely than adopted patients to have a family history of temper outbursts.[9] Of 25 subjects with DSM-IV IED evaluated via the family history method, 8 (32 per cent) of subjects had a first-degree relative with probable IED, 20 (80 per cent) had at least one first-degree relative with a substance use disorder, 14 (56 per cent) a mood disorder, and 14 (56 per cent) an impulse control disorder.[6] A blinded, controlled family history study using broadly-defined IED criteria found a significantly increased morbid risk of the condition in relatives of affected probands (26 per cent) compared with relatives of control probands (8 per cent).[4]

Psychobiology

Persons with impulsive aggression have been consistently found to have abnormalities in serotonergic function.[4] Although most studies included subjects with impulsive aggression and personality disorders, a few included persons with IED or possible IED. Thus, in a study of 58 violent offenders and impulsive fire-setters, 33 (57 per cent) of whom had DSM-III IED, lower cerebrospinal fluid (CSF) concentrations of 5-hydroxyindoleacetic acid (5-HIAA) were found in the impulsive offenders and fire-setters than in the non-impulsive offenders and normal control subjects.[10]

In a functional magnetic resonance imaging (MRI) study of response to social threat, 10 subjects with IED showed exaggerated amygdala reactivity and diminished orbitofrontal cortex activation to faces expressing anger compared with controls.[11] The authors noted these findings were similar to other disorders characterized by impulsive aggression, including borderline personality and bipolar disorders, and that they supported a link between a dysfunctional frontal-limbic network and aggression.

Treatment response

Clinical experience suggests that IED may be less responsive to insight-oriented and more responsive to cognitive behavioural therapies, particularly those stressing anger management.[4,6,12] Medications reported effective in definite or probable IED, some in controlled trials, include antiepileptics (e.g. phenytoin, carbamazepine, oxcarbazepine), antidepressants (e.g. tricyclics, serotonin reuptake inhibitors), mood stabilizers (e.g. lithium, valproate), β-blockers, psychostimulants, and even antiandrogens. Mood stabilizer monotherapy and antidepressant augmentation of mood stabilizers have both been reported to successfully treat IED and/or anger attacks in patients with bipolar disorders.[6,7] Antidepressants have been reported to be effective in anger attacks associated with

major depression.[12] Finally, serotonin reuptake inhibitors, mood stabilizers, antiepileptics, and antipsychotics may be effective for impulsive-aggressive behaviour in personality-disordered patients.[13]

Kleptomania

Definition and clinical features

Kleptomania is defined in DSM-IV as follows:

- recurrent failure to resist impulses to steal objects that are not needed for personal use or for their monetary value (criterion A);
- increasing sense of tension immediately before committing the theft (criterion B);
- pleasure, gratification, or relief at the time of committing the theft (criterion C);
- the stealing is not committed to express anger or vengeance and is not in response to a delusion or a hallucination (criterion D);
- the stealing is not better accounted for by conduct disorder, a manic episode, or antisocial personality disorder (criterion E).

In ICD-10, kleptomania (or pathological stealing) is defined as the repeated failure to resist impulses to steal objects that are not acquired for personal use or monetary gain.

An increasing number of studies have systematically examined the phenomenology of groups of people with DSM-defined kleptomania.[14–17] In these studies, most subjects described irresistible impulses or urges to steal, tension with the impulses, and tension relief either during or shortly after the act of theft (as required by the DSM criteria). Many subjects described the impulses as senseless, intrusive, uncomfortable, and uncontrollable. Many tried to resist the impulses with varying degrees of success. Some reported pleasurable feelings during the act of theft, often described as 'a rush,' 'a high,' or 'a thrill.' Most patients reported instances of impulsive stealing, but some also described premeditated stealing, the aim of which was sometimes to relieve the impulses to steal. Many subjects reported that they had lied to conceal their stealing. Some subjects developed rules for their stealing behaviour—for instance, stealing only from work or from certain types of shops (e.g. drug stores but not department stores), or stealing certain items but not others (e.g. jewellery but not clothing). Many subjects considered their stealing to be wrong, and many, but not all, reported guilt or remorse after stealing. Subjects who had been arrested for shoplifting reported that it had varying effects on their symptoms—some stopped stealing completely, some stopped for a limited amount of time, while others reported that their stealing was unaffected. Some stated they continued to steal once incarcerated.

These studies have also found that some subjects with apparent kleptomania report varying degrees of amnesia surrounding the act of stealing.[17] Many of these subjects deny impulses, tension, or relief with their thefts. Other subjects who are not amnesiac for their stealing episodes may also deny experiencing impulses, tension, relief, and/or pleasure. For these subjects, stealing appears to have become automatic or habit-like.[17]

Epidemiology and course

Kleptomania is presumed to be rare but its prevalence is unknown. Available studies suggest that only a small portion of shoplifters (from none to 8 per cent) represent true cases of kleptomania.[14] However, it has been argued that these rates may be spuriously low because psychiatric evaluations may not have always been sufficiently thorough, operational diagnostic criteria were rarely used, and kleptomania may have been under-represented in the samples due to selection bias (i.e. people with repeated apprehensions were more likely to be legally rather than psychiatrically referred). Also, kleptomania may be relatively common in clinical populations; it was the second most common lifetime impulse control disorder in a group of adult psychiatric inpatients assessed with a structured interview, present in 9.3 per cent of the sample.[18]

Kleptomania is probably more common in women than in men.[14–17] Many cases begin in adolescence or early adulthood, and often follow an episodic or a chronic course.

Associated psychopathology and comorbidity

Clinical studies show that kleptomania often co-occurs with other Axis I psychiatric disorders, including mood, anxiety, substance use, eating, and impulse control disorders.[14–18] In the only controlled study,[16] 10 patients with kleptomania had significantly higher rates of comorbid psychiatric disorders, particularly mood disorders, other impulse control disorders, and substance abuse or dependence (mainly nicotine dependence), than 29 psychiatric comparison patients and 60 patients with alcohol abuse or dependence. Several studies, including the one controlled study, found especially high rates of bipolar disorders.[15–17] Conversely, high rates of kleptomania have been found in women with eating disorders[14] and patients with depressive disorders.[19]

Preliminary data suggest patients with kleptomania may also have high rates of certain Axis II disorders.[17] However, the relationship between kleptomania and antisocial personality disorder is not understood.

Family studies

Uncontrolled studies suggest kleptomania may be associated with increased familial rates of mood, substance use, anxiety, and possibly impulse control disorders.[17] For example, of 103 first-degree relatives of 20 patients with DSM-IIIR-defined kleptomania evaluated blindly by the family history method, 22 (21 per cent) had a major mood disorder, 21 (20 per cent) had a substance use disorder, and 13 (13 per cent) had an anxiety disorder, including seven (7 per cent) with obsessive compulsive disorder[15] Also, two (2 per cent) had apparent kleptomania. However, a controlled family study found similar rates of kleptomania in first-degree relatives of probands with obsessive compulsive disorder and those of control probands.[20]

Psychobiology

Preliminary research suggests kleptomania may be associated with serotonergic and frontal lobe dysfunction. In one study, the number of platelet serotonin transporters, evaluated via [3H] paroxetine binding, was lower in 20 patients with obsessive-compulsive related disorders, including five patients with kleptomania, than in 20 healthy control subjects.[17] In another study, 10 females with DSM-IV kleptomania were more likely than controls to have decreased white matter microstructural integrity in inferior frontal brain regions when evaluated with diffusion tensor imaging.[21]

Treatment response

Although no controlled psychological treatment studies of kleptomania have been published, various types of cognitive behavioural therapy may be effective.[12,17] There are also successful reports of the use of psychodynamic psychotherapies, but there are negative reports as well.[12,15]

Medical treatments with antidepressant, mood-stabilizing, or anxiolytic properties have been reported to be effective in kleptomania, primarily in case reports and case series. These treatments include tricyclics, serotonin reuptake inhibitors, trazodone, lithium, valproate, electroconvulsive therapy, and benzodiazepines.[12,15,17] There are also reports of patients with kleptomania responding to the opioid antagonist naltrexone and the antiglutamatergic agent topiramate.[12,17]

However, in the only controlled pharmacotherapy study of kleptomania published to date, an open-label trial of escitalopram treatment in 24 subjects followed by double-blind discontinuation in 15 of 19 responders, there was no difference in response rate (defined as greater than a 50 per cent decrease in theft episodes per week) between subjects receiving escitalopram (3 [43 per cent]) and those receiving placebo (4 [50 per cent]).[22]

Pyromania

Definition and clinical features

Pyromania is defined in DSM-IV as follows: deliberate and purposeful fire-setting on more than one occasion (criterion A) that is associated with tension or affective arousal before the act (criterion B), fascination with, interest in, curiosity about, or attraction to fire and its situational contexts (criterion C), and pleasure, gratification, or relief when setting fires, or when witnessing or participating in their aftermath (criterion D). Also, the fire-setting is not done for monetary gain, as an expression of sociopolitical ideology, to conceal criminal activity, to express anger or vengeance, to improve one's living circumstances, in response to a delusion or hallucination, or as a result of impaired judgement (criterion E), and is not better accounted for by conduct disorder, a manic episode, or antisocial personality disorder (criterion F). In ICD-10, pyromania (or pathological fire-setting) is defined as multiple acts of, or attempts at, setting fire to property or other objects, without apparent motive, and by a persistent preoccupation with subjects related to fire and burning. The essential features are as follows:

- repeated fire-setting without any obvious motive such as monetary gain, revenge, or political extremism
- an intense interest in watching fires burn
- reported feelings of increasing tension before the act, and intense excitement immediately after it has been carried out.

Although the authors were unable to locate any systematic reports of a group of people with pyromania by either of the above criteria sets, there are numerous case reports and case series of people with repetitive fire-setting behaviour who would probably meet these criteria for pyromania. For example, in what is still probably the largest study of pathological fire-setting, in 1951, Lewis and Yarnell[23] evaluated 1 145 of 2 000 American case records of males 16 years of age and older from the National Board of Fire Underwriters (selection criteria were otherwise not clearly specified). They concluded that 688 of these males were best classified as 'pyromaniacs' as 'they set fires for no practical reason and received no material profit from the act, their only motive being to obtain some sort of sensual satisfaction'. Lewis and Yarnell did not provide quantitative data summarizing these 688 cases, but stated that 50 of the subjects 'approached true pyromania', in that they were able to give a 'classical description of the irresistible impulse'. Specifically, before they set fires, these subjects described 'mounting tension; . . . restlessness; the urge for motion; . . . conversion symptoms such as headaches, palpitations, ringing in the ears, and the gradual merging of their identity into a state of unreality'.

Epidemiology and course

The prevalence of pyromania is unknown.[19] Although there are numerous studies of fire-setting behaviour, few of these studies systematically assessed pyromania in their subjects. Those that did use variable definitions of pyromania and reported widely discrepant rates. For example, in their 1951 study of 1 145 adult males with pathological fire-setting, Lewis and Yarnell[23] reported that 688 (60 per cent) could be classified as having broadly defined pyromania, but only 50 (4 per cent) as having the 'true' disorder.

Pyromania is probably more common in males than females and usually begins in adolescence or early adulthood.[19,23] How often childhood fire-setting represents pyromania is unknown. Clinical descriptions indicate that the course of pyromania may be episodic or chronic, but its course into old age is unknown.

Associated psychopathology and comorbidity

There are no studies of the psychiatric comorbidity of a group of people with well-defined pyromania. However, there are case reports of people with apparent pyromania who have comorbid mood, obsessive compulsive, eating, paraphilic, and possibly psychotic disorders.[23] In addition, impulsive fire-setters have been reported to have high rates of mood, substance use, and cluster B personality disorders, as well as suicide attempts.[10]

Family studies

There are no family history studies of pyromania, but studies of impulsive fire-setters suggest elevated familial rates of substance use disorders.[8]

Biological studies

There are no biological studies of pyromania, but studies of impulsive fire-setters suggest they have abnormalities in central serotonergic neurotransmission.[10]

Treatment response

There are no systematic treatment studies of pyromania.[12,19] There is one case of an 18-year-old male with DSM-IV pyromania and a chief complaint of 'feeling addicted to setting fires' who responded to the combination of topiramate and cognitive behaviour therapy.[24] There is also a case report of two men in both of whom pyromania appeared to be part of a paraphilia and responded to antiandrogen medication.[25]

Clinical reports on the treatment of pathological fire-setting in general stress use of various psychological interventions (e.g. cognitive behavioural, psychoeducational, supportive, and insight-oriented) to address the fire-setting behaviour, and appropriate

treatment of any comorbid psychiatric disorders. Preliminary data suggest combined psychosocial treatment approaches may be helpful in reducing further fire-setting behaviour, at least in juveniles.[19]

Trichotillomania

Definition and clinical features

Trichotillomania is defined in DSM-IV as follows:

- recurrent pulling out of one's hair resulting in noticeable hair loss
- an increasing sense of tension immediately before pulling out the hair or when attempting to resist the behaviour
- pleasure, gratification, or relief when pulling out the hair
- the disturbance is not better accounted for by another mental disorder and is not due to a general medical condition (e.g. a dermatological condition)
- the disturbance causes clinically significant distress or impairment in social, occupational, or other important areas of functioning.

In ICD-10, trichotillomania is defined as noticeable hair-loss due to a recurrent failure to resist impulses to pull out hairs. ICD-10 further states the hair-pulling is usually preceded by mounting tension and is followed by a sense of relief or gratification and that the diagnosis should not be made if there is a pre-existing inflammation of the skin, or if the hair pulling is in response to a delusion or a hallucination.

Hair is most often pulled from the scalp but also from the eyelashes, eyebrows, face, axilla, arms, legs, abdomen, and pubis.[26,27] Extracted hair may be chewed or swallowed. Medical complications include trichobezoars (hairballs that form in the stomach) and, uncommonly, obstruction or perforation of the stomach or bowel.

Some authorities have argued that both the DSM-IV and ICD-10 criteria for trichotillomania are too narrow, noting that patients with distressing hair pulling behaviour, especially children, may not always experience impulses and/or tension before hair pulling or relief with or after hair pulling.[26–28] Indeed, for some persons, the hair pulling may be automatic or habit-like and not associated with urges, tension, or relief. In addition, the hair loss may not be noticeable. For this reason and because hair pulling is a self-grooming behaviour, some authorities have argued that trichotillomania should be grouped with other self-grooming behaviours that may become problematic (e.g. skin picking and nail biting, which are discussed later) into a family of grooming disorders or body-focused impulse control disorders.[20,26,27]

Epidemiology and course

The prevalence of DSM-IV or ICD-10 defined trichotillomania is unknown, but survey studies suggest between 0.5 per cent—3.5 per cent of college students report problematic hair pulling.[26,27]

Clinical studies indicate trichotillomania is more common in females than in males; may begin in childhood, adolescence, or adulthood; and may have an episodic or chronic course.[26,27] Spontaneous remissions may occur, particularly in children with recent onset of the disorder.

Associated psychopathology and comorbidity

Trichotillomania often co-occurs with mood, anxiety, eating, substance use, and other impulse control disorders in clinical samples of adults.[26,27] It may also co-occur with various personality disorders, with histrionic, borderline, and obsessive compulsive commonly being cited.[26,27] In paediatric samples, trichotillomania is similarly associated with mood, anxiety, and substance use disorders.[26]

Family Studies

Preliminary family research suggests that trichotillomania may be associated with increased rates of obsessive-compulsive and grooming disorders among first-degree relatives.[26] A controlled family study of 22 probands with compulsive hair pulling, 17 (77 per cent) of whom met DSM-III-R criteria for trichotillomania, found that depression, alcoholism, drug abuse, obsessive compulsive disorder, and antisocial personality disorder were significantly more frequent among the first degree relatives of hair pullers than relatives of control probands.[28] Conversely, another controlled family study found significantly higher rates of grooming disorders (trichotillomania as well as pathological skin picking, pathological nail biting, and impulse control disorder NOS) in first-degree relatives of probands with obsessive compulsive disorder than in first-degree relatives of control probands.[20]

Psychobiology

Neuroimaging studies in subjects with trichotillomania have shown hyperactivity in the cerebellum and right superior parietal lobe as well as possible structural abnormalities of the left putamen, left inferior frontal gyrus, right cuneal cortex, and cerebellum.[26,27,29] Neuropsychological abnormalities found in trichotillomania patients have included increased error rates in spatial processing, divided attention, nonverbal memory, and executive functioning.[26,29]

Genetic studies suggest trichotillomania may be associated with sequence variants in the slit and trk-like 1 (SLITRK1) gene and the T10ZC polymorphism of the serotonin receptor 2A gene.[30,31]

Treatment response

There are a few published reports of the successful treatment of trichotillomania with insight-oriented psychotherapies, but there are many successful reports with various behavioural-based therapies.[12,26,27] Indeed, to date, four randomized, controlled studies supporting the effectiveness of behavioural treatments in adult trichotillomania have been published. In these studies, habit reversal was more effective than negative practice training (N=34); CBT was more effective than clomipramine and placebo (N=16); behaviour therapy was superior to fluoxetine and a wait-list control (N=43); and acceptance and commitment therapy plus habit reversal was superior to wait-list control (N=25).[12,26,27] In addition, one randomized, controlled trial found a cognitive behavioural therapy package of awareness training, stimulus control, and habit-reversal training was superior to minimal attention control in paediatric trichotillomania.[27]

Although many case reports and open trials describe successful treatment of trichotillomania with various serotonin reuptake inhibitors, controlled studies have yielded mixed results.[12,26,27] Two small (N=13 and N=12) double-blind, crossover trials found

clomipramine was superior to desipramine and equivalent to fluoxetine (which had beneficial effects), respectively, in reducing hair-pulling symptoms. In contrast, 2 slightly larger (N=21 and N=23) placebo-controlled, double-blind crossover studies of fluoxetine (both up to 80 mg/day) in adult chronic hair pullers found fluoxetine was not superior to placebo in suppressing hair-pulling symptoms.[12,26,27] In addition, as noted earlier, in the two controlled comparisons which found cognitive behaviour therapy or behaviour therapy superior to clomipramine and fluoxetine in 16 and 43 patients with trichotillomania, respectively, neither drug was superior to placebo in reducing trichotillomanic symptoms.[12]

Despite these negative studies, thymoleptics other than serotonin reuptake inhibitors have been reported to be effective for trichotillomania in case reports and case series. These include antidepressants such as imipramine, amitriptyline, isocarboxazid, trazodone, mianserin, and bupropion; the mood stabilizers lithium, olanzapine, and quetiapine; and various antimanic antipsychotics—used as either monotherapy or adjunctively with serotonin reuptake inhibitors.[12,26,27]

Other medications described as being effective for trichotillomania, primarily in case reports or case series, are buspirone, fenfluramine, topiramate, inositol, the progestin levonorgestrel, and naltrexone.[12,26,27,32,33] Naltrexone was reported superior to placebo in one small controlled trial which has only been presented in abstract form.[12] Case reports also describe the successful use of topical steroid ointments in combination with psychotropics when skin is irritated.[12]

Compulsive buying disorder

History and clinical description

Although compulsive buying disorder (also called compulsive shopping, buying mania, and oniomania) is not classified in DSM-IV or ICD-10 as a mental disorder, diagnostic criteria have been proposed.[34,35] These include being frequently preoccupied with buying or subject to irresistible, intrusive, and/or senseless impulses to buy; frequently buying unneeded items or more than can be afforded; shopping for periods longer than intended; and experiencing adverse consequences, such as marked distress, impaired social or occupational functioning, and/or financial problems.[35] Persons with compulsive buying disorder often report irresistible or uncontrollable impulses to buy or shop; mounting tension or anxiety with the impulses; and relief of tension and/or pleasurable feelings (e.g. 'a high', 'a buzz', or 'a rush') with the act of buying or shopping. The disorder is associated with distress, financial and legal difficulties, and impairment in social and vocational functioning.[34,35]

Epidemiology and course

Compulsive buying behaviour is thought to be common, with an estimated lifetime prevalence of 5.8 per cent in the United States general adult population.[36] Indeed, in a recent study of the prevalence of various impulse control disorders in a psychiatric inpatient population, compulsive buying disorder was the most common current (9.3 per cent) and lifetime (9.3 per cent) impulse control disorder diagnosis.[18]

Compulsive buying disorder is probably more common in women than men.[34,35] It may begin in adolescence or adulthood and usually has either an episodic or a chronic course. The course of compulsive buying disorder into old age is unknown.

Associated psychopathology and comorbidity

Compulsive buying disorder often co-occurs with mood, anxiety, substance use, eating, and other impulse control disorders in clinical samples.[34,35] It may also be associated with certain personality disorders, but this comorbidity has received less systematic attention.[34]

Family studies

Preliminary research, including one controlled study, suggests compulsive buying disorder is associated with increased familial rates of mood, substance use, and possibly impulse control disorders.[34,35]

Psychobiology

In a molecular genetic study, no association was found between two serotonin transporter gene polymorphisms and compulsive buying disorder.[34]

Treatment response

Isolated reports of psychoanalytic and insight-oriented psychotherapy in compulsive buying disorder have mostly been unsuccessful. Cognitive behavioural therapy may hold promise. Two patients with compulsive buying disorder each responding to cue exposure plus response prevention after failing clomipramine treatment have been described.[12] In addition, a randomized study found group cognitive behavioural therapy (N=28) superior to wait-list control (N=11) in reducing compulsive buying episodes, time spent buying, and scores on buying symptom measures in 39 patients with compulsive buying disorder.[37] Support groups patterned after Alcoholics Anonymous, such as Debtors Anonymous, self-help books, and financial counselling are available, but their effectiveness has not been formally evaluated.[12,34]

Various antidepressant medications have been reported to be effective for compulsive buying in case reports and open trials, but two randomized, placebo-controlled, double blind studies of fluvoxamine in a total of 54 patients with compulsive buying (N=17 and N=37, respectively) failed to show separation between drug and placebo.[12,34] Both studies, however, were limited by high placebo response rates, possibly due to the use of diaries to record buying behaviour. In a 7-week, open-label trial of citalopram (N=24) followed by a 9-week double-blind, placebo-controlled continuation trial that omitted use of shopping diaries for the 15 subjects who met responder criteria, none of 7 patients randomized to remain on citalopram relapsed as compared with 5 (63 per cent) of 8 patients randomized to receive placebo (P=0.019)[12,34].

Patients with compulsive buying have also been reported to respond to mood stabilizers, naltrexone (at 100 mg/day but not 50 mg/day), and topiramate.[12,34]

Repetitive self-mutilation

Clinical description

Repetitive self-mutilation, also called impulsive deliberate self-harm, parasuicide, or self-injurious behaviour, is the repeated,

direct destruction of body tissue without suicidal intent.[38,39] Examples include skin cutting, skin burning, self-hitting, severe skin scratching, and even bone breaking. A wide range of body parts are mutilated, such as arms, legs, abdomen, head, chest, and genitals.

Numerous clinical studies suggest that this syndrome often meets the DSM-IV and ICD-10 definitions of impulse control disorders.[38] Specifically, repetitive self-mutilation is characterized by intrusive, recurrent, and irresistible impulses to harm oneself without suicidal intent that are associated with increasing tension, anxiety, anger, or other dysphoric affective states, along with relief of the uncomfortable affect with or shortly after the act of self-harm. In addition, the act of self-harm is often not associated with pain (i.e. associated with analgesia) and performed privately.[38,39]

Epidemiology and course

The prevalence of narrowly defined repetitive self-mutilation is unknown.[38,39] Clinical studies, however, suggest that the condition is more common in females than males, usually begins early in life (e.g. late childhood, adolescence, and early adulthood), and may persist for 10 to 15 years.[38,39]

Associated psychopathology and comorbidity

Repetitive self-mutilation often co-occurs with other Axis I and II psychiatric disorders.[38,39] These include mood, substance use, eating, psychotic, dissociative, and borderline personality disorders. Repetitive self mutilation may also co-occur with suicide attempts and adverse childhood experiences in patients with certain pathologies, especially borderline personality disorder.[39] Of note, although deliberate self injury is a core feature of borderline personality disorder, not all patients with repetitive self mutilation have borderline personality disorder.[38]

Family history

No family history studies of repetitive self-mutilation have been conducted.

Psychobiology

Although studies have consistently found an association between low central CSF 5-H1AA levels with both impulsive aggression and violent suicide, the results of such studies in patients with repetitive self mutilation have been mixed—with some, but not all, finding similar reductions.[38,39] One study found that broadly-defined self harm was associated with allelic variation in the tryptophan hydroxylase gene (TPH A779C), but not with polymorphisms of five other serotonergic genes.[40]

Studies have found increased pain thresholds in borderline personality patients with repetitive self mutilation who are analgesic to the pain of their self injurious behaviour, suggesting dysfunction the endogenous opioid system.[38,39] In support of this possibility, one study found elevated plasma metenkephalin studies in a small group of analgesic self-injuring persons. Another study, however, found pretreatment with naltrexone did not reduce the anesthesia (as evaluated by the cold pressor test) of a similar group of subjects.[39]

Treatment response

There are no controlled treatment studies of narrowly-defined repetitive self-mutilation. However, two psychological treatments, dialectal behaviour therapy and psychoanalytically-oriented partial hospitalization, have each been shown superior to 'treatment as usual' in decreasing chronic parasuicidal behaviour in women with borderline personality disorder.[39] In addition, a 1998 meta-analysis of 20 treatment trials of broadly-defined deliberate self harm indicated significantly reduced repetition of self harm for problem solving therapy and provision of an emergency contract card in addition to standard care.[41]

Regarding medical treatments, agents with antidepressant, mood-stabilizing, antipsychotic, anticonvulsant, and anti-opiate properties have been reported to be effective in case reports or case series.[12,33,39] In the above noted 1998 meta-analysis, a significantly reduced rate of further self harm was observed for depot flupenthixol versus placebo in the one study of antipsychotic medication that was located and analyzed.[41] The two studies of antidepressants evaluated, however, showed no benefit.

Pathological skin picking

Clinical description

Pathological skin picking (also called neurotic or psychogenic excoriation, compulsive skin picking, dermatotillomania, and *acné excorié*) is excessive scratching, picking, gouging, or squeezing of the skin sometimes in response to an itch or other skin sensation or to remove a lesion on the skin.[42,43] Most patients use fingernails to excoriate the skin, but the teeth and instruments (for example, tweezers, nail files, pins, or knives) are also used. Pathological skin picking causes substantial distress in patients, with most experiencing functional impairment and many reporting medical complications, some severe enough to warrant surgery.

Although not recognized as a distinct DSM-IV or ICD-10 disorder, pathological skin picking resembles an impulse control disorder in that patients sometimes experience an increase in tension prior to picking with transient relief or pleasure with picking or immediately afterwards. Many patients find themselves acting automatically. It also has compulsive features, in that it is repetitive, ritualistic, anxiety reducing, often resisted, and egodystonic. Moreover, some patients describe obsessions about an irregularity on the skin or preoccupations with having smooth skin.

Epidemiology and course

Pathological skin picking may occur in about 2 per cent of dermatology clinic patients, predominately in women, and up to 3.8 per cent of college students.[42,43] The disorder may begin in adolescence or adulthood, and the mean duration of symptoms has ranged from 5 to 18 years, with a better prognosis for patients who have had the symptoms for less than 1 year.[42]

Associated psychopathology and comorbidity

Pathological skin picking often co-occurs with mood, anxiety, and somatoform disorders.[42] It is especially common in body dysmorphic disorder.[43] The comorbidity of pathological skin picking and personality disorders has not been systematically studied.

Family studies

Preliminary family history data suggest first-degree relatives of probands with pathological skin picking may have elevated rates of mood and substance use disorders.[42]

Treatment response

Various behavioural treatments (e.g. habit reversal) may be effective in pathological skin picking.[12] One small placebo-controlled trial (N=21) found that fluoxetine (mean dose of 55 mg/day) may be beneficial[12]. Other serotonin reuptake inhibitors, the tricyclic doxepin (which has been hypothesized to have antipruritic properties due to its antihistaminic effects), inositol, the glutamate-modulating agent riluzole, and certain direct skin treatments (dermatologic and surgical) may also be effective.[12,32,42,44,45]

Onychophagia

Clinical description

Onychophagia is repetitive and excessive nail-biting.[46] The cuticles and skin around the nails are also frequently bitten, picked, or clipped. Onychotillomania, the excessive picking, clipping, or tearing of the nail, may be a variant.

Although not classified as a psychiatric disorder in DSM-IV or ICD-10, onychophagia resembles an impulse control disorder in that the behaviour is often irresistible, automatic, and associated with an increase of tension before and relief or pleasure during or immediately after its enactment.[46] It also has compulsive features in that it is repetitive, resisted, and associated with relief of anxiety.

Epidemiology and course

Nail-biting is more common in children than adults, and may affect 5 to 10 per cent of adults over the age of 30 years.[46] Boys and girls are affected equally until after the age of 10 years, when nail-biting becomes more common in boys.

Associated psychopathology and comorbidity

Onychophagia may be associated with mood, anxiety, and substance use disorders. Of 25 adult subjects who underwent a medication trial for onychophagia, 17 (68 per cent) had a lifetime Axis I psychiatric disorder—despite the exclusion of subjects with obsessive–compulsive disorder, a primary major affective disorder, current substance abuse, or psychosis.[46] Four subjects (16 per cent) had at least one personality disorder.

Family studies

Severe nail biting may be familial.[46,47] Of 112 family members of 25 subjects entering a medication trial for onychophagia, seven (6 per cent) had severe nail-damaging behaviour, four (4 per cent) were severe nail-biters, and three (3 per cent) picked or chewed their hands or feet.[46] In addition, twin studies have found higher concordance rates of nail biting in monozygotic compared with dizygotic twins.[47]

Treatment response

Various cognitive behavioural therapies (especially habit reversal, but also self-monitoring, use of bitter tasting substances, competing responses, and negative practice training) are probably effective in onychophagia.[12] In the only controlled pharmacotherapy study of onychophagia, clomipramine (mean dose 120 mg/day) was superior to desipramine (mean dose 135 mg/day) in eliminating nail-biting, reducing nail-biting severity and impairment, and in improving overall clinical progress.[46]

Conclusion

Growing research shows that the impulse control disorders are much more common than once thought to be. The consistency of the 'structure' of the irresistible impulse (a core disturbance of impulsivity and compulsivity) together with increasing research showing that it responds to certain treatments, especially cognitive-behavioural psychotherapies and medical treatments with thymoleptic or anticraving properties, regardless of its 'content' (the specific impulse experienced), strongly suggest that it is an important psychopathological symptom, and that impulse control disorders are legitimate mental disorders that are in fact likely to be related despite their apparent differences.

4.13.2 Special psychiatric problems relating to gambling

Emanuel Moran

Introduction

Gambling is an activity with the following elements:

- A contract between two or more people, which is based on a forecast of the outcome of an uncertain event involving random processes.
- Property, referred to as the stake, is transferred between those taking part, so that some gain at the expense of others.
- The property transfer depends on the outcome or result of the uncertain event, which has been forecast.
- Participation is voluntary and not necessarily related to gaining the property, but used to obtain an experience.

Clinical features

Gambling misuse is a behavioural disorder that can usually be recognized by the presence of any of the following features:

- Excessive gambling either in terms of the money spent or the time devoted.
- Intermittent or continuous preoccupation with gambling and the development of tolerance and craving for it.
- Loss of control over gambling and 'chasing of losses', despite the realization that damage is resulting.
- Disorder affecting the person who is gambling and the family:
  - financial disturbances, such as debt and shortage;
  - social disturbances, such as loss of employment and friends, running away from home, eviction, marital problems, divorce, behaviour disorders in the children of the family, criminality and imprisonment;
  - psychological disturbances, such as depression and attempted suicide.

Classification

In the past, this syndrome has been referred to as compulsive gambling. However, it is not a true obsessive–compulsive state but a heterogeneous group of conditions, characterized by excessive gambling resulting in disturbance for those involved. The term 'pathological gambling' is more appropriate, since it is not based on any assumptions regarding the underlying processes.[1]

ICD-10[2] describes pathological gambling as a form of behaviour under 'habit and impulse disorders'. On the other hand, DSM-IV[3] implies a homogeneous disease entity and provides criteria for its recognition under 'impulse-control disorders not elsewhere classified'. The ICD-10 approach is preferable since it emphasizes the fact that the condition is a behavioural disorder resulting from faulty habits.

Five varieties of pathological gambling can be recognized[4,5]:

- Subcultural gambling arises out of the person's background, which is one of socially accepted heavy gambling.
- Impulsive gambling is characterized by loss of control for varying periods and the tendency to be associated with tolerance, craving, and dependence on the activity.
- Neurotic gambling occurs as a response to an emotional problem, particularly in a disturbed relationship in marriage or during adolescence.
- Symptomatic gambling occurs in mental illness, usually depression, which is the primary disorder.
- Psychopathic gambling is part of the generalized disturbance of behaviour that characterizes antisocial personality disorder.

Diagnosis

For various social reasons, pathological gambling is most easily recognized in men since they tend to patronize those types of gambling that have a high turnover of money so that excess is more likely to become apparent.

Women have tended to gamble on lotteries, bingo, and football pools. These may not involve such large sums of money and excess often presents with disturbances in the social sphere rather than through the accumulation of large debts. However, the greater general acceptance of gambling and the advent of remote gambling via the Internet, television, and mobile devices is changing the situation considerably.

While pathological gambling is seen in all age groups, an increasing number of children and young people are presenting with the condition as a result of gambling on slot/gaming machines. Also, in recent years, remote gambling among children and young people has led to increasing problems. This is in spite of the fact that most jurisdictions treat gambling as an adult activity. Pathological gambling in adulthood frequently has its origins in heavy gambling in childhood and adolescence.

Aetiology and epidemiology

The nature of gambling

The experience of risk provides amusement, thrill, and excitement and is therefore pleasurable. These experiences make gambling attractive and the stake money is used to purchase them, with winnings as an occasional bonus. A few, who gamble professionally, are also able to win money regularly because they have sources of information that reduce the uncertainty, as in betting on horses and dogs. Their gambling is planned and deliberate.

Gambling is usually organized commercially with the odds in favour of the provider. There is therefore an in-built financial disadvantage to those who use the facilities. In slot/gaming machines where the provider is at a distance from the gambling event, this is often not apparent to those who take part.

Commercial gambling involves large sums of money, and has traditionally been confined to licensed premises. Those present have gone there because they have decided to take part in the gambling. However, developments in technology have made it possible to provide gambling facilities on a remote basis via the Internet, television, and mobile devices.

A number of features inherent in the activity of gambling have effects that make it difficult for a person to stop.

Psychological effects

- Underlying all gambling activity is operant conditioning with intermittent variable ratio reinforcement.[6] This is a most effective schedule for habit-formation and produces a stable, persistent response. Consequently, the long-term net gain or loss to those who gamble is almost irrelevant to the continuation of the activity. It is most dramatically seen in slot/gaming machines, which consequently are the main source of profit for the gambling industry.
- Rapid turnover gambling as in casinos restricts the ability of those who gamble to apply any considered judgement. Inevitably, gambling becomes more impulsive, easily leading to excessive participation.
- The assessment of probability of winning (psychological probability) in the gambling situation differs from the mathematical probability. At low probabilities, it is higher than the mathematical probability and at moderate and high probabilities, it is lower. This even occurs in people who are mathematically knowledgeable.

- In a gambling situation involving only random processes, where the outcome of successive events is completely independent, there is usually the irrational belief that a string of losses makes a win more likely. This is the negative recency effect, which is also referred to as the'Monte Carlo Fallacy' since it forms the basis of many spurious gambling systems, especially in roulette. Paradoxically, it is associated with the belief that a string of wins is likely to continue ('a lucky streak'). Also, a 'near win' generally tends to be treated as a prelude to a win. These illogical ways of thinking encourage continuous gambling and are exploited by slot/gaming machines and lottery scratch cards called 'heart stoppers'.
- Large prizes, even at very low probabilities, entice the gambler because of the *possibility* of winning. The stimulant effect of roll-overs in lotteries illustrates this.
- Skill in gambling is usually overrated and often implies an unrealistic ability to control the uncertain event that is the subject of the gamble. Thus, in dog and horse race betting, punters tend to place their bets just before 'the off' in the fantasy that this will affect the result.
- There is a tendency to lose track of time during a gambling session.

These psychological effects have been increased as a result of recent developments in commercial gambling.

- Loyalty cards providing rewards for money spent on gambling in a particular facility.
- Remote gambling on the Internet, television, and mobile devices has resulted in the following:
  - The convenience and anonymity of gambling being available in an isolated domestic setting, without the checks and constraints that can be exercised by the presence of others as in licensed premises.
  - Monetary credit in the form of e-cash systems, reducing the likelihood that those gambling will set a limit on the money staked.
  - Behavioural targeting and messages on some online gambling sites encouraging further gambling when an attempt is made to stop.
  - Difficulty in preventing children and young people from having access, especially since the advent of online social networks.

Physical effects

- A gambling loss in normal subjects immediately results in particular localized activity in the medial frontal cortex of the brain. This is then associated with subsequent *more risky* gambling choices. This is consistent with the negative recency effect.
- Disturbances involving the reward pathways in the brain are significantly associated with excessive gambling.
- There is a great range and strength of emotions during gambling decisions associated with cortical responses in the brain to the expectation of winning money.
- Even normal, social levels of drinking alcohol that alter self-control over decision-making, increase the difficulty in deciding at what point to stop, when losing, in a gambling situation.

Predisposing factors

In the presence of available gambling facilities, certain predispositions may increase the likelihood of pathological gambling.

Morbid risk-taking

Since gambling is a type of risk-taking, it lends itself to be used by those who, for reasons related to their personality, have a high need for risk. They spend large sums of money on the intangible commodity of risk, which may easily pass unnoticed because it is fleeting.

This morbid propensity to take risks shows itself in other ways. Thus, the incidence of attempted suicide is high among those whose gambling is pathological.[5]

Other personality factors

Freud's formulation of gambling was that it resembles masturbation, is a substitute for it, and is resorted to in the context of unresolved Oedipal difficulties.[7] Others have pointed out that pathological gambling may be a manifestation of self-punishment, with an unconscious desire to lose, arising from a psychological mechanism referred to as 'psychic masochism'.[8]

Those whose gambling is pathological appear to have other predisposing personality traits. They view their behaviour as being largely determined by factors outside their personal control. They also tend towards greater impulsivity.[5,9]

Learning processes

Apart from the winnings and losses, the gambling situation itself may affect learning. As far as the random processes inherent in gambling are concerned, all participants, even a total failure, stand on an equal footing. This may be the only circumstance in which some people have this experience. Gambling may therefore provide a means of dealing with morbid anxiety in the presence of feelings of inadequacy, leading to a conditioned avoidance reaction.

Mental disorder

Pathological gambling may occur in any mental disorder. However, it is most commonly associated with depression. More usually, a neurotic type of depression occurs after a bout of heavy gambling with large losses. In symptomatic pathological gambling, the depression is primary and the gambling is a response to the tension and feelings of guilt that occur in depression. This latter situation is similar to alcohol misuse and shoplifting, as part of the depressive syndrome. Pathological gambling may also be a manifestation of antisocial personality disorder.

Misuse of alcohol and pathological gambling can occur together; either may be the primary disorder and either may lead to the other.

Constitutional factors and physical disorder

Twin studies have demonstrated that the likelihood of pathological gambling occurring in a person is influenced, to an important degree, by inherited factors and/or experiences shared during childhood.[10]

There also appears to be a significant association between pathological gambling and genetic abnormalities involving the dopamine reward pathways.[11] Disturbances of serotonergic, noradrenergic, and dopaminergic neurotransmitter systems have

all been implicated in the aetiology of pathological gambling. This is particularly so in relation to the arousal, behavioural initiation, behavioural disinhibition, and reward/reinforcement mechanisms that are evident in this condition.[12]

There have been reports of pathological gambling associated with dopamine agonist administration for Parkinsonism.[13]

Course and prognosis

The natural history of pathological gambling is one characterized by exacerbations and remissions, often related to life events. Important elements in this are relationships within the family, especially with the spouse/partner. An example of this is the not infrequent sequence of an exacerbation of heavy gambling in the husband, at the time of the wife's first pregnancy.

The outlook in pathological gambling is usually determined by the integrity of the underlying personality. In those in whom the condition appears as a symptom of a neurotic disorder or depression, the prognosis depends on that of the underlying disorder.

Management and treatment

Pathological gambling involves a whole way of life, which has many ramifications. If its management is to be successful, there need to be major changes in the lifestyle of the person concerned. It is best dealt with by a team approach involving at least a psychiatrist, psychologist, and social worker and must include the spouse/partner. Recently, counselling services have been set up but their efficacy has yet to be established.

Assessment of the problem

The following aspects are important:

- An appraisal of the extent and amount of present gambling.
- A history of the development of the gambling from its early beginnings, which is best done if the person being assessed provides the information by means of a detailed written narrative.
- A discussion of this written narrative.
- An indication of the person's motivation, since many who seek help for pathological gambling readily admit that they enjoy it and only want assistance for the problems that have resulted.
- At least initially, an immediate period of total abstinence from gambling.

Supervision of the finances

Excessive gambling is usually associated with a disturbed appreciation of the value of money. In view of this and the continued temptation to gamble, the family finances should be dealt with as follows:

- All monies should be controlled, at least for some time, by the spouse/partner or some trusted person.
- Regular income from wages/salaries should be paid into a bank account over which the spouse/partner or trusted person has sole control.
- A detailed statement should be drawn up of all the outstanding debts, as well as an inventory of the income and outgoings of the person-seeking help and his or her family.
- The person whose gambling has been pathological should discuss the matter with all creditors and agree a repayment plan. This should be consistent with the person's regular income and circumstances to avoid a situation where there would be the temptation to gamble in order to maintain repayments. Since debts are often considerable, these may have to continue over many years.
- After a period of abstinence from gambling, the person whose gambling has been pathological needs to become gradually involved in working jointly with whoever controls the finances.

Counselling

On the basis of information obtained during the course of the initial assessment, the following aspects need further consideration:

- The features inherent in gambling that affect people so that they find it difficult to stop should be highlighted and discussed.
- Social relationships of the person whose gambling has become pathological and the spouse/partner should be reviewed, especially if there have been serious marital problems predating the pathological gambling.
- The way spare time is spent, what friends are cultivated, and what interests are pursued should be reviewed. Since incitement to gamble will have occurred in the past within specific settings, arrangements need to be made to avoid these or, at least, to be prepared for them.
- A joint contract to be reviewed regularly spelling out in detail those types of behaviour to be avoided as well as those to be encouraged may be found helpful.

Gamblers Anonymous

This form of self-help for pathological gambling is organized in regular local groups. As well as meetings for those who have a gambling disorder, there are also separate ones for their spouses/partners. Quite apart from the valuable work done in the group setting, Gamblers Anonymous provides a useful means of establishing alternative social contacts from those that were associated with gambling. Indeed, for some people, Gamblers Anonymous may be the vehicle through which all the necessary help can be provided. Even if this is not the case, Gamblers Anonymous still provides a valuable form of support for the individual and the family.

Psychological treatments

A variety of psychological treatments have been advocated but, in general, their long-term efficacy has not been established. A good outcome has been reported after a cognitive behavioural approach.[14] Also, controlled gambling, rather than permanent abstinence, has led to a reported successful outcome after behavioural treatment.[15]

Psychiatric treatments

Specialist treatment from a psychiatrist and/or a psychotherapist for a neurotic disorder or severe depression may be required, if these clearly underlie the pathological gambling.

Prevention

In view of the nature of gambling and the importance of the social causation of pathological gambling, it is vital that it should be seen as an activity that requires moderation. Unfortunately, the recent increasing reliance of governments and states on gambling for revenue purposes is resulting in a vast growth in the availability of gambling facilities and the incitements to participate.

This has been associated with public policies that actively promote gambling and also claim to encourage moderation. The inconsistency in trying to do both inevitably has a harmful effect on any educational attempt to provide a sensible attitude to gambling. It also undermines any help for those whose gambling has become excessive.

Sleep–wake disorders

Contents

4.14.1 Basic aspects of sleep–wake disorders

Gregory Stores

Introduction

A sound working knowledge of the diagnosis, significance, and treatment of sleep disorders is essential in all branches of clinical psychiatry. Unfortunately, however, psychiatrists and psychologists share with other specialties and disciplines an apparently universal neglect of sleep and its disorders in their training. Surveys in the United States and Europe point to the consistently meagre coverage of these topics in their courses at both undergraduate and postgraduate levels.

The following account is an introductory overview of normal sleep, the effects of sleep disturbance, sleep disorders and the risk of failure to recognize them in psychiatric practice, assessment of sleep disturbance, and the various forms of treatment that are available. The aim is to provide a background for the other chapters in this section.

The close links between the field of sleep disorders and psychiatry which make it essential that psychiatrists are familiar with the field are as follows:

- Sleep disturbance is an almost invariable feature and complication of psychiatric disorders from childhood to old age, with the risk of further reducing the individual's capacity to cope with their difficulties (see Table 4.14.1.3 for further details).
- Sleep disturbance can presage psychiatric disorder.
- Some psychotropic medications produce significant sleep disturbance.
- Of importance to liason psychiatry is the fact that many general medical or paediatric disorders disturb sleep sufficiently to contribute to psychological or psychiatric problems.
- Because of lack of familiarity with sleep disorders and their various manifestations, such disorders may well be misinterpreted as primary psychiatric disorders (or, indeed, other clinical conditions) with the result that effective treatments for the sleep disorder are unwittingly withheld (see later).

Some of these points will be amplified in later sections of this chapter.

Basic features of normal sleep

The scientific study of sleep and its disorders is largely confined to the last several decades. Essentially interdisciplinary advances have displaced earlier speculative accounts including those in psychiatry concerning the significance of dreams, for example. They are well described in recent textbooks of sleep disorders medicine (see recommended sources). Only general points are mentioned here, with special reference to psychiatry where possible.

The nature of sleep

Sleep has characteristic physiological features which distinguish it from other states of relative inactivity. Two distinct sleep states have been defined, that is non-rapid eye movement (**NREM**) sleep and rapid eye movement (**REM**) sleep. The onset of sleep is not simply the shutdown of wakefulness but also the switching between wakefulness, NREM and REM sleep involve complicated active neurochemical mechanisms in different parts of the brain.

The functions of sleep

Debate continues about the various theories concerning sleep, each of which has emphasized physical and psychological restoration and recovery, energy conservation, memory consolidation, discharge of emotions, brain growth and various other biological functions including somatic growth and repair, and maintenance of immune

systems. No one theory accounts for all the complexities of sleep and it seems likely that sleep serves multiple purposes.

From the practical point of view, the most obvious observation is that both physical and psychological impairment follows persistent sleep disturbance. Animals totally deprived of sleep for a long periods die with loss of temperature regulation and multiple system failure. As described later, the adverse effects of chronic sleep loss (considered to be common in modern society) on mood, behaviour, and cognitive function can be substantial, with various consequences for personal, social, occupational, educational, and family functioning.

Sleep stages

Conventionally, standard criteria are used to identify different sleep stages according to their characteristic physiological features especially in the electroencephalogram (**EEG**), electrooculogram (**EOG**), and electromyogram (**EMG**).

NREM sleep is divided into four stages of increasing depth. **Stage I** occurs at sleep onset or following arousal from another stage of sleep. This stage represents 4–16 per cent of the main sleep period. **Stage II** contains more slow EEG activity but is still relatively light sleep. It accounts for 45–55 per cent of overnight sleep. **Stage III** (4–6 per cent of total sleep time) contains yet more slow EEG activity. **Stage IV** is characterized by the slowest activity and constitutes 12–15 per cent of sleep. The combination of stages III and IV is called slow wave sleep (**SWS**) or delta sleep and is considered to be the deepest form of sleep from which awakening is particularly difficult. The arousal disorders such as sleepwalking arise from SWS.

REM sleep is physiologically very different. Brain metabolism is highest in this stage of sleep. Spontaneous rapid eye movements are seen and the skeletal musculature is effectively paralysed. Heart rate, blood pressure, and respiration are all variable, body temperature regulation ceases temporarily, and penile and clitoral tumescence occurs. REM sleep usually takes up 20–25 per cent of total sleep time. Most dreams, including nightmares, occur in REM sleep.

Sleep architecture

NREM and REM sleep alternate cyclically throughout the night starting with NREM sleep lasting about 80 min followed by about 10 min of REM sleep. This 90 min sleep cycle is repeated three to six times each night. Each REM period typically ends with a brief arousal or transition into light NREM sleep.

In successive cycles the amount of NREM sleep decreases and the amount of REM sleep increases. SWS is usually confined to the first two sleep cycles. The diagrammatic representation of overnight sleep is known as a **hypnogram**, a simplified form of which is shown in Fig. 4.14.1.1.

In addition to this conventional sleep staging, there has been increasing interest in the microstructural fragmentation of sleep by frequent, brief arousals (seen mainly in the EEG) lasting a matter of seconds without obvious clinical accompaniments. This subtle type of sleep disruption, overlooked by conventional sleep staging, is increasingly associated with impairment of daytime performance, mood, and behaviour.

Circadian sleep–wake rhythms

The timing of sleep (but not its amount) is regulated by a circadian 'clock' in the suprachiasmatic nucleus (**SCN**) of the hypothalamus.

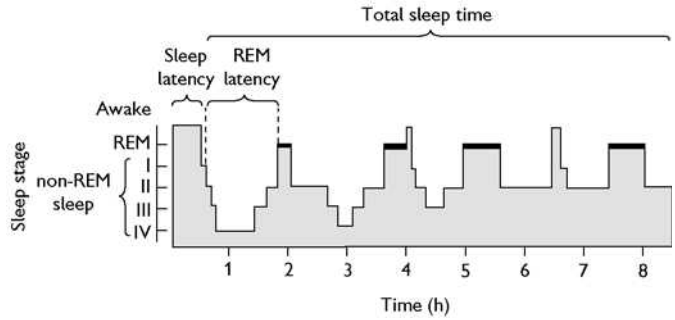

Fig. 4.14.1.1 Diagram of an overnight hypnogram in a young adult.

The intrinsic circadian sleep–wake rhythm is close to 24 h in human adults. Other species are different, an extreme example being dolphins and some other creatures which shut down one cerebral hemisphere at a time ('unihemispheric sleep'), allowing them to be constantly alert. From an early age the individual sleep–wake rhythm has to synchronize with the 24-h day–night rhythm. The main *zeitgeber* by which this is achieved ('entrainment') is sunlight but social cues, such as mealtimes and social activities, are also important.

The SCN also controls other biological rhythms including body temperature and cortisol production with which the sleep–wake rhythm is normally synchronized. In contrast, growth hormone is locked to the sleep–wake cycle and is released with the onset of SWS, whatever its timing.

Melatonin is related to the light–dark cycle rather than the sleep–wake cycle. It is secreted by the pineal gland during darkness and suppressed by exposure to bright light ('the hormone of darkness'). It influences circadian rhythms via the SCN pacemaker which in turn, regulates melatonin secretion by relaying light information to the pineal gland. The widespread popularity of melatonin as a sleep-promoting agent is not justified by what little is known about its action and clinical effectiveness.

Changes with age

Changes in basic aspects of sleep are prominent from birth to old age, although individual differences are seen at all ages. Changes of clinical significance include the following:

- **Total sleep time** decreases with age. Average daily values are as follows: newborns 6–18 h; young children 10 h; adolescents 9 h (although often they obtain significantly less than this); adults 7.5–8 h, including possibly the same in elderly people. The total amount of sleep includes daytime napping in children up to the age of about 3 years.
- **SWS** is particularly prominent in prepubertal children who sleep very soundly. Its decline begins in early adolescence and continues throughout childhood.
- The proportion of **REM sleep** declines from 50 per cent or more of total sleep time in the newborn (more than this in premature babies) to 20–25 per cent by 2 years. This figure remains fairly constant throughout the rest of life. The high level of REM sleep in very early life suggests a role in cerebral maturation but the reason for its persistence throughout life is unclear. Memory processing appears to depend on sleep. However, people deprived

of REM sleep, experimentally or pathologically, can be relatively unaffected either emotionally or cognitively. Deep sleep decreases in the elderly.

- **NREM–REM sleep cycles** occur at intervals of 50–60 min in infants who often enter REM at the start of their sleep period. This interval between sleep cycles remains until adolescence when the periodicity changes to 90–100 min, which persists into adult life. The amounts of NREM and REM in each sleep cycle is about equal in early infancy. Afterwards, NREM sleep (especially SWS) predominates in the earlier cycles and REM sleep in the later cycles.
- **Continuity of sleep** is greatest in pre-pubertal children (as mentioned previously) and least at the extremes of age. Infants are easily awakened and so are the elderly who also wake spontaneously more often. Fragmentation of sleep by brief arousals, or very brief awakenings, is particularly common in old age.
- **Circadian sleep–wake rhythms** change considerably in early development. Full-term neomates show 3–4-h sleep–wake cycles. Sleep periods have largely shifted to the night and wakefulness to daytime by 12 months, except for napping which gradually diminishes and has usually stopped by about 3 years of age. However, a physiological tendency towards an afternoon nap remains throughout the rest of the life. Although repeated brief waking at night is more common in infancy and early childhood than later, it remains a normal occurrence throughout life, increasing in frequency again in old age. The clinical problem arises when there is difficulty returning to sleep after such awakenings.

Psychological effects of sleep disturbance

There is extensive clinical and experimental evidence that sustained sleep disturbance can have serious adverse psychological effects.[1,2] The term sleep disturbance covers the following:

- Loss of sleep (i.e. shortened duration).
- Impaired quality of sleep (repeated disruption of sleep architecture).
- Inappropriate timing of the sleep period in relation to day–night rhythms (as in the various circadian sleep rhythm disorders such as jet lag, shift work, or the more frequently encountered forms seen in clinical practice, as discussed later).

Experimental studies of **total sleep loss** demonstrate a progressive deterioration in cognitive function, mood, and behaviour related to length of sleep loss. However, inter- and also intra-individual differences in susceptibility are seen, reflecting such factors as motivation, personality, and usual sleep requirements. Task characteristics (e.g. brief or prolonged and monotonous tasks), timing of the task in relation to the circadian sleep–wake rhythm, and physical environmental factors such as noise and other distracting stimuli, are also important.

Variations for similar reasons are important in **partial sleep deprivation** experiments which (like those concerning fragmentation of sleep) are much closer to real-life sleep disturbance caused by social activities, job demands, and other aspects of modern lifestyle. These studies raise the issues of how much sleep is needed for optimal daytime functioning and whether these requirements are not being met. It has been argued that there is 'national sleep debt' in the United States and other western countries, and that by sleeping longer than they do habitually, many people would increase their performance and improve their well-being during the day.

The usual subjective effects of sleep disturbance are irritability, fatigue, poor concentration, and depression. More dramatic effects are described with prolonged and severe sleep disturbance, such as disorientation, illusions, hallucinations, persecutory ideas, and inappropriate behaviour with impaired awareness ('automatic behaviour') caused by frequent microsleeps. Psychometric studies have shown that sleep disturbance can produce a range of cognitive impairments, again depending on its duration and individual susceptibility. Sustained attention (vigilance) is particularly vulnerable and possibility abstract thinking and divergent intelligence or creativity.

The experimental findings are in keeping with the results from studies of various occupational groups including junior hospital doctors and drivers of various types of vehicle, in which reduced performance or accidents are associated with sleep disturbance. The common and increasing practice of night-shift work (as part of the '24 h society') is contrary to the fundamental biorhythm of sleeping at night and being awake during the day, and is often accompanied by a reduction in total sleep time and poor quality sleep. It is not surprising that working shifts commonly results in loss of well-being, physical complaints, and impaired productivity and safety, as well as physical disorders. Similarly, the distribution over the 24 h period of road accidents (especially those not involving other vehicles) and other mishaps at work, correspond to that of the levels of sleep tendency assessed objectively. Even industrial and engineering disasters have been attributed to sleep loss and impaired performance on the part of key personnel.

Additional evidence that sleep disturbance affects daytime function comes from neuropsychological studies of certain sleep disorders. Impaired performance on prolonged and complex tasks of subjects with narcolepsy has been shown to be secondary to the effects of their daytime sleepiness rather than an intrinsic neurological deficit. In the many adult patients with obstructive sleep apnoea, attention memory impairment (like depression and irritability commonly reported by these patients) are also largely attributable to daytime sleepiness. There is some evidence that deficits in more complicated 'executive functions' (formulating goals, planning, and carrying out plans effectively) are not necessarily reversed when their sleepiness is relieved by treatment. This might be the result of irreversible anoxic brain changes in the later stages of the condition. Clearly, early detection and treatment of this condition is essential to prevent this happening.

When return to normal sleep is possible, recovery from short periods of sleep disturbance occurs after much less sleep than that originally lost, for example, after one night's sleep following sleep loss over several days and nights. Reversal of the effects of long sleep disturbance in real-life is likely to be complicated, for example by emotional consequences of the disturbance.

Many of the above observations about the psychological effects of sleep disturbance (and their reversibility) have been made on young adult subjects or patients. The area is largely unexplored in other age groups but there is no reason why the general principle should not apply to children and the elderly including demented patients in whom sleep disturbance is particularly prominent.

Another group on whom further research is particularly required are people with learning disabilities (intellectual disability).

The available literature provides good reason to believe that the sleep disorders, especially in the more severely disabled groups, not only affects the majority but also are unusually severe and long-lasting because of lack of appropriate advice and treatment. The sleep disturbance is a problem in its own right and is often associated with various cognitive and behavioural abnormalities which might, at least partly, be the consequence of the sleep disturbance. Sleep disturbance in the duration or the quality of sleep may be one of the few ways of improving to some extent the psychological well-being of people with learning disabilities or dementia (and that of their carers) whose basic condition itself cannot be improved. In the case of the learning disabled, contrary to the common supposition by both professionals and relatives, success can usually be achieved (even in severe and long-standing problems), given an accurate diagnosis of the type of sleep disorder which may be predominantly behavioural or physical in type depending on the cause of the learning disability.

Sleep disturbance in the aetiology of psychiatric illness

Various 'psychotic' and other abnormal psychological phenomena were mentioned earlier resulting from prolonged and severe sleep disturbance, but these are reversed when normal sleep is restored. It remains an open question how often sleep disturbance is a primary cause of psychiatric illness. Evidence is patchy, tentative, and still in need of clarification.

- Over a wide age range, patients with a prior history of insomnia have been found consistently to be at significantly increased risk for severe depression. This could be interpreted in different ways including that sleep disturbance and the depression have a common underlying pathology, or that the sleep problems are an early sign of depression.
- A less fundamental role (but again implying preventative possibilities) is the suggestion that sleep deprivation late in pregnancy and in labour and childbirth at night might trigger post-natal depression.
- Abnormal circadian sleep–wake rhythms have been implicated in various depressive disorders including seasonal affective disorder (SAD). Light therapy has been used to correct the abnormality and relieve the depression and other symptoms.
- Disordered REM sleep mechanisms have (questionably) been considered as fundamental in the development of post-traumatic stress disorder symptoms.
- Some forms of attention-deficit hyperactivity disorder in children are attributed to persistent sleep disturbance.
- In a proportion of patients with schizophrenia, narcolepsy has been reported as the cause of their psychotic symptoms.

Disorders of sleep

Sleep complaints

The starting point for the clinician is the patient's sleep complaint. They are of three basic types:

- Not enough sleep, or unrefreshing sleep (**insomnia**).
- Sleeping too much (**excessive daytime sleepiness** or **hypersomnia**).
- Disturbed episodes during or otherwise related to sleep (**parasomnias**).

The detailed accounts later in this section are organized in relation to these main types of sleep complaint: insomnias (Chapter 4.14.2); excessive daytime sleepiness (Chapter 4.14.3); and parasomnias (Chapter 4.14.4). Sleep problems in childhood and adolescence are discussed in Chapter 9.2.9.

Whatever the clinical setting in which sleep complaints are investigated, the essential aim is to identify the specific sleep disorder from the many other conditions that can give rise to such complaints. Some sleep disorders may cause more than one type of complaint, and a patient may have more than one sleep disorder. The question arises how best to classify the many sleep disorders that have been described.

International classification of sleep disorders—second edition 2005 (ICSD-2)

This system, derived from wide international consultation, is the latest attempt to organize rationally the many ways in which sleep can be disturbed. ICSD-2 replaced the ICSD-Revised scheme outlined in the first edition of this textbook. More than 90 different sleep disorders are grouped as shown in Table 4.14.1.1. The grouping reflects the fact that knowledge about individual sleep disorders is very varied. The basic pathophysiology of some is quite well documented; in others little is known beyond their manifestations, and even they are subject to change as clinical observations improve. As a result, the ICSD-2 groupings are a mixture of those based on a common complaint (e.g. insomnia or hypersomnia), others on presumed aetiology (circadian rhythm sleep–wake disorders), and yet others are grouped according to the organ system from which the problems arise (such as sleep-related breathing disorders). Two additional groups in the system reflect current uncertainty about their status as disorders, or about their true nature.

Each sleep disorder is described in a standardized fashion using a series of sub-headings which include clinical features, demographics, pathology, and differential diagnosis. Treatments are not covered. Some publications are recommended concerning each sleep disorder. An attempt has been made throughout ICSD-2 to highlight aspects of sleep disorders of particular relevance to children.

In all, ICSD-2 provides a concise, easily accessible and up-to-date source of information for consultation by the clinician. Without being over-technical, it is more comprehensive and informative than current ICSD-10 and DSM-IV systems.

Sleep disorders mistaken for primarily psychological or psychiatric conditions

Sleep disorders manifest themselves in many ways. Failure to realize this can result in the misdiagnosis of primary sleep disorders as other types of clinical conditions of psychiatric, neurological, or otherwise medical conditions especially if there is limited familiarity with the sleep disorders field (which, unfortunately, is generally the case). Clearly such mistakes compromise patient care. The following are some of the main examples of this problem. Further details, with examples, are available elsewhere.[3]

Table 4.14.1.1 ICSD-2 groups of sleep disorders

I *Insomnias* The many psychological and physical causes of difficulty getting off to sleep, not staying asleep, early morning wakening, and feeling un-refreshed by sleep are included here including stress, poor sleep habits, and various mental and medical conditions.
II *Sleep-related breathing disorders* This group includes the common condition of obstructive sleep apnoea in adults and in children which often causes daytime sleepiness and other serious effects including changes in mood and behaviour. Central apnoea and various types of hypoventilation/hypoxaemic syndromes are also part of this group.
III *Hypersomnias of central origin not due to a circadian rhythm sleep disorder, sleep-related breathing disorder, or other cause of disturbed nocturnal sleep* Included here are narcolepsy and the causes of intermittent or recurrent hypersomnia such as the Kleine–Levin syndrome.
IV *Circadian rhythm sleep disorders* These disorders are characterized by a mistiming (and often disruption) of the sleep period, resulting in insomnia and/or hypersomnia. A prominent example is the delayed sleep phase syndrome common in adolescence. The advanced sleep phase syndrome can be seen in the elderly in which the sleep period begins in the evening with waking early when sleep requirements have been met. Irregular sleep–wake rhythms may be the result of an ill-organized way of life and substance abuse. Jet lag and nightshift work disorder are further examples of sleep problems caused by disturbance of the biological clock controlling the sleep–wake cycle.
V *Parasomnias* These are abnormal behaviours or sensations during or otherwise closely related to sleep. Many can be categorized according to the stage of sleep with which they are usually associated for example NREM sleep (sleepwalking) and REM sleep (nightmares, REM sleep behaviour disorder). Other parasomnias of particular psychiatric interest include sleep-related dissociative disorders and sleep-related eating disorders.
VI Sleep-related movement disorders These include the restless leg syndrome and periodic limb movement disorder.
VII Isolated symptoms, apparently normal variants and unresolved issues
VIII Other sleep disorders The classificatory scheme also includes an appendix on sleep disorders associated with conditions classifiable elsewhere such as sleep-related epilepsy, headaches, gastro-oesophageal reflux. A further appendix is concerned with other psychiatric and behavioural disorders frequently encountered in the differential diagnosis of sleep disorders. This appendix covers mood disorders, anxiety disorders, somatoform disorders, schizophrenia and other psychiatric disorders, personality disorders, and disorders of a psychiatric or behavioural type first diagnosed in infancy, childhood, or adolescence.

- Persistently not obtaining enough sleep, or having poor quality sleep because of interruptions by frequent subclinical arousals (as in obstructive sleep apnoea), is likely to cause tiredness, fatigue, irritability, poor concentration, impaired performance (possibly causing injuries or accidents at work or while driving), or depression. Out of the various possible explanations for such changes of behaviour, sleep disturbance may well be overlooked with failure to appreciate that, with improvement in sleep (which is usually possible with the right advice), such problems can be resolved. Occupational groups at special risk of sleep disturbance and its harmful effects include some clinicians.
- Excessive sleepiness, whatever its cause out of the many possibilities including physical conditions, is often misjudged as laziness, disinterest, daydreaming, lack of motivation, depression, intellectual inadequacy, or a number of other unwelcome states of mind. Sometimes, in very sleepy states, periods of 'automatic behaviour' occur, i.e. prolonged, complex, and possibly inappropriate behaviour with impaired awareness of events and, therefore, amnesia for them. Such episodes, the result of repeated 'microsleeps', can easily be misconstrued as reprehensible or dissociative features, misbehaviour, or prolonged seizure states. The paradoxical effect in young children of sleepiness causing over-activity has sometimes led to a diagnosis of attention-deficit hyperactivity disorder (ADHD) inappropriately treated with stimulant drugs instead of treatment for the sleep disorder.

A number of specific sleep disorders are at particular risk of being misinterpreted.

- In so-called delayed sleep phase syndrome, in which there is difficulty getting to sleep until very late, and problems getting up in the morning because of a shift in this timing of the sleep phase, is considered to be particularly common in adolescents who may be mistakenly thought to be awkward, lazy, irresponsible, or indulging in school refusal of the more usual type. In fact, this sleep disorder at that age is the result of a combination of normal pubertal biological body clock changes and alterations in lifestyle involving staying up late for social reasons or for study.
- It is not generally appreciated that even very complicated behaviour is possible whilst a person is still asleep as in sleepwalking episodes. Those with agitated sleepwalking or sleep terrors may appear to be very fearful and distressed and rush about and cry out as if escaping from danger. Other sleepwalkers develop an eating disorder with excessive weight gain due to the amount of food they consume while they are still asleep at night. Yet others behave in an aggressive or destructive way causing injury to themselves or other people and, at times sexual or other serious offences have been committed during a sleepwalking episode. If it is not known that such complicated actions are compatible with still being asleep, it is likely to be assumed that the person was awake at the time and aware of what he or she was doing, and, therefore, responsible for what had happened.
- Obstructive sleep apnoea is another case in point where this essentially physical disorder may be mistaken for being something very different from its true nature. The impairment of sleep quality, which characterizes this condition, can cause excessive daytime sleepiness, changes of personality, as well as adverse affects on social life and performance at work, as well as intellectual deterioration to the extent that dementia is suspected.
- Narcolepsy/cataplexy is also at serious risk of being misdiagnosed, sometimes for many years. Neurosis or depression is commonly mistaken for the narcolepsy symptoms.
- In REM sleep behaviour disorder there is a pathological retention of muscle tone during REM sleep so that a person can act out their dreams and behave violently if they have violent dreams. The dramatic behaviour that may result, including attacks on the sleeping partner, is easily misconstrued as intentional aggression.

- The complicated behaviour (far removed from that seen in other seizure states) that characterizes nocturnal frontal lobe epilepsy is often mistakenly thought to be evidence of a psychiatric disorder.
- In addition, sleep paralysis may be misconstrued as a psychotic disorder when (not uncommonly) accompanied by hallucinatory experiences.

In addition to sleep disorders being mistaken for psychiatric disorder, the opposite problem arises occasionally, that is some patients simulate excessive daytime sleepiness in order to avoid a psychologically troubling situation. Similarly, apparent parasomnias during sleep have sometimes been shown by polysomnography to occur when the patient is actually awake.

Detection and assessment of sleep disorders

As suggested earlier, evidence of a sleep disturbance should be actively sought in members of the general population and the various groups, including psychiatric patients, who are at special risk of sleep disorders. Otherwise, many instances of even severe sleep disturbance will continue to go unrecognized and untreated.

Sleep history

Routinely, all patients should be asked the following screening questions:

- Do you sleep long enough or well enough?
- Are you very sleepy during the day?
- Do you do unusual things or have strange experiences at night?

Ideally, their partner or other relatives should also be asked the same questions about the patient because the existence or severity of some forms of sleep disturbance are not known to the patient. In the case of children, parents are the main source of information but teachers' observations about daytime sleepiness or disturbance are also important.

If the answer to any of these enquiries is positive, a detailed sleep history is required. As traditional clinical history-taking schedules pay little attention to sleep, additional sleep-related enquiries will need to be made, covering the following points about the sleep problem.

- Precise nature of the sleep complaint, its onset, development, and current patterns.
- Medical or psychological factors at the onset of the sleep problem or which might have maintained it.
- Patterns of occurrence of the symptoms that is factors making them better or worse, weekdays compared to weekends, or work compared with holiday periods.
- Effect on mood, behaviour, work, social life, other family members.
- Past and present treatments for sleep problems and their effects.
- Past and present medication or other treatments for other illness or disorder.

In addition, detailed information is needed concerning the following:

- The patient's typical 24-h sleep–wake schedule. This can usually start with the evening meal, followed by preparation for and timing of bedtime, time and process of getting to sleep, events during the night, time and ease of waking up and getting up, level of alertness, and mental state and behaviour during the day.
- An attempt should be made to establish the duration, continuity, and timing of the patient's overnight sleep as these are the most important aspects of sleep for daytime functioning. It is also important to identify events of particular diagnostic significance, for example loud snoring.
- Sleep hygiene.

Compilation of a sleep history can be aided by the use of a preliminary sleep questionnaire (e.g. ref.[4]).

Sleep diary

Systematic recording in a booklet each day over 2 weeks or more, using a standardized format, avoids the bias or distortion of retrospective generalizations.

Other histories

Medical and psychiatric histories should include past and current treatment details (in view of the wide range of illnesses or disorders and their treatment with which sleep disturbance is associated). **Social history** should include occupational, marital, and recreational factors (drinking, smoking, drug use), which may affect sleep. **Family history** may be positive, for example in sleepwalking and associated arousal disorders.

Review of systems

Breathing difficulties and nocturia, for example, are associated with sleep disturbance. Severe obstructive sleep apnoea can cause cardio-respiratory and other cardiovascular complications.

Physical and mental state examination

Particular attention should be paid to the following:

- Evidence of any systemic illness including cardio-respiratory disease or neurological disorder (such as Parkinson's disease or stroke) which may disturb sleep.
- Obesity, oral and pharyngeal abnormalities, retrognathia, or mid-face deformity (predisposing to upper airway obstruction).
- Depression or other psychiatric disorder.
- Intellectual impairment, especially features of intellectual disability or dementia (including specific retardation syndromes) in view of their strong association with sleep disturbance.

Audio–video recording and actigraphy

Audio–video recordings can be very instructive in the parasomnias, sometimes revealing a very different picture than that provided in the clinic. Home video systems can be used where admission to hospital is not feasible. Similarly, monitoring of body movements via means of wrist-watch-like devices (**actigraphy**) can be used at home, if necessary, to quantify basic circadian sleep–wake patterns.

Polysomnography (PSG)

Physiological sleep studies are necessary for diagnosis in only the minority of sleep disorders. Traditionally this has entailed admission to a sleep laboratory. However, especially where such facilities are difficult to obtain, where the laboratory situation is unacceptable to patients (including some children or patients who are psychiatrically disturbed), **home PSG**, using portable systems, is useful, although the procedure has yet to be fully standardized and for some disorders is best seen as only a screening procedure. Recording in the home environment has the further advantage that, if the patient is allowed to adapt to the recording procedure before bedtime, the results from a single night's recording can be representative of the patient's habitual sleep. In contrast 'first night effects' are prominent in laboratory recordings and more than one night of polysomnography is required to allow adaptation to take place.

Basic polysomnography entails the recording of EEG, EOG, and EMG. This allows sleep to be staged and a hypnogram to be compiled as illustrated in Fig. 4.14.1.1. Usually the recording is made overnight but it may be continued during the day if required. Basic measures obtained from this information are as follows: total sleep time, time awake and number of awakenings, amount of REM and NREM sleep and their distribution overnight.

PSG can be extended to additional physiological measures, especially the following:

- Respiratory variables and audio–video recordings for sleep-related breathing problems.
- Additional EEG channels (combined with video) if nocturnal epilepsy is suspected.
- Anterior tibialis EMG for the detection of period limb movements in sleep.

Main indications for PSG are:

- The investigation of excessive daytime sleepiness, including the diagnosis of sleep apnoea, narcolepsy, or PLMS.
- The diagnosis of parasomnias where their nature is unclear from the clinical details, where PSG findings contribute essentially to the diagnosis (e.g. REM sleep behaviour disorder), where the possibility of epilepsy exists, or whether there may be more than one parasomnia present.
- As an objective check on the accuracy of the sleep complaint, or response to treatment.

Other investigations

Further laboratory investigations may be appropriate depending on the nature of the sleep problem and the purpose of the assessment.

- **A multiple sleep latency test** (**MSLT**), involving the recording of basic PSG variables, quantifies the degree of daytime sleepiness by measuring the time a patient takes to fall asleep during five opportunities to do so during the day. In adults, a mean sleep latency of 5 min or less indicates pathological sleepiness (usually of organic origin); 5 to 10 min is a grey area which usually includes excessive sleepiness associated with primary psychiatric disorder; while longer than 10 min is normal. These values do not apply in children whose sleep tendency varies with age.
- **HLA typing**, and possibly **CSF hypocretin (orexin) levels** for the investigation of narcolepsy, and **nocturnal penile tumescence monitoring** in the differential diagnosis of organic versus psychogenic impotence, are examples of other specific tests that may be appropriate depending on the clinical problem.

Treatment approaches for sleep disorders

In clinical practice, the pharmacological approach to treatment of sleep problems (especially insomnia) is generally overemphasized, especially in the use of hypnotic-sedative drugs. Table 4.14.1.2 provides some indication of the wide range of available types of treatment, as well as general principles of management, for adults and children. They are roughly arranged in order of the frequency of their use in the comprehensive management of sleep disorders in general. An appropriate choice from this range requires an accurate diagnosis of the underlying sleep disorder. Further details are provided in later contributions to this section on sleep disorders. Claims for the effectiveness of these various measures are based on widespread clinical experience and reports. Few randomized controlled trials have not been published, as yet.

Certain aspects of treatment with special relevance to psychiatric practice are included in Table 4.14.1.3.

Clinical sleep disorders in psychiatric conditions

As mentioned earlier, sleep disturbance is a feature of many psychiatric disorders at all ages. Sometimes a sleep disturbance is profound and constitutes one of the defining characteristics of the psychiatric condition. This aspect of the psychiatric state requires careful definition and quite possibly treatment in its own right, alongside primarily psychiatric help, in order to facilitate recovery.

Table 4.14.1.3 outlines the main types of sleep problem or disorder associated with various psychiatric conditions. Emphasis has been placed on clinical sleep problems rather than PSG abnormalities which are seen in some of the conditions which (although interesting and of potential pathophysiological significance) are

Table 4.14.1.2 Examples of treatment approaches for sleep disorders in adults

General principles
Explain the problem, reassure where appropriate and provide support
Encourage good sleep hygiene (see Chapter 4.14.2)
Where possible treat the underlying cause of the sleep disturbance (e.g. medical or psychiatric disorder)
Take safety or protective measures (e.g. for hazardous parasomnias)
Specific behavioural treatments for insomnia (Chapter 4.14.2)
Chronotherapy (for circadian sleep-wake rhythm disorders)
Sleep phase retiming
Light therapy
Medication
Hypnotics (very selective and short-term)
Stimulants (narcolepsy)
Melatonin (for some circadian sleep–wake rhythm disorders)
Physical measures (e.g. for obstructive sleep apnoea)
Continuous positive airway pressure (CPAP)
Surgery (selected cases)

Table 4.14.1.3 Clinical sleep disturbance in psychiatric disorders

Psychiatric condition	Likely/possible sleep problem/disorder	Possible treatment issues/principles (see also text for general points)
Depression		*General* Emphasis on treatment of depression Possible sleep complications of ADs: drowsiness, insomnia (including SSRIs), RLS, PLMS, RBD
	Insomnia	Early treatment required to prevent worsening of depression Sedating ADs may be helpful
	EDS (minority)	More stimulating ADs may be appropriate Light therapy for SAD
Mania	Profound insomnia	Vigorous treatment required Mood-stimulating drugs may cause arousal disorders
Anxiety disorders	Insomnia and disrupted (poor quality) sleep PTSD nightmares Nocturnal panic attacks	In addition to behavioural treatments; larger dose of antipsychotics at bedtime may be helpful
Eating disorders	Insomnia (especially anorexia nervosa) EDS (especially bulimia nervosa) Sleepwalking with eating behaviours	General principles for insomnia (see Chapter 4.14.2) Possibly SSRIs See Chapter 4.14.4 for management of sleepwalking
Schizophrenia	Insomnia	Most neuroleptics promote sleep As in other psychotic states, behavioural sleep treatments and sleep hygiene are important
Alcohol and other substance abuse (including withdrawal states)	Insomnia including poor qualitysleep Disrupted sleep-wake cycle	Avoid sedative-hypnotic drugs Sleep hygiene principles (Chapter 4.14) and chronotherapy for sleep–wake cycle abnormalities
Alzheimer's disease and other dementing disorders	Progressive insomnia with fragmented sleep and sleep–wake cycle disorders including nocturnal agitated wandering	General principles for insomnia treatments; Sleep problems with some anti-dementia drugs Low-dose antipsychotics, if necessary Promote day–night cues including regular experience of daylight; discourage daytime napping
	RBD	Clonazepam
Child and adult ADHD	Insomnia	Stimulants can add to the sleep problem

KEY:

ADs = Antidepressants
ADHD = Attention-deficit hyperactivity disorder
EDS = Excessive daytime sleepiness
PLMS = Periodic limb movements in sleep
RBD = REM sleep behaviour disorder
RLS = Restless legs syndrome
SAD = Seasonal affective disorder
SSRI = Selective serotonin reuptake inhibitors

not necessarily accompanied by clinical manifestations. A prime example of this is the reduced time between onset of sleep and the start of the first REM sleep period ('REM latency') in certain forms of severe depression. This can be viewed as a type of biological marker which may persist even after the depression itself has lifted, and which may also be seen in relatives of a depressed person with this PSG finding without they themselves suffering from depression. However, the basic significance of reduced REM latency is, as yet, obscure and not helped by the fact that it has also been described in other psychiatric conditions, narcolepsy, following withdrawal from REM sleep-suppressing substances, during recovery from sleep deprivation, and a number of other diverse circumstances.

Another aspect of the pathophysiological relationship between sleep and mood which awaits clarification is a paradox that, while depression is usually associated with sleep disturbance and loss, sleep deprivation is reported to have an antidepressant effect in some patients although the effect does not persist beyond the period of depression.

Clinical sleep disorders associated with neurological and other medical illness

Of obvious relevance to psychiatric practice in general, but liaison psychiatry in particular, is the fact that disturbed sleep (often severe) is associated with many medical conditions. Main examples of this are shown in Table 4.14.1.4 together with mention of treatment issues in relation to each type of illness. Additional general considerations regarding treatment are as follows:

- The main emphasis in the management of sleep disorders in this context should be placed on the treatment of the medical

Table 4.14.1.4 Clinical sleep disturbance in neurological and other medical illness

Medical condition	Likely/possible sleep problem/disorder	Possible treatment issues/principles (see also text for general points)
Parkinson's disease and/or related syndromes	Progressive insomnia including poor quality sleep	Mainly behavioural treatment and sleep hygiene measures as in other insomnias (see Chapter 4.14.2)
	Parasomnias (e.g. nightmares, nocturnal hallucinations)	Consider possible effects of anti-Parkinson's medication on these and other sleep problems
	EDS including sleep attacks	Possibly daytime stimulants
	PLMS	Usual treatments for PLMS, if severe
	RBD	Clonazepam usually effective
Epilepsy	Disrupted sleep depending on type, cause, and severity	Sleep generally improves with seizure control
	EDS	Sedating AEDs can be a factor
Stroke	Insomnia	Usual measures for insomnias
	OSA	
Head injury	Effects depend on type and severity	
	Poor quality sleep	Avoid respiratory depressant substances
	OSA, EDS	Usual measures for OSA (see Chapter 4.14.3)
Neuromuscular disease	OSA, EDS	As above
Tourette syndrome	Disrupted sleep	Treatment of tic disorder should improve sleep
	Sleepwalking	
Cardiovascular disease		
Congestive heart failure	Central sleep apnoea, orthopnoea	Some antihypertensive, hypolipidaemic and antiarrythmic drugs can cause insomnia
Coronary heart disease	Nocturnal angina	Beta blockers can produce insomnia and nightmares
Respiratory disease		
COPD	Nocturnal dyspnoea	Hypnotics contraindicated in respiratory disease
Asthma	Nocturnal awakenings, EDS	Theophylline can cause insomnia
Gastrointestinal disorders (peptic ulcer, reflux oesophagitis)	Nocturnal awakenings	
Rheumatological disorders and other chronic pain conditions (including cancer)	Insomnia, disrupted sleep, EDS	Cortico-steroids and NSAI agents can disturb sleep Major analgesics have sedative effects Various anti-cancer drugs can disrupt sleep
Iron deficiency	PLMS	Treat underlying condition
	RLS	
Endocrine disease		
Diabetes	Awakenings from nocturnia or painful peripheral neuropathy	
	OSA	
Hyperthyroidism	Insomnia	
Myxoedema	OSA	
Chronic renal failure	Sleep disruption	Improvement with haemodialysis
	EDS	
	OSA	
	RLS and PLMS	
ICU patients	Severe sleep disruption and deprivation including sleep–wake cycle disorders causing confusional and psychotic states	Cause of reason for intensive care relevant, plus sleep disrupting effect of ICU environment, procedures and medications
Obesity	OSA	Complications of obesity (e.g. diabetes, joint diseases) affect sleep

KEY

AED = Anti-epileptic drugs
COPD = Chronic obstructive pulmonary disease
EDS = Excessive daytime sleepiness
ICU = Intensive care unit
NSAI = Non-steroidal anti-inflammatory
OSA = Obstructive sleep apnoea
PLMS = Periodic limb movements in sleep
RBD = REM sleep behaviour disorder
RLS = Restless legs syndrome

condition itself, although additional treatment for the sleep disorder may well be required.

- Treatment for other, co-morbid conditions may well be needed, in particular anxiety and depression which will have their own adverse effects on sleep.
- Hypnotic drugs should be used very sparingly (especially in the elderly) because of their potential complications as described in Chapter 6.2.2. In view of their respiratory-depressand effects, benzodiazepines in particular are contraindicated in sleep apnoea and in the presence of other severe respiratory disease.
- The possible effects on sleep of over-the-counter medications also need to be considered. Nasal decongestants and anorectics are stimulants and can cause insomnia. The same is true of caffeine-containing drinks used as 'energy boosters'. Non-prescribed sleeping preparations (which usually contain anti-histamines) may well cause daytime drowsiness.

As mentioned earlier, the link between medical illness and sleep disturbance may operate in the opposite direction. For example, chronic sleep loss or disruption is associated with the development of such chronic health problems as coronary artery disease or diabetes.

4.14.2 Insomnias

Colin A. Espie and Delwyn J. Bartlett

Introduction

Most people's experiences of poor sleep are memorable, because sleeplessness and its daytime consequences are unpleasant. There are those, however, for whom insomnia is the norm. Persistent and severe sleep disturbance affects at least one in 10 adults and one in five older adults, thus representing a considerable public health concern. Sleep disruption is central to a number of medical and psychiatric disorders, and insomnia is usually treated by general practitioners. Therefore differential diagnosis is important, and respiratory physicians, neurologists, psychiatrists, and clinical psychologists need to be involved. The purpose of this chapter is to summarize current understanding of the insomnias, their appraisal, and treatment. Particular emphasis will be placed upon evidence-based practical management.

Clinical features

Insomnia often remains unreported, and finally presents when a poor sleep pattern is well established. Alcohol has long been a first-line self-administered sleep aid, and recent years have seen an increasing use of 'over-the-counter' preparations and 'self-help' strategies. The clinical presentation is commonly of a frustrated patient, trapped in a vicious circle of anxiety and poor sleep, who reports having 'tried everything'.[1,2]

There may be concern about the pattern of sleep. This is the most quantifiable aspect of self-report relating to, for example, length of time taken to fall asleep, frequency and duration of wakenings, or total amount of sleep. A poorly established sleep pattern can lead to unpredictability of what sleep will be like on any given night. Patients often report poor quality of sleep, and subjective perceived quality can be a critically important outcome variable. Typical reports relate to light sleep and sleep felt to be unrestorative. Although it may be unclear how such complaints relate to EEG sleep architecture, the clinician should not overlook qualitative report as it may reflect underlying pathophysiology. Concerns are normally expressed also about the daytime effects of poor sleep. These can be cognitive effects, such as fatigue, sleepiness, inattention, and some impairments in performance, or emotional effects, such as irritability and anxiety.[2]

Classification

The *International Classification of Sleep Disorders* (second edition: **ICSD-2**)[3] was published in 2005 and provides the most comprehensive account of sleep disorders, both for descriptive purposes and for differential diagnosis (see Chapter 4.14.1). ICSD-2 describes insomnias as disorders of initiating and maintaining sleep. Patients may have either sleep-onset problems or wakenings from sleep, or both of these. Table 4.14.2.1 summarizes the principal classifications that relate to the insomnias, along with some other sleep disorders where patients commonly present with insomnia symptoms. As can be seen, concomitant symptomatology, potential aetiological factors, and sleeplessness require careful assessment in order to reach a valid diagnosis.

Table 4.14.2.1 The classification and differential diagnosis of the insomnias within ICSD-2

Classification	Sleep disorder	Essential features, complaint of insomnia plus
Insomnias	Psychophysiological insomnia	Learned sleep preventing associations, conditioned arousal, 'racing mind' phenomenon
	Paradoxical insomnia	Complaint of poor sleep disproportionate to sleep pattern and sleep duration
	Idiopathic insomnia	Insomnia typically begins in childhood or from birth
	Insomnia due to a mental disorder	Course of sleep disturbance concurrent with mental disorder
	Inadequate sleep hygiene	Daily living activities inconsistent with maintaining good-quality sleep
	Insomnia due to a medical disorder	Course of sleep disturbance concurrent with mental disorder
	Insomnia due to drug or substance	Sleep disruption caused by prescription medication, recreational drug, caffeine, alcohol or foodstuff
	Adjustment insomnia	Presence of identifiable stressor, insomnia resolves or is expected to resolve when stressor is removed
Sleep-related breathing disorders	Obstructive sleep apnoea syndrome	Excessive sleepiness, obstructed breathing in sleep, associated symptoms include snoring and a dry mouth
	Periodic limb movement disorder	Episodes of repetitive, highly stereotyped limb movements occurring in sleep
	Restless legs syndrome	Strong, nearly irresistible urge to move legs relieved by walking
Circadian rhythm sleep disorders	Delayed sleep phase type	Phase delay of major sleep episode, initial insomnia, excessive sleepiness in morning
	Advanced sleep-phase type	Phase advance of major sleep episode, inability to stay awake in evening, early wakening

Diagnosis and differential diagnosis

Severity of insomnia is judged along dimensions of frequency, intensity, and duration, as well as impact on daytime functioning and quality of life. Generally, the criteria for severe and chronic insomnia are a minimum duration of 6 months with problems presenting three or more nights per week. Restlessness, irritability, anxiety, daytime fatigue, and tiredness commonly accompany such presentations.[2] Mild and moderate insomnia may be diagnosed where problems are less intrusive.

Most patients presenting with insomnia have psychophysiological difficulty initiating and/or maintaining sleep. Usually marked functional effects and somatized tension associated with sleep are evident. The patient reports extreme tiredness while being unable to sleep satisfactorily and appears preoccupied with sleep and its consequences. This contrasts, for example, with the circadian disorders where, in delayed sleep-phase type, the patient may not feel sleepy until late in the normal sleep period, and in advanced sleep-phase type, may waken early and be unable to return to sleep. Taking a history, incorporating screening questions on restlessness, limb movements, and breathing can help to diagnose obstructive sleep apnoea syndrome, periodic limb movement disorder, and restless legs syndrome, although full polysomnographic evaluation may also be required.[4] However, polysomnography is not essential for the diagnosis of insomnia, for which sleep diary monitoring (see Chapter 4.14.1) is usually the most useful form of assessment.[2] Wrist actigraphy is an inexpensive objective evaluation, which estimates sleep/wakefulness based upon body movement.[5] Continuous recordings can be made over 5 to 10 consecutive 24 h periods. It is useful in identifying paradoxical insomnia, and charted data can be inspected for circadian anomalies.

Other causes of insomnia are reported in Table 4.14.2.1 and should not be overlooked. In particular, insomnias due to a drug or substance can include hypnotic-dependent sleep disorder, associated most commonly with benzodiazepine (BZ) drugs where withdrawal leads to exacerbation of the primary problem.[6] This can be mistaken for a severe underlying insomnia and hence reinforce hypnotic dependency. Likewise, a wide range of psychiatric conditions, particularly affective disorders, has associated sleep symptomatology (see Chapter 4.14.1). A primary diagnosis of psychophysiological insomnia cannot be made where diagnostic criteria for DSM-IV Axis I or Axis II disorders are fulfilled. However, it is very important to note that sleep disturbance often precedes depression. The bulk of the psychiatric epidemiological data indicate that insomnia is an independent risk factor for first episode depressive illness, and for recurrence of depression, in adults of all ages.[7,8] Insomnia should not be assumed to be simply a symptom of underlying depression, even when depression is present. Unless the illness courses clearly co-vary it is best to make a diagnosis of co-morbid insomnia. Similar caveats apply to insomnia associated with medical disorders, both in terms of identifying a primary illness, and concluding that insomnia has *the* status of an associated/ co-morbid disorder (see Chapter 4.14.1).

Epidemiology

Insomnia affects one-third of adults occasionally, and 9 to 12 per cent on a chronic basis. It is more common in women, in shift workers, and in patients with medical and psychiatric disorders. Prevalence amongst older adults has been estimated at up to 25 per cent and sleepiness and hypnotic drugs are risk factors for injury and fracture.[9] The decline in prescription of anxiolytics has been greater than the rate of decline for hypnotics [taking BZ and benzodiazepine receptor agonists (BzRAs) together]. Furthermore, there is increasing use of (off-label) sedative antidepressants primarily to treat insomnia.

Aetiology

Many patients report having been marginal light sleepers before developing insomnia.[4] Sleep disturbance often arises during life change or stress, and such adjustment sleep disorder may represent a normal transient disruption of sleep. However, secondary factors, such as anxiety over sleep and faulty sleep–wake conditioning, may

exacerbate and maintain the insomnia as a chronic problem when sleep itself becomes a focus for concern. People with insomnia may be hyperaroused relative to normal sleepers, for example having higher levels of cortisol and ACTH, and also find it difficult to 'down-regulate' their arousal at bedtime.[2,10,11]

Course and prognosis

There has been little research on the natural course of insomnia. However, untreated psychophysiological insomnia can last for decades, and may gradually worsen over time. Indeed, there is a developmental trend for sleep pattern to deteriorate, with increasing age. On the other hand, delayed sleep-phase syndrome and insufficient sleep hygiene can be associated with lifestyle problems and may ameliorate as these are resolved. Although certain insomnias *tend* to persist if untreated, prognosis with effective treatment can be very good.

Treatment

A review of the evidence

(a) Drug therapy

Traditionally, insomnia has been treated pharmacologically. Barbiturates were superseded by BZ compounds during the 1960s and 1970s. These drugs were safer in overdose, were thought to have fewer side effects, and to be less *addictive*. Controlled studies have demonstrated that a considerable number of BZ, of short to intermediate half-life, are effective hypnotic agents. However, from the mid-1970s potential problems became apparent, both during administration and withdrawal. Longer-acting hypnotics were prone to carry-over effects of morning lethargy, and shorter-acting drugs to 'rebound insomnia'.[6] Furthermore, tolerance develops, leading either to increased dosing or switching to alternative medication. Although BZs used for short periods/intermittently can maintain effectiveness, these are not the treatment of choice in chronic insomnia,[12] and are contraindicated in older adults and where insomnia may involve sleep-related breathing disorder because of their potentially depressant effects on respiration. A number of BZ compounds have been removed from the market in the United Kingdom, United States, and elsewhere.

Contemporary hypnotic therapy has extended to include BzRAs (often referred to as the 'z' drugs), and more recently melatonin receptor agonists (MeRAs) have been introduced. Whereas the place in therapeutics of MeRAs has yet to become established, the BzRAs are often thought to offer more sustained benefit for insomnia, and to have fewer adverse effects. Nevertheless, there remains uncertainty about the effectiveness of BzRAs in chronic insomnia.[13]

(b) Psychological therapy

Psychological treatment for chronic insomnia, primarily in the form of cognitive behavioural therapy (CBT), has been extensively investigated in over 100 controlled studies during the past 20 years. Five meta-analyses and numerous systematic reviews have demonstrated that CBT is associated with large effect size changes (measured in standardized z scores) in the primary symptom measures of sleep latency (difficulty getting to sleep) and wake time after sleep-onset (difficulty remaining asleep).[14,15] Around 70 per cent of patients with persistent sleep problems appear to benefit from CBT and effects are maintained to long-term follow-up. It is thought that CBT achieves these outcomes because it tackles directly the dysfunctional thoughts and maladaptive behaviours that otherwise maintain insomnia. Recent controlled studies have shown that CBT may be effective in general practice settings with nurses delivering the intervention according to a standard protocol.[16,17] Despite the superior efficacy of CBT relative to medication for insomnia, and these recent demonstrations of CBT working in real-world settings, practical problems remain in making CBT widely available.

Within the CBT model, a number of strategies have strong empirical support. Behavioural procedures such as stimulus control and sleep restriction, and cognitive strategies such as paradoxical intention and thought restructuring have been extensively investigated[2,14,15] and are outlined briefly below.

(c) Melatonin, light therapy, and exercise

The pineal hormone melatonin has been the subject of highly publicized claims. However, scientific research has been limited. Several controlled studies support its sleep-promoting effects, but the use of melatonin continues to be controversial. At best it may be useful as a chronobiotic for reducing sleep latency.[18] Several MeRA products are currently under formal evaluation, so more data may be available soon.

Bright light is a potent marker for human circadian rhythms, and has been known for some time to enable the resetting of such rhythms in advanced sleep-phase syndrome and delayed sleep-phase syndrome.[19] The results of studies investigating the efficacy of bright light against psychological treatments for psychophysiological insomnia are awaited. A limiting factor to the value of light therapy is that continued treatment may be required to maintain therapeutic effects.

Athletic people sleep well, although this may be more to do with behavioural patterning than aerobic fitness. Nevertheless, there is evidence that exercise can have positive effects upon sleep quality, particularly if taken late afternoon or early evening, and in otherwise relatively fit individuals.[20] Morning exercise can also be an effective modality to encourage the same waking time and early morning light exposure; which help to reset sleep patterns on a daily basis.

Advice about management

(a) General perspective

Non-pharmacological treatment using CBT procedures should be preferred over pharmacological treatment, in cases of severe persistent insomnia. Hypnotic agents should be recommended mainly for short-term or occasional use, although longer-term trial data are now becoming available. The practitioner should be aware of morning-after effects, and potential problems of withdrawal and dependency, not only with BZs but also possibly with BzRAs. Psychological intervention may also facilitate reduction or discontinuation of medication in hypnotic-dependent person with insomnias.[21] There is limited support for the use of melatonin or exercise as treatments of choice, although light therapy seems effective for circadian disorders.

(b) Using cognitive behavioural therapies

Brief descriptions of effective management strategies are presented in Tables 4.14.2.2 and 4.14.2.3. The following text provides

Table 4.14.2.2 Summary description of sleep hygiene and education components for the treatment of chronic insomnia

Components of sleep education
The need for sleep and its functions
Sleep patterns across the lifespan
Sleep as a process with stages/phases
Factors adversely affecting steep
The effects of sleep loss
The concept of insomnia
Measuring sleep and sleep problems
Components of sleep hygiene treatment
Bedroom comfortable for sleep
Regular exercise, timing, and fitness
Stable and appropriate diet
Undesirable effects of caffeine and other stimulants
Moderation of alcohol consumption
Other common 'self-help' strategies

explanation of underlying psychological models and further information on implementation.

(i) Sleep education and sleep hygiene

The simple provision of information ameliorates the sense of being out of control. Inaccurate attributions are challenged and misunderstandings corrected by understanding what sleep is, how ommon insomnia can be, how sleep changes with age, good sleep hygiene practices, and some facts about sleep loss. Similarly, sleep hygiene provides patients with a starting point for self-management. These techniques are best construed as introductory but they will not of themselves treat insomnia effectively.

Table 4.14.2.3 Summary description of cognitive behavioural components for the treatment of chronic insomnia

Components of stimulus control and sleep restriction treatment
Define individual sleep requirements
Establish parameters for bedtime period (threshold time and rising time)
Eliminate daytime napping
Differentiate rest from sleep
Schedule sleep periods with respect to needs
Establish 7 day per week compliance
Remove incompatible activity from bedroom environment
Rise from bed if wakeful (>20 min)
Avoid recovery sleep as 'compensation'
Establish stability from night to night
Adjust the sleep period as sleep efficiency improves
Components of cognitive intervention
Identify thought patterns and content that intrude
Address (mis)attributions connecting sleep and waking life
Establish rehearsal/planning time in early evening
Relaxation and imagery training
Distraction and thought blocking
Develop accurate beliefs/attributions about sleep and sleep loss
Challenge negative and invalid thoughts
Eliminate 'effort' to control sleep
Motivate to maintain behaviour and cognitive change
Utilize relapse-prevention techniques

(ii) Stimulus control treatment

Stimulus control increases the bedroom's cueing potential for sleep. For good sleepers, the pre-bedtime period and the stimulus environment trigger positive associations of sleepiness and sleep. For the poor sleeper, however, the bedroom triggers associations with restlessness and lengthy night-time wakening via a stimulus-response relationship, thereby continuing to promote wakefulness and arousal. The model is similar to phobic conditions where a conditioned stimulus precipitates an anxiety response.

Treatment involves removing from the bedroom all stimuli which are potentially sleep-incompatible. Reading and watching television, for example, are confined to living rooms. Sleeping is excluded from living areas and from daytime, and wakefulness is excluded from the bedroom. The individual is instructed to get up if not asleep within 15–20 min or if wakeful during the night. Conceptually, stimulus control is a reconditioning treatment which forces discrimination between daytime and sleeping environments.

(iii) Sleep restriction therapy

Sleep restriction restricts sleep to the length of time which the person is likely to sleep. This may be equivalent to promoting 'core sleep' at the expense of 'optional sleep'. Sleep restriction primarily aims to improve sleep efficiency. Since sleep efficiency is the ratio of time asleep to time in bed, it can be improved either by increasing the numerator (time spent asleep) or by reducing the denominator (time spent in bed). People with insomnia generally seek the former, but this may not be necessary, either biologically or psychologically. Sleep restriction first involves recording in a sleep diary and calculating average nightly sleep duration. The aim, then, is to obtain this average each night. This is achieved by setting rising time as an 'anchor' each day and delaying going to bed until a 'threshold time' which permits this designated amount of sleep. Thus, the sleep period is compressed and sleep efficiency is likely to increase. The permitted 'sleep window' can then be titrated week-by-week in 15 increments in response to sleep efficiency improvements.

(iv) Cognitive control

This technique aims to deal with thought material in advance of bedtime and to reduce intrusive bedtime thinking. The person with insomnia is asked to set aside 15 to 20 min in the early evening to rehearse the day and to plan ahead for tomorrow; thus putting the day to rest. It is a technique for dealing with unfinished business and may be most effective for rehearsal, planning, and self-evaluative thoughts which are important to the individual and which, if not dealt with, may intrude during the sleep-onset period.

(v) Thought suppression

Thought-stopping and articulatory suppression attempt to interrupt the flow of thoughts. No attempt is made to deal with thought material *per se* but rather to attenuate thinking. With articulatory suppression the patient is instructed to repeat, subvocally, the word 'the' every 3 s. This procedure is derived from the experimental psychology literature. Articulatory suppression is thought to occupy the short-term memory store used in the processing of

information. The type of material most likely to respond is repetitive but non-affect-laden thoughts, not powerful enough to demand attention. Additionally, this technique may be useful during the night to enable rapid return to sleep.

(vi) Imagery and relaxation

There is a wide range of relaxation methods including progressive relaxation, imagery training, biofeedback, meditation, hypnosis, and autogenic training, but little evidence to indicate superiority of any one approach. Furthermore, there is little evidence to support either the presumption that people with insomnia are hyperaroused in physiological terms, or that relaxation has its effect through autonomic change. At the cognitive level, these techniques may act through distraction and the promotion of mastery. During relaxation, the mind focuses upon alternative themes such as visualized images or physiological responses. In meditation the focus is upon a 'mantra' and in self-hypnosis upon positive self-statements. Relaxation may be effective for thought processes that are anxiety-based, confused, and which flit from topic-to-topic.

(vii) Cognitive restructuring

Cognitive restructuring challenges faulty beliefs which maintain wakefulness and the helplessness which many people with insomnia report. It appears to work through appraisal by testing the validity of assumptions against evidence and real-life experience. As an evaluative technique, it may be effective with beliefs that are irrational but compelling. If such thoughts, for example 'I am going to be incapable at work tomorrow', are not challenged, they will create high levels of preoccupation and anxiety and sleep is unlikely to occur. With cognitive restructuring, the person with insomnia learns alternative responses to replace inaccurate thinking.

(viii) Paradoxical intention

Finally, the technique of paradoxical intention is useful in situations where performance anxiety has developed, that is, where the effort to produce a response inhibits that response itself. The paradoxical instruction is to allow sleep to occur naturally through passively attempting to remain quietly wakeful rather than attempting to fall asleep. Paradox may be regarded as a decatastrophizing technique since it appears to act upon the ultimate anxious thought (of remaining awake indefinitely) initially by focusing on and enhancing this thought (a habituation model) and then subjecting it to appraisal through rationalization and experience. By intending to remain awake, and failing to do so, the strength of the sleep drive is re-established, and performance effort is reduced.

Possibilities for prevention

There is insufficient knowledge of the natural course of transient sleep disorders. Mention has been made of adjustment sleep disorder and of the association of life events and stressors with the onset of insomnia. Systematic research is required to establish the 'setting conditions' for the secondary maintenance of insomnia beyond an initial normative reaction to events. Perhaps there is an interaction with a predisposing tendency to light sleep, or with introspection and worry. The instinct to increase opportunity to sleep (spend longer in bed to catch up) when insomnia symptoms develop should probably be resisted. If anything it may be better to advise patients to limit sleep opportunity so that their pattern knits together again more quickly.

The establishment and maintenance of a regular 'tight' routine, both pre-bedtime and in terms of sleep schedule, seem to be important preventive factors. Such chronobehavioural functioning can be at risk of disruption by, for example, jet lag, shift work, weekend patterns differing from weekday, adolescent lifestyle, and retirement. Adherence to, and/or reinstatement of, an adaptive pattern seems crucial.

It is important not to underestimate the importance of attitudes and beliefs in the presentation of insomnia. Exaggerated or emotionally and mentally arousing thoughts should be dealt with promptly. Sleep loss can be distressing, but patients should be reminded that nature seeks to restore equilibrium. What they need to do is to provide the conditions under which sleep can occur rather than attempt directly to control the sleep process. Expectations are important also, since it is the breach of these which generally give rise to anxiety and dysfunctional beliefs about sleep requirements. More often than not sleep-related expectations are unrealistic and require reappraisal, even more so in older adults.

Finally, prevention should be extended to the known extrinsic causes of certain sleep disorders. Where alcohol, stimulants, or proprietary drugs interfere with sleep and the recovery of the normal sleep process, attention should be paid to these factors. Better still, patients should be encouraged to seek advice early rather than go down the path of self-administered treatment. Avoiding the use of hypnotic agents, both in general practice and during acute admissions to hospital, would substantially reduce the number of iatrogenic cases of chronic insomnia.

4.14.3 Excessive sleepiness

Michel Billiard

Introduction

Excessive sleepiness is not an homogeneous concept. It can manifest itself as bouts of sleepiness, irresistible and refreshing sleep episodes, abnormal lengthening of night sleep with a major difficulty waking up in the morning or at the end of a nap or even periods of a week or so of almost continuous sleep recurring at several months' intervals.

According to the recent second edition of the *International Classification of Sleep Disorders* (*ICSD*-2),[1] disorders of excessive sleepiness are distributed within three chapters: sleep-related breathing disorders, hypersomnias of central origin not due to a circadian rhythm sleep disorder, sleep-related breathing disorders, or other cause of disturbed nocturnal sleep, and circadian rhythm sleep disorders.

However in this volume aimed at psychiatrists, the presentation of disorders of excessive sleepiness will obey another logic. Following "Generalities" including epidemiology, morbidity, clinical work-up, and laboratory tests, the various aetiologies will be presented according to the following six subchapters:

- Hypersomnia not due to substance or known physiological condition (non-organic hypersomnia or psychiatric hypersomnia)
- Hypersomnia due to drug or substance
- Behaviourally induced insufficient sleep syndrome
- Hypersomnia in the context of sleep-related breathing disorders
- Hypersomnias of central origin
- And the special case of delayed sleep phase syndrome.

Epidemiology

Contrary to common thinking, excessive sleepiness is neither exceptional nor rare. Epidemiological surveys generally agree on a figure of severe sleepiness (daily and embarrassing) in 5 per cent of the general population and of moderate sleepiness (occasional) in another 15 per cent.[2] Interestingly, only a fraction of these subjects are aware of their condition, due to the fact that they progressively lose reference to a normal state of alertness. As a consequence many subjects will not consult their physician for excessive sleepiness but will be brought to him by the spouse, worried about his or her falling asleep repeatedly in the middle of the day, or even referred by the company's doctor due to unexplained car accidents or poor work efficiency.

Morbidity

Excessive sleepiness has a severe impact on the life of patients. Nearly half of the patients with excessive sleepiness report automobile accidents. Many have lost jobs because of their sleepiness. In addition, sleepiness is disruptive of family life. Cognitive function is also impaired by sleepiness. In children excessive sleepiness has been associated with learning disability and in adults memory problems are frequent.

Clinical work-up and laboratory tests

Whatever the circumstance of the first visit, the patient should be interviewed on the history of excessive sleepiness, the type and severity of it, the associated symptoms, the familial and occupational consequences, the past and current treatments, and the personal and familial medical past-history.

In addition, the subject will complete a self-administered behavioural scale, the Epworth sleepiness scale. This scale asks the subject to rate the probability of dozing from 0 (would never doze) to

3 (high chance of dozing) in eight more or less soporific daily situations. A score of over 10 is taken to indicate abnormal sleepiness.

The subject will then undergo a physical and psychological examination.

Laboratory tests will be chosen according to the clinical impression.

The most frequently used test is the *multiple sleep latency test* (MSLT). The test was developed on the basis of the following principle. The sleepier the subject, the faster he falls asleep. The test is based on 20 min polygraphic recordings (EEG, EOG, EMG) repeated every 2 h (four or five times a day) starting 2 h about after morning awakening. The global sleepiness index is provided by the mean latency to sleep in the four or five tests. A sleep laboratory of less than 5 min indicates pathologic sleepiness, a sleep latency from 10 to 20 min is considerd as normal, and latencies falling between the normal and the pathological values are considered as a diagnostic grey area.

Another test, the *maintenance of wakefulness test* (MWT), is a variant of the MSLT. It was designed to evaluate treatment efficiency in patients with excessive sleepiness. The major difference with the MSLT is in the instruction given to the test subject. The subject being tested is told to attempt to remain awake. The subject is seated in comfortable position in bed, as opposed to lying down in the MSLT, with low lighting behind him (7.5 W at 1 m). Specific recommendations include using a four-trial, 40 min version of the MWT. A mean sleep latency of less than 8 min on the 40 min MWT is abnormal and scores between 8 and 40 min are of uncertain significance.

Prolonged polysomnographic recordings, obtained by either traditional laboratory polysomnographic monitoring or ambulatory recordings, provide a good picture of the actual time asleep within the 24 h period. However, this procedure is neither validated nor standardized.

In addition, whenever there is some doubt about the possibility of hypersomnia associated with a psychiatric disorder, a *psychometric/psychiatric evaluation* will be performed.

Aetiology and treatment

Hypersomnia not due to substance or known physiological condition

It explains about 5 to 7 per cent of cases of hypersomnia seen in sleep disorders centres. Women are more susceptible than men.

Excessive daytime sleepiness is reported. Subjects show an elevated score on the Epworth sleepiness scale. Night sleep is perceived as non-restorative and generally of poor quality. Patients are often intensely focused on their hypersomnia, and psychiatric symptoms typically become apparent only after prolonged interview or psychometric testing. Poor work attendance, abruptly leaving work because of a perceived need to sleep are common. Polysomnography typically shows a prolonged sleep latency, an increased wake time after sleep onset, and a low sleep efficiency. REM latency may be shortened in the case of bipolar disorder. Contrasting with the elevated score on the Epworth sleepiness scale, sleep latency on the MSLT is often within normal limits. A 24 h continuous sleep recording typically shows considerable time spent in bed during day and night, a behaviour referred to as clinophilia, from the Greek κλινη (bed) and φιλεω (love).

Psychiatric interview is essential to diagnose the underlying condition. Causative psychiatric conditions include bipolar type II disorder, dysthymic disorder, undifferentiated somatoform disorder, adjustment disorder, or personality disorder.

Conventional drugs such as antidepressants or anxiolytics are often insufficient. Modafinil, an awakening drug given at a daily dose of 100 to 200 mg, is usually active.

In the group of psychiatric disorders a separate place should be reserved to seasonal affective disorder remarkable for episodes of major depression occurring only during the winter months, associated with fatigue, loss of concentration, increased appetite for carbohydrates, weight gain, and increased sleep duration. Morning bright light treatment (2500 lux for 2 h) is efficient.

Hypersomnia due to drug or substance

A wide spectrum of medications used in psychiatry may be responsible for excessive sleepiness.

(a) Anxiolytics and hypnotics

Benzodiazepines have sedative effects, but these effects vary with dose, administration (single or repeated dose), age, and state of the subject (normal, anxious, or depressed). Non-benzodiazepines usually induce limited sleepiness only.

(b) Antidepressants

Tricyclic antidepressants have sedative properties depending on the molecule, dose, and the subject to whom they are administered. SSRI can also induce sleepiness with high within-patient variability. Venlafaxin, a serotonine, and norepinephrine reuptake blocker may induce excessive sleepiness.

(c) Neuroleptics

The degree of sedation varies widely from subject to subject. Empirically, three-fourth of the patients treated with neuroleptic phenothiazines experience sleepiness in a dependent manner. Among the newer agents clozapine is the most sedating drug, followed by olanzapine and quetiapine. Risperidone and sertindole are less sedating drugs.

Behaviourally induced insufficient sleep syndrome

According to ICSD-2, this syndrome occurs when an individual persistently fails to obtain the amount of sleep required to maintain normal levels of alertness. Behaviourally induced insufficient sleep syndrome is likely the most common cause of daytime sleepiness. In a population-based study conducted in Japan among 3030 subjects aged 20 years and older, 29 per cent slept less than 6 h per night, and 23 per cent reported having insufficient sleep.[3] The syndrome is likely to be widespread in truck drivers, working mothers, family doctors, executives, and students. The main symptoms are excessive sleepiness in the afternoon or early evening, decrease of diurnal performances, and, of interest to the psychiatrist, irritability, nervousness, and depression. Diagnosis of the syndrome is relatively easy provided that a thorough interview is conducted. The most rational treatment is an increase of daily total sleep time, either by spending more time in bed at night, or by taking one or two naps per day.

Hypersomnia in the context of sleep-related breathing disorders

The most frequent condition among these disorders is the obstructive sleep apnoea syndrome. This syndrome was first described by

Guilleminault *et al.*[4] It is most frequent in 50-year-old males. According to Young *et al.*[5] the prevalence of obstructive sleep apnoeas accompanied by excessive daytime sleepiness in North America is 4 per cent in men and 2 per cent in women.

Clinical features include night-time and daytime symptoms. Night-time symptoms are represented by loud snoring, apnoeic episodes ending with sonorous breathing resumption, nocturia, severe fatigue upon awakening, and sometimes headache. Daytime symptoms are dominated by excessive sleepiness, which varies in intensity among patients. Other symptoms include irritability, negligence, loss of concentration, loss of libido, impotence, and sometimes depression.

Patients are often obese or mildly obese. High blood pressure is a frequent feature. The ear, nose, and throat examination usually reveals a narrow upper airway due to close-set posterior tonsillar pillars, an abnormally long and hypotonic soft palate, a hypertrophic uvula, or macroglossia.

The positive diagnosis rests on polysomnography allowing the observation of nocturnal disrupted sleep and the identification of apnoeas and of their type (obstructive, central, or mixed) as well as their consequences on heart rate, oxygen desaturation, and degree of somnolence.

Of note, some subjects do not have apnoeas or hypopnoeas but increasing respiratory effort resulting in respiratory effort-related arousals (RERAs) and are believed to be as much at risk for complications. This state is most accurately identified with a quantative measurement of airflow and oesophageal manometry.

Obstructive sleep apnoea patients are at risk for systemic hypertension, occasional arrhythmias and conduction disturbances, cardiac or cerebral ischaemia, functional cognitive impairment, and depression. In a multicentre telephone survey carried-out in 1994–1999 in five European countries, among 18 980 subjects aged 15 to 100 years, 18 per cent of the individuals receiving a diagnosis of major depression also had a sleep-related breathing disorder and 17.6 per cent of the individuals receiving a diagnosis of sleep-related breathing disorder also had a diagnosis of major depression.[6]

There are several possible approaches to treatment:

- Weight loss may be beneficial. Avoidance of alcohol and sedatives should be recommended in all cases.
- Continuous positive airway pressure (CPAP) at night is the most widely used treatment. Good compliance requires proper preparation for the patient and an adaptation period.
- Oral appliances are suitable in mild obstructive sleep apnoea syndrome.
- Surgery consists mainly in nasal reconstruction in case of symptomatic airway blockade caused by bony, cartilaginous, or hypertrophied tissues that interfere with nasal breathing during sleep.

Hypersomnias of central origin

(a) Narcolepsy

First described in 1877[7] and given its name by Gelineau in 1880,[8] narcolepsy is now distinguished into three entities, narcolepsy with cataplexy, narcolepsy without cataplexy, and narcolepsy due to medical condition.

(i) Narcolepsy with cataplexy

Narcolepsy with cataplexy is not an exceptional condition. According to most recent evaluations its prevalence is 0.20 to 0.40 per 1000, i.e. slightly less than the prevalence of multiple sleep sclerosis.

Narcolepsy with cataplexy is characterized by two cardinal symptoms, excessive daytime sleepiness/irresistible sleep episodes and cataplexy, and other clinical features that are not necessarily part of the actual clinical picture.

Excessive sleepiness occurs daily. It comes in waves of varying degree of severity, depending on the individual, building up into irresistible and refreshing episodes of sleep. Excessive sleepiness is brought on by passive situations such as watching TV, being a passenger in a car, or attending a lecture. However it can also awkwardly occur in unexpected situations such as eating, walking, swimming, or driving a car. Excessive sleepiness may lead to automatic behaviour, such as saying totally inappropriate words or sentences, arranging objects in unlikely places, or driving a vehicle to an unintended destination.

Cataplexy is the most specific symptom. It consists of a sudden bilateral loss of voluntary muscle tone with preserved consciousness. It is triggered by environmental factors which are usually positive, such as a fit of laughter, receiving a compliment, humour expressed by the subject himself, the sight of prey for the hunter, the perception of a fish biting at the hook for the angler, a well-caught ball at tennis, or by anger, but almost never by stress or fear. All the striated muscles may be affected except the extra-ocular and respiratory musculature, leading to the progressive slackening of the whole body. More often however the attack is partial, involving certain muscles only, for example the jaw muscles, producing sudden difficulty in articulating words; the facial muscles, responsible for a grimace; or the thigh muscles, causing a brief unlocking of the knees. Consciousness is maintained during the episode. Cataplexy varies in duration from a split second to several minutes. Attack frequency varies from only a few per year, or even less, to several per day. In rare cases, especially after abrupt withdrawal of antidepressant medication, episodes of cataplexy may repeat themselves for minutes or hours, a state referred to as "status cataplecticus".

The other clinical features are deemed accessory to the extent that they are not indispensable for diagnosis.

Hallucinations, whether hypnagogic (at the onset of sleep) or hypnopompic (on awakening), are vivid perceptual experiences, not dreams, either visual, or auditory or kinetic. Patients may perceive someone entering and walking in the room, find themselves flying through the air or falling from a skyscraper. In some cases of unrecognized narcolepsy with daytime hypnagogic/hypnopompic hallucinations, the patient may be mistakenly diagnosed as having a delusional psychosis.

Sleep paralysis is a sudden inability to move during the transition from sleep to wakefulness or vice versa, while the subject is conscious. It is often accompanied by hypnagogic hallucinations. It is very unpleasant. In narcoleptic patients sleep paralysis may last up to 10 min.

Nocturnal sleep disruption occurs in approximately 50 per cent of cases, depending on age and the time elapsed since the onset of condition. The patient typically falls asleep as soon as he gets to bed, but his sleep is disturbed by recurring awakenings. He may complain of disturbing dreams.

REM-sleep behaviour disorder is frequent, either as a mere polysomnographic finding, excess of muscle tone or phasic EMG twitching activity during REM sleep, or as clinically significant complaint manifesting itself as an attempted enactment of distinctly altered, unpleasant, action-filled, and violent dreams in which the individual is being confronted, attacked, or chased by unfamiliar people. Periodic limb movements in sleep are more frequent than in normal subjects.

Physical examination is normal except for a frequently increased body mass index, especially in children at the onset of the condition. Noteworthy is the abolition of deep tendon reflexes during a cataplectic attack.

In a majority of cases, excessive daytime sleepiness is the first symptom to appear. In some patients, cataplexy occurs at the same time as excessive daytime sleepiness, but more often is delayed by one or several years. It is extremely rare for cataplexy to be the first clinical manifestation of narcolepsy with cataplexy.

The clinical diagnosis is based on clinical features. However, additional tests are highly recommended to confirm the diagnosis. The first test is polysomnography followed by an MSLT. At night a sleep onset REM period (SOREMP) is highly specific. It is observed in 25 to 50 per cent of cases. An increase in the amount of stage 1 NREM sleep and repeated awakenings are frequent findings. The MSLT shows a mean sleep latency of less than 8 min and two or more SOREMPs. However, some patients, especially in middle or old age, with clear-cut excessive daytime sleepiness and cataplexy, may have only one SOREMP, or even none during the MSLT procedure.

Today a CSF level of hypocretin-1 below 110 pg/mL is recognized as highly specific and sensitive for narcolepsy with cataplexy. However, up to 10 per cent of narcolepsy with cataplexy patients have normal levels of hypocretin-1.

There is no set pattern of evolution across patients. Excessive daytime sleepiness and irresistible episodes of sleep persist throughout life, but may diminish with age in some subjects. Cataplexy may spontaneously diminish with time or even totally disappear in some patients.

Narcolepsy is a very incapacitating disease. It interferes with every aspect of life. Education, performance at school and workplace, driving capability, recreational activities, interpersonal relationships, sexual life, and self-esteem. Depression is a frequent consequence of narcolepsy.

The mainstay of treatment is pharmacological although taking naps alleviates excessive sleepiness and refraining from emotion may prevent cataplexy.

Modafinil is the first-line treatment of excessive daytime sleepiness and irresistible episodes of sleep. Methylphenidate is less used today. Based on several large randomized controlled trials showing the activity of sodium oxybate on excessive daytime sleepiness and irresistible episodes of sleep, there is a growing practice in the United States to use it for the later indications. However, adverse effects including nausea, nocturnal enuresis, confusional arousals, malaise, and headache are not exceptional. Sodium oxybate is the only registered treatment for cataplexy. Other treatments are antidepressants, including tricyclics, selective serotonion reuptake inhibitors (SSRIS) and more recently new antidepressants such as venlafaxine or atomoxetine, the later being increasingly used despite few or non-randomized placebo-controlled clinical trials. As for disturbed nocturnal sleep the most widely used treatment is still hypnotics. However, the same randomized controlled trials have shown the activity of sodium oxybate against disturbed nocturnal sleep.

(ii) Narcolepsy without cataplexy

Narcolepsy without cataplexy is described as excessive daytime sleepiness and irresistible episodes of sleep unaccompanied by cataplexy. Automatic behaviour may be present as may hypnagogic hallucinations or sleep paralysis. Nocturnal sleep is usually less disturbed than in narcolepsy with cataplexy. When the subject is young, cataplexy may develop later in the course of the disorder.

Given the risk of overdiagnosing, a positive diagnosis of narcolepsy without cataplexy cannot be done without an all-night polysomnography followed by an MSLT documenting a mean sleep latency of less than 8 min and two or more SOREMPs.

(iii) Narcolepsy due to medical condition

As in the two previous categories, the patient has a complaint of excessive daytime sleepiness occurring almost daily for at least 3 months. However, the distinct feature of this subtype of narcolepsy is the existence of a significant underlying medical or neurological disorder accounting for the excessive daytime sleepiness and/or cataplexy.

According to the *ICSD*-2 the diagnosis of narcolepsy due to medical condition can be made only if one of the following is observed:

- a definite history of cataplexy
- a polysomnographic monitoring followed by an MSLT demonstrating a mean sleep latency of less than 8 min with two or more SOREMPs
- hypocretin-1 levels in the CSF lower than 110 pg/ml, provided the patient is not comatose.

In addition, a consistent chronological link with the presumed underlying disease must be established.

Narcolepsy due to a medical condition is extremely rare.

(b) Idiopathic hypersomnia

In comparison with narcolepsy, which is characterized by well-defined clinical, polysomnographic, and biochemical features, idiopathic hypersomnia is not as well delineated.

Its first description dates back to 1976,[9] almost a century after that of narcolepsy. According to various sleep disorders centres series populations the ratio of idiopathic hypersomnia to narcolepsy with cataplexy would be around 15 per cent.

Idiopathic hypersomnia includes two forms referred to as idiopathic hypersomnia with long sleep time and idiopathic hypersomnia without long sleep time. The first one is remarkable for three symptoms: a complaint of constant or recurrent excessive sleepiness and unwanted naps, usually longer and less irresitible than in narcolepsy, and non-refreshing irrespective of their duration; night sleep is sound, uninterrupted, and prolonged; morning or nap awakening is laborious. Subjects do not awaken to the ringing of a clock, of a telephone, and often rely on their family members who must use vigorous and repeated procedures to wake them up. Even then patients may remain confused, unable to react adequately to external stimuli, a state referred to as "sleep drunkenness" In contrast, idiopathic hypersomnia without long sleep time stands as isolated excessive daytime sleepiness.

The diagnosis of idiopathic hypersomnia is mainly based on clinical features. However, laboratory tests are necessary to rule out other hypersomniac conditions. Polysomnographic monitoring of nocturnal sleep demonstrates normal sleep, except for its prolonged duration in the case of idiopathic hypersomnia with long sleep time. NREM and REM sleep are in normal proportions. There is no SOREMP. Sleep apnoeas and periodic limb movements should theoretically be absent, but may be acceptable in the case of an early onset of idiopathic hypersomnia and of their late occurrence. The MSLT usually demonstrates a mean sleep latency less than 8 min, but is typically longer than in narcolepsy. Fewer than two SOREMPs are present. In cases with normal MSLT findings, several authors have suggested the use of long-term sleep monitoring to document the excessive amount of sleep.

In contrast with narcolepsy, onset of idiopathic hypersomnia is much more progressive. The disorder is generally stable and long lasting. Complications are mostly social and professional.

Treatment of idiopathic hypersomnia relies mainly on modafinil. However, awakening difficulties are hardly improved by this treatment.

(c) Recurrent hypersomnia

The most classic form of recurrent hypersomnia is the Kleine–Levin syndrome.[10] This is an uncommon disorder with roughly 300 cases published in the world literature. Adolescent males are most commonly affected.

The syndrome is characterized by recurrent episodes of hypersomnia associated with behavioural disorders including binge eating (rapid consumption of a large amount of food on a compulsory manner), oversexuality in the form of sexual advances, shamlessly expressed fantasies or masturbation in public, irritability, odd behaviours (like standing on the head, singing loudly, talking in a childish manner), and cognitive disorders, feeling of unreality, confusion, visual or auditory hallucinations. Simultaneous occurrence of all these symptoms is more the exception than the rule however. During the episode the patient may sleep as long as 14 to 18 h per day, waking or getting up only to eat and void.

Body weight gain of a few kilograms can be observed during the episode.

Amnesia of the episode, transient dysphoria, or elation with insomnia for 1 or 2 days, may follow the episode itself. During asymptomatic intervals patients sleep normally and do not experience behavioural or cognitive disorders.

Diagnosis of the Kleine–Levin syndrome is essentially clinical and laboratory tests merely serve to exclude the possibility of rare recurrent hypersomnias of secondary origin, organic, or psychiatric. Of note due to disordered behavioural features, especially hypersexuality, it is not rare that patients are first hospitalized on psychiatric wards and given antipsychotic drugs.

The course is usually benign with episodes lessening in frequency, duration, and severity. Complications are mainly social and occupational.

Treatment of the Kleine–Levin syndrome is not well codified. The effects of stimulant drugs such as modafinil or methylphenidate on the hypersomniac episodes are difficult to assess given that the methods of evaluation are purely subjective and that the episodes vanish spontaneously within a few days. A prophylactic treatment based on mood stabilizers (carbamazepine, lithium carbonate, and more recently valproic acid) deserves to be prescribed in severe cases. Positive results, that is absence of recurrence of the symptoms throughout the period of administration and recurrence with discontinuation, has been reported.

(d) Hypersomnias associated with various medical disorders

(i) Associated with neurological diseases

Hypersomnia may occur in any intracranial pressure syndrome, but it may also result from tumours affecting the diencephalon, specially the ventro-lateral posterior part of the hypothalamus or the peduncular region, with no associated intracranial hypertension. Cases of narcolepsy secondary to brain tumours affecting the hypothalamus or the midbrain region have been reported.

Uni or bilateral paramedian thalamic infarcts and paramedian pedunculo thalamic infarcts are the most typical causes of hypersomnia of vascular origin.

A non-negligible fraction of patients with Parkinson's disease present excessive sleepiness. This is even more the case of patients with multiple system atrophy.

Normal pressure hydrocephalus, Arnold–Chiari malformation, myotonic dystrophy, may also lead to excessive sleepiness.

(ii) Associated with infectious diseases

Intense fatigue and severe excessive sleepiness may develop in the month following Epstein–Barr disease. The same holds true of atypical viral pneumonia, hepatitis B viral infection and the Guillain–Barré syndrome. Hypersomnia tends to go into gradual remission after several months or years.

Disorders of alertness and/or consciousness are found in virtually all patients affected by viral encephalitis.

Human African Trypanosomiasis (sleeping sickness) is a subacute or chronic parasitic disease caused by the inoculation of a protozoan, *Trypanosoma brucei* transmitted by the tsetse fly. It is endemic to certain regions of tropical Africa. The form found in West and Central Africa is due to *Trypanosoma gambiense*. The invasion of the central nervous system is characterized by meningoencephalitis with abnormal sleepiness, headache, trembling, dyskenesia, choreoathetosis, and mood changes. Polysomnography has shown episodes of sleep occurring randomly day and night and SOREMPs.

(iii) Associated with endocrine diseases

Hypothyroidism and acromegaly are the two main sources of hypersomnia, usually due to obstructive sleep apnoea syndrome.

(iv) Post-traumatic hypersomnia

Excessive daytime sleepiness appearing during the year following a head injury may be considered *a priori* as post-traumatic. This typically presents as extended night sleep and episodes of daytime sleep. Brain imaging may reveal lesions affecting the hypothalamic region or brainstem, midbrain or pontine tegmentum, rarely hydrocephalia, or more often the absence of any significant lesions.

The delayed sleep phase syndrome

The major sleep episode is usually delayed 3 to 6 hours relative to conventional sleep-wake times. Affected individuals complain of great difficulty falling asleep at a socially acceptable time, but once sleep ensues, sleep is reported to be normal. Enforced conventional

wake time usually results in morning excessive sleepiness. The disorder has been associated with mental disorders, particularly in adolescents. Schizoid and avoidant personality features are frequently associated with this disorder.

Treatment rests on various approaches including chronotherapy, light exposure, and melatonin therapy.

Conclusion

Hypersomnia deserves to be taken into consideration by the psychiatrist. It may be the consequence of a psychiatric disorder or of its treatment, but it may also be non psychiatric in nature and result in psychiatric symptoms.

4.14.4 Parasomnias

Carlos H. Schenck, and Mark W. Mahowald

In all of us, even in good men, there is a lawless, wild-beast nature which peers out in sleep. –Plato, *The Republic*

Relevance of parasomnias to psychiatrists

Parasomnias are defined as undesirable physical and/or experiential phenomena accompanying sleep that involve skeletal muscle activity (movements, behaviours), autonomic nervous system changes, and/or emotional-perceptual events.[1] Parasomnias can emerge during entry into sleep, within sleep, or during arousals from any stage of sleep; therefore, all of sleep carries a vulnerability for parasomnias.[1] Parasomnias can be objectively diagnosed by means of polysomnography (i.e. the physiologic monitoring of sleep—figures 4.14.4.1, 4.14.4.2), and can be successfully treated in the majority of cases.[2–5] Understanding of the parasomnias, based on polysomnographic documentation, has expanded greatly over the past two decades, as new disorders have been identified, and as known disorders have been recognized to occur more frequently, across a broader age group, and with more serious consequences than previously understood.[1–10] Parasomnias demonstrate how our instinctual behaviours, such as locomotion, feeding, sex, and aggression, can be released during sleep, itself a basic instinct. There are at least eight reasons why parasomnias should be of interest and importance to psychiatrists:

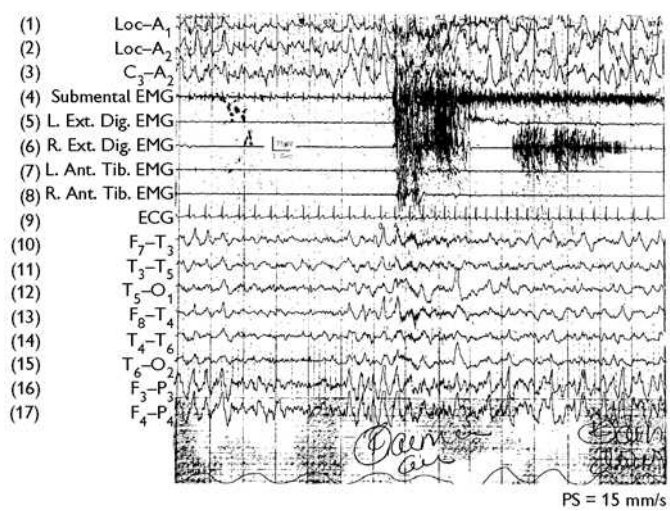

Fig. 4.14.4.1 Polysomnogram of a disordered arousal, with the persistence of sleep, in a 23-year-old man with a history of sleepwalking and sleep terrors. After a behavioural arousal from slow-wave sleep (with arm lifted up and then down), the EEG shows irregular delta and theta activity and superimposed faster frequencies. Immediately preceding the arousal, there is a cluster of three high-amplitude delta waves (channel 3). Electro-occulogram, channels 1. 2; EEG, channels 3, 10–17; EMG, electromyogram. (Reproduced from C.H. Schenck *et al.* Analysis of polysomnographic events surrounding 252 slow-wave sleep arousals in thirty-eight adults with injurious sleepwalking and sleep terrors. *Journal of Clinical Neurophysiology*, **15**, 159–66, copyright 1998, American Clinical Neurophysiology Society)

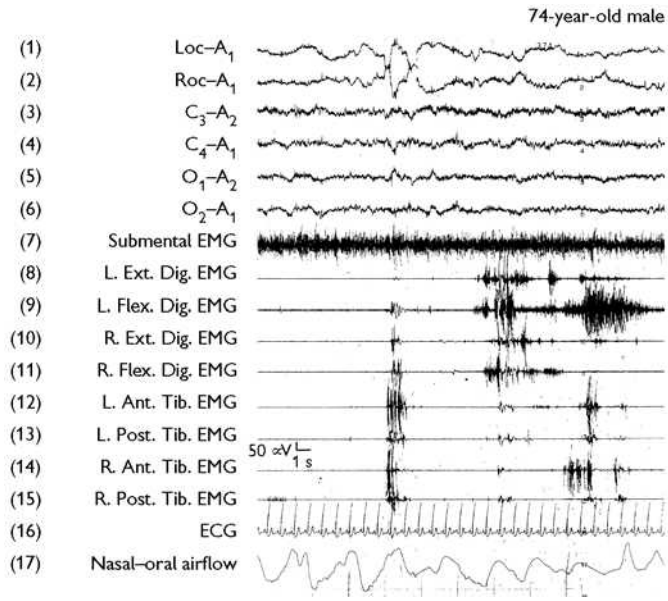

Fig. 4.14.4.2 Polysomnogram of disordered rapid eye movement (REM) sleep in a man with REM sleep behaviour disorder who eventually developed Parkinson's disease. There is complete loss of 'REM-atonia', as the submental electromyogram (EMG) shows continuous muscle tone (channel 7). The appearance of a rapid eye movement (channels 1, 2) signals the onset of excessive muscle twitching in the upper/lower extremity EMGs (channels 8–15). The EEG (channels 3–6) shows the typical low-voltage fast-frequency desynchronized activity of REM sleep. ECG rate (channel 16) remains constant despite generalized muscle twitching, which is a common finding in REM sleep behaviour disorder. Elecro-oculogram: channels 1,2.

1 Parasomnias can be misdiagnosed and inappropriately treated as a psychiatric disorder.

2 Parasomnias can be a direct manifestation of a psychiatric disorder, e.g. dissociative disorder, nocturnal bulimia nervosa.

3 The emergence and/or recurrence of a parasomnia can be triggered by stress.

4 Psychotropic medications can induce the initial emergence of a parasomnia, or aggravate a preexisting parasomnia.

5 Parasomnias can cause psychological distress or can induce or reactivate a psychiatric disorder in the patient or bed partner on account of repeated loss of self-control during sleep and sleep-related injuries.

6 Familiarity with the parasomnias will allow psychiatrists to be more fully aware of the various medical and neurological disorders, and their therapies, that can be associated with disturbed (sleep-related) behaviour and disturbed dreaming.

7 Parasomnias present a special opportunity for interlinking animal basic science research (including parasomnia animal models) with human (sleep) behavioural disorders.

8 Parasomnias carry forensic implications, as exemplified by the newly-recognized entity of 'Parasomnia Pseudo-suicide.' Also, psychiatrists are often asked to render an expert opinion in medicolegal cases pertaining to sleep-related violence.

Classification of parasomnias

Parasomnias can be classified according to whether the signs or symptoms are primary phenomena of sleep itself, or whether they are secondary phenomena derived from various underlying disorders, with sleep facilitating the nocturnal manifestation of these disorders.[6] Table 4.14.4.1 contains such a classification, and provides a context (along with other current sources[1,11]) for the parasomnias to be discussed in this chapter. Parasomnias demonstrate how sleep and wakefulness are not mutually exclusive states. Features of rapid eye movement (REM) sleep, non-REM sleep and wakefulness can occur simultaneously, and with rapid oscillations.[12] Status dissociatus represents the most extreme form of state dissociation.[13]

Clinical evaluation of parasomnias

The evaluation of complex and violent nocturnal behaviours at our centre (Minnesota Regional Sleep Disorders Center) includes the following:[2,14]

1 Clinical sleep-wake interview, with review of medical records, and review of a patient questionnaire that covers sleep-wake, medical, psychiatric and alcohol/chemical use and abuse history, review of systems, family history, and past or current physical, sexual, and emotional abuse.

2 Psychiatric and neurologic interviews and examinations, including psychometric testing.

Table 4.14.4.1 Classification of parasomnias: primary and secondary sleep phenomena

Primary sleep phenomena
Non-REM sleep
Disorders of arousal: sleepwalking/sleep terrors/confusional arousal
REM sleep
REM sleep behaviour disorder (RBD)
Dream anxiety attacks (nightmares)
Miscellaneous (including mixed non-REM/REM sleep)
Parasomnia overlap disorder (sleepwalking/sleep terrors/RBD)
Sleep related eating disorder
Restless legs syndrome/periodic limb movements in sleep
Obstructive sleep apnoea-related parasomnias
Rhythmic movement disorders
Status dissociatus
Bruxism
Secondary sleep phenomena
Central nervous system
Seizures (conventional, unconventional)
Headaches
Psychiatric
Nocturnal dissociative disorders
Nocturnal panic attacks
Nocturnal bulimia nervosa
Post-traumatic stress disorder
Cardiopulmonary (arrhythmias, asthma, etc.)
Gastrointestinal (gastro-oesophageal reflux etc)
Malingering

Modified from Mahowald and Ettinger.[7]

3 Extensive overnight polysomnographic monitoring at a hospital sleep laboratory, with continuous audio-visual recording. Figures 4.14.4.1, 4.14.4.2 depict the polysomnographic montage that includes the electro-oculogram, EEG, chin and four-limb electromyograms, ECG, and nasal-oral airflow (with full respiratory monitoring whenever indicated). Polysomnographic recording speeds of 15 to 30 mm/s are employed in order to detect epileptiform activity. Urine toxicology screening is performed whenever indicated.

4 Daytime multiple sleep latency testing, if there is a complaint or suspicion of excessive daytime sleepiness or fatigue (methods discussed in Narcolepsy chapter).

Causes of sleep related injury

A report on a series of 100 consecutive adults presenting to a multidisciplinary sleep disorders centre on account of sleep-related injury identified five causes:[2]

1 Sleepwalking/sleep terrors (M:F 3:2; mean age of onset, 5 years);

2 REM sleep behaviour disorder (predominantly male; mean age of onset, 57 years)

3 Dissociative disorders (Mostly female mean age of onset, 21 years)

4 Nocturnal seizures (uncommon)

5 Obstructive sleep apnoea/periodic limb movements (uncommon).

The sleep-related injuries included ecchymoses, lacerations, and fractures in 95 per cent, 30 per cent, and 9 per cent of patients respectively.

Non-REM sleep parasomnias: sleepwalking and sleep terrors

The polysomnographic correlates of sleepwalking and sleep terrors were first identified in the 1960s and 1970s by Gastaut and Broughton,[15, 16] Kales *et al.*,[17] and Fisher *et al.*[18] from France, Canada, and the United States. Sleepwalking and sleep terrors are classified as 'disorders of arousal,' and typically arise from delta non-REM (slow wave) sleep and usually affect children, but adults can also be afflicted, and suffer from sleep-related injuries and adverse social consequences.[2,9,10,19–24]

Clinical findings

Sleepwalking (SW) is characterized by complex, automatic behaviours, such as aimlessly wandering about, nonsensically carrying objects from one place to another, rearranging furniture, eating inappropriately, urinating in cupboards, going outdoors, and on rare occasion, driving a car.[1,25,26] The eyes are usually wide open and have a glassy stare, and there may be some mumbling. However, communication with a sleepwalker is usually poor or impossible. Frenzied or aggressive behaviour, the wielding of weapons (knives, guns), or the calm suspension of judgement (e.g. leaving via a bedroom window, wandering far outdoors) can result in inadvertent injury or death to self or others. Homicidal sleepwalking can occur.[25]

Sleepwalking episodes usually emerge 15–120 minutes after sleep onset, but can occur throughout the entire sleep period in adults. The duration of each episode can vary widely. The following is a wife's description.[2]

'He seems to have the strength of 10 men and shoots straight up from bed onto his feet in one motion. He's landed clear across the room on many occasions and has pulled down curtains (bending the rods), upset lamps, and so forth. He's grabbed me and pulled on me, hurting my arms, because he's usually dreaming that he's getting me out of danger . . . He's landed on the floor so hard that he's injured his own body . . . There are low windows right beside our bed and I'm afraid he'll go through them some night.'

Sleep terrors (ST) are characterized by sudden, loud, terrified screaming and prominent autonomic nervous system activation (tachycardia, tachypnea, diaphoresis, mydriasis) that usually appears early in the sleep period, although episodes in adults can occur at any time of the night. The individual may sit up rapidly while screaming, and engage in frenzied activity, such as bolting out of bed, and becoming injured.

Childhood sleepwalking and sleep terrors are characterized by complete amnesia for the events. In adult SW and ST, there can be subsequent recall of the behavioural episode, and also recall of dream-like mentation that usually involves being threatened by imminent danger.[2,27] The distinction between ST and agitated SW in adults is often blurred, with both states being admixed in response to a perceived threat.[24]

The prevalence of SW has been estimated to be as high as 17 per cent in childhood (peaking at age 4–8), and recent data indicate a higher prevalence in adults (4 per cent) than previously recognized.[28–30] The prevalence of ST in children can be greater than 6 per cent and greater than 2 per cent in adults.[1] A familial-genetic basis for SW and ST has been well-established.[30,31] Non-injurious SW does not have a gender preference,[1] although injurious SW appears to be more male-predominant.[2] Sleep terrors do not have a gender preference.[1] 'Confusional arousals' comprise another category of 'disorder of arousal,' and represent partial manifestations of sleepwalking and sleep terrors in which aggression and sexual impulses can be released.[1,10]

Polysomnographic findings

Sleepwalking/sleep terrors episodes arise abruptly during arousals from delta non-REM sleep.[1,15–18] In a systematic study of 38 adults with injurious SW/ST,[24] three postarousal EEG patterns were detected: diffuse, rhythmic delta activity; diffuse delta and theta activity intermixed with alpha and beta activity; and prominent alpha and beta activity. Thus, the postarousal EEG can show the complete persistence of sleep, the admixture of sleep and wakefulness, or complete wakefulness. Figure 4.14.4.1 shows the polysomnogram of a disordered arousal from slow-wave sleep.

Although the sleep architecture (i.e. distribution of sleep stages) is usually normal in SW and ST, the 'micro-structure' of non-REM sleep in adult SW/ST can be perturbed, with increased micro-arousals and increased rate of the 'cyclic alternating EEG pattern'.[1,2,21,23]

Association with medical and psychiatric risk factors

Sleepwalking and sleep terrors may be triggered by sleep deprivation, febrile illness, alcohol use or abuse, pregnancy, menstruation, obstructive sleep apnea, periodic limb movements, nocturnal

seizures, medical and neurological disorders, and psychotropic medications—especially zolpidem, lithium carbonate and anticholinergic agents.[1]

A strong association between sleepwalking/sleep terrors and psychopathology in adults was suggested by an early literature, but polysomnograpic monitoring was not conducted, and there were considerable methodological problems. The recent literature reporting PSG-confirmed cases has indicated that most adult cases are not closely associated with a psychiatric disorder, although stress can play a promoting role[2,19,29,22,32]. Genetic-constitutional factors appear to be predominant in adult and childhood sleepwalking/sleep terrors.[1]

Treatment

Treatment (especially in childhood SW/ST) is usually not necessary, other than identifying and minimizing any identified risk factors, and safety measure to avoid accidental injury. In cases involving sleep-related injury, pharmacological treatment is necessary and can be life-saving. A benzodiazepine, such as clonazepam (0.25–1.5 mg) taken 1 hour before sleep onset is usually effective. Alprazolam, diazepam, imipramine, and paroxetine can also be used. Teaching a patient self-hypnosis can be effective in milder cases of either adult or childhood SW/ST.[33] Treatment of any concurrent psychiatric disorder does not usually control sleepwalking/sleep terrors.[2,22] Attempts to waken the patient may cause confusion and distress.

REM sleep behaviour disorder (RBD)

Although various aspects of RBD have been identified by European, Japanese and American investigators since 1966,[34] RBD was not formally recognized and named until 1986–1987,[35,36] and it is incorporated within the international classification of sleep disorders.[1] A typical clinical presentation of RBD is contained in the description of the index case:[35]

> 'A 67-year-old dextral man was referred because of violent behavior during sleep . . . 4 years before referral . . . he experienced the first 'physically moving dream' several hours after sleep onset; he found himself out of bed attempting to carry out a dream. This episode signaled the onset of an increasingly frequent and progressively severe sleep disorder; he would punch and kick his wife, fall out of bed, stagger about the room, crash into objects, and injure himself . . . his wife began to sleep in another room 2 years before referral. They remain happily married, believing that these nocturnal behaviors are out of his control and discordant with his waking personality.'

Mammalian REM sleep, REM atonia, and paradox lost

REM sleep in mammals involves a highly energized state of brain activity, with both tonic (i.e. continuous) and phasic (i.e. intermittent) activations occurring across a spectrum of physiologic parameters.[36] REM sleep has two major synonyms: 'active sleep,' because of the high level of brain activity during REM sleep, and 'paradoxical sleep,' because of the nearly complete suppression of muscle tone despite the high level of brain activity. This generalized skeletal muscle atonia ('REM-atonia') is one of the three defining features of mammalian REM sleep, besides rapid eye movements and a desynchronized EEG. The loss of the customary paradox of REM sleep in RBD bears serious clinical consequences: 'paradox lost' means loss of safe sleep.[9]

Animal model of RBD

In 1965, Jouvet and Delorme reported from France that experimental pontine lesions in cats caused permanent loss of REM-atonia, and the cats displayed attack and exploratory behaviours during REM sleep that resembled dream-enactment (oneirism). This experiment established the first animal model of RBD.[34]

Clinical and polysomnographic findings

Between 1982 and 1991, 96 patients at our centre were diagnosed with chronic RBD. (There is an acute form of RBD that can emerge during withdrawal from ethanol or sedative-hypnotic abuse and with anti-cholinergic and other drug intoxication states.[36] Data on this series[37] are contained in Table 2, and are concordant with the published world literature.[34,36] The older male predominance in RBD is striking, although females and virtually all age groups are represented. Approximately half of RBD cases are closely associated with neurological disorders, predominantly neurodegenerative disorders (especially parkinsonism), narcolepsy and stroke. In fact, RBD may be the first sign of a parkinsonian disorder whose other (classic) manifestations may not emerge until several years or even decades after the onset of RBD.[36,38,39] Thus, routine neurological evaluations are indicated in the long-term management of RBD. The prevalence of RBD is estimated to be from 0.38 per cent to 0.5 per cent.[1] The course is usually progressive; spontaneous

Table 4.14.4.2 Findings in 96 patients with chronic REM sleep behaviour disorder (RBD)

Categories	Percentage (*N*)	Comments
Gender		
Male	87.5 (84)	Mean age of RBD onset (*N* = 90): 52 years (range 9–81)
Female	12.5 (12)	Mean age at polysomnography: 58 years (range 10–83)
Chief complaint		
Sleep injury	79.2 (76)	Ecchymoses (76); lacerations (32); fractures (7)
Sleep disruption	20.8 (20)	
Altered dream process and content	87.5 (84)	More vivid, intense, action filled, violent (reported as severe nightmares)
Dream-enacting behaviours	87.5 (84)	Talking, laughing, yelling, swearing, gesturing, reaching, grabbing, arm flailing, punching, kicking, sitting, jumping out of bed, crawling, running
Clonazepam treatment		
Efficacy (*N* = 67)		
Complete	79.1 (44/67)	Rapid control of problematic sleep behaviours *and* altered dreams, sustained for up to 9 years
Partial	11.9 (8/67)	
Total	91.0 (61/67)	

Modified from Schenck *et al.*[36]

remissions are very rare. Patients with RBD usually have calm and pleasant personalities, and do not display irritability or anger while awake, even though their dreams are highly aggressive.[40] Figure 4.14.4.2 depicts a typical polysomnogram of RBD with attempted dream-enactment.

Association of RBD with psychiatric disorders and Stress

Psychiatric disorders are rarely associated with RBD.[34,41] Fluoxetine treatment of obsessive compulsive disorder,[42] or cessation of use or abuse of REM-suppressing agents (viz. ethanol, amphetamine, cocaine, imipramine) can trigger RBD.[36,43] Tricyclic antidepressants, selective serotonin reuptake inhibitors, venlafaxine, mirtazapine, and monoamine oxidase inhibitors can induce or aggravate RBD. In four cases, major stress involving divorce, automobile accident, sea disaster, or public humiliation triggered RBD.[2,34,43]

Diagnosis of RBD

The diagnostic criteria of RBD are as follows:[1,36]

1 Polysomnographic abnormality during REM sleep: elevated submental electromyographic tone and/or excessive phasic submental and/or limb electromyographic twitching.

2 Documentation of abnormal REM sleep behaviours during polysomnographic studies, or a history of injurious or disruptive sleep behaviours.

3 Absence of EEG epileptiform activity during REM sleep.

Treatment of RBD

Clonazepam is remarkably effective in controlling both the behavioural and the dream-disordered components of RBD, at a usual bedtime dose of 0.5 to 1.0 mg. The long-term efficacy and safety of chronic, nightly clonazepam treatment of RBD has been established.[3] Other treatments include melatonin, pramipexole, etc.[36] Maximizing the safety of the sleeping environment should always be encouraged.

Parasomnia overlap disorder: sleepwalking/ sleep terrors/RBD

A group of 33 patients has been reported with polysomnogram-documented sleepwalking, sleep terrors, and RBD.[8] The mean age was 34 years, the mean age of parasomnia onset was 15 years (range: 1–66), and 70 per cent were male. An idiopathic subgroup (N=22) had a significantly earlier mean age of parasomnia onset (9 years) than a symptomatic subgroup (27) whose parasomnia began with either a neurologic disorder (N=6), nocturnal paroxysmal atrial fibrillation (N=1), post-traumatic stress disorder/ major depression (N=1), chronic ethanol/amphetamine abuse and withdrawal (N=1), or mixed disorders (schizophrenia; brain trauma; substance abuse [N=2]). The rate of psychiatric disorders was not elevated; group scores on various psychometric tests were not elevated. Forty-five percent (N=15) had previously received psychologic or psychiatric therapy for their parasomnia, without benefit. Treatment, usually with clonazepam, was effective for most patients. The natural history of this disorder is not yet known. Other cases of Parasomnia Overlap Disorder have been reported.[34,36]

Sleep related eating disorder

The 'night-eating syndrome' was first reported in 1955, and featured abnormal eating during full wakefulness in insomniac patients. Over the next 35 years, abnormal nocturnal eating received scant attention in the literature, until a series of 19 cases (expanded to 38 cases) with polysomnographic data was published on the new entity of sleep related eating disorder,[1,4,44] which featured abnormal eating during partial arousals from sleep in patients with other parasomnias or those who were idiopathic. Reports from various countries have now been published.[45–49]

Clinical findings

Pathological sleep-related eating has characteristic features, as identified in two separate series of adult cases.[4,44,48] Neither daytime binge-eating nor obsessive-compulsive disorder was diagnosed in any patient. Sleep-related eating was not associated with either the onset or the course of a psychiatric disorder. Patients do not usually experience hunger or thirst during their 'driven' nocturnal eating and drinking. A typical behavioural sequence consists of 'automatic' arising from bed, and going straight to the kitchen with a compulsive 'out of control' urge to eat. Alcohol is almost never consumed, even in former alcohol abusers. Thick substances, such as milkshakes, peanut butter, and brownies, are preferentially consumed at night. Purging does not take place, either at night or in the morning. Sleep-related eating is usually invariant, and is not influenced by day of the week or sleeping away from home. More than 40 per cent of patients in one series were overweight from the nocturnal eating, according to standardized body mass index criteria.[4]

Sleep related eating is most commonly associated with sleepwalking, but also with restless legs syndrome, obstructive sleep apnoea, narcolepsy, zolpidem/triazolam/midazolam/other psychotropic medication use or abuse, cessation of cigarette smoking, cessation of alcohol, opiate and cocaine abuse; cessation of cigarette smoking; stress (particularly involving separation anxiety), and various medical/neurological disorders (e.g. autoimmune hepatitis, encephalitis, migraines). Rarely, anorexia or bulimia nervosa or a dissociative disorder can be associated with sleep-related eating.[45]

Prescribing a monoamine oxidase inhibitor to a patient with sleep related eating disorder can be hazardous, since indiscriminate food consumption at night could jeopardize the mandatory dietary restrictions of MAOI treatment.

Treatment

Treatment, with one notable exception, is primarily directed at controlling the underlying sleep disorder. For cases associated with restless legs syndrome, therapy with dopaminergics (at times supplemented with an opiate such as codeine) is usually effective; likewise, therapy of obstructive sleep apnoea with nasal continuous positive airway pressure is often effective in controlling the sleep related eating. In contrast, in cases that are idiopathic and in those cases associated with sleepwalking, therapy with the anticonvulsant topiramate (that suppresses overeating urges) was effective in two-thirds of cases in two reported series.[5,50]

Sleep related eating disorder shares many features in common with the 'night eating syndrome' in adults,[49,51] although there are usually major differences in regards to level of consciousness during nocturnal eating, association with other sleep disorders,

and response to therapy. It is likely that these two conditions sit at opposite poles of a spectrum of abnormal nocturnal eating.

Sleep related dissociative disorders

A nocturnal dissociative disorder with polysomnographic monitoring was first reported in 1976 by Rice and Fisher in a man with daytime and night-time fugues that began after his father's death.[52] Another polysomnogram-documented case was described in a woman with a history of being physically and sexually assaulted.[1] A series of eight cases was reported from our centre in 1989.[53]

Clinical manifestations

The onset may be sudden or gradual, and the course is chronic. There usually is a history of repeated physical and sexual abuse in childhood and/or adulthood. In a series of eight cases, seven were female who also had daytime states of dissociation with self-mutilating behaviours, such as genital cutting, self-burning, and punching through windows.[53] One male patient had exclusively nocturnal episodes in which he acted like a jungle cat. Patients may report sleep phobia as a consequence of bed-related and sleep-related sexual and physical abuse.

A typical spell during polysomnographic monitoring involves complex and lengthy behaviours that emerge during well-established EEG wakefulness, after a prior episode of sleep.[53] The nocturnal episodes appear to be re-enactments of previous assaults.

Treatment

Treatment involves long-term therapy of the dissociative disorders and of associated psychiatric disorders, usually initiated in a specialized in-patient setting. Bedtime administration of benzodiazepines may aggravate a nocturnal dissociative disorder.

Restless legs syndrome (RLS)

RLS, first described in 1945 by Ekbom from Sweden, is a chronic disorder that often results in severe insomnia, and can be incapacitating.[1,54] It is characterized by unpleasant and at times painful sensations in the lower extremities that emerge during periods of inactivity, particularly during the transition from wakefulness to sleep. These abnormal sensations are relieved by movement or stimulation of the legs, such as walking, stomping the feet, rubbing or squeezing the legs, taking hot showers, or applying hot packs or ointments to the legs.

Both the RLS and the therapeutic interventions just described are incompatible with successful entry into sleep. The more severely affected individuals cannot easily sit still while watching television or a film, or during protracted plane or train journeys. RLS is quite common, affecting up to 10 per cent of the general population, and tends to become more prevalent with increasing age. It affects females more than males. Childhood cases, though rare, at times may masquerade as 'attention deficit disorder with hyperactivity,' or as 'growing pains.'

Most RLS cases are idiopathic with a strong familial basis. Caffeine, fatigue, or stress may worsen the symptoms. There is no evidence that RLS is related to psychiatric disorders, although the symptoms of RLS may suggest a primary anxiety disorder and through impairment of the duration and quality of sleep it can affect daytime mood and behaviour. Also, neuroleptic-induced akathisia can mimic RLS. Secondary RLS can be associated with peripheral neuropathies, renal disease, and psychotropic medications (especially the SSRIs, venlafaxine, and tricyclic antidepressants).

Nearly all patients with RLS have 'periodic limb movements' (PLMs) of non-REM sleep (formerly called 'nocturnal myoclonus'). PLMs are characterized by periodic (every 15–40 sec) movements of the legs, viz. slow dorsi-flexion, which may or may not be associated with arousals. Excessive arousals during sleep from any cause, including PLMs, may result in daytime fatigue or sleepiness.

RLS can usually be diagnosed by history alone, and polysomnographic monitoring is usually not indicated. The syndrome is one of the major organic causes of insomnia, and commonly responds to treatment that includes use of dopaminergics (e.g. pramipexole, ropinerole, levodopa), opiates, and benzodiazepines (e.g. clonazepam). Combinations of these drugs are often necessary. Since RLS is a chronic disorder that often worsens with advancing age, chronic long-term treatment is usually warranted.

Differential diagnosis of dream-enacting behaviours and other parasomnias

A history of dream-enacting behaviours does not automatically implicate RBD. Other diagnoses include sleepwalking/sleep terrors;[2,9] obstructive sleep apnoea, with apnoea-induced arousals from REM sleep being associated with violent behaviours and vivid REM-related dreams;[2,55] nocturnal complex seizures, with the 'dreams' being the seizure equivalents;[34] sleep related dissociative disorders, with the 'dreams' being wakeful memories of past abuse;[53] intoxication states; and malingering.

Other parasomnias of interest to psychiatrists include sexual parasomnias ('sleepsex', 'sexsomnia'),[10] nocturnal panic attacks, which arise from Stages II and III non-REM sleep,[56] sleep related trichotillomania, nocturnal frontal lobe epilepsy,[11] and rhythmic movement disorders of non-REM and REM sleep, including head-banging and body rocking. Finally, expanded knowledge on the parasomnias has allowed for the recognition of a new medical-legal entity called 'parasomnia pseudo-suicide'.[58] This term refers to the unfortunate, but unintentional, fatal consequence of complex, sleep-related behaviours that may be erroneously attributed to suicide.[1]

Forensic guidelines for psychiatrists

The legal implications of automatic behaviour have long been discussed and debated. With regard to sleep-related automatic behaviours, the objective identification of a sleep disorder does not establish causality for any given deed. Guidelines have been developed to assist in determining the role of a sleep disorder in an act of violence.[57]

- There should be reason (by history or by formal sleep laboratory evaluation) to suspect a bona fide sleep disorder. Similar episodes, with benign or morbid outcome, should have occurred previously. (Note that disorders of arousal may begin in adulthood).
- The duration of the action is usually brief (minutes).
- The behaviour is usually abrupt, immediate, impulsive, and senseless—without apparent motivation. Although ostensibly

purposeful, it is completely inappropriate to the total situation, out of (waking) character for the individual, and without evidence of premeditation.

- The victim is someone who merely happened to be present and who may have been the stimulus for the arousal.
- Immediately after return to consciousness, there is perplexity or horror, without an attempt to escape, conceal, or cover up the action. There is evidence of lack of awareness on the part of the individual during the event.
- There is usually some degree of amnesia for the event, however, this amnesia may not be complete.
- In the case of ST or SW or sleep drunkenness, the act may (a) occur on awakening, (rarely immediately upon falling asleep) and usually at least 1 hour after sleep onset; (b) occur on attempts to awaken the subject; and (c) have been potentiated by alcohol ingestion, sedative or hypnotic administration or prior sleep deprivation.

The American Academy of Neurology and other professional organizations have developed guidelines for expert witnesses, with the most stringent being as follows.

- The expert should be willing to submit his or her testimony for peer review.
- The expert must be impartial and be willing to prepare his or her testimony for use by either or both the plaintiff or defendant. Ideally, the expert should assume the role of 'friend of the court.'

4.15.1 Epidemiology and causes of suicide

Jouko K. Lonnqvist

Definition of suicide and the reliability of suicide statistics

Suicidal behaviour or suicidality can be conceptualized as a continuum ranging from suicidal ideation and communications to suicide attempts and completed suicide. A developmental process which leads to suicidal ideation, suicidal communication, self-destructive behaviour, in some cases even to suicide, and its consequences to the survivors is often referred to as a suicidal process. There is no single unanimously accepted definition of suicide, although in most proposed definitions it is considered as a fatal act of self-injury (self-harm) undertaken with more or less conscious self-destructive intent, however vague and ambiguous. Since the deceased cannot testify as to his or her intent, the conclusions about this must be drawn by inference. The evidence required for this inference depends on many factors, for example the mode of death, the use of autopsy, age, gender, social and occupational status, and the social stigma of suicide in the person's culture. The assessment of suicide intent is always based on a balance of probabilities.

Besides the conceptual problems, there are differences in operational definitions of suicidal behaviour which may lead to lack of uniformity of case definition and difficulties in comparing suicide statistics. The reliability of suicide statistics is influenced by whether suicide is ascertained by legal officials as in the United Kingdom and Ireland, or by medical examiners as elsewhere in Europe. In general, suicides tend to be undercounted, whereas non-suicidal deaths are very rarely misidentified as suicides. Most misclassified suicides fall into the category of undetermined deaths and are more like suicides than accidents. Underestimation is reasoned to be less than 10 per cent in the more developed countries, which allows rate comparisons between countries and over time. Despite problems in the recording of suicide, reports on suicide rates among different cultures or people suggest a true variation in suicide mortality.[1,2]

The suicide process and the act of suicide

Suicide is a mode of death usually consequent to a complex and multifaceted behaviour pattern. It is typically seen as the fatal outcome of a long-term process shaped by a number of interacting cultural, social, situational, psychological, and biological factors. Suicide is a rare, shocking, and very individual final act, which often leaves the survivors helpless. The suicide process model is used to organize and clarify the complexity of factors associated with suicide (Fig. 4.15.1.1).

Suicide is usually preceded by years of suicidal behaviour or feelings, and plans and warnings. In about half of all suicides, a previous attempt is found in the person's history, which offers, in theory, an opportunity for suicide intervention wherever suicide attempts occur. Male suicide attempts are more violent and the first attempt more likely to end in death. Successful suicide prevention calls for sensitive understanding of suicidal intent and active early intervention.[3]

Various risk or protective factors underlie suicidal behaviour. An appearance of suicidality means either an intensified effect of risk factors or a weakened effect of protective factors. For example, a separation from someone close may precipitate a suicidal imbalance in a vulnerable person due to the adverse life event as a stressor and the broken social network as a loss of social support.

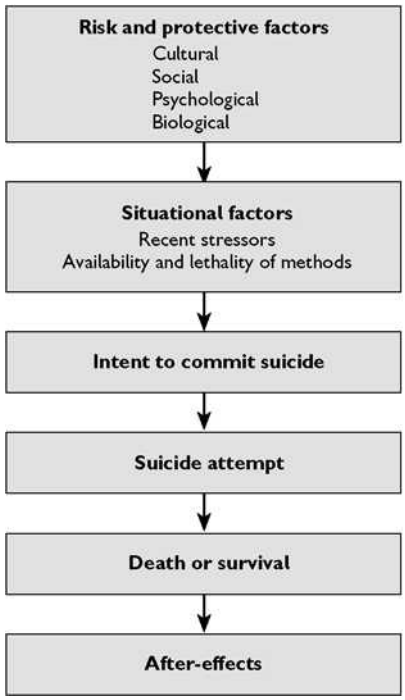

Fig. 4.15.1.1 The suicide process model.

The treating personnel and relatives of the suicide victim tend to overemphasize the meaning of the most recent events in the course of the suicide process. A precipitating factor may well be decisive in explaining the precise timing of suicide in the long course of a person's suicide process. Often, however, it also allows a simple and rational explanation in the face of the complexity of suicide.

The choice of a specific method takes place at the very end of the suicide process and represents the last possibility to intervene. Hanging is universally available and it is the most common suicide method globally. In many countries the ready access to firearms makes them potentially dangerous, especially among male adolescents and young adults. Restricting access to handguns might be expected to reduce the suicide rate of young people. Previously, domestic gas was frequently used as a suicide method, and detoxification resulted in a significant decrease in suicide rates. Nowadays, the increasing suicide rate in many Asian societies has been largely linked with pesticides and other poisons. Restrictive availability of lethal measures may also be important in the clinical treatment of individual suicidal patients. Restriction in availability of dangerous means is a strategy based on the fact that suicidal crises are often brief, suicidal acts are often impulsive, and the long-term suicide rate of serious suicide attempts is remarkably low.[4–6]

Firearms, carbon monoxide, and hanging are active suicide methods with the highest potential to cause death. Jumping from a height or leaping in the front of a moving vehicle are more passive ways, but are also highly damaging in nature. Poisoning, drowning, or wrist cutting are typically methods which leave more time for help seeking and intervention.

Imitation means learning the use of a specific suicide method from a model which is overtly available in a culture, community, institution, or mass media. Imitation may have a significant effect on the choice of a suicide method, especially at schools, in psychiatric hospital wards, and in the general population of young people. The most famous example of imitation is the effect of Goethe's novel *The Sorrows of Young Werther*, which was widely read in Europe about 200 years ago. The suicide of the hero was imitated to such an extent that authorities in several European countries banned the novel. The 'Werther effect' also appeared after the death of Marilyn Monroe; the suicide rate rose about 10 per cent over the next 10 days. Recommendations for reporting of suicide have encouraged avoidance of repetitive and excessive reports, descriptions of technical details, simplified explanations for suicide, presenting suicide as means of coping with personal problems, or glorifying suicide victims.[7]

Most suicides are solitary and private, but a few result from a pact between people to die together. Suicide pacts are exceptional, accounting for less than 1 per cent of all suicides.

Suicide always has a major impact on the survivors. Suicide is a threatening event not only among close family members, but also in the surrounding population, including treating personnel and the people at the victim's workplace. The major challenges after a suicide, in addition to a normal mourning process, are dealing with shame and guilt feelings, and the crisis of survivors. Sharing of the traumatic experience and social support should be arranged immediately and continued, if necessary, at least some months after the suicide.

Epidemiology and public health aspects of suicide

Every year one million people commit suicide, accounting for 1 to 2 per cent of total global mortality. Suicide is a leading cause of premature death, especially among young adults. It is the fifth highest cause of years of life lost in the developed world. In many westernized countries, suicide is a more frequent cause of death than traffic accidents. According to World Health Organization (**WHO**) statistics, the annual world-wide incidence of completed suicide was 16 per 100 000 persons in 2000. This means that globally one person commits suicide every minute. Suicide is estimated to represent two per cent of the total global burden of disease.

The long-term trend in suicide mortality has been increasing at least during the last 50 years. The rank order of suicide mortality in the European region in 2001 to 2003 shows that most of the countries with high suicide mortality are located in Eastern Europe (Table 4.15.1.1). Outside this region, suicide mortality has been high in Japan and China. Everywhere, the male suicide rate is clearly higher than the female rate; China is the only exception with a very high female suicide rate.

The suicide rate of elderly people has been higher than in the younger age groups almost universally. However, in many Western countries, the suicide rate for people aged 65 years and over has been declining for decades. This change is associated with the growth of the general well being and the better social and health services.

Traditionally the incidence of suicide has been low in the younger age group (15–24), but during the past 40 years the suicide rate has been rising in many Western countries, especially among young males.

Table 4.15.1.1 Suicide rates per 100 000 by country, 2001–2003

United States of America	17.6	4.1
Thailand	12.0	3.8
Singapore	11.4	7.6
Kuwait	2.5	1.4

A long list of major public health concerns in the field of suicidology has emerged:

- suicidal ideation and suicide attempts are surprisingly common in the general population
- the high rate of suicides among adolescents and young adults
- unemployment as a major risk factor for suicide
- easy access to lethal suicide methods such as psychotropic or analgesic drugs, guns, and motor vehicles
- high alcohol consumption and increasing substance misuse
- undertreatment of major psychiatric disorders such as depression and schizophrenia
- suicide models projected by the mass media.

These findings indicate that rapid growth and continuous changes in society are simultaneously causing instability and disturbing the development of integration. Some regions and groups of people are inevitably affected negatively by this development, and large numbers of people are thus moving towards a greater risk of suicide.

Determinants of suicide

Usually, suicide has no single cause. It is the endpoint of an individual process, in which several interacting determinants or risk factors can be identified (Tables 4.15.1.2 and 4.15.1.3). Risk factors are by their nature cultural, social, situational, psychological, biological, and even genetic.[8]

(a) Cultural factors in suicide

Culture defines basic attitudes towards life and death, and also towards suicide in society. We still have stigma against suicide. A hundred years ago, suicide was illegal in many European countries. Similarly, most churches overtly opposed suicide and allowed suicide victims to be buried only outside the cemetery. Religion was also a major integrating force between individuals and the community. In a modern secularized society, religion is still a

Table 4.15.1.2 Risk factors for suicide: sociodemographic variables

Gender	Male
Age	Elderly
Social status	Low
Educational status	Low
Marital status	Unmarried, separated, divorced, widowed
Residential status	Living alone
Employment status	Unemployed, retired, insecure employment
Economic status	Weak (males)
Profession	Farmer, female doctor, student, sailor
Special subpopulations	Students, prisoners, immigrants, refugees, religious sects
Special institutions	Hospitals, prisons, army
Region	Uneven distribution locally by urban–rural, residential, or subcultural area
Season and time	Spring and autumn, weekend, evening, anniversary
Life events	Adverse life events such as losses and separations, criminal charges
Social support	Low
Social integration	Lacking

Table 4.15.1.3 Clinical determinants of suicide

Family history	Suicidal behaviour, mental disorders
Mental disorders	Any disorder, depression, substance use disorders, personality disorders, schizophrenia
Contact with psychiatric services	Any contacts, recent contacts, post-discharge period, psychotropic drugs
Psychiatric symptoms	Hopeless, helpless, depressive, psychotic, delirious, anxious, aggressive, introversive
Suicidal behaviour	Previous suicide attempts, suicidal ideations, death wishes, indirect gestures
Physical health	Severe physical illness such as cancer, AIDS, stroke, and epilepsy; permanent sickness
Availability of suicide methods	Easy access to lethal methods

meaningful and protective factor for many individuals in a suicidal crisis. Western culture has had a tendency to emphasize the individuals's free will and the shouldering of responsibility for one's life, while egoistic and anomic trends in society have intensified and altruism has almost disappeared. Such changes may have increased the incidence of suicide in society. The cultural background of suicide is a deep structure inherited over generations. Cultural factors also prevent rapid changes in suicidal behaviour, which is evident among immigrants, whose mode and rate of suicide usually lie somewhere between the original and the host cultures.[9]

(b) Sociological theories on suicide

Classic sociology views suicide as a social, not an individual, phenomenon. The suicide victim's moral predisposition to commit suicide, not his or her individual experiences, is felt to be the crucial factor. Moral predisposition means the degree to which the victim is involved in more or less integrated groups and in the values of those groups. Suicides are seen as a disturbance or symptom of a relationship between society and individuals. In 1897, Durkheim published his famous work on suicide and described four basic types. Anomic suicide reflects a situation where an individual is no longer guided by the society due to its weakness, like the suicide of an unemployed and rejected alcoholic without any support from society. Altruistic suicide is illustrated by a society which can exert a strong influence on an individual's decision to sacrifice his or her life, as did the captain of the *Titanic*, for example. Egoistic suicide is an individualistic decision of a person no longer dependent on others' control or opinion such as a person who has arranged an assisted suicide. Fatalistic suicide is seen as a result of strict rules in a society which have proved decisive for the destiny of an individual, for example the suicide of a person held as a slave.[10] There are also newer social theories of suicide which stress more the joint effects of social factors. The concept of social isolation has been clinically useful in understanding the socio-ecological and social-psychiatric background of suicide.[11] Some sociologists have underlined the individual meanings associated with suicide.

(c) Life events and social support

The life situation preceding suicide is typically characterized by an excess of adverse life events and recent stressors. Usually, the sum effect of events is overwhelming and more important than a single life event. Job problems, family discord, somatic illness, financial trouble, unemployment, separation, and death and illness in the family are the most common life events preceding suicide. Somatic illness and retirement are age-specifically connected with the suicides of elderly men, while separation, financial troubles, job problems, and unemployment are more common among younger men. Severely disabling somatic illness is a very important risk factor for suicide in elderly male patients. In general, suicide among men is more often related to recent stressors than it is among women.

In most cases, life events are not accidental, but are usually also dependent on the individual's own behaviour. Personality features, even mental disorders, often explain the difficulties the victim has had. Among male alcoholics, life stress is connected with family discord and separations in all age groups. Other sources of stress in alcoholic male suicides are unemployment and financial troubles, whereas in depressive non-alcoholic male victims life stress is associated more with somatic illness. Among alcoholic males, adverse life events and living alone clearly have an enhancing effect on suicidality. Among females, life events as psychosocial stress are less strongly connected with suicide. Depression and adverse interpersonal life events are more frequent contributors to female than male suicides.[12]

(d) Psychology of suicide

Early psychological theories of suicide focussed on the concept of the self. A classical example is Freud's theory assuming that self-destructive behaviour in depression represents aggression directed against a part of the self that has incorporated a loss or rejection of a love object. In his later theory of suicide, Freud presented the construction of the dual instincts, where Eros is a life-sustaining and life-enhancing drive in constant interaction with Thanatos, the aggressive death instinct.

Later psychodynamic thinking on suicide focussed more on the self in relation to others. Failures in the developmental and adaptational processes are reflected in negative self-images and distorted cognitive schemas, leading to such feelings as depression, hopelessness, rage, shame, guilt, and anxiety. It is widely held that psychological pain is found as a common element at the core of all suicidal behaviours; suicide occurs when the individual can no longer endure the pain. Most recent psychological theories of suicide accept a multifactorial causation of suicide resulting from an interaction of predisposing and precipitating factors.[13] A person moves towards a suicidal crisis depending on the stressors and presence or absence of protective factors in his or her life.

(e) Neurobiological determinants of suicide

Suicidal behaviour is highly familial. Relatives of patients who commit suicide are themselves more likely to commit suicide than relatives of patients who do not commit suicide. Liability to suicidal behaviour may be a familially transmitted trait which is partly independent on the specific mental disorders. Since the heritability of liability to suicidal behaviour appears to be on the order of 30–50 per cent, interactions with environmental factors must also be significant.

Results of adoption studies suggest that genetic factors rather than familial environmental factors are the determinants of familial concordance for suicidal behaviour. Among biological relatives

of adopted suicide victims there is a higher incidence of suicide than among the relatives of non-suicide controls or among the adoptive relatives of the suicide victims. Also identical twins have a higher concordance for suicide, attempted suicide, and suicide ideation compared with non-identical twins.[14]

The findings that genetic factors contribute to suicidal behaviour has stimulated studies aimed at identifying susceptibility genes. So far molecular genetic studies have focussed on the serontonergic pathway. Two genes have emerged as being involved in the vulnerability to suicidality: the tryptophan hydroxylase 1 (TPH1) gene, as a quantitative risk factor for suicidal behaviour, and serotonin transporter gene (5-HTTLPR), which is consistently associated with impulsive-aggressive personality traits.[15] Patients who have seriously attempted suicide by violent means have low levels of the serotonin metabolite 5-hydroxyindole acetic acid in their cerebrospinal fluid.[16] These and other neurobiological changes are discussed in Chapter 4.15.3.

Basic characteristics of the suicide victim

Persons at greatest risk of suicide are usually middle-aged or older, non-married men with poor social and economic position, and a family history of mental disorders and suicidal behaviour. Usually they are living alone, and often unemployed or with insecure employment. They also typically have marked recent life stress and a weak social network. Most suffer from depression, and feel hopeless and many have a comorbid substance abuse or personality disorder. Almost all elderly victims have comorbid physical illness or are permanently disabled. Most have previously contacted health care, and communicated their suicidal tendencies at least indirectly, although usually without receiving adequate psychiatric treatment. Half of them have previously attempted suicide.

Mental disorders and suicide

Virtually all mental disorders carry an increased risk of suicide.[17] The suicide risk in functional mental disorders is double that in substance use disorders, which in turn carry double the risk of suicide compared to organic disorders. The greatest risk of suicide among all clinical states is in attempted suicide, which carries about 40 times the expected value (Table 4.15.1.4). In anorexia nervosa and major depression, the risk is about 20-fold, and in other mood disorders and psychoses about 10 to 15 times higher than expected. In anxiety, personality, and substance use disorders the suicide risk is at lower levels, but about 5 to 10 times higher than the expected value. In subtance disorders the risk is dependent on the type of disorder, being clearly lowest in alcohol, cannabis, and nicotine abusers.[17]

Psychological autopsy studies have been used to construct an overall view of suicide by collecting all available relevant information on the victim's life preceding his or her death. In psychological autopsy studies, mental disorders of suicide victims have been assessed using DSM-diagnoses and large unselected samples. In two recent meta-analyses[18,19] the victim received at least one diagnosis on Axis I in 87 to 90 per cent of the suicides. In all studies, depressive disorders (43 per cent) and substance use disorders (26 per cent), personality disorders (16 per cent) and psychoses (9 per cent) were frequent and comorbidity was common.

Table 4.15.1.4 Rank order of suicide in mental disorders

Suicide attempt
Anorexia nervosa
Major depression
Mood disorders not otherwise specified
Reactive psychoses
Bipolar disorder
Dysthymia
Schizophrenia
Anxiety disorders
Personality disorders
Substance use disorders

In two European psychological autopsy studies[20,21] from Finland and Northern Ireland, the distribution of the principal diagnoses was similar (Table 4.15.1.5). The most common psychiatric diagnoses in suicide were major depression and alcohol dependence. Major mood disorders together comprised 42 to 36 per cent and substance use disorders, 19 to 30 per cent of all suicides. Comorbidity was a major finding in both samples, most commonly substance use disorder with major depression. A recent European psychological autopsy study gave similar results underlining, however, the role of personality disorders as a risk factor for suicide.[22]

Table 4.15.1.5 Principal diagnoses of suicide victims in Finland and Northern Ireland

Diagnosis	Finland (%) (n = 229)	Northern Ireland (%) (n = 118)
Major depression	30	31
Depressive disorder not otherwise specified	9	—
Dysthymia	—	1
Bipolar disorder	3	4
Alcohol dependence	17	24
Alcohol misuse	2	4

Anxiety disorders	1	5
Adjustment disorder	3	3
Organic mental disorders	2	1
Other Axis I disorders	2	2
Personality disorder	9	3
No diagnosis	2	10
Insufficient information for assessment	7	—

The mortality risk for suicide in major depression is 20 times that expected, and 15-to 20-fold in all affective disorders. Every sixth death among depressive people treated as psychiatric patients is by suicide.[23] The risk of suicide varies across the subclasses of depression, and is related to the selection of suicidal patients for the various types of treatment. The risk is highest for depressive inpatients, even during the postdischarge period, and much lower among psychiatric outpatients, although clearly lowest for those treated for depression in primary care.[24] A meta-analysis found a hierarchy of life-time suicide prevalence: eight per cent in people ever admitted for suicidality, four per cent in patients admitted with affective disorder but not for suicidality, and two per cent in mixed inpatient and outpatient populations.[24]

Depression of suicide victims differ qualitatively from that of living controls; it seems to be more severe and accompanied more often by insomnia, weight or appetite loss, feelings of worthlessness, inappropriate guilt, and thoughts of death or suicidal ideation.[26] In addition, impulsive and aggressive behaviour, alcohol and drug abuse and dependence, and cluster B personality disorders increase the risk of suicide in individuals with major depression.[27] Inadequate and inefficient antidepressant treatment of depressed suicide victims has been a persistent finding in several studies. Less than half of suicide victims with major depression have been in contact with psychiatric care at the time of suicide. However, there is some evidence that good monitoring and maintenance treatment in high-risk groups of patients may be able to decrease their suicide rates.[28]

Alcohol and drugs, often combined, are a major risk or a precipitating factor for suicide. They may intensify the suicidal intent, offer a constantly available suicide method, worsen the somatic status of the victim, and increase the risk of complications after the attempt. Alcohol and drugs impair judgement and lower the threshold to suicide. Alcohol is detected in about every third case at the moment of suicide.[29] The lifetime risk of suicide has been estimated at 7 per cent for alcohol dependence, with only slight variation over the life.[30] The suicide rate in heavy drinking is 3.5 times and in alcohol use disorders ten times higher than that in the general population.[31] In drug dependence or abuse it is 15 times higher than expected.[17,31] The role of substance use disorders varies greatly by country. In a recent study from Estonia, alcohol dependence was found in a half of suicide victims.[32]

The suicide risk in schizophrenia appears to be almost 10 times higher than in the general population.[17] The lifetime risk of suicide in schizophrenia is estimated to be 5 per cent.[30,33] The great majority of schizophrenic patients commit suicide in the active phase of the disorder after having suffered depressive symptoms. Suicide in schizophrenia is thus less of a surprise; it is typically preceded by a previous attempt, and suicidal intent has been communicated at least as often as in non-schizophrenic suicides.[34] Schizophrenic suicide victims differ from other schizophrenic patients by having suicidal thoughts and previous suicide attempts, being more depressive, and having more positive symptoms.[35] Undertreatment, comorbidity, treatment non-compliance, and a high frequency of non-responders are also common problems among schizophrenic suicide victims. Adequacy of comprehensive care is crucial for suicide prevention in schizophrenia, especially among actively psychotic patients with recent suicidal behaviour and depressive symptoms.[36]

Personality disorders are tightly connected with suicide. Most of the suicide victims with personality disorder, especially with borderline and emotionally unstable personality disorder, have also comorbid depressive disorder or substance abuse. They often suffer from impulsive and aggressive behaviour.[20,22,27,38] This kind of comorbidity is very frequent among the young suicide victims.

Mental disorders, particularly depressive disorders, substance abuse, and antisocial behaviour have an important role in the adolescent suicides. The diagnostic distribution of mental disorders among them is surprisingly similar to that of the young and even middle-aged adults.[39]
